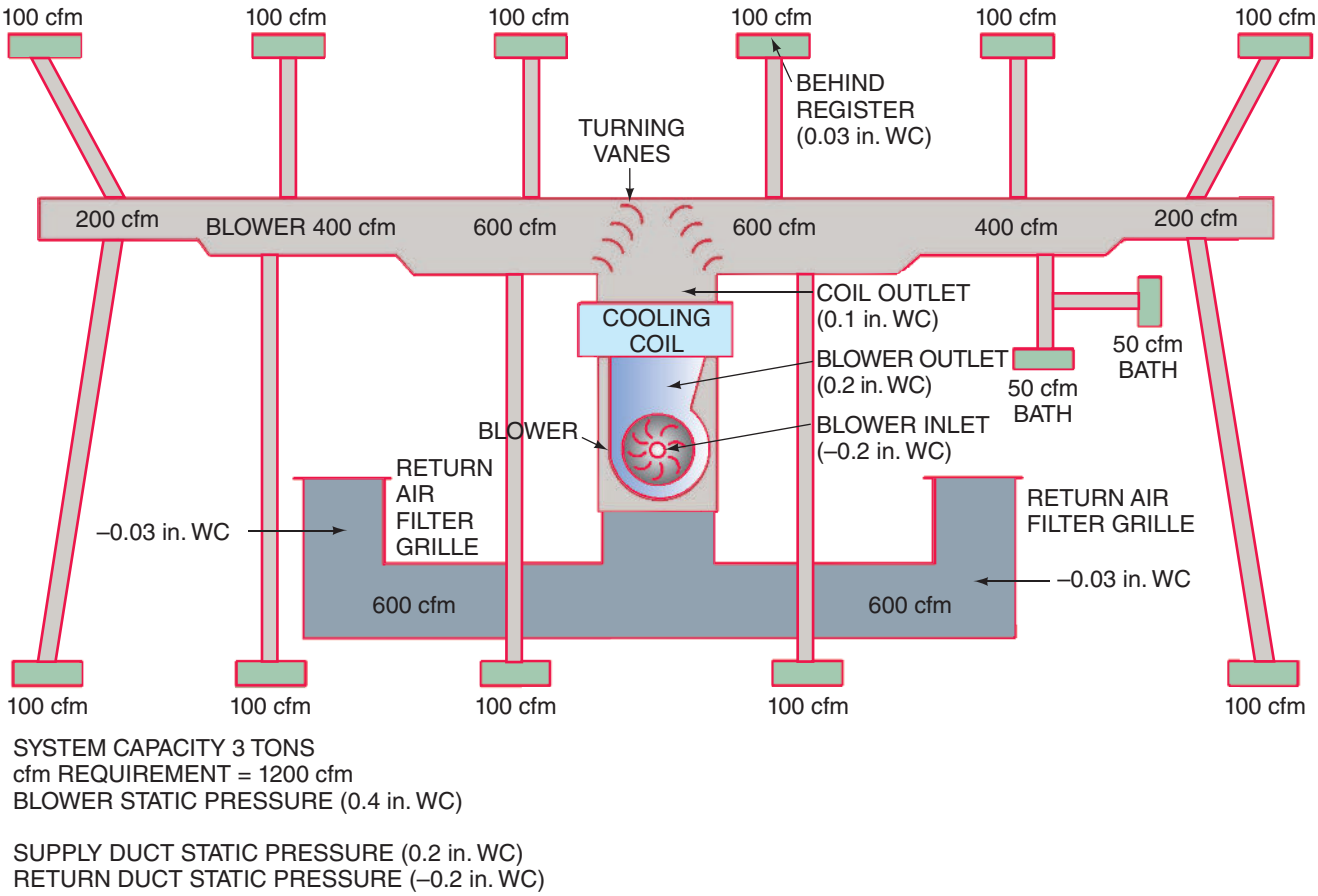
Figure 37.84 A duct system.



1. Ranch-style home requires 3 tons of cooling.
2. Cooling provided by a 3-ton cooling coil in the ductwork.
3. The heat is provided by a 100,000 Btu/h furnace input, 80,000 Btu/h output (80% efficiency).
4. The blower has a capacity of 1360 cfm of air while operating against 0.40 in. WC static pressure with the system blower operating at medium-high speed, **Figure 37.85**. This system requires only 1200 cfm of air in the cooling mode. The system blower will easily be able to achieve this rate of airflow.
5. The system has 11 outlets, each requiring 100 cfm in the main part of the house, and 2 outlets, each requiring 50 cfm, located in the bathrooms. Most of these outlets are on the exterior walls of the house and distribute the conditioned air to the outside walls.
6. The return air is taken into the system from a common hallway, one return at each end of the hall.
7. While reviewing this system, think of the entire house as the system. The supply air must leave the supply registers and sweep the walls. It then makes its way through the

rooms to the door adjacent to the hall. The air then flows under the door and makes its way to the return-air grille.

8. The return-air grille is where the duct system starts. A slight negative pressure (in relation to the room pressure) at the grille gives the air the incentive to enter the system. The filters are located in the return-air grilles. The pressure on the blower side of the filter will be −0.03 in. WC, which is less than the pressure in the room, so the room pressure pushes the air through the filter into the return duct.
9. As the air proceeds down the duct toward the blower, the pressure continues to decrease. The lowest pressure in the system is at the blower's inlet, −0.20 in. WC below the room pressure.
10. The air is forced through the blower and the pressure of the air increases. The greatest pressure in the system is at the blower outlet, 0.20 in. WC above the room pressure. The pressure difference between the inlet and the outlet of the blower is 0.40 in. WC.
11. The air is then pushed through the heat exchanger in the furnace, where the air experiences an additional pressure drop.
12. The air then moves through the cooling coil, where it enters the supply duct system at a pressure of 0.10 in. WC.
13. The air will undergo a slight pressure drop as it passes through the tee that splits the duct into two reducing extended plenums, one for each end of the house. This tee in the duct has turning vanes to help reduce the pressure drop as the air passes through the fitting.
14. The first section of each reducing trunk has to handle an equal amount of air. One half of the total cfm, 600 cfm, will flow to the left, while the other 600 cfm will flow to the right. The first two branches on each side will deliver 100 cfm each. This reduces the capacity of the trunk to 400 cfm on each side. A smaller trunk can be used at this point, and materials can be conserved while maintaining the correct air velocity.
15. The duct is reduced to a smaller size to handle 400 cfm on each side. Because another 200 cfm of air is distributed to the conditioned space, another reduction can be made.
16. The last part of the reducing trunk on each side of the system needs to handle only 200 cfm for each side of the system.

This supply duct system will distribute the air for this house with minimal noise and maximum comfort. The pressure in the duct will be about the same all along the duct because the air was distributed off the trunk line and the duct size was reduced to keep the pressure inside the duct at the prescribed value.

At each branch, dampers should be installed in the duct to balance the system air supply to each room. The system will furnish 100 cfm to each outlet, but if a room does not need that much air, the dampers can be adjusted. The branch to each bathroom will need to be adjusted to 50 cfm each.

The return-air system is the same size on each side of the system. It returns 600 cfm per side with the filters located in the return air grilles in the halls. The furnace blower is located far enough from the grilles so that it will not be heard.

Entire books have been written on duct sizing and air distribution system design. Manufacturers' representatives may also be helpful for specific applications. Manufacturers also offer classes in duct sizing that use their methods and techniques.

37.19 MEASURING AIR MOVEMENT FOR BALANCING

Air balancing is sometimes accomplished by measuring the air leaving each supply register. When one outlet has too much air, the damper in that run is throttled to slow down the air. This, of course, redistributes air to the other outlets and will increase their flow.

The air quantity of an individual duct can be measured in the field to some degree of accuracy by using instruments to determine the average velocity of the air in the duct. To accomplish this, a velometer is used. Multiple velocity readings must be taken in a uniform cross-sectional pattern of the duct. The average of the readings taken is used for the calculation. This process is called *traversing* the duct. The average velocity, along with the cross-sectional area of the duct, is used to determine the airflow though a duct, expressed in cfm. For example, if the air in a 1-ft^2 duct (12 in. × 12 in. = 144 in^2) is traveling at a velocity of 1 ft/min, the volume of air passing a point in the duct is 1 cfm. If the velocity is 100 ft/min, the volume of air passing the same point is 100 cfm. The cross-sectional area of the duct is multiplied by the average velocity of the air to determine the volume of the moving air, **Figure 37.86**. **Figure 37.87** shows the patterns used while traversing the duct.

When you know the average velocity of the air in any duct, you can determine the cfm using the following formula:

$$\text{cfm} = \text{Area (ft}^2) \times \text{Velocity (fpm)}$$

For example, suppose a duct is 20 in. × 30 in. and the average velocity is 850 fpm. The cfm can be found by first finding the area in square feet:

$$\text{Area} = \text{Width} \times \text{Height}$$
$$\text{Area} = 20 \text{ in.} \times 30 \text{ in.}$$
$$\text{Area} = \frac{600 \text{ in}^2}{144 \text{ in}^2/\text{ft}^2}$$
$$\text{Area} = 4.2 \text{ ft}^2$$
$$\text{cfm} = \text{Area} \times \text{Velocity}$$
$$\text{cfm} = 4.2 \text{ ft}^2 \times 850 \text{ fpm}$$
$$\text{cfm} = 3570 \text{ ft}^3 \text{ of air per minute}$$

(D)

Suppose the duct were round and had a diameter of 12 in. with an average velocity of 900 fpm.

$$\text{Area} = \pi \times \text{Radius squared}$$

$$\text{Area} = 3.14 \times 6 \times 6$$

$$\text{Area} = \frac{113 \text{ in}^2}{144 \text{ in}^2/\text{ft}^2}$$

$$\text{Area} = 0.78 \text{ ft}^2$$

$$\text{cfm} = \text{Area} \times \text{Velocity}$$

$$\text{cfm} = 0.78 \text{ ft}^2 \times 900$$

$$\text{cfm} = 702 \text{ ft}^3 \text{ of air per minute}$$

Special techniques and good instrumentation must be used to find the correct average velocity in a duct. For example, readings should not be taken within 10 duct diameters of the nearest fitting. This means that long, straight runs are desirable for taking accurate readings. This is not always possible because of the fittings and takeoffs in a typical system, particularly residential systems. The proper duct traverse must be used and it is different for round duct than for square or rectangular duct. **Figure 37.87** shows the pattern that should be used for traversing square, rectangular, and round duct for the most accurate average reading. See Section 37.21 for some practical tips for measuring airflow.

37.20 THE AIR FRICTION CHART

The system described in the previous section can be plotted on the friction chart, **Figure 37.88.** This chart is for volumes of air up to 2000 cfm. **Figure 37.89** shows a chart for larger

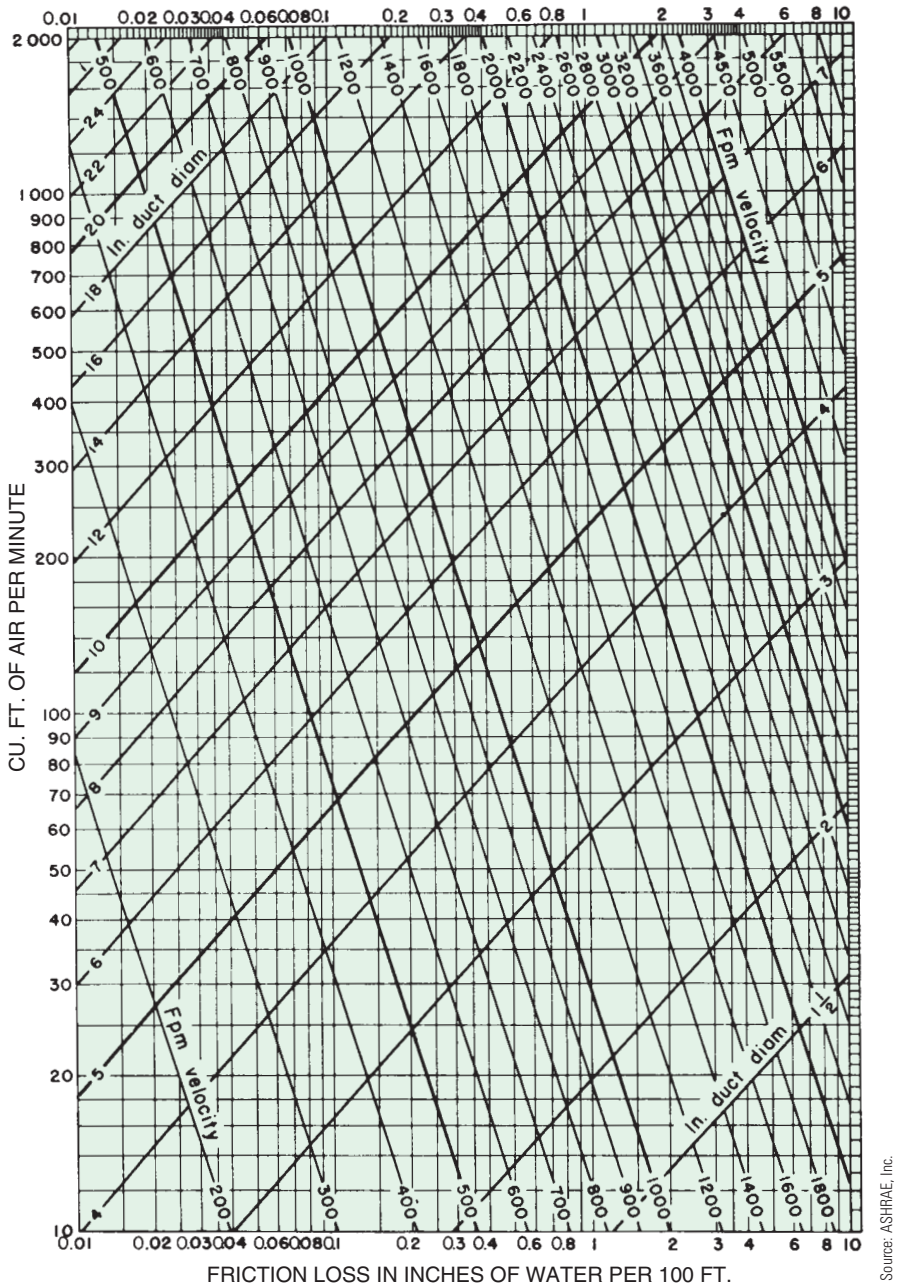
Figure 37.88 An air friction chart.



systems, up to 100,000 cfm. The horizontal lines on the chart represent airflow in cfm, as indicated by the scale on the left side of the chart. Round duct diameters, expressed in inches, are represented by the lines that slope from the bottom-left to the top-right of the chart. The velocity of the airflow is represented by the lines that run from the top-left to the bottom-right of the chart. The vertical lines on the chart represent the friction rate.

The duct sizes are rated in round-pipe sizes on the chart and can be converted to square or rectangular duct by using the table in **Figure 37.90**. The round-pipe sizes are for galvanized steel duct material and assume that the air is at standard conditions and has a density of 0.075 lb/ft^3. Other charts are available for ductboard and flexible duct. The friction loss is expressed in inches of water column per 100 ft of duct, and the scale is shown along the top and bottom of the chart. For example, using this chart, a run of pipe that carries 100 cfm (on the left of the chart) can be plotted over the intersection of the 6-in. pipe line. When this pipe is carrying 100 cfm of air, it has a velocity of just over 500 ft/min and a pressure drop of 0.085 in. WC/100 ft. A 50-ft run would have half the pressure drop—0.0425 in. WC.

The friction chart can be used by the designer to size the duct system before the job price is quoted. This duct sizing

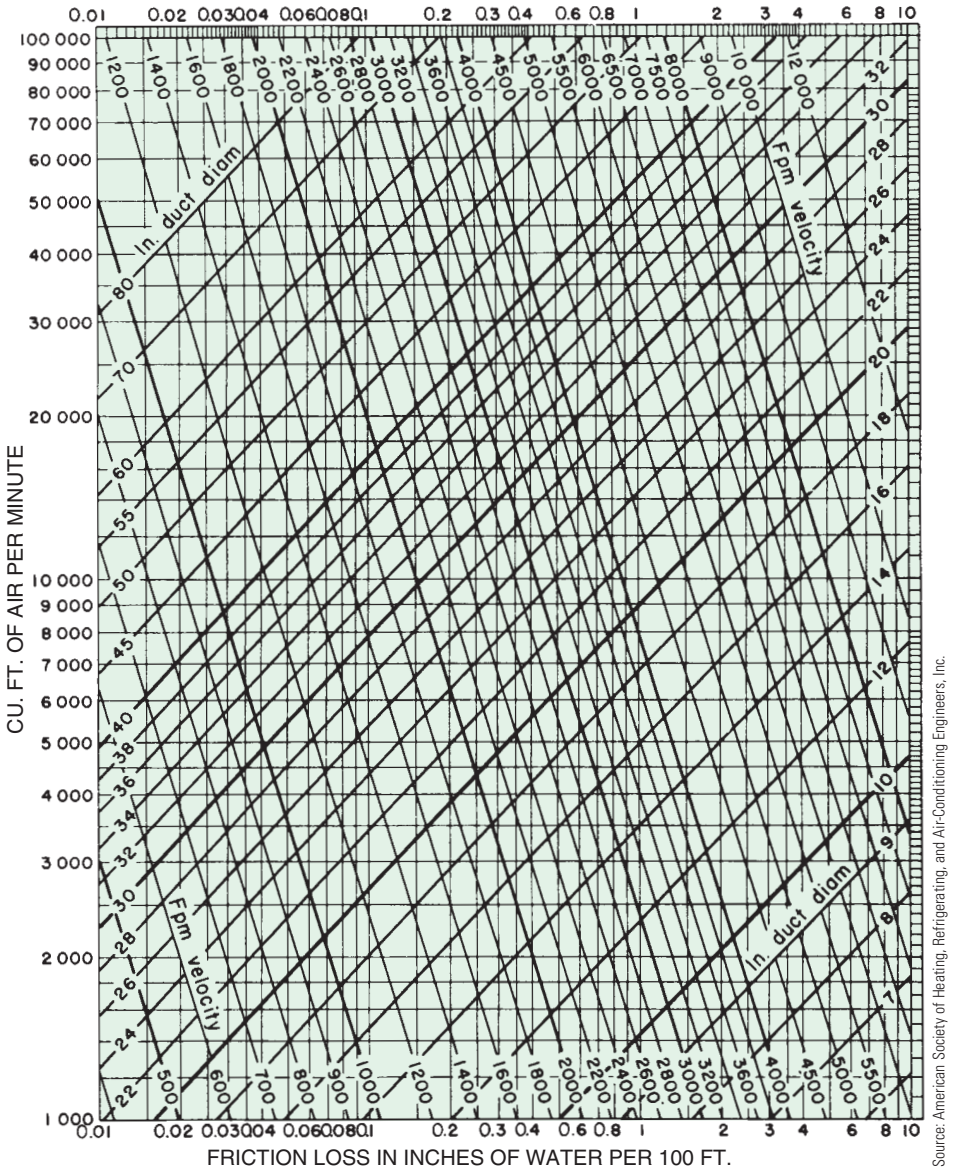
Figure 37.89 A friction chart for larger duct systems.



provides the sizes that will be used for figuring the duct materials. The duct should be sized using the chart in **Figure 37.88** and the recommended velocities from the table in **Figure 37.91**. In the previous example, a 4-in. pipe could have been used, but the velocity would have been nearly 1200 ft/min. This would be noisy, and the fan may not have enough capacity to push sufficient air through the duct.

High-velocity systems have been designed and used successfully in small applications. Such systems normally have a high air velocity in the trunk and branch ducts; the velocity is then reduced at the register to avoid drafts from the high-velocity air. If the air velocity is not reduced at the register, the register has a streamlined effect and is normally located in the corners of the room where someone is not likely to walk under it.

The friction chart also can be used by the field technician to troubleshoot airflow problems. Airflow problems come from system design, installation, and owner problems. System design problems can be a result of a poor choice of blower or incorrect duct sizes. They may result from not understanding the fact that the air friction chart is for 100 ft of duct only. The technician should have an understanding of how to size ductwork to determine whether or not a particular duct is sized correctly.

To size duct properly, the technician must understand the calculation of pressure drop in fittings and pipe. The pressure drop in duct is calculated and read on the friction chart in feet of duct, from the air handler to the terminal outlet. This is a straightforward measurement. The fittings are calculated in a different manner. Pressure drop across different types of fittings in in. WC has been determined by laboratory experiment and is known. This pressure drop has been converted to equivalent feet of duct for the convenience of the designer and technician. The technician must know the type of fittings used in the system and then consult a chart for the equivalent feet of duct, **Figure 37.92.** The

Average Stores, Cafeterias	1,500	800	2,000	1,600	1,500	1,200

equivalent feet of duct for all of the fittings for a particular run must be added together and then added to the actual duct length to determine the proper duct size for a particular run.

When a duct run is under 100 ft, a corrected friction factor must be used or the duct will not have enough resistance to airflow and too much flow will occur. The corrected friction factor may be determined by multiplying the design friction loss in the duct system times 100 (the friction loss used on the chart) and dividing by the actual length of run. For example, a system may have a duct run handling 300 cfm of air to an inside room. This duct is very close to the main duct and air handler. There are 60 effective feet, including the friction loss in the fittings and the duct length, **Figure 37.93**. The blower may be capable of moving the correct airflow in the supply duct with a friction loss of 0.36 in. WC. The cooling coil may have a loss of 0.24 and the supply registers a loss of 0.03.

(C)

When the coil and register loss are subtracted from the friction loss for the supply duct, the duct must be designed for a loss of 0.09 in. WC (0.36 − 0.27 = 0.09).

The following describes a mistake the designer made and how the technician discovered it. The designer chose 9-in. duct from the friction chart at the junction of 0.09 in. WC and 300 cfm, from **Figure 37.88**, without making a correction for the fact that the duct is only 60 ft long. The technician corrected the static pressure loss of 60 ft of duct using the formula:

$$\text{Adjusted Static} = \frac{\text{Design Static} \times 100}{\text{Total Equivalent Length of Duct}}$$

$$= \frac{0.09 \times 100}{60}$$

$$= 0.15$$

Using this adjusted static pressure, the technician referred to the friction chart and plotted at 300 cfm, then moved to the right to 0.15 adjusted static. The duct size now became 8-in. duct. This is not a significant savings in materials, but it does now reflect accurate friction rate and velocity information. An alternative is to use a throttling damper where the branch line leaves the trunk duct. **The key to this problem is correcting the static pressure to an adjusted value.** This causes the chart to undersize the duct for the purpose of reducing the airflow to this run because it is less than 100 ft long. Otherwise, the air will have so little resistance that too much air will flow from this run, starving other runs. One run that is oversized will not make too much difference, but a whole system sized using the same technique will experience problems.

This problem illustrates a run that is under 100 ft. The same technique applies to a run that is more than 100 ft, except that the run will be undersized and starved for air. For example, suppose that another run off the same system requires 300 cfm of air and is a total of 170 ft (fittings and actual duct length), **Figure 37.94**. The designer sized the duct for 300 cfm at a static pressure loss of 0.09 and chose a duct size of 9 in. round.

The technician finds the airflow is too low and checks the figures using the formula:

$$\text{Adjusted Static} = \frac{\text{Design Static} \times 100}{\text{Total Equivalent Length of Duct}}$$

$$= \frac{0.09 \times 100}{170}$$

$$= 0.053$$

When the duct is sized using the adjusted static, the chart reading oversizes the duct, and it moves the correct amount of air. In this case, the technician enters the chart at 300 cfm, moves to the right to 0.053, and finds the correct duct size to be 10 in. instead of 9 in. This is the reason this system is starved for air. All duct is first sized in round, then converted to square or rectangular. **NOTE:** *All runs of duct are measured from air handler to the end of the run for sizing.*•

As the previous examples show, when some duct is undersized and some oversized the result will probably produce problems. The technician should pay close attention to any job with airflow problems and try to find the original duct-sizing calculations. This will make possible a full analysis of a problem duct installation. Any equipment supplier will help in selecting the correct blower and equipment. Suppliers may even help with the duct design.

37.21 PRACTICAL TROUBLESHOOTING TECHNIQUES

Most duct systems are either residential or commercial installations. Residential systems will be discussed first. Generally, residential systems have less than 5 tons of cooling and 200,000 Btu/h of heating. These systems are often installed based on experience rather than on the use of industry-approved design techniques. Many contractors estimate how much air should be delivered to a particular room in a home using rules of thumb. Since most areas in residential structures are open to each other, deficiencies in the system design are often not noticed. It is strongly recommended, however, that nationally recognized methods, such as ACCA Manual D, be used to properly design and lay out residential air distribution systems. One characteristic that is common to most residential air distribution systems is that they typically have short duct runs. As explained earlier, for instruments to work correctly, measurements must be made in long runs of duct. Therefore, instruments may not be necessary for locating and repairing airflow problems. Most testing of residential duct systems is performed at the registers and grilles because of this lack of long duct runs. Commercial systems are much different and will require the use of instruments.

RESIDENTIAL DUCT SYSTEM PROBLEMS

Many contractors size the branch duct system in residences using two sizes of duct for economy of the installation. The duct to the rooms is often sized as 6-in. or 8-in. round (which may be converted to square or rectangular duct) with dampers in each run to adjust the airflow. A 6-in. round duct will move 100 cfm of air with a friction loss of about 0.08 in. WC pressure drop per 100 ft. An 8-in. round duct will move 200 cfm of air with a friction loss of about 0.075 in. WC. Many contractors divide the house into 100- and 200-cfm zones and use dampers to compensate for any airflow unbalance. The trunk duct that furnishes the air to the branch ducts is often sized by simply choosing a size that will furnish the required number of branch ducts off the main. Larger rooms will have several outlet registers. Although this may seem careless, it is simple and practical. When a system is designed in this manner, the technician must know if there is adequate airflow at the terminal units and the supply registers.

The simple way to check for airflow is to see if you can feel the airflow at a distance of about 2 to 3 ft from each register. If the registers are floor registers and it is the cooling season, you can walk to each register, one at a time, while holding your hand down at your side. This can often be done while touring the home with the homeowner, who may not even be aware of what you are doing. If you find one that has a very low flow, follow the duct from the trunk to the register. The following are some problems that you may encounter:

- Flex duct runs may be too long. Sometimes the installing contractor will use an entire 25-ft box of duct for a 15-ft run and just leave the excess in the attic. Some installers simply do not want to cut off the extra duct.
- When the system is installed in a new home, construction debris can often be found in the duct. The register holes should be covered during construction when floor registers are used.
- Runs may have been disconnected. Duct systems that are run where people, such as cable TV or telephone repair technicians, crawl over or step on them can become disconnected or crushed.
- The damper on one or more of the branch ducts may be closed. Look for the damper handle that is supposed to be installed where you can see it. Even if the duct is insulated on the outside, the handle should protrude out of the insulation. If the damper handle is under the insulation, it can often be found by feel.
- Flexible duct will collapse inside if it is installed with tight bends. This may not be easy to see from the outside.
- When the duct is lined on the inside, it is hard to determine where the obstruction may be. The sure sign of obstruction is reduced airflow at the supply registers for that trunk run.
- Look for furniture that is placed over registers. In some cases homeowners will block registers and grilles because they feel a draft. Floor registers or grilles can be covered with area rugs, **Figure 37.95**.

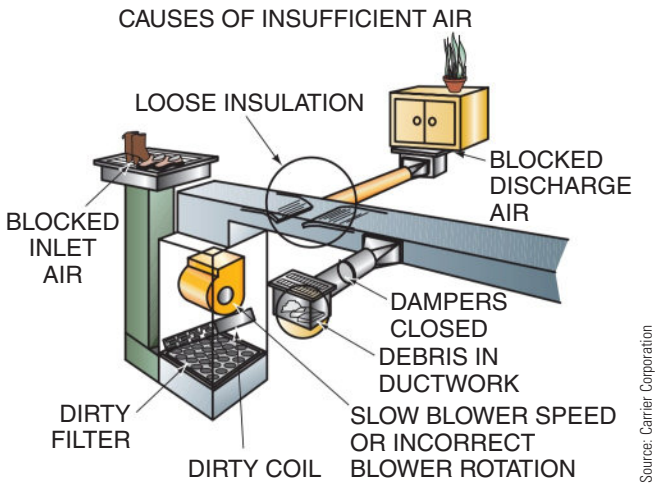
Figure 37.95 Obstructed airflow.



- The wrong filter media may have been chosen. Many companies advertise better filters for residential systems. A better filter will have a tighter weave and offer more air restriction. If the filter rack was designed for a typical media filter and a high-density filter is used, it is likely that the airflow is reduced to the point of low flow. This is because the high-density filters require more area for the same airflow. Take the filter out and recheck the airflow. Refer to Unit 34, "Indoor Air Quality," for more information on air filters.

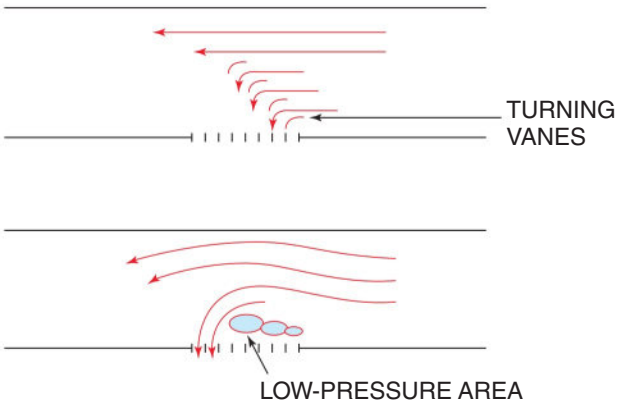
After checking each individual register for noticeable airflow, look for signs of airflow into the return-air grilles. If the return-air grille is oversized, you may not notice airflow. A piece of paper placed close to the grille will be sucked onto the grille surface with only a slight amount of airflow velocity. Oversized return-air grilles are often desirable because they reduce the air noise.

To verify airflow for floor and sidewall registers, tie a piece of ribbon about 12 in. long to the end of a stick or piece of wire. Hold it over the register. The ribbon will show the air pattern by waving in the air; if there is no airflow, it will not wave. This does not work as well with ceiling registers because the airflow is usually down, just as the thread or ribbon would normally hang.

If you are using instruments to measure air velocity instruments, readings can be taken at the various registers. The industry standard for the maximum recommended air velocity for a supply register in a home is 750 fpm, **Figure 37.91**. You should be able to feel this airflow.

The airflow from a register is not the same across the entire surface of the register. Although it may seem that the static pressure in a duct would provide even pressure to all surfaces of the register, there are other considerations. For example, when a register is mounted on the duct itself, the air turning into the register can create a low-pressure area at one end, **Figure 37.96**. This situation may be remedied by the use

Figure 37.96 This register is installed just after a reducing transition and will need turning vanes to turn the air into the register.



of turning vanes at the register. Manufacturers of registers and grilles provide tables that show what the airflow through each device is at a particular velocity. A major consideration is that the velocity is often not a constant across the entire device.

If you think there is an overall low airflow problem because there does not seem to be enough air at all of the registers, do a total system examination, starting with the filter. The air handler is often shipped with a filter already installed in the cabinet. The installer who installs a return-air filter grille may forget to remove the filter shipped with the unit. Even if the common return filter is faithfully changed, the filter at the air handler will still eventually become obstructed. An overall airflow reduction would result in low suction pressure in the cooling mode and a high temperature rise across the furnace in the heating mode. Reduced airflow can cause the furnace to trip off on a high limit control because of high heat exchanger temperatures. The technician can check the recommended air temperature rise in most furnaces. If the rise is above the maximum, there is not enough air. For example, if a gas furnace manufacturer recommends an air temperature rise of between 45°F and 65°F and the rise is 80°F, there is not enough airflow to satisfy the furnace manufacturer's specifications. It is easy for the technician to measure the temperature rise across the appliance by measuring the difference between the supply and return air temperatures.

An amperage reading of the fan motor may provide a clue to overall reduced airflow. If the fan is supposed to have a draw of 7 A and it is drawing only 4 A, suspect an obstruction or even an undersized duct. When a new system is started up for the first time and the airflow is established, the technician should record the fan motor amperage on the unit to use later for comparison testing.

When a system has one or two common return-air grilles, the average air velocity can be taken at the grilles and calculated to find the overall airflow. The free or usable area of the grille is first measured, then the average velocity across the

grille is multiplied by the area [(cubic feet per minute = velocity (feet per minute) × area (square feet)]. The effective area of the grille is not the overall area of the grille because of the grille's louvers. The effective area of the grille is about 70% of the measured area in square feet. For example, suppose that the average velocity of a return-air grille is 350 fpm and the measured size of the grille opening is 14 in. × 20 in. The total area would be 1.944 ft^2 (14 × 20/144 = 1.944 ft^2). Since only 70% of the grille area is usable because of the louvers, the actual usable area is 1.944 × 0.7, or 1.44 ft^2. The volume of air would be cfm = velocity × area, 350 × 1.44 = 504 cfm. This is approximately the amount of airflow required for a 1½-ton system for cooling. If the return-air grille is too small, it will normally make a whistling sound as air passes through it. Be sure to check the manufacturer's specifications for specific grilles, as different grilles have different effective areas.

Other methods may be used for determining the flow for a residential system. These are discussed in the individual units that apply to gas, oil, or electric heat. These methods determine the airflow by measuring the energy input to the airstream and calculating the airflow.

No matter what method you use, the accuracy will probably be within ±20%. This is about as close as you can get for residential systems, assuming they are not leaking air at the duct connections. **NOTE:** *All air measurements for residential systems should be performed at maximum airflow. Any system that is both heating and cooling and that has a multiple-speed motor may have a different airflow for heating versus cooling. Switch the room thermostat to FAN ON for all testing. This will be the maximum airflow.*

If you discover there is not enough air for the total system and there are no physical barriers, the next step is to see if the air volume delivered by the blower can be increased. If the system has a belt-drive blower, check the amperage as compared with the motor full-load amperage. If the blower motor amperage is low, the pulleys might be able to be adjusted to increase the airflow rate through the duct system.

COMMERCIAL DUCT SYSTEMS

Commercial duct systems vary greatly depending on the size of the buildings. Commercial duct systems should always have a blueprint of the duct layout along with a set of specifications that tell how much air should be flowing at any particular part of the system. This makes it easier to use the proper instruments and identify problems.

When a large multistory building is erected, a certified testing and balancing company should be present at the building system's start-up to verify that the airflow is correct before the building is turned over to the owner-operator. The company will verify the total building airflow, including the flow in all of the trunk ducts, in all of the branch ducts, and at the terminal units. These airflows are supposed to match the building specifications within an acceptable range, which is usually about 10% for comfort cooling applications. Upon completion, a balancing report is completed, verifying that all airflow rates are within the acceptable range.

An advantage of commercial high-rise buildings is that they usually have a separate air distribution system for each floor and the individual floors of the building are often similar in layout to each other. Troubleshooting airflow problems in large systems involves reading the prints to determine what the airflow is supposed to be under the conditions you are trying to check. If the system is a variable-air-volume (VAV) system, the airflow may be reduced because of the thermostat setting. If it is a constant flow system, the flow should be known. In either case, when the correct air volume is known, measure the airflow with quality instruments.

There should be test ports in the duct where the testing and balancing company took its readings from. If not, you will have to make your own. Be sure to use the correct drill size and wear eye protection when making these test holes. Make certain the blower is off when drilling airflow measurement holes in the duct to avoid having metal shavings blow in your eyes. Testing will involve taking traverse readings of the duct, determining the average velocity of the air, and then using the airflow formula to determine the cfm of air. Commercial duct systems often have *dampers* that divert or divide the airflow in ductwork. These dampers can be adjusted to cause more or less air to flow into branch ducts, **Figure 37.97**. The system prints and drawings should provide information regarding the desired cfm in each duct run. If there are no prints available at the building, you may be able to get a copy of the original drawings from the installing contractor, the engineering firm, or the building architect. Be sure to plug the test ports when you are finished. Tapered rubber stoppers are commonly used for this.

Flow hoods are available for measuring the airflow at terminal units. These flow hoods fit over the register, sealing off

Figure 37.97 This splitter, or diverter, damper can help control how much airflow is in the two different ducts.

the air, **Figure 37.98**. Because they read out directly in cfm, the readings can be easily compared to the job specifications.

Total airflow of commercial systems can be verified by checking the main duct for the correct airflow. If the airflow in the main supply duct is not correct, the technician should check for any problems that could reduce the airflow. Filters should be checked first. Dampers may be blocking airflow if they are not positioned correctly. All large blowers are powered by three-phase power, and fan motors should be checked for proper rotation. It is not uncommon for a motor to be running backward because some technician reversed two wires while servicing the electrical system. A squirrel cage blower will run just as well in either direction, but it will only discharge a fraction of the correct volume if the blower is rotating in the wrong direction. This reduction in airflow may not be noticed until peak season on some systems. **SAFETY PRECAUTION:** *The technician is responsible for obtaining air pressure and velocity readings in ductwork. This involves drilling and punching holes in metal duct. Use a grounded drill cord or a cordless drill and be careful with drill bits and the rotating drill. Sheet metal can cause serious cuts, and air blowing from the duct can blow chips into your eyes, so be sure to de-energize the blower before making any test holes in the duct. Protective eyewear must be worn.*•

Figure 37.98 This hood fits directly over ceiling registers up to about 2 ft × 2 ft. The hood forces the air from the register through the meter and displays the airflow in cfm.

SUMMARY

- Air is passed through conditioning equipment and then returned to the room to heat or cool the space.
- Infiltration is the term used to describe air that leaks into a structure.
- Ventilation is the process of introducing air to the conditioning equipment and (often) conditioning this air before it enters the conditioned space.
- The duct system distributes air to the conditioned space. It consists of the blower (or fan), the supply duct, and the return duct.
- The blower uses energy to move the air.
- The centrifugal-type blower is used to move large amounts of air in ductwork, which offers resistance to the movement of air.
- Fans and blowers are not positive-displacement devices.
- Small centrifugal blowers use energy in proportion to the amount of air they move.
- 1 in. WC is the amount of pressure needed to raise a column of water 1 in.
- 1 psi will support a column of water 27.7 in., or 2.31 ft, high.
- The atmospheric pressure of 14.696 psia will support a column of water 34 ft high (14.696 × 2.31).
- Static pressure is the pressure pushing outward on the interior surfaces of the duct.
- Velocity pressure is moving pressure created by the velocity of the air in the duct.
- Total pressure is the mathematical sum of the velocity pressure and the static pressure.
- The pitot tube is a probe device used to measure the air pressures in a duct.
- Air velocity (fpm) in a duct can be multiplied by the cross-sectional area (ft^2) of the duct to obtain the amount of air passing that particular point in cubic feet per minute.
- Typical supply duct systems used are plenum, extended plenum, reducing extended plenum, and perimeter loop.
- Branch ducts should always have balancing dampers to balance the air to the individual areas.
- Zoning allows a single air-conditioning system to provide individual room temperature control. When a system is zoned, each zone has its own zone damper and space thermostat.
- Zoned systems can provide simultaneous heating and cooling to different zones.
- When the air is distributed in the conditioned space, it is common practice to distribute the air along the outside walls of the structure.
- The amount of throw tells how far the air from a diffuser will reach into the conditioned space.
- Each foot of duct, supply or return, has a friction loss that can be plotted on a friction chart for round duct.
- Round duct sizes can be converted to square or rectangular equivalents for sizing and friction readings.

REVIEW QUESTIONS

1. Name five changes that are made to air to condition it.
2. The two ways that fresh air enters a structure are _____ and _____.
3. Which of the following types of fan is used to move large amounts of air against a low static pressure drop?
   A. Vane axial
   B. Centrifugal
   C. Large
   D. Propeller
4. True or False: Turbulence in airflow causes friction drop.
5. Name two types of blower drives.
6. Pressure in ductwork is expressed in which of the following?
   A. Inches of water column
   B. Psig
   C. Psia
   D. Inches of Hg
7. What is a common instrument used to measure pressure in ductwork?
8. The three pressures created by moving air in ductwork are _____ pressure, _____ pressure, and _____ pressure.
9. Name the two types of return-air systems in residential installations.
10. What is the component that distributes air in the conditioned space?
11. Warm air heats a room better if distributed
    A. low in the room.
    B. high in the room.
    C. behind the furniture.
    D. under the curtains.
12. Name four materials used to manufacture duct.
13. The name of the fitting where the branch line connects to the main duct is the _____ _____.
14. True or False: Air for cooling circulates better through the conditioned space when it is introduced to the space through floor registers.
15. Why are dampers recommended in all branch-line ducts?
16. Zoning an air-conditioning or heating system allows for
    A. temperature control of individual rooms or areas in the space.
    B. simultaneous heating and cooling of individual rooms in a structure.
    C. Neither A nor B is a characteristic of a zoned system.
    D. Both A and B are characteristics of a zoned system.
17. Multiple-zone systems often use a(n) _____ or a(n) _____ _____ to alleviate the problem of excess air when only some zones are calling for conditioning.
18. True or False: Zoning an air-conditioning system can only be done when the system is initially designed and installed.
19. The duct sizes on the air friction chart are expressed in which of the following?
    A. Square
    B. Round
    C. Oval
    D. Rectangular
20. The average velocity of a 16-in. round duct is 800 fpm; the airflow in the duct is _____ cfm.
21. If a rectangular duct system (12 in. × 26 in.) has an average velocity of 700 fpm, what is the airflow?
22. The equivalent feet of pressure drop for a group 3-G branch-line takeoff is
    A. 30 ft.
    B. 20 ft.
    C. 10 ft.
    D. 5 ft.

UNIT 38

INSTALLATION

OBJECTIVES

After completing this unit, you should be able to

- list three crafts involved in air-conditioning installation.
- identify types of duct system installations.
- describe the installation of metal duct.
- describe the installation of ductboard systems.
- describe the installation of flexible duct.
- recognize good installation practices for package air-conditioning equipment.
- discuss different connections for package air-conditioning equipment.
- describe the split air-conditioning system installation.
- recognize correct refrigeration piping practices.
- state start-up procedures for air-conditioning equipment.

SAFETY CHECKLIST

- ☑ Be careful when handling sharp tools, fasteners, and metal duct. Wear gloves whenever practicable.
- ☑ Use only grounded, double-insulated, or cordless electrical tools.
- ☑ Wear gloves, goggles, and clothing that will protect your skin when working with or around fiberglass insulation.
- ☑ Extreme care should be used when working with any electrical circuit. All safety rules must be adhered to. Particular care should be taken while working with any primary power supply to a building because the fuse that protects that circuit may be on the power pole outside. Keep the power off whenever possible when installing or servicing equipment. Lock and tag the panel. There should be only one key. Keep this on your person at all times.
- ☑ Although low-voltage circuits are generally harmless, you can experience shock if you are wet and touch live wires. Use precautions for all electrical circuits.
- ☑ Before starting a system for the first time, examine all electrical connections and moving parts. Connections, pulleys, or other moving parts may be loose.
- ☑ Follow all manufacturer's instructions before and during initial start-up.

38.1 INTRODUCTION TO EQUIPMENT INSTALLATION

Installing air-conditioning equipment requires three crafts: duct, electrical, and mechanical, which includes refrigeration. Some contractors use separate crews to carry out the different tasks. Others may perform the duties of two of the crafts within their own company and subcontract the third to a more specialized contractor. Some small contractors do all three jobs with a few highly skilled people. The three job disciplines are often licensed at local and state levels and may be licensed by different departments.

Included in the following sections are duct installation procedures for (1) all-metal square or rectangular duct, (2) all-metal round duct, (3) fiberglass ductboard, and (4) flexible duct. **NOTE:** *Local codes must be followed while performing all work.*

38.2 INSTALLING SQUARE AND RECTANGULAR DUCT

Square metal duct is fabricated in a sheet metal shop by qualified sheet metal layout and fabrication personnel. The duct is then moved to the job site and assembled to make a system. Because the all-metal duct system is rigid, all dimensions have to be precise, or the job will not fit together properly. The duct must sometimes rise over objects or go beneath them and still measure out correctly so that the takeoff will reach the correct branch location. The branch duct must be the correct dimension for it to reach the terminal point, the boot for the room register. **Figure 38.1** illustrates an example of a duct system layout. The measuring, fabricating, and installing of the duct system must all be done properly in order to ensure a proper installation. If the system is not properly measured, there is no way that the fabricators will be able to create the correct duct sections. Improperly fabricated duct sections cannot be installed without having to make modifications to the sections or having to remake some sections. This results in lost time and money for the installation company.

Square duct or rectangular duct is assembled with S fasteners, often referred to as slips, and drive clips, which make a duct connection nearly airtight. If further sealing is needed, a special product called mastic may be applied to the duct joints with a stiff paintbrush, **Figure 38.2**. It dries hard but is slightly pliable. Mastic helps create an airtight seal, minimizing air leaks in the duct system.

While the duct is being assembled, it has to be fastened to the structure for support. This can be accomplished in

several ways. In an attic installation it may be laid flat or be hung by hanger straps. The duct should be supported so that it will be steady when the blower starts and will not transmit noise to the structure. The rush of air (which has weight) down the duct will move the duct if it is not fastened. Vibration eliminators next to the blower section will prevent the transmission of noise down the duct. See **Figure 38.3** for a flexible duct connector that can be installed between the blower and the metal duct. When installed, the metal portions of the connector should not touch each other to help ensure that sound does not transmit. Flexible connectors are always recommended, but not always used. **Figure 38.4** illustrates an example of a flexible

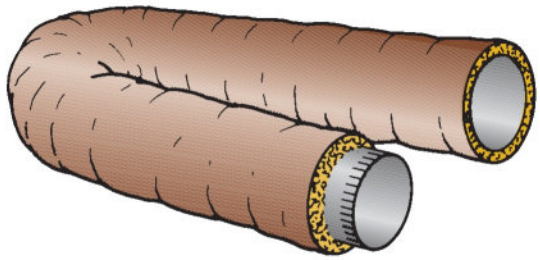
Figure 38.4 A round flexible duct connector.



connector used to dampen sound that can be installed at the end of each run. Although often made of a rubber-type material, these connectors are commonly referred to as canvas connectors or canvas collars.

Metal duct can be purchased in the popular sizes for small and medium systems from some supply houses. This makes metal duct systems available to the small contractor who may not have a sheet metal shop. The standard duct sizes can be assembled with an assortment of standard fittings to build a system that appears to be custom-made for the job, **Figure 38.5**.

38.3 INSTALLING ROUND METAL DUCT SYSTEMS

Round metal duct systems are easy to install and are available from some supply houses in standard sizes for small and medium systems. These systems, which use reducing fittings from a main trunk line, may be assembled in the field. They must be fastened together at all connections. Self-tapping sheet metal screws are popular fasteners. The screws are held by a magnetized screw holder while an electric drill turns and starts the screw, **Figure 38.6**. Each connection should have a minimum of three screws spaced evenly to keep the duct steady. A good installer can fasten the connections as fast as the screws can be placed in the screw holder, **Figure 38.7**. A reversible, cordless, variable-speed drill is the ideal tool to use.

Round metal duct requires more clearance space than square or rectangular duct. It must be supported and mounted at the correct intervals to keep it straight. Exposed round metal duct does not look as good as square duct and rectangular duct, so it is often used in places that are out of sight. **SAFETY PRECAUTION:** *Be careful when handling the sharp tools and fasteners. Use grounded, double-insulated, or cordless electrical tools.*•

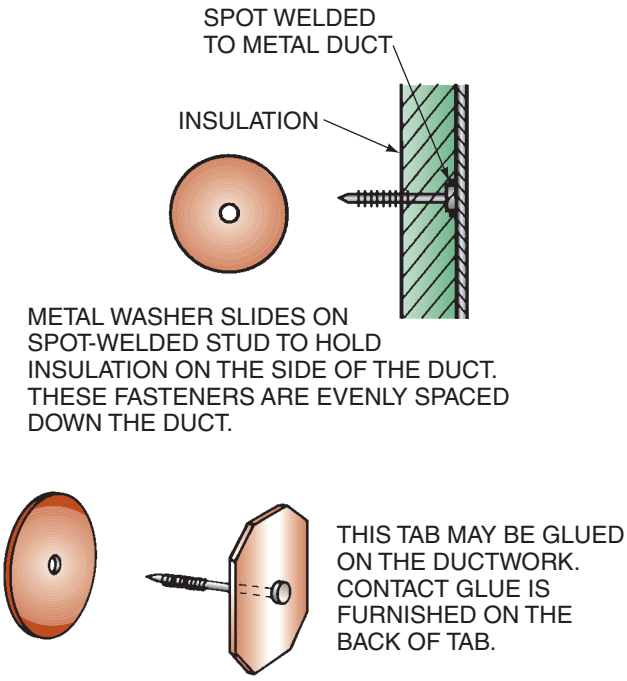
38.4 INSULATION AND ACOUSTICAL LINING FOR METAL DUCT

Insulation and acoustical lining for metal duct can be applied to the inside or the outside of the duct. Insulation is typically wrapped around the duct, and acoustical lining is applied to the interior of the duct. When lining is to be applied to the inside, it is usually done in the fabrication shop. The lining can be fastened with tabs, glue, or both. The tabs, which are fastened to the inside of the duct, have a shaft that looks like a nail protruding from the duct wall. The liner and a washer are pushed over the tab shaft. The tab base, **Figure 38.8**, *is fastened to the inside of the duct by glue or spot welding. Spot welding with an electrical spot must be used to weld the tab and is the most permanent method, but it is difficult to do and expensive. Liner that is glued to the duct may come loose and block airflow, perhaps years from the installation date. This problem is difficult to find and repair, particularly if the duct is in a wall or framed in by the building structure. The glue must be applied correctly, and even then may not hold forever. Using tabs with glue is a more permanent method.*

When acoustical lining is to be applied to the interior surfaces of the ductwork, adjustments must be made to its cross-sectional dimensions. Since the acoustical lining is typically 1" thick, the amount of air the duct can carry can be greatly reduced, especially in smaller ductwork. Consider a section of 10" × 10" duct-work that has a cross-sectional area of 100 in². If 1" lining is installed in the duct, the interior measurements become 8" × 8" and the cross-sectional area drops to 64 in², **Figure 38.9**. *This is a 36% reduction in duct area!*

Figure 38.8 A tab that holds the fiberglass duct liner to the inside of the duct.



The liner is normally fiberglass and is coated on the air side to keep the airflow from eroding the fibers. An antimicrobial coating is often added to the liner to reduce the potential of microbial growth on the insulation. Some dust will accumulate on the duct liner over time. This dust can support mold growth should the liner become damp for any reason.

Many pounds of air pass through a duct each season. An average air-conditioning system handles 400 cfm/ton of air. A 3-ton system handles 1200 cfm or 72,000 cfh (1200 cfm × 60 min/h = 72,000 cfh); 72,000 cfh ÷ 13.35 ft³/lb = 5393 lb of air per hour. This is more than 2½ tons of air per hour.

SAFETY PRECAUTION: *Fiberglass insulation may irritate the skin. Gloves and goggles should be worn while handling it.*•

38.5 INSTALLING DUCTBOARD SYSTEMS

Fiberglass ductboard is popular among many contractors because it requires little special training to construct a system, **Figure 38.10**. *Special knives can be used to fabricate the duct in the field. If the knives are not available, simple cuts and joints*

Figure 38.9 Acoustical lining reduces the cross-sectional area of the duct.

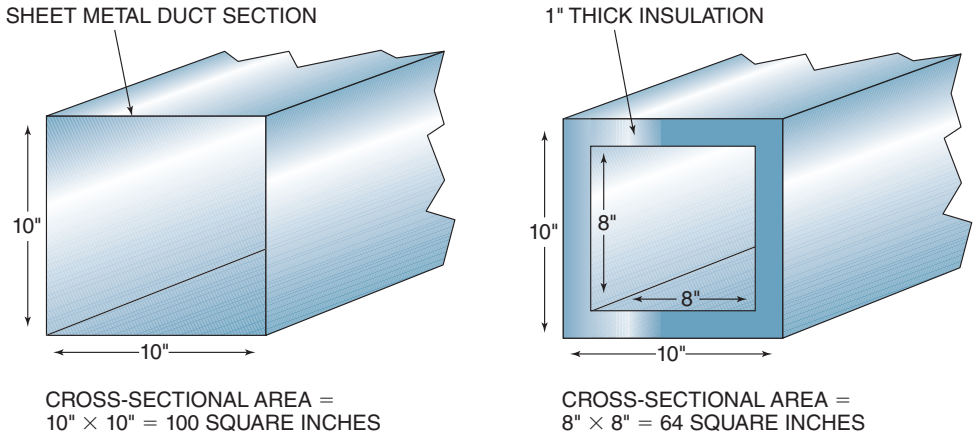

Figure 38.10 Ducts manufactured from compressed fiberglass with foil backing.

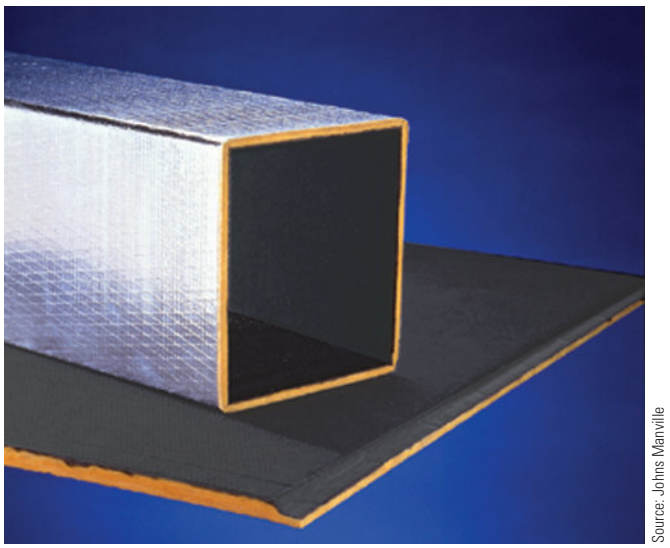

Figure 38.11 The outer skin is lapped over, and the backing of one piece is stapled to the backing of the other piece.

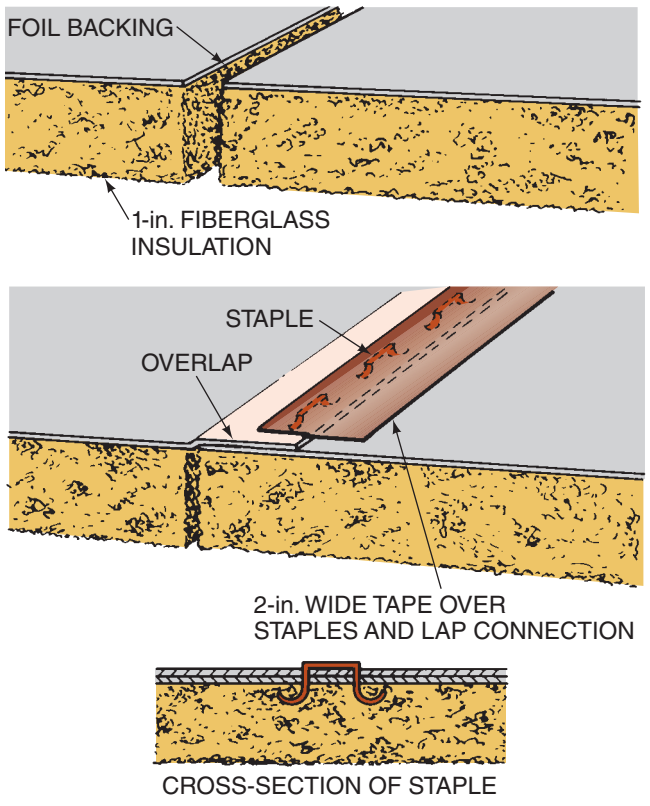

can be made with a utility or contractor's knife. Fiberglass ductboard come with insulation already attached to the outside skin. The skin is made of foil with a fiber running through it to give it strength. When assembling this duct, it is important to cut some of the insulation away so that the outer skin can lap over the surface that it is joining. The two skins are strengthened by stapling them together and taping to make them airtight, **Figure 38.11**.

Fiberglass ductboard can be made into almost all of the configurations that metal duct can. It is lightweight and easy to transport because the duct can be cut, laid out flat, and assembled at the job site. The original shipping boxes can be used to transport the ductboard and to keep it dry. Metal duct fittings, on the other hand, are large and take up a lot of space in a truck. Round fiberglass duct is as easy to install as flat ductboard because it can also be cut with a knife.

Fiberglass duct must be supported like metal duct to keep it straight. The weight of the ductboard itself will cause it to sag over long spans. A broad hanger that will not cut the cover of the ductboard is necessary. Like metal duct, fiberglass duct deadens sound because the inside of the duct has a coating (like the coating in metal duct liner that keeps the duct fibers from eroding) that helps to deaden any air or fan noise that may be transmitted into the duct. The duct itself is not rigid and does not carry sound.

38.6 INSTALLING FLEXIBLE DUCT

Flexible duct has a flexible liner and may have a fiberglass outer jacket for insulation if needed, for example, where heat exchange takes place between the air in the duct and the space where the duct is routed. The outer jacket is held by a moisture-resistant cover made of fiber-reinforced foil or vinyl. The duct may be used for the supply or return and should be run in a direct path to keep bends from narrowing the duct. Sharp bends can greatly reduce the airflow and should be avoided.

In the supply system, flexible duct may be used to connect the main trunk to the boot at the room diffuser. (The boot is the fitting that connects the duct to the supply register. In this case, it has a round connection on one end for the flexible duct and a rectangular connection on the other end where the floor register fastens to it.) The flexibility of the duct makes it valuable as a connector for metal duct systems. The metal duct can be installed close to the boot and the flexible duct can be used to make the final connection. Flexible duct used at the end of a metal duct run will help reduce any noise that may be traveling through the duct. This can help reduce the noise in the conditioned space if the blower or heater is noisy. Long runs of flexible duct are not recommended unless the friction loss is taken into account.

Flexible duct must be properly supported. A support band of 1.5 in. or more in width is the best method of keeping the duct from collapsing and reducing its inside dimension. Some flexible duct has built-in eyelet holes for hanging the duct. Tight turns should be avoided to keep the duct from collapsing on the inside and reducing the inside dimension. Flexible duct should be stretched to a comfortable length to keep the liner from closing up and creating friction loss.

38.7 ELECTRICAL INSTALLATION

The air-conditioning technician should be familiar with certain guidelines regarding electrical installation to make sure that the unit has the correct power supply and that the power supply is safe for the equipment, the service technician, and the owner. The control voltage for the space thermostat is often installed by the air-conditioning contractor even if the line-voltage power supply is installed by a licensed electrical technician.

The power supply must include the correct voltage and wiring practices, including wire size. The law requires the manufacturer to provide a nameplate with each electrical device that gives the voltage requirements and the current the unit will draw, **Figure 38.12**. The applied voltage (the voltage that the unit will actually be using) should be within ±10% of the rated voltage of the unit. That is, if the rated voltage of a unit is 230 V, the maximum operating voltage at which the unit should be allowed to operate would be 253 V (230 × 1.10 = 253). The minimum voltage would be 207 V (230 × 90 = 207). Some motors are rated at 208/230 V. This is a versatile rating because the unit will operate at ±208/230 V. The lower limit would be 187 V (208 × 90 = 187) and the upper limit would be 253 V (230 × 1.10 = 253).

NOTE: *If the unit operates for a long time beyond these limits, the motors and controls will be damaged.*•

Package equipment has one power supply for the unit. If the sytem is a split system there will be two power supplies: one for the inside unit and one for the outside unit. Both power supplies will go back to a main panel, but there will be a separate fuse or breaker for each at the main panel, **Figure 38.13**.

SAFETY PRECAUTION: *A disconnect or cutoff switch should be within 25 ft of each unit and within sight of the unit.*• If the disconnect is around a corner, someone may turn on the unit while the technician is working on the electrical system.

SAFETY PRECAUTION: *Care should be used while working with any electrical circuit. All safety rules must be adhered to. Particular care should be taken while working on the primary power supply to any building because the fuse that protects that circuit may be on the power pole outside. A screwdriver touched across phases may throw off pieces of hot metal before the outside fuse responds.*•

Wire-sizing tables specify the wire size that each component will need. The *National Electrical Code* (*NEC*) provides installation standards, including workmanship, wire sizes, methods of

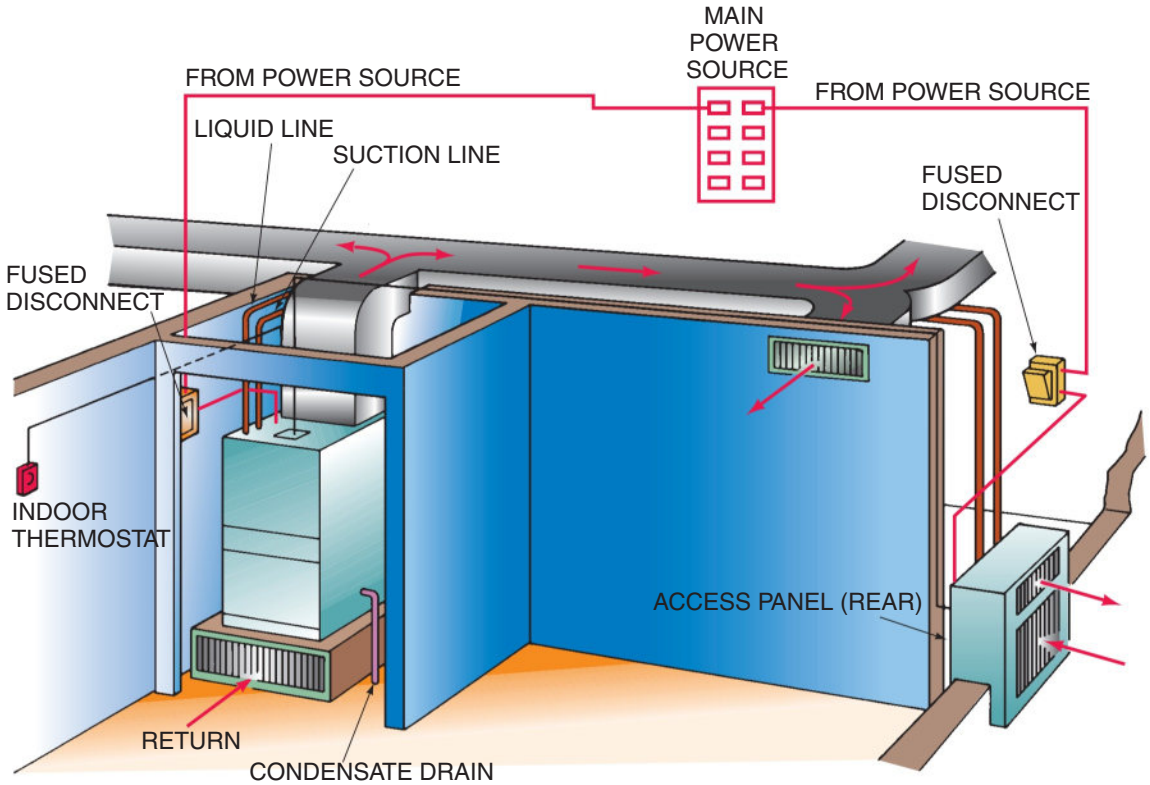
Figure 38.13 Wiring connecting indoor and outdoor units to the main power service.



routing wires, and types of enclosures for wiring and disconnects. Use it for all electrical wiring installation unless a local code prevails. The control-voltage wiring in air-conditioning and heating equipment is the line voltage that is reduced through a step-down transformer. It is installed with color-coded or numbered wires so that the circuit can be followed through the various components. For example, the 230-V power supply is often at the air handler, which may be in a closet, an attic, a basement, or a crawl space. The interconnecting wiring may have to leave the air handler and go to the room thermostat and the condensing unit at the back of the house. The air handler may be used as the junction for these connections, **Figure 38.14**.

Figure 38.14 This pictorial diagram shows the relative position of the wiring as it is routed to the room thermostat, the air handler, and the condensing unit.

Figure 38.15 This is called 18–8 thermostat wire. Its size is 18 gauge and there are 8 wires in the cable.

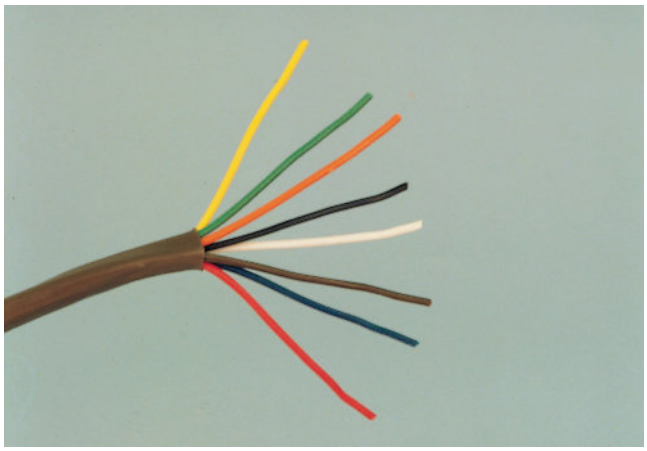

Photo by Bill Johnson

The control wire is a light-duty wire because it carries a low voltage and current. The standard wire size is 18 gauge. A standard air-conditioning cable has four wires each of 18 gauge in the same plastic-coated sheath and is called 18–4 (18 gauge, 4 wires). Red, white, yellow, and green wires are in the cable. Some wires may have eight conductors and are called 18–8, **Figure 38.15**. The cable or sheath can be installed by the air-conditioning contractor in most areas because it is low voltage. An electrical license may be required in some areas. **SAFETY PRECAUTION:** *Although low-voltage circuits are generally harmless, you can be hurt if you are wet and touch live wires. Use precautions for all electrical circuits.*•

38.8 INSTALLING THE REFRIGERATION SYSTEM

Both package and split systems include the mechanical or refrigeration part of the air-conditioning unit.

PACKAGE SYSTEMS

Package or self-contained equipment includes all components in one cabinet or housing. The window air-conditioner is a small package unit. Larger package systems may have 100 tons of air-conditioning capacity. The package unit is available in several different configurations for different applications, some of which are described here.

1. An air-to-air application is similar to a window air conditioner except that it has two motors. Because this unit is the most common, it will be discussed here. The term *air-to-air* refers to the fact that the refrigeration unit absorbs its heat from the air and rejects it into the air, **Figure 38.16**.
2. **Figure 38.17** shows an air-to-water unit. This system absorbs heat from the conditioned space air and rejects

Figure 38.16 An air-to-air unit.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

the heat into water. The water is wasted or passed through a cooling tower to reject the heat to the atmosphere. This system is sometimes called a water-cooled package unit.

3. Water-to-water describes the equipment in **Figure 38.18**. It has two water heat exchangers and is used in large commercial systems. The water is cooled and then circulated through the building to absorb the structure's heat, **Figure 38.19**. This system uses two pumps and two water circuits in addition to the fans to circulate the air in the conditioned space. To properly maintain this system, you need to be able to service pumps and water circuits.
4. Water-to-air describes the equipment in **Figure 38.20**. The unit absorbs heat from the water circuit and rejects the heat directly into the atmosphere. This equipment is used for larger commercial systems.

Air-cooled air-conditioning systems are by far the most common in residential and light commercial installations. These units must be set on a firm foundation. For rooftop installations the unit may be furnished with a roof curb. The roof curb raises the unit off the roof and provides waterproof duct connections to the conditioned space below. In new construction, the roof curb can be shipped separately and a roofer can install it, **Figure 38.21**. The air-conditioning contractor can then set the package unit on the roof curb for a watertight installation. The foundation for another type of an installation located beside the conditioned space may have a foundation made of high-impact plastic, concrete, or a metal frame, **Figure 38.22**. The unit should be placed where the water level cannot reach it.

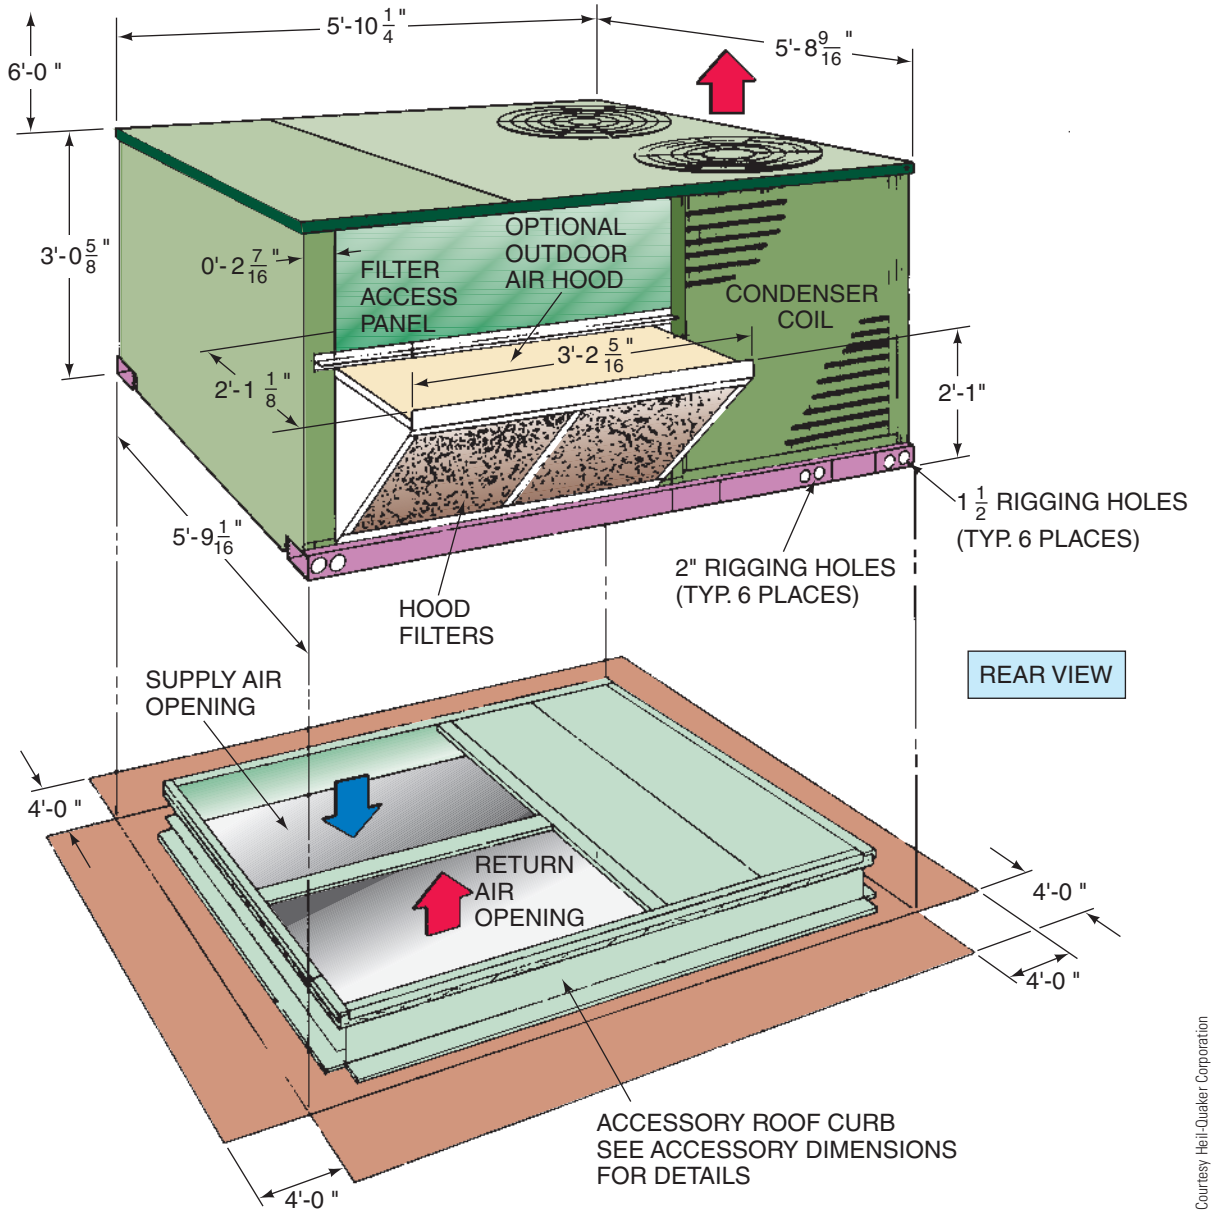
VIBRATION ISOLATION

The foundation of the unit should be placed in such a manner that vibration from the unit is not transmitted into the building. Some system for isolating vibration from the

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 38.21 This unit will sit on the roof curb.



Courtesy Heil-Quaker Corporation

building structure may be needed. Two common methods are rubber and cork pads and spring isolators. Rubber and cork pads are the simplest and least expensive method for simple installations, **Figure 38.23**. The pads come in sheets that can be cut to the desired size. They are placed under the unit at the point where the unit rests on its foundation. If there are raised areas on the bottom of the unit that make contact, the pads may be placed there. Spring isolators may also be used and need to be matched to the weight of the unit. The springs will compress and lose their effectiveness under too heavy a load. They also may be too stiff for a light load if not chosen correctly.

DUCT CONNECTIONS FOR PACKAGE EQUIPMENT

The ductwork that enters the structure may be furnished by the manufacturer or made by the contractor. Manufacturers furnish a variety of connections for rooftop installations but do not normally provide many factory-made fittings for those going through a wall. See **Figure 38.24** for a rooftop installation.

Package equipment comes in two different duct connection configurations relative to the placement of the return and supply ducts, either side by side or over and under. In the *side-by-side*

Figure 38.22 Various types of unit pads or foundations (A)–(C).

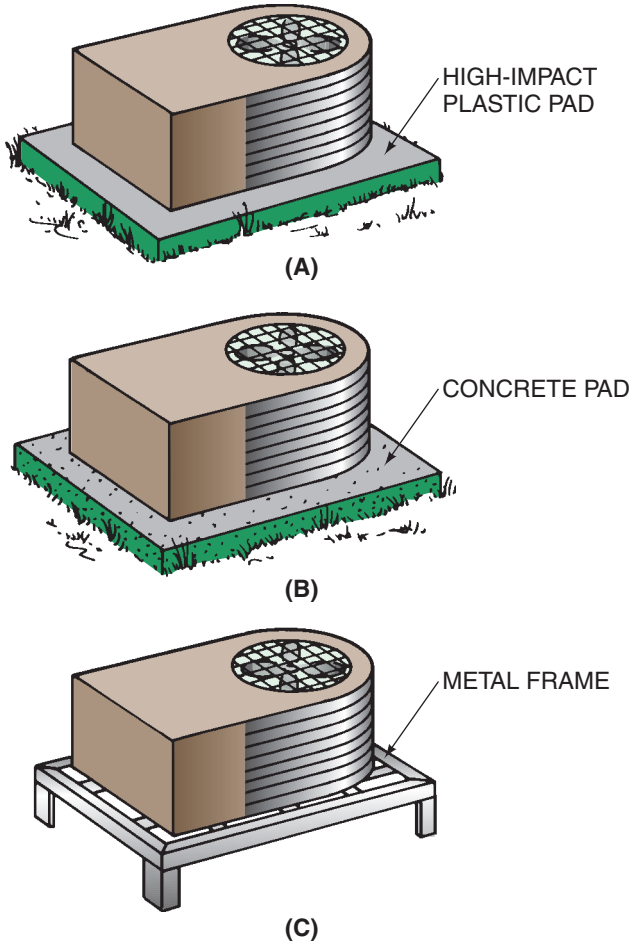

Figure 38.23 (A) Rubber and cork pads may be placed under the unit to reduce vibration. (B) Some smaller pads are constructed of a single cork layer.

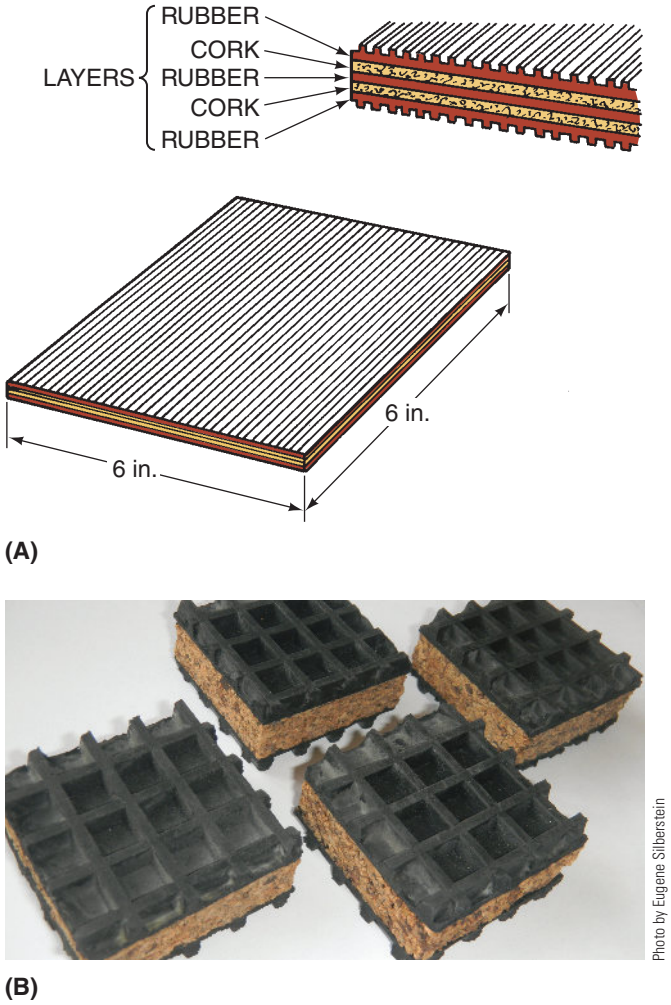

Figure 38.24 Duct connector for a rooftop installation.

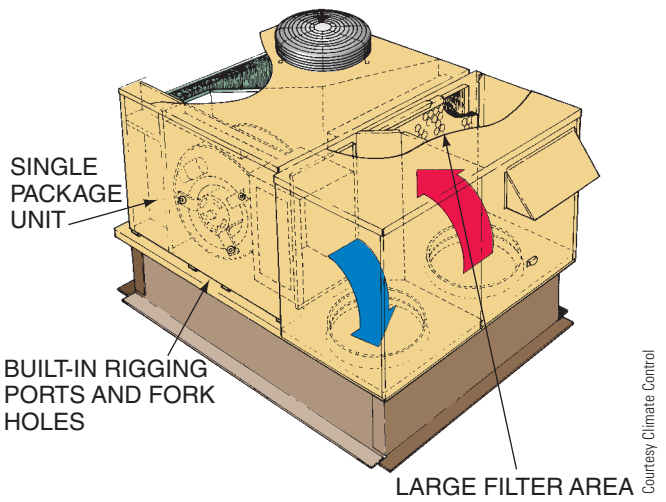

pattern, the return duct connection is beside the supply connection, **Figure 38.25**, and the connections are almost the same size. However, there is a large difference in the connection sizes on an over-and-under unit. If the unit is installed in a crawl space, the return duct must run on the correct side of the supply duct if the crawl space is low. It is difficult to cross a return duct over or under a supply duct if there is not enough room. The side-by-side duct design makes it easier to connect the duct to the unit because of the sizes of the connections on the unit. They are closer to square in dimension than are the over-and-under duct connections. If the duct has to rise or fall going into the crawl space, a standard duct size can be used.

The *over-and-under* connection is more difficult to fasten ductwork to because the connections are more oblong, **Figure 38.26**. They are wide because they extend from one side of the unit to the other and shallow because one is on top of the other. A duct transition fitting is almost always necessary to connect this unit to the ductwork. The transition is normally from wide shallow duct to almost square. When over-and-under systems are used, the duct system may be designed to be shallow and wide to keep from complicating

Figure 38.25 This air-to-air package unit has side-by-side duct connections.

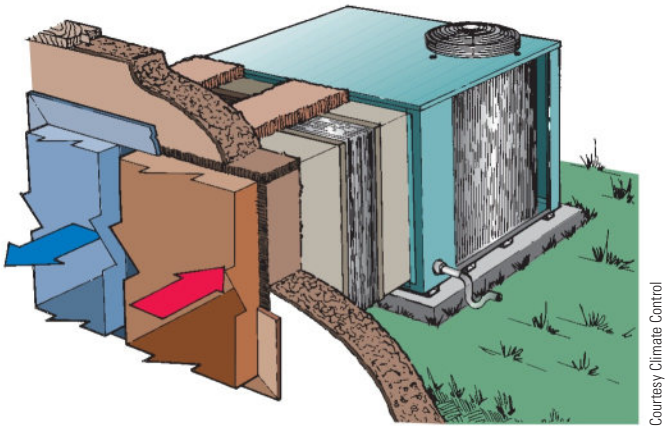

Figure 38.26 Over-and-under duct connections.

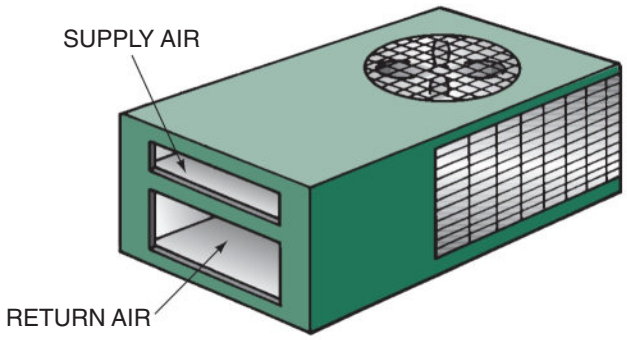

the duct transition. The duct connection in either style must be watertight and insulated, **Figure 38.27**. Some contractors cover the duct with a weatherproof hood.

At some time package equipment will need replacing. The duct system usually outlasts two or three units. Manufacturers may change their equipment style from over and under to side by side. This complicates choosing new equipment because when ducting already exists for an over-and-under connection, an over-and-under unit may not be as easy to find as a side-by-side unit, **Figure 38.28**.

Package air conditioners have no refrigerant piping that needs to be field installed. The piping is assembled within the unit at the factory. The refrigerant charge is included in the price of the equipment. Except for electrical and duct connections, the equipment is ready to start. One precaution must be observed, however. Most of these systems use refrigerants that have an affinity (attraction) for the oil in the system. The refrigerant will all be in the compressor if it is not forced out by a crankcase heater. **NOTE:** *All manufacturers that use crankcase heaters on their compressors issue a warning to leave the crankcase heater energized for some time, perhaps as long as 24 hours, before starting the compressor.* The installing contractor must

Figure 38.27 An air-to-air package unit installed through a wall.

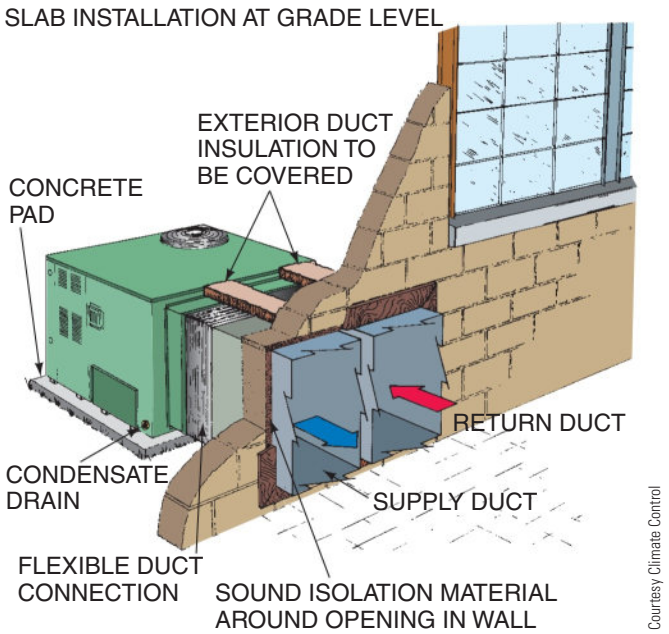

Figure 38.28 An air-cooled package unit with over-and-under duct connections. The manufacturer has changed the design to a side-by-side duct connection, so the installing contractor has a problem.

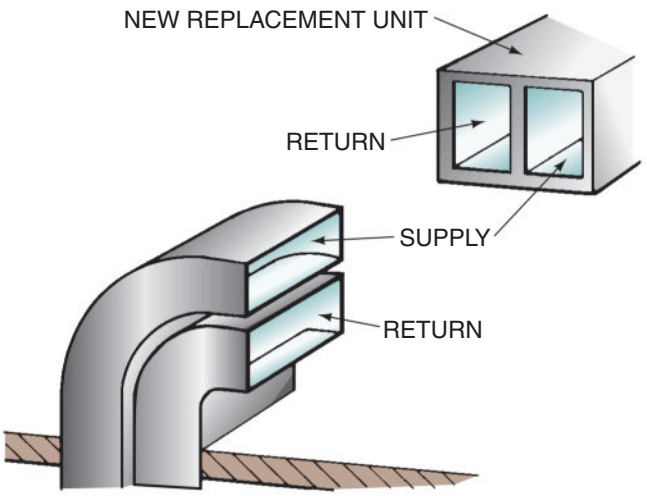

coordinate the electrical connection and start-up times closely because the unit should not be started immediately when the power is connected.

38.9 INSTALLING SPLIT-SYSTEM AIR CONDITIONERS

In split-system units, the evaporator is normally located close to the blower section regardless of whether the blower is in a furnace or in a special air handler. The air handler (blower section)

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

and coil must be located on a solid base or suspended from a strong support. The base for the air handler in upflow and downflow equipment often may be fireproof and rigid. Some vertical-mount air-handler units have a wall-hanging support.

When a unit is installed horizontally, it may rest on the ceiling joists in an attic, **Figure 38.29**, or on a foundation of blocks or concrete in a crawl space. Be sure to check local codes about resting the horizontal unit on the ceiling joists, as not all jurisdictions allow this practice. The air handler may be hung from the floor or ceiling joists in different ways, **Figure 38.30**. If the air handler is hung from above, vibration isolators are often located under it to keep blower noise or vibration from being transmitted into the structure. **Figure 38.31** is a trapeze hanger using vibration isolation pads.

The air handler (fan section) should always be installed so that it will be easily accessible for future service. The air handler will always contain the blower and sometimes the controls and heat exchanger. Most manufacturers have designed their air handlers or furnaces so that, when installed vertically, they are totally accessible from the front. This works well for closet installations where there is insufficient room between the closet walls and the sidewalls of the furnace or air handler. **Figure 38.32** is an electric furnace used as an air-conditioning air handler. When a furnace or air handler is located in a crawl space, side access is important, so the air handler should be located off the ground next to the floor joists. The ductwork also will be installed off the ground, **Figure 38.33**. If the air handler is top-access, it will have to be located lower than the duct and the duct must make a transition downward to the air handler on the supply and

Figure 38.29 A furnace located in an attic crawl space. See the manufacturer's instructions for suggestions. The unit may require a fireproofed base.

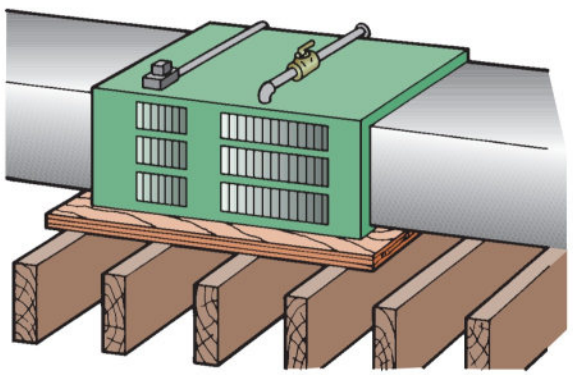

Figure 38.30 The air handler is hung from above, and the ductwork is connected and hung at the same height.

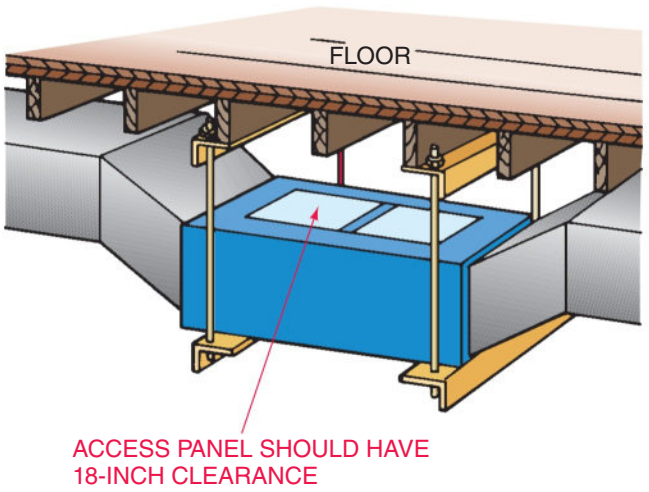

Figure 38.35 An evaporator installed in an attic crawl space.

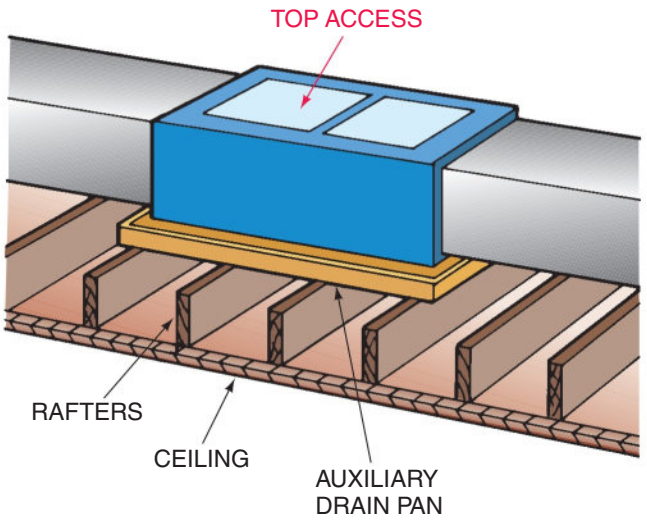

CONDENSATE DRAIN PIPING

When installing the evaporator, provisions must be made for the condensate that will be collected in the air-conditioning cycle. An air conditioner in a climate with average humidity will collect about 3 pints (pt) of condensate per hour of operation for each ton of air-conditioning. A 3-ton system would condense about 9 pt per hour of operation. This is more than a gallon of condensate per hour, or more than 24 gal in a 24-hour operating period. This can add up to a great deal of water over a period of time. If the unit is near a drain that is below the drain pan, simply pipe the condensate to the drain, **Figure 38.36**. A trap in the drain line will hold some water and keep air from pulling into the unit from the termination point of the drain. The drain may terminate in an area where foreign particles may be pulled into the drain pan. The trap will prevent this, **Figure 38.37**. If no drain is close to the unit, the condensate must be drained or pumped to another location, **Figure 38.38**. Some locations call for the condensate to be piped to a dry well. A dry well is a hole in the ground filled with stones and gravel. The condensate is drained into the well and absorbed into the ground, **Figure 38.39**. For this to be successful, the soil must be able to absorb the amount of water that the unit will collect.

When the evaporator and drain are located above the conditioned space, an auxiliary drain pan under the unit is recommended and often required, **Figure 38.40**. Airborne particles, such as dust and pollen, can get into the drains. Algae will also grow in the water in the lines, traps, and pans and may eventually plug the drain. If the drain system is plugged, the auxiliary drain pan will catch the overflow

and keep the water from damaging whatever is below it. This auxiliary drain should be piped to a conspicuous place. The owner should be warned that if the water ever comes from this drain line, a service call is necessary. Some contractors pipe this drain to the end of the house and out next to a driveway or patio so that if water were ever to drain from this point it would be readily noticed, **Figure 38.41**. Some auxiliary drain pans do not have any drain or piping connections at all. Instead, they have float switches located in the pan that are wired in series with the low-voltage power supply. If water accumulates in the auxiliary drain pan,

the float will rise and open the control circuit. The system will not operate until the service technician responds to the no-cooling call that will result.

38.10 THE SPLIT-SYSTEM CONDENSING UNIT

The condensing unit location is separate from that of the evaporator. The following must be considered carefully when placing a condensing unit:

1. Proper air circulation
2. Convenience for piping and electrical service
3. Future service
4. Natural water and roof drainage
5. Solar influence
6. Appearance

AIR CIRCULATION AND INSTALLATION

The unit must have adequate air circulation. The air discharge from the condenser may be from the side or from the top. Discharged air must not hit an object and circulate back through the condenser. The air leaving the condenser is warm or hot and will create high head pressure and poor operating efficiency if it passes through the condenser again. Follow the manufacturer's literature for minimum clearances for the unit, **Figure 38.42**.

ELECTRICAL AND PIPING CONSIDERATIONS

The refrigerant piping and the electrical service must be connected to the condensing unit. Piping is discussed later in this unit, but, for now, realize that the piping will be routed between the evaporator and the condenser. When the condenser is located next to a house, the piping must be routed between the house and the unit, usually behind or beside the house with the piping routed next to the ground. If the unit is placed too far from the house, the piping and electrical service become natural obstructions between the house and the unit.

Figure 38.42 The condensing unit for a split system located so that it has adequate airflow and service room.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Children may jump on the piping and electrical conduit. If the unit is placed too close to the house, it may be difficult to remove the service panels. Before placing the unit, study the electrical and the refrigeration line connections and make them as short as practical, leaving adequate room for service.

SERVICE ACCESSIBILITY

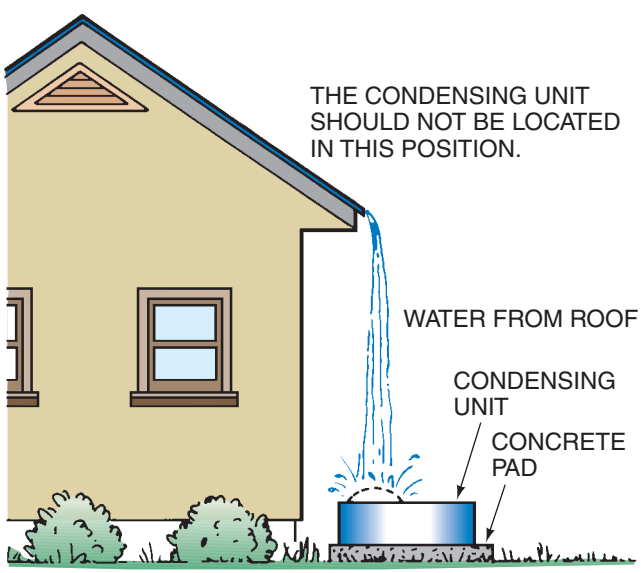
Unit placement may determine whether a service technician gives good service or barely adequate service. The technician must be able to see what is being worked on. A unit is often placed so that the technician can touch a particular component but is unable to see it, or, by shifting positions, can see the component but not touch it. The technician should be able to both see and touch the work at the same time.

WATER DRAINAGE FROM NATURAL SOURCES

The natural drainage of the ground water and roof water should be considered in unit placement. **SAFETY PRECAUTION:** *The unit should not be located in a low place where groundwater will rise in the unit. If this happens, the controls may short to ground, and the wiring will be ruined.* All units should be placed on a base pad of some sort. Concrete and high-impact plastic are commonly used. Metal frames can be used to raise the unit when needed.

The roof drainage from a structure may run off into gutters. The condensing unit should not be located where the gutter drain or roof drainage will pour down onto it. Condensing units are made to withstand rainwater but not large volumes of drainage. If it is a top-discharge unit, the drainage from above will be directly into the fan motor, **Figure 38.43**.

Figure 38.43 This unit is located improperly and allows the roof drain to pour down into the top of the unit.



SOLAR INFLUENCE

If possible, put the condensing unit on the shady side of the house because the sun shining on the panels and coils will lower the efficiency. However, the difference is not crucial, and it would not pay to pipe the refrigerant tubing and electrical lines long distances just to keep the sun from shining on the unit. Shade helps cool the unit, but it may also cause problems. Some trees have small leaves, sap, berries, or flowers that may harm the finish of the unit. Pine needles may fall into the unit, and the pine pitch that falls on the cabinet may harm the finish and outweigh the benefit of placing the unit in the shade of many types of trees.

PLACING A CONDENSING UNIT FOR BEST APPEARANCE

The condensing unit should be located where it will not be noticeable or will not make objectionable noise. When located on the side of a house, the unit may be hidden from the street with a low shrub. If the unit is a side-discharge type, the fan discharge must be away from the shrub or the shrub may not survive. A top-discharge unit will not affect plants, but the noise of the unit will be higher, which may be objectionable in a bedroom located above the unit.

Locating the condensing unit at the back of the house may place it closer to the evaporator and would mean shorter piping, but the back of the house is the usual location of patios and porches, and the homeowner may not want to hear the unit while sitting outside. In such a case, a side location at the end of the house where there are no bedrooms may be the best choice.

Each location has its considerations. The salesperson and the technician should consult with the owner about locating the various components. The salesperson should be familiar with all local code requirements. Local codes provide guidelines, for example, with respect to how close a condensing unit can be to the property line. Issues such as this need to be investigated before the location is selected to avoid having to relocate the unit later on. A floor plan of the structure may help. Some companies use large graph paper to draw a rough floor plan to scale when estimating the job. The location of the equipment can be indicated on the rough floor plan to help identify potential problems. The floor plan can be shown to homeowners to help them understand the contractor's suggestions.

38.11 INSTALLING REFRIGERANT PIPING ON SPLIT-SYSTEMS

The refrigerant piping is always a big consideration when installing a split-system air conditioner. The choice of the piping system may make a difference in the start-up time. The piping should always be kept as short as practical. For an air-conditioning installation, three methods are

used to connect the evaporator and the condensing unit on almost all equipment under 5 tons (refrigeration systems for commercial refrigeration are not the same): (1) contractor-furnished piping; (2) flare or compression fittings, with the manufacturer furnishing the tubing (called a line set); and (3) precharged tubing with sealed quick-connect fittings, called a precharged line set. **In all of these systems the operating charge for the system is shipped in the equipment.**

THE REFRIGERANT CHARGE

Regardless of the source of the connecting tubing, the complete operating charge for the system is normally furnished by the manufacturer. The charge is shipped in the condensing unit. The manufacturer furnishes enough charge to operate the unit with a predetermined line length, typically 25 ft. Be sure to check the installation and start-up instructions that come with the equipment to learn more about the refrigerant charge and its associated refrigerant line length. The manufacturer holds and stores the refrigerant charge in the condensing unit with service valves if the tubing uses flare or compression fittings. With quick-connect line sets, the correct operating charge for the line set is included in the actual lines. See **Figure 38.44** for an example of both service valves and quick-connect fittings. *As of January 1, 2010, it became illegal to manufacture or import air-conditioning equipment that is precharged with either R-22 or R-142b. This law covers equipment components such as line sets, condensing units, and evaporator coils. For example, precharged line sets can be used to service existing equipment as long as the line set was manufactured before January 1, 2010.*

When service valves are used, the piping is fastened to the valves by flare or compression fittings. Some manufacturers provide the option of soldering to the service valve connection. The piping is always hard-drawn or soft copper. In installations where the piping is exposed, straight pipe may look better and hard-drawn tubing may be used with factory elbows for the turns. When the piping is not exposed, soft copper is easily formed around corners where a long radius will be satisfactory.

THE LINE SET

Manufacturer-furnished tubing is called a *line set*. *The suction line is insulated,* and the tubing may be charged with nitrogen, contained by rubber plugs in the tube ends. When the rubber plugs are removed, the nitrogen rushes out with a loud hiss. This indicates that the tubing is not leaking. Make sure you know the type of system you are working on when installing the line set. Some ductless split systems, for example, have the metering device in the outdoor unit, so both field-installed refrigerant lines are on the low-pressure side of the system and both will need to be insulated. Uncoil tubing from the end of the coil. Place one end of the coil on the ground and unroll it while keeping your foot on the tubing end on the ground, **Figure 38.45**. **NOTE:** *Be careful not to kink the tubing when going around corners, or it may collapse. Because of the insulation on the pipe, you may not even see the kink.*

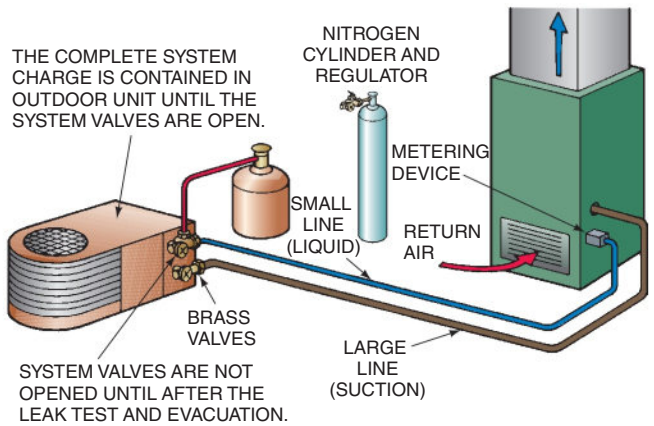
TUBING LEAK TEST AND EVACUATION

When the piping is routed and in place, the following procedure is commonly used to make the final connections:

1. The tubing is fastened at the evaporator end. Many tubing sets offer either compression fittings or a braze connection. Flaring also may be an option. Brazed connections are the connection of choice when done correctly. When the tubing has flare nuts, a drop of oil applied to the back of the flare will help prevent the flare nut from turning the tubing when the flare connection is tightened. The suction line may be as large as 1⅛-in. OD tubing. Large tubing connections will have to be made very tight. Two adjustable wrenches are recommended. The liquid line will not be any smaller than ¼-in. OD tubing, and it may be as large as ½-in. OD on larger systems.
2. The smaller (liquid) line is fastened to the condensing unit service valve.
3. The larger (suction) line is fastened.
4. The service valves are still closed. Allow a small amount of the system refrigerant into the line set and evaporator through the Schrader valve ports for leak-checking purposes. Add nitrogen to bring the pressure in the line set and evaporator up to the test pressure.
5. After the leak check, you are allowed to release the trace amount of refrigerant and nitrogen to the atmosphere. Connect the vacuum pump to the line set and evaporator portion of the system and evacuate it to a deep vacuum, **Figure 38.46.** *4R EPA rules allow this process using a trace of the system refrigerant and nitrogen as a de minimis loss of refrigerant. 4R*
6. When the evacuation is complete, open the valves at the condensing unit. The complete charge should be stored in the unit. Check the manufacturer's installation manual for the correct charge for the length of line set. Follow the instructions for the correct charge, if needed.

Figure 38.46 After all line set connections are made tight, the line set is leak checked using refrigerant and nitrogen. The line set is then evacuated, and the system valves are opened.



Line sets come in standard lengths of 25 or 50 ft. If lengths other than these are needed, the manufacturer should be consulted. If the line length has to be changed from the standard length, the manufacturer will also recommend how to adjust the unit charge for the new line length. Most units are shipped with a charge for 25 ft of line. If the line is shortened, refrigerant must be recovered. If the line is longer than 25 ft, refrigerant must be added.

ALTERED LINE-SET LENGTHS

When line sets must be altered, they may be treated as a self-contained system of their own. The following procedures should be followed:

1. Alter the line sets as needed for the proper length. The nitrogen charge will escape during this alteration. **Do not remove the rubber plugs.**
2. When the alterations are complete, the lines may be pressured to about 25 psig to leak check any connections you have made. The rubber plugs should stay in place. If you desire to pressure test with higher pressures, remove the rubber plugs and connect evaporator and condenser ends; you may safely pressurize the lines, and the evaporator coil, to the factory test-pressure indicated on the evaporator coil. The line's service port is common to the line side of the system. If the valves are not opened at this time, the line set and evaporator may be thought of as a sealed system of their own for pressure testing and evacuation, **Figure 38.47.**
3. After the leak test has been completed, evacuate the line set (and evaporator, if connected). When all connections are made and checked, the system valves may be opened and the system started.

Figure 38.47 Altering the line set. After the line set has been altered, it is connected as in Figure 38.46 and charged with nitrogen and a trace gas of system refrigerant for leak-checking purposes. After checking for leaks, the refrigerant trace gas and nitrogen are released to the atmosphere. The line set and evaporator are then evacuated. After evacuation, the system valves are opened and the system is ready to run.

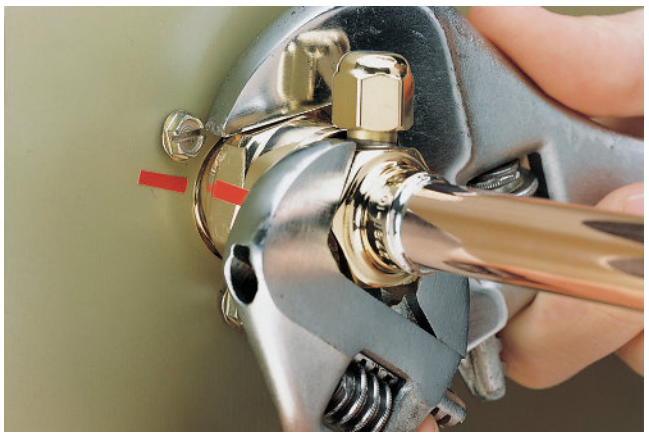
PRECHARGED LINE SETS (QUICK-CONNECT LINE SETS)

Precharged line sets with quick-connect fittings are shipped in most of the standard lengths. The difference between line sets and precharged line sets is that the correct refrigerant operating charge is shipped in the precharged line set. Refrigerant does not have to be added or taken out unless the line set is altered. The following procedures are recommended for connecting precharged line sets with quick-connect fittings:

1. Roll the tubing out straight.
2. Determine the routing of the tubing from the evaporator to the condenser and put it in place.
3. Remove any protective plastic caps on the evaporator fittings. Place a drop of refrigerant oil (this is sometimes furnished with the tubing set) on the neoprene O-rings of each line fitting. The O-ring is used to prevent refrigerant from leaking out while the fitting is being connected; it serves no purpose after the connection is made tight. It may tear while making the connection if it is not lubricated.
4. Start the threaded fitting and tighten hand tight. Making sure that several threads can be tightened by hand will ensure that the fitting is not cross-threaded.
5. When the fitting is tightened hand tight, finish tightening the connection with a wrench. You may hear a slight escaping of vapor while making the fitting tight; this purges the fitting of any air that may have been in the fitting. The O-ring should be seating at this time. Once you have started tightening the fitting, do not stop until you are finished. Two adjustable wrenches are recommended, **Figure 38.48**. If you stop in the middle, some of the system charge may be lost.
6. Tighten all fittings as indicated.
7. After all connections have been tightened, leak check all connections that you have made.

Figure 38.48 Using two wrenches to tighten fittings—one to hold the nut with the service tap on it and one to turn the movable nut next to the cabinet.



Reprinted with the permission of Aeroquip Corporation

ALTERED PRECHARGED LINE SETS

When the lengths of quick-connect line sets are altered, the charge will also have to be altered. The line set may be treated as a self-contained system for alterations. The following is the recommended procedure:

1. *4R Before connecting the line set, recover the refrigerant. Do not just cut the line because both the liquid and suction lines contain some liquid refrigerant. Recovering the refrigerant is required. 4R*
2. Cut the line set and alter the length as needed.
3. Pressure test the line set.
4. Evacuate the line set to a low vacuum.
5. Valve off the vacuum pump and pressurize it to about 10 psig on just the line set (using refrigerant that is the same as the refrigerant in the system) and connect it to the system using the procedures already given.
6. Read the manufacturer's recommendation as to the amount of charge for the new line lengths and add this much refrigerant to the system. If no recommendations are provided, see **Figure 38.49** for a table of liquid-line and suction-line

Figure 38.49 A table of liquid-line capacities.

capacities for some commonly encountered refrigerant capacities. The liquid line should contain the most refrigerant, and the proper charge should be added to that line to make up for what was lost when the line was cut. If an R-410A air-conditioning system is being installed with a 40-ft line set (½″ liquid line and 1⅛″ suction line) and the system's holding charge is sufficient for a 25-ft refrigerant line set, refrigerant will need to be added to the system. The amount of refrigerant to be added will be for the additional 15 ft of refrigerant line set. The amount of refrigerant will be, from **Figure 38.49**, 15 ft × (0.035 + 5.35), or 80.8 ounces of R410A.

PIPING ADVICE

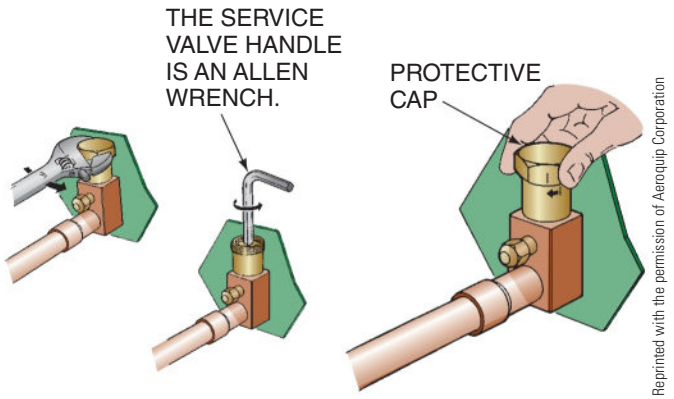
The piping practices that have been described for air-conditioning equipment are typical of most manufacturers' recommendations. **The manufacturer's recommendation should always be followed.** Each manufacturer ships installation and start-up literature inside the shipping crate. If it is not there, request it from the manufacturer.

38.12 EQUIPMENT START-UP

The final step in installation is starting the equipment. The manufacturer will furnish start-up instructions. After the unit or units are in place, are leak checked, have the correct factory charge furnished by the manufacturer, and are wired for line and control voltage, follow these guidelines:

1. The line voltage must be connected to the unit disconnect panel. This should be done by a licensed electrician. Disconnect a low-voltage wire, such as the Y wire at the condensing unit, to prevent the compressor from starting. Turn on the line voltage. The line voltage allows the crankcase heater to heat the compressor crankcase. **NOTE:** *This applies to any unit with crankcase heaters. Heat must be applied to the compressor crankcase for the amount of time the manufacturer recommends (usually not more than 24 h). Heating the crankcase boils out any refrigerant before the compressor is started. If the compressor is started with liquid in the crankcase, some of the liquid will reach the compressor cylinders and may cause damage. The oil also will foam and provide only marginal lubrication until the system has run for some time.*•
2. It is normally a good idea to plan on energizing the crankcase heater in the afternoon and starting the unit the next day. Before you leave, make sure that the crankcase heater is hot.
3. If the system has service valves, open them. **NOTE:** *Some units have valves that do not have back seats. Do not try to back seat these valves, or you may damage the valve.*• Open the valve until resistance is felt, then stop, **Figure 38.50**.
4. Check the line voltage at the installation site and make sure that it is within the recommended limits.

Figure 38.50 Service valves furnished with equipment may not have a "back seat." Do not try to turn the valve system all the way out.



Reprinted with the permission of Aeroquip Corporation

5. Check all electrical connections, including those made at the factory, and ensure that they are tight and secure. **SAFETY PRECAUTION:** *Turn the power off when checking electrical connections.*•
6. Set the fan switch on the room thermostat to FAN ON and check the indoor blower for proper operation and current draw. You should feel air at all registers normally about 2 to 3 ft above a floor register. Make sure that no air blockages exist at the supply and return openings.
7. Turn the fan switch to FAN AUTO, and with the HEAT-OFF-COOL selector switch to the OFF position, replace the Y wire at the condensing unit. **SAFETY PRECAUTION:** *The power at the unit is turned off and the panel is locked and tagged while making this connection.*•
8. Place your ammeter on the common wire to the compressor, have someone move the HEAT-OFF-COOL selector switch to COOL, and slide the temperature setting to call for cooling. The compressor should start.
9. In most cases, the manufacturer will provide detailed information regarding the procedures to follow to ensure that the system is properly charged. Refer to Unit 10, "System Charging," for details regarding proper system charging methods. Regardless of the manufacturer, evaluating the refrigerant charge in an air-conditioning system relies on a number of factors that might include:
   - Outside ambient temperature
   - Return air temperature (wet-bulb and/or dry-bulb)
   - Condenser saturation temperature
   - Evaporator saturation temperature
   - Evaporator superheat
   - Condenser subcooling

New generation field tools and instruments make the taking and evaluating of system readings much easier. For example, a set of sensors, **Figure 38.51**, can be used to monitor system pressures and saturation temperatures, as well as evaporator superheat and condenser subcooling. This particular set contains two pressure sensors, one for the high side and one for

the low side, and two temperature sensors, one for the high side and one for the low side. The pressure sensors are connected to the service ports on the system, **Figure 38-52**, and the temperature sensors are simply clamped onto the suction and liquid lines of the system, **Figure 38-53**.

Once the four sensors have been secured, the system's operating pressures and temperatures, as well as superheat and subcooling, can be obtained from a smart phone or other compatible device, **Figure 38-54**. Once the application has been launched, the technician can select the correct refrigerant for the system in order to ensure proper readings, **Figure 38-55**.

The amperage of the compressor is a good indicator of system performance. If the outside temperature is hot and there is a significant heat load on the evaporator, the compressor will be pumping at near capacity. The amperage draw of the compressor motor will be near nameplate amperage. It is rare for the compressor amperage to be higher than the nameplate rating due only to the system load. It is also normal for the compressor amperage to be slightly below the nameplate rating.

SAFETY PRECAUTION: *Before starting the system, examine all electrical connections and moving parts. The equipment may have faults and defects that can be harmful (e.g., a loose pulley may fly off when the motor starts to turn). Remember that vessels and hoses are under pressure. Always be mindful of potential electrical shock.*•

SUMMARY

- Duct systems are normally constructed of square, rectangular, or round metal; ductboard; or flexible material.
- Square and rectangular metal duct systems are assembled with S fasteners and drive clips.
- The first fitting in a duct system may be a vibration eliminator to keep any fan noise or vibration from being transmitted into the duct.
- Insulation may be applied to the inside or outside of any metal duct system that may exchange heat with the ambient.
- When the duct is insulated on the outside, a vapor barrier must be used to keep moisture from forming on the duct surface if the duct surface is below the dew point temperature of the ambient.
- Flexible duct is a flexible liner that may have a cover of fiberglass that is held in place with vinyl or reinforced foil.
- The electrical installation includes choosing the correct enclosures, wire sizes, and fuses or breakers.
- The electrical contractor will normally install the line-voltage wiring, and the air-conditioning contractor will usually install the low-voltage control wiring. Local codes should be consulted before any wiring is done.
- The low-voltage control wiring is normally color-coded.
- Air-conditioning equipment is manufactured in package systems and split systems.
- Air-to-air package equipment installation consists of placing the unit on a foundation, connecting the ductwork, and connecting the electrical service and control wiring.
- The duct connections in package equipment may be made through a roof or through a wall at the end of a structure.
- Roof installations have waterproof roof curbs and factory-made duct systems.
- Isolation pads or springs placed under the equipment prevent equipment noise from traveling into the structure.
- Two refrigerant lines connect the evaporator and the condensing unit; the large line is the insulated suction line, and the small line is the liquid line.
- The air handler and condensing unit should be installed so that they are accessible for service.
- Provision for a condensate drain must be made for the evaporator.
- A secondary drain pan should be provided if the evaporator is located above the conditioned space.
- The condensing unit should not be located where its noise will be bothersome.
- Line sets come in standard lengths of 25 and 50 ft. The system charge is normally for 25 ft when the whole charge is stored in the condensing unit.
- Line sets may be altered in length. The refrigerant charge must be adjusted when the lines are altered.
- The start-up procedure for the equipment is in the manufacturer's literature. Before start-up, check the electrical connections, the fans, the airflow, and the refrigerant charge.

REVIEW QUESTIONS

1. The three crafts normally associated with an air-conditioning installation are _____, _____, and _____.
2. True or False: The flexible duct system is the most economical.
3. Name the two fasteners that typically fasten square or rectangular connections.
4. What fastener is normally used to fasten round duct connections?
5. True or False: Insulation on duct does not prevent duct from sweating.
6. When insulation on the inside of the duct comes loose it causes
   A. the system to shut off.
   B. high head pressure.
   C. increased airflow.
   D. reduced airflow.
7. Most duct insulation is made of _____.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

8. What is the purpose of the flexible duct connector?
9. What happens if flexible duct is turned too sharply around a corner?
10. Why must flexible duct be stretched slightly for straight runs?
11. Explain how flexible duct is supported when installed.
12. The two duct connection combinations for a package unit are _____ and _____.
13. What are the differences between a package system and a split system?
14. True or False: A package unit comes from the factory with the charge inside.
15. Name three criteria for a good location for an air-cooled condensing unit.

UNIT 39

RESIDENTIAL ENERGY AUDITING

OBJECTIVES

After studying this unit, you should be able to

- describe the three broad categories of a residential energy audit.
- discuss the meaning of thermal boundaries.
- briefly describe a base load inspection.
- list and briefly explain the five diagnostic tests of a residential energy audit.
- discuss health and safety issues as they relate to indoor air quality for energy audits.
- describe infrared scanning using a thermal imaging camera as it applies to auditing.
- discuss how sealing air leaks in a residential structure will help save energy.
- discuss what is meant by a duct leakage test.
- briefly describe the differences between total duct air leakage tests and duct leakage tests to the outdoors.
- explain what is meant by a blower door test.
- list some ways of sealing air leaks for energy conservation in a residential house.
- explain what part combustion efficiency plays in a residential energy audit.
- discuss what is meant by furnace efficiency testing.
- explain the importance of draft as it applies to combustion appliances.
- discuss the importance and safety issues of properly venting combustion appliances.
- describe different flame safeguard controls and their importance for the health and safety of the home's residents.
- explain high-efficiency gas furnace anatomy.
- state the importance of numerical analysis and reporting for residential energy audits.
- describe the difference between base load and seasonal usage of energy as it applies to a home.
- discuss what is meant by a home's energy index.

SAFETY CHECKLIST

- ☑ Blower door testing may cause some safety problems within the structure especially with combustion appliances. The negative pressure or vacuum of 50 Pascals may cause combustion appliances to backdraft. It is important to shut off all combustion appliances when performing a blower door test.
- ☑ The auditor must also identify all thermal boundaries, conditioned zones, and combustion appliance zones (CAZ) in the house, close all exterior windows and doors, and open all interior doors before performing a blower door test.
- ☑ Return duct air leaks within a combustion appliance zone (CAZ) need to be sealed. If not sealed, the CAZ can become depressurized and cause the combustion appliances to backdraft. Backdrafting can cause harmful combustion by-products to enter the conditioned space and be potentially dangerous to humans.
- ☑ The energy auditor must anticipate any safety issues before performing a blower door test by turning off all combustion appliances, inspecting all sources of pollutants like fireplaces or wood stoves, and inspecting for any large air leaks that may prevent the blower door from achieving the desired vacuum level. The auditor must plug these openings temporarily.
- ☑ Because it may contain asbestos, vermiculite insulation poses a health hazard when performing a blower door test on a structure. It is strongly recommended not to perform a blower door test that draws a negative pressure on the home if this type of insulation insulates any part of the structure. Blower door tests that put a positive pressure on the structure to check for air exfiltration can be used.
- ☑ Recessed light fixtures (can lights) can be a major source of heat loss, but you need to be careful how close you place insulation next to a fixture unless it is marked (IC)—designed for direct insulation contact. Otherwise, a fire hazard exists. Recessed light fixtures are also rated for insulation contact and air tightness (ICAT). Check your local building codes for recommendations.

39.1 INTRODUCTION

Residential (home) energy audits not only provide homeowners with an opportunity to lower their monthly utility bills, they also can help our nation become less dependent on foreign oil by conserving energy. The conservation of natural resources is an added attraction for many homeowners to have an energy audit performed on their home. Homeowners can cut utility bills by 15% or more by following energy audit recommendations. However, before energy conservation and savings can occur, energy audit recommendations must be followed. It is important that we all do our part to make this world a better world to live in.

According to the United States Department of Energy (DOE), 55% of the energy used by the average home goes toward space heating and space cooling. The U.S. Department of Energy also says that a home's heating and cooling

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. costs can be reduced by as much as 30% through proper insulation and air-sealing techniques. The DOE further says that 12% of a home's total energy bill usually goes toward heating water for household use. Federal help to pay for these modifications may be available through state and local utilities or from low-income housing programs. Check with local utilities or city or the DOE-sponsored Database of State Incentives for Renewables and Efficiency (DSIRE).

Much research has been conducted by the U.S. Department of Energy's Building America and Home Performance with ENERGY STAR, sponsored by the U.S Environmental Protection Agency (EPA) and the DOE. Home Performance with ENERGY STAR offers a comprehensive, whole-house approach to improving the energy efficiency and comfort of existing homes and the testing of combustion products. The DOE's Building America program has worked with some of the nation's leading building scientists and more than 300 production builders on over 40,000 new homes at the time of this writing. Building America research applies building science to the goal of achieving efficient, comfortable, healthy, and durable homes.

There are a number of organizations that offer certifications for home auditors and contractors including:

1. Association for Energy Engineers (AEE)
2. Building Performance Institute (BPI)
3. Green Mechanical Council
4. Residential Energy Services Network (RESNET)

BPI offers the Building Analyst certification and RESNET offers the HERS Rater certification. Historically, BPI certification has focused on understanding the building science of retrofitting existing homes; RESNET has focused on building science in new home construction. BPI is a nonprofit organization that accredits auditors, contractors, and other building professionals. Auditors and building analysts specialize in evaluating building systems and potential energy savings in homes.

A certified BPI Building Analyst energy auditor has passed both written and field exams, and must recertify every three years. Contractors learn about building systems and are trained to install energy-efficient measures. The Green Mechanical Council offers a certification series which includes two written exams and a field or performance based examination. The written examinations includes a Load Calculation Analyst exam as well as a Residential Energy Analyst exam. The performance or field exam requires observation and validation that the candidate can apply their knowledge of energy audit tasks in the field. The Green Mechanical Certification is most often utilized in conjunction with a training curriculum developed by HVAC Excellence. A certified RESNET energy auditor is called a HERS Rater. HERS is an acronym for the Home Energy Rating System. A written exam and field observation along with continuing education is required to become a HERS Rater. HERS provides a mile-per-gallon type of rating for expected energy consumption in homes based on computer models. Each home receives a score that can be compared with other new or existing homes. The lower the score, the more energy efficient the home is. An easy way to find an energy contractor is through a national or regional retrofit program. One such program is Home Performance with ENERGY STAR. This program is a national program from the EPA and the DOE that promotes a comprehensive, whole-house approach to energy-efficiency improvements.

Green awareness, global warming, energy efficiency, energy savings, sustainability, and high-performance buildings are on the environmental and energy forefront. Energy audits of residential, commercial, or industrial buildings have become an integral part of evaluating and assessing an existing building's energy performance. Higher efficiency standards have been established for the energy performance of new buildings, and higher levels of training and certification have been developed for auditors, contractors, and HVAC/R technicians to meet the needs of more sophisticated, energy-efficient buildings and HVAC/R equipment. This unit will cover residential energy audits, which are also referred to as home energy audits.

39.2 RESIDENTIAL (HOME) ENERGY AUDITING

More HVAC/R contractors are offering home auditing services because of its direct impact on a home's heating and cooling costs. Once the home audit is completed, they perform **weatherization** techniques to improve the energy efficiency of the residential structure. The terms *residential energy audit* and *home energy audit* are often used interchangeably. A residential energy audit can be defined as the steps taken to increase the homeowner's comfort, safety, and health and the life of the home, while conserving energy and saving the homeowner money. Audits also are environmentally beneficial because they decrease environmental pollution. The home energy audit can be divided into three broad categories:

1. Screening, visual inspections, and measurements
2. Diagnostic testing
3. Numerical analysis with reporting

The depth of the energy audit will depend on the homeowner's commitment to energy and cost savings, the qualifications and capabilities of the energy auditor, and what program, if any, is requiring certain energy-saving parameters to be tested, quantified, and reported. However, a comprehensive residential energy audit generally consists of the following:

1. Screening is a preliminary evaluation of the homeowner's needs. It can involve gathering information by phone calls or completing an Internet-based pre-audit by homeowners themselves. During this phase, a walk-through visual inspection of the residential structure to diagram and record the square footages and volumes of all rooms is performed. Visual inspections should include both the

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

interior and exterior of the residence. HVAC systems should also be visually inspected for proper installation and safety concerns. The walk-through visual phase should identify any health and safety issues relating to asbestos, fiberglass, radon, mold, venting, ventilation, or the like. (Please refer to Unit 34, "Indoor Air Quality," for more detailed information on indoor air pollutants and safety.) Especially when the house and its HVAC duct system may be pressurized and/or depressurized when performing parts of the testing phase of the energy audit, safety issues are of major concern. The testing phase of the energy audit can also alter the operation of the HVAC equipment. Moisture levels, ventilation rates, and indoor air quality within a residence can also be altered if proposed changes or energy conservation measures (ECMs) recommended by the auditor's report are adopted.

2. Diagnostic testing and evaluation of the home and its systems is perhaps the most important phase of a residential audit. Systems include the building envelope, lighting, indoor air quality, water heating, and the HVAC systems. The inspection and evaluation should be done by a qualified, reputable expert in residential energy auditing. A blower door test on the entire structure in conjunction with an infrared inspection using a thermal imaging camera is often performed in this phase of the energy audit. Also employed are duct pressurization tests with a duct blower to test for leaky air ducts. Combustion efficiency tests for safety and energy savings are also performed at this diagnostic phase, along with HVAC/R diagnostics, which include refrigerant charge checks, duct airflow and pressure measurements, and specific temperature measurements.
3. Numerical analysis and review of the home's energy-consumption history, which will include both electrical and heating fuel bills, is an important part of a residential audit, as well as comparing the energy-consumption history of the audited home to other homes of similar size. Looking for any patterns of energy consumption and any opportunities to improve energy efficiencies is very important.

The findings should be analyzed and reported both manually and with reputable computer analysis simulation software in a detailed written report to the homeowner. The report should include a numerical analysis on where energy is being used, lost, or wasted and how to fix any energy-related problems. The report should also suggest any human behavioral changes that will help with **energy conservation measures (ECMs)**. In addition, the report should include recommendations for fixes or changes that will benefit the homeowner by saving the most money and/or energy. The report should also educate the homeowner on how to maximize the payoffs from the energy audit's findings by tapping potential financial support from federal, state, and local sources and/or utility companies. It should include information on tax incentives, grants, and rebates that may help cover the cost of the audit.

39.3 PERFORMING A HOME ENERGY AUDIT

SCREENING, VISUAL INSPECTIONS, AND MEASUREMENT

Performing a home energy audit starts with a visual inspection of a home and its energy systems, which include:

- the building envelope,
- HVAC systems,
- base load inspection, and
- indoor air quality.

VISUAL INSPECTION OF THE BUILDING ENVELOPE (EXTERIOR)

The age and type of construction of the residential structure must be identified. A visual inspection of the home's exterior should be the energy auditor's first task. The exterior visual inspection gives the auditor a general idea of the condition of the home's exterior and what construction materials make up its **shell**, or envelope. How much heat flows through the shell of the house will depend on three factors:

1. Any solar heat gains depend on the area and color of the shell's external surfaces and the solar transmittance and area of the windows.
2. It is the thermal resistance of the insulation and the surface area of the shell of the house that will determine how much heat is transmitted through the shell.
3. Air leakage through the shell will be determined by the pressure difference between the inside and outside of the shell and the size of the holes or cracks where the air is leaking.

Sealing and insulating the envelope or shell of a home is often the most cost-effective way to improve energy efficiency and comfort. Air leaks and insulation issues often go unnoticed simply because they cannot be seen unless a thermal imaging camera and chemical smoke generators are used. Thermal imaging photography and the use of chemical smoke generators will be covered in detail later in this unit.

The condition and materials of construction of the doors, windows, roof, siding, and any overhangs should be inspected. Modern multipane windows with vinyl, wood, or fiberglass frames far outperform old metal-frame, single-pane models in terms of air leakage. (Please refer to Unit 42, "Heat Gains and Heat Losses in Structures," for more detailed information on heat gains and heat loss through residential structures.) Site issues are also noted in this phase of the audit, such as roofs and windows shaded by trees, awnings, overhangs, or other structures. What direction each side of the home faces should be noted, because that may affect solar heat gains. The foundation of the house should

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

also be visually inspected in this phase of the audit—its condition, how much of the foundation is exposed directly to the outside air, and any drainage problems or existing moisture stains. The condition of all chimneys and exhaust vents should also be inspected.

VISUAL INSPECTION OF THE BUILDING ENVELOPE (INTERIOR)

Once the exterior of the home has been inspected, the auditor moves to the interior of the residential structure. Measurements made with a laser distance meter are used to determine square footage and volume calculations of each room in the house. All walls, ceilings, attics, floors, and foundations are inspected for insulation, and the type and thickness of the insulation are observed. *First, the insulation in the attic, ceilings, exterior and basement walls, floors, and crawl spaces is checked to see if it meets the levels recommended for the area. Insulation is measured in R-values—the higher the R-value, the better the walls and roof will resist the transfer of heat.*

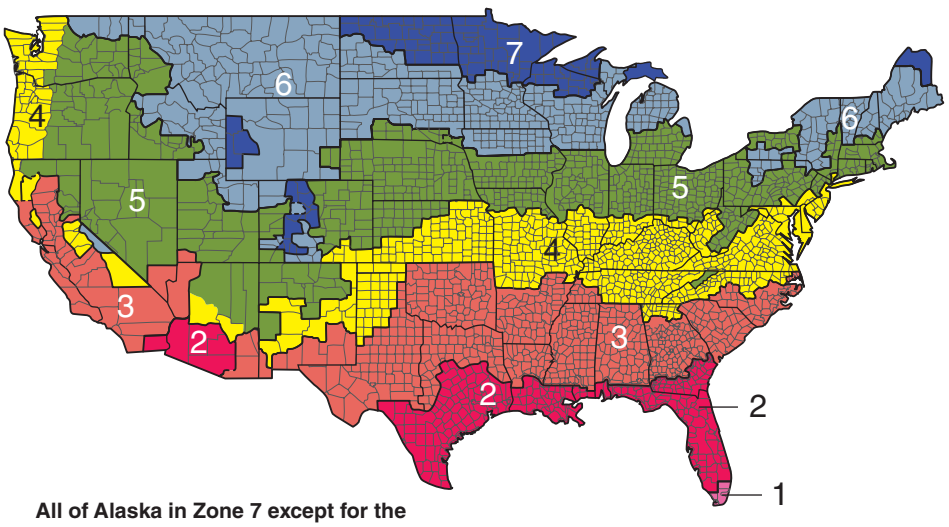
DOE recommends ranges of R-values based on local heating and cooling costs and climate conditions in different areas of the nation. The map and chart in **Figures 39.1** and **Figure 39.2**, respectively, show the DOE recommendations for different geographical areas. State and local code minimum insulation requirements may be less than the DOE recommendations, which are based on cost-effectiveness. For more customized insulation recommendations, a **Zip Code Insulation Calculator tool** can provide insulation levels for new or existing homes based on zip code and other basic information about the home.

INSULATION TIPS

Although insulation can be made from a variety of materials, it usually comes in four types; each type has different characteristics.

1. **Rolls and batts, or blankets**—flexible products made from mineral fibers, such as fiberglass and rock wool. They are available in widths suited to standard spacings

Figure 39.1 U.S. Department of Energy's specific zone maps of the United States used in conjunction with Figure 39.2 for recommended total R-values for new wood-framed houses in various zones.



All of Alaska in Zone 7 except for the following boroughs in Zone 8:

- Bethel
- Northwest Arctic
- Dellingham
- Southeast Fairbanks
- Fairbanks N. Star
- Wade Hampton
- Nome
- Yukon-Koyukuk
- North Slope

Zone 1 includes

- Hawaii
- Guam
- Puerto Rico
- Virgin Islands

Courtesy U.S. Department of Energy

of wall studs and attic or floor joists: 2 × 4 walls can hold R-13 or R-15 batts; 2 × 6 walls can have R-19 or R-21 products.

2. **Loose-fill insulation**—usually made of fiberglass, rock wool, or cellulose in the form of loose fibers or fiber pellets; it should be blown into spaces using special pneumatic equipment. The blown-in material conforms readily to building cavities and attics. Therefore, loose-fill insulation is well suited for places where it is difficult to install other types of insulation.
3. **Rigid foam insulation**—typically more expensive than fiber insulation, but very effective in buildings with space limitations and where higher R-values are needed. Foam insulation R-values range from R-4 to R-6.5 per inch of thickness, which is up to 2 times greater than most other insulating materials of the same thickness.
4. **Foam-in-place insulation**—can be blown into walls and reduces air leakage, if blown into cracks, such as around window and door frames.

SAFETY PRECAUTION: *Because some vermiculite insulation may contain asbestos, it may pose a health hazard.*•

- *Consider factors such as the climate, building design, and budget when selecting insulation R-values for a home.*
- *Use higher-density insulation, such as rigid foam boards, in cathedral ceilings and on exterior walls.*
- *Ventilation helps with moisture control and with reducing summer cooling bills. Attic vents can be installed along the entire ceiling cavity to help ensure proper airflow from the soffit to the attic to make a home more comfortable and energy efficient. Do not ventilate an attic if there is insulation on the underside of the roof. Check with a qualified contractor.*
- *Recessed light fixtures (can lights) can be a major source of heat loss, but care needs to be taken when placing insulation next to a fixture unless it is marked IC—designed for direct insulation contact. Another option is to replace the recessed fixtures with ones that are rated for insulation contact and air tightness (ICAT),* **Figure 39.3(A)**. *Local building codes should be checked for recommendations.*
- *One of the most cost-effective ways to make a home more comfortable year-round is to add insulation to the attic,* **Figure 39.3(B)**.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 39.3 (A) Replace old, leaky can fixtures with insulated, airtight recessed light fixtures and caulk them where the house meets the drywall.

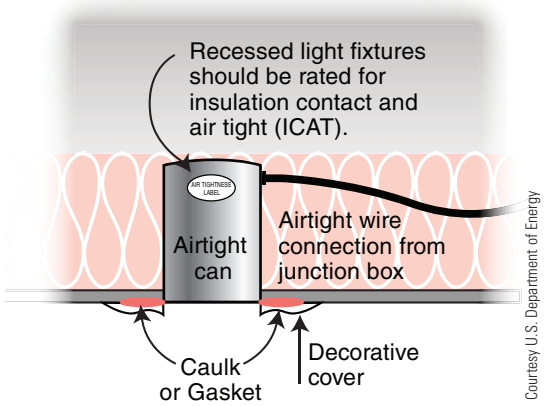

Figure 39.3 (B) A well-insulated attic.

SAFETY PRECAUTION: *Follow the installation instructions as specified on the product packaging and wear the proper protective gear when installing insulation.*•

Adding insulation to an attic is relatively easy and very cost-effective. To find out if there is enough attic insulation, measure its thickness. If it is less than R-30 (11 in. of fiberglass or rock wool or 8 in. of cellulose), there is probably a benefit from adding more. Most U.S. homes should have between R-30 and R-60 insulation in the attic, including the attic trap or access door. If the attic has enough insulation and the home still feels drafty and cold in the winter or too warm in the summer, chances are insulation needs to be added to the exterior walls as well. This is a more expensive measure that usually requires a contractor, but it may be worth the cost if in a very hot or cold climate. When the exterior siding on a home is replaced, it is a good time to consider adding insulation.

Insulation may also need to be added to a crawl space or basement. Check with a professional contractor. For new homes in most climates, money and energy will be saved if a combination of cavity insulation and insulative sheathing is installed. Cavity insulation can be installed at levels up to R-15 in a 2 in. × 4 in. wall and up to R-21 in a 2 in. × 6 in. wall. The insulative sheathing, used in addition to cavity insulation, helps to reduce the energy that would otherwise be lost through the wood frame. **Figure 39.2** shows the recommended combinations. For example, in Zone 5, either a 2 × 4 wall could be insulated with R-13 or a 2 × 6 wall with R-21. For either of those two walls, an inch of insulative sheathing that has an R-value of R-5 or R-6 should also be used.

Today, new products on the market provide both insulation and structural support and they should be considered for new home construction or additions. Structural insulated panels, known as SIPs, and masonry products like insulating concrete forms are among these. Some homebuilders are even using an old technique borrowed from the pioneers: building walls using straw bales. Radiant barriers (in hot climates), reflective insulation, and foundation insulation should all be considered for new home construction. Check with your contractor for more information about these options.

Look and smell for any moisture problems which have caused stains or mold issues. Make sure crawl spaces are well ventilated and covered with a sealed ground moisture barrier to control ground moisture. Look in the attic for any moisture, mold, or large air leakage problems. Keep an eye out for any health and safety issues that the attic may hide. Inspect the wiring in the attic and look to make sure all lighting that protrudes through the ceiling is insulated properly.

Identify the **thermal boundaries** and the components that make up the thermal boundary in the residence. Thermal boundaries consist of insulation and an air barrier that surrounds a conditioned space. **Thermal bypasses** are areas in the thermal boundary where air can either infiltrate or exfiltrate. **Conditioned spaces** include the areas of the residence that are heated or cooled. Unconditioned spaces are areas of the residence that are not heated or cooled. Examples of unconditioned spaces are crawlspaces, attached garages, and attics. Some houses contain unintentionally conditioned spaces. These spaces are usually warmed by waste heat and include boiler rooms or furnace rooms. They are also referred to as **intermediate zones**. **Figure 39.4** illustrates boundaries, spaces, and zones. All conditioned spaces should have a thermal boundary surrounding them made up of insulation and an air space barrier.

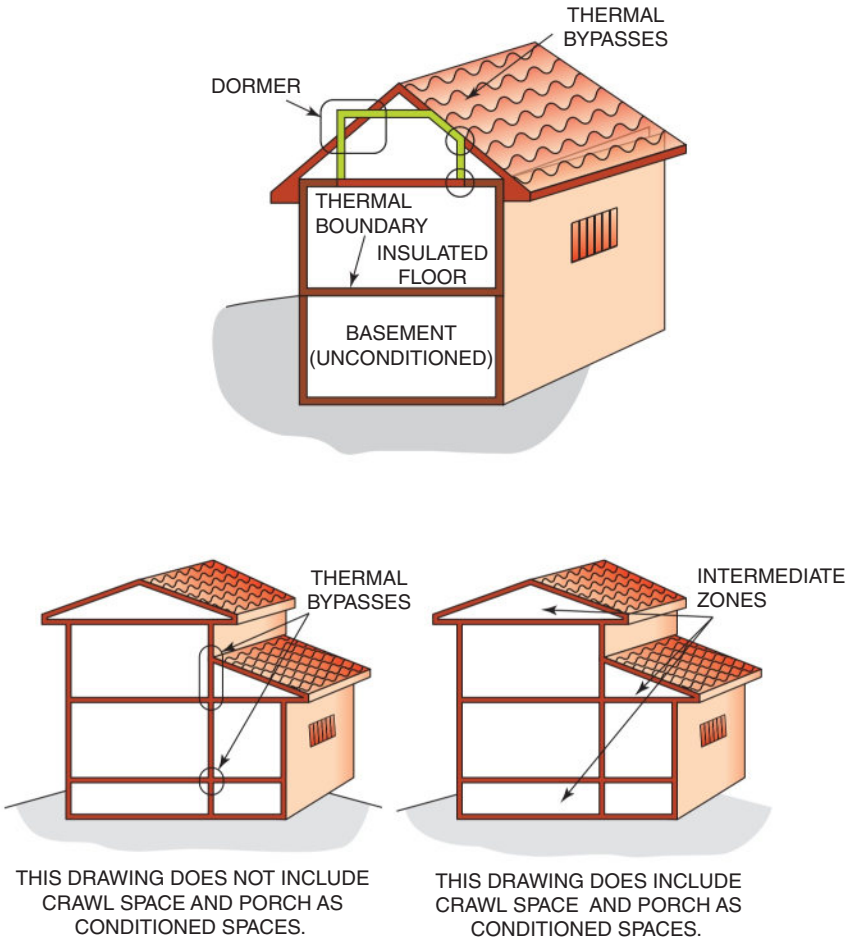
Figure 39.4 House boundaries, spaces, and zones.



VISUAL INSPECTION OF THE COOLING SYSTEM

The condenser fan in the outdoor condensing unit should be operational and the condenser coil clean and free of debris. *The condenser's airflow should not be short-cycled or restricted. Often, awnings, overhangs, or bushes can rebound or short-cycle hot air back to the condensing coil causing high condensing pressures and unwanted inefficiencies. The extended surfaces or fins on the condensing coil may need straightening to allow more air flow to pass through for better heat transfer.*

The suction line of the air-conditioning unit or gas line of a heat pump should have good insulation. Uninsulated suction lines can lower vapor densities coming back to the compressor, which causes system inefficiencies. The condensing unit should be located on the proper side of the house, away from mid-afternoon solar gains.

The air conditioner's evaporator coil and filter should be visually inspected, if easily accessible. They should not be clogged with debris, algae, or mold and the evaporator coil drain should not be clogged and backed up with condensate. Standing water can cause algae, bacteria, and viruses to be present around the evaporator coil and drain pan. If it is the cooling season, a reading of the return-air and cool-air discharge temperature and relative humidity should be taken and a note of its temperature for later analysis.

All windows should be inspected for type and condition. Check to see if they are shaded by trees, overhangs, or awnings, that may decrease any solar gains. Windows should be inspected for low **emittance** (low-e) factors. (Low emittance is also referred to as low emissivity factor.) Any shading factors on the roof should be observed as well as any **reflectivity** factors and insulation qualities.

VISUAL INSPECTION OF THE HEATING SYSTEM

The age, condition, and efficiency of the heating equipment and whether older units can be upgraded to newer, higher-efficiency models should be determined. Any heating system

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. problem found during the inspection can be documented and solved later in the audit.

The flue gases should be inspected to determine the combustion efficiency of the heating equipment, as should the condition of air filters, ducts, piping, and radiators. Any blockage of supply-air outlets and leaking ductwork should be noted. The thermostat should also be programmed to a reasonable, yet economical, heating setting.

Safety issues relating to venting of appliances should be identified. The flame in the furnace and water heater should be watched for signs of roll-out, which may indicate **backdrafting**. The auditor should be alert to signs of combustion by-product spillage at the water heater and furnace, make sure the furnace and water heater vents are properly sloped and sized for their input ratings, and inspect how far any chimney or vent connector is from a combustible material.

Visual signs of corrosion on water heaters and boilers should be noted. If the furnace is a forced-air furnace, the combustion chamber should be inspected for rust, corrosion or signs of deterioration. Water stains on the floor near the boiler that lead toward the drain could mean the boiler is running too hot and the pressure relief valve is opening. The zone valves should be inspected for proper operation and to make sure they have not been manually overridden to stay in the open position.

BASE LOAD INSPECTION

Base loads are consistent, everyday consumers of energy within a residential structure. It is important that these energy-consuming loads be evaluated in a residential energy audit. Together they can make a significant contribution to daily energy usage in a home. These everyday loads are often referred to by energy auditors as **LAMEL** loads. LAMEL is an acronym for lighting, appliance, and miscellaneous electrical loads. Typical residential base loads or LAMELs are listed below:

- Lights
- Refrigerators
- Freezers
- Water heaters
- Clothes dryers
- Computers
- Printers
- Copiers
- Cell phone chargers

LAMEL loads include what used to be referred to as phantom, vampire, or plug loads. The auditor should inspect lighting to see if there are appropriate or too many lighting levels in the residence and make note if the lighting is incandescent, compact fluorescent, or light emitting diode (LED). Compact fluorescent is much more energy-efficient. Base loads will be covered in more detail later in the unit.

The exterior (condenser) coils of all refrigerators and/or freezers should be inspected to make sure that there is proper air circulation through them and that they are not clogged with dirt, dust, lint, or fuzz. Any of these materials clogging the condenser coil will impede heat transfer out of the coil. This will raise the condensing pressure and cause unwanted inefficiencies and higher power usage. The refrigerator/freezer electricity (power) consumption should be measured. Refrigerator temperatures should range from 35° to 39°F. Freezer compartments should range from 0° to −10°F, depending on the particular product frozen and the length of time the homeowner plans to keep the frozen goods.

The water heater temperature should be below 120°F. Water leakage from the water heater should be noted and what type of energy (natural gas, propane, fuel oil, or electricity) is heating the water in the water heater. Whether the water heater has an insulating blanket on its exterior should be noted. If the water heater is a combustion appliance, it should be inspected for any backdrafting problems.

The interior drum of the clothes dryer should be inspected, as should the vent to the outdoors and the lint screen for excessive lint build-up. What type of energy is used in drying the clothes should be noted, and the age of the clothes dryer.

INDOOR AIR QUALITY

Energy audits and weatherization often identify and interact with a home's indoor air quality. Health and safety issues relating to the following list are identified and dealt with during an energy audit and weatherization process:

- Asbestos
- Fiberglass
- Radon
- Mold
- Pollen
- Venting issues
- Moisture issues
- Backdrafting
- Ventilation
- Cigarette smoke
- Cooking odors
- Carpet offgassing
- Paints
- Finishes
- Cleaning chemicals
- Pesticides
- Pet dander
- Dust mites
- Home electronics

Safety issues are of major concern especially when the house and its HVAC duct system may be pressurized and/or depressurized when performing parts of the testing phase

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). of the energy audit. The testing phase of the audit can also alter the operation of the HVAC equipment. Moisture levels, ventilation rates, and indoor air quality within a residence can also be altered if proposed changes recommended by the auditor's report are adopted. Also, once the testing phase is over and the home is sealed and weatherized, its structure will be much tighter and combustion appliance backdrafting issues may have to be dealt with, **Figure 39.5**. Often, because homes are so "airtight" after sealing and weatherization, an energy recovery ventilator may have to be installed in the home for safety reasons and moisture management, **Figure 39.6**. Energy recovery ventilators bring in fresh intake air from the outside of the home which experiences a heat exchange with warmer, stale exhaust air being exhausted from the inside of the home. The auditor may also recommend that air from the outside be brought into the CAV zone to supply combustion air for all combustion appliances. (For a more detailed analysis on indoor air quality in houses and energy recovery ventilators, please refer to Unit 34, "Indoor Air Quality.")

39.4 DIAGNOSTIC TESTING

Diagnostic testing and evaluation of the home and it systems that consume energy is probably the most important phase of the energy audit. *These diagnostic tests bring out many of the building's "hidden unknowns," such as structural and ductwork air leakages, moisture problems, combustion efficiencies, refrigerant charges, and wasted heat leakages, which can be quantified by diagnostic testing.* The most common diagnostic tests performed during a residential energy audit are:

- Blower door testing
- Infrared scanning testing (by thermal imaging camera)
- Duct leakage testing
- Combustion efficiency and safety testing
- HVAC/R system testing

39.5 BLOWER DOOR TESTING

Blower door tests give the auditor insight on how tight or leaky the home's building envelope is overall. Blower doors consist of a frame and shroud that fit inside the door frame of a house. The shroud or membrane forms an airtight seal on an outside doorway of the residence. Mounted in each blower door is a variable-speed fan that allows the fan to suck air out of the house to create a low-level vacuum (negative pressure) on the inside of the house, **Figure 39.7**. Blower door instruments include gauges like manometers and anemometers that

can measure the flow of air through the blower door's fan at a set pressure differential between the inside and outside of the house, **Figure 39.8**. The set pressure differential is 50 **Pascals** for air-tightness testing. The slight vacuum on the inside of the house of 50 Pascals is measured **with reference to (WRT)** the outdoor pressure. However, if a thermal imaging camera is used in conjunction with a blower door test for air **infiltration** and **exfiltration** inspections, 20 Pascals is used for the pressure differential.

The Pascal (Pa) is the Systems International (SI) or metric unit for measuring pressure. One Pascal is a very small amount of pressure.

$$1 \text{ Pascal (Pa)} = 0.004 \text{ in. of water column (in. WC)} = 0.000145 \text{ pounds/in}^2 \text{ (psi)}$$

or

$$1 \text{ Pa} = 0.004 \text{ in. WC} = 0.000145 \text{ psi}$$

For comparison purposes, if a person were to put a straw in a glass of water and suck the water up 1 in. in the straw, the negative pressure needed to do this would be 1 in. of water column, or approximately 250 Pascals. Wind stack effects on buildings usually generate air pressures across the building's shell that range from 0.05 to 10 Pascals. Bathroom exhaust fans also generate negative pressures that fall between 1.0 and 10 Pascals.

Figure 39.8 Blower door instrumentation, which includes digital gauges like manometers and anemometers that measure the flow of air through the blower door's fan at a set pressure differential between the inside and outside of the house.

Courtesy The Energy Conservatory

Instrumentation that accompanies a blower door inspection includes pressure gauges with which a technician can measure the flow of air through the fan as well as the pressure differential between the living space and the outdoors. The greater the airflow in CFM through the blower door's fan required to reach a certain pressure differential (50 Pascals), the leakier the house is. The blower door test alone will give a general idea of the relative "leakiness" of a home. **Figure 39.9** shows air leakages into a residential structure using a blower door test. **Figure 39.10** shows common areas that leak air in and out of a residential structure.

It takes a certain amount of airflow through the blower door to maintain a constant vacuum of 50 Pascals inside a home. This airflow is measured in cubic feet per minute (CFM) and is referred to as **CFM_{50}**. For example, a house that measures 1,700 CFM_{50} on the blower door's digital manometer means that the house has 1,700 CFM of air leakage while the blower door is connected and pulling 50 Pascals of vacuum on the house. By comparing that flow to the volume (ft^3) of air in the building, an auditor can determine the number of **air changes per hour (ACH_{50})** that occur to the structure at a 50 Pascal pressure differential between the house and the outdoors. This will tell the auditor the air leakage rate of the structure and how well the structure is sealed. This leakage rate measurement can be used to compare to the leakage rate measured after the house is air-sealed. (Air-sealing a structure will be covered later in this unit.) To figure out the ACH_{50} for the house, auditors use the following equation:

$$ACH_{50} = (CFM_{50} \times 60) \text{ divided by the (House's Conditioned Volume)}$$

where

ACH_{50} = Air changes per hour
60 = 60 min/h
House Conditioned Volume = Total Volume of the Conditioned House in Cubic Feet (ft^3)

Suppose a house had a conditioned volume of 15,660 ft^3 and the blower door test measured 600 CFM_{50}. The ACH_{50} of the house would be:

$$ACH_{50} = (600 \text{ CFM}_{50} \times 60 \text{ min/h}) \text{ divided by } (15{,}660 \text{ ft}^3)$$
$$ACH_{50} = 2.29$$

The standard for an Energy Star dwelling is 4 ACH at 50 Pascals for Department of Energy climate zones 5, 6, 7, see **Figure 39.1**. For comparison purposes, some older homes can test at 20 ACH at 50 Pascals.

Blower door testing may cause some safety problems within the structure, especially with combustion appliances. The negative pressure or vacuum of 50 Pascals may cause combustion appliances to backdraft.

SAFETY PRECAUTION: *Even fireplaces or woodstoves may backdraft and cause ash to enter the structure during the blower door testing procedures.* If combustion appliances are left on, by-products of combustion or other pollutants may enter the structure during testing. The auditor must anticipate any safety issues before performing a blower door test by

1. turning off all combustion appliances,
2. inspecting all sources of pollutants like fireplaces or wood stoves,
3. inspecting for any large air leakages that may prevent the blower door from achieving the desired vacuum level and plugging these openings temporarily,
4. identifying all thermal boundaries and conditioned zones in the house,
5. closing all windows and doors, and
6. opening all interior doors.

Blower doors can also be used to create a positive pressure in a house. In these cases, the blower door is often used in conjunction with a duct blower for testing air lost to the outdoors in ductwork systems. The duct blower used in conjunction with the blower door will be covered later in the unit under the heading "Duct Leakage to the Outdoors."

39.6 INFRARED SCANNING USING A THERMAL IMAGING CAMERA

Standard digital cameras capture images of objects that reflect visible light. The visible light spectrum consists of white light broken into its many component colors (red, orange, yellow, green, blue, indigo, and violet). Thermal imaging cameras, often referred to as an infrared cameras, create pictures by detecting infrared energy or heat. Infrared energy has a lower frequency than visible light. The thermal imaging camera then assigns colors based on the temperature differences it detects. **Figure 39.11(A)** is a photo taken by a thermal imaging camera that shows heat escaping the building envelope. **Figure 39.11(B)** shows a thermal imaging camera. **Figure 39.11(C)** shows an energy auditor taking a thermal image on the interior of a window and the surrounding window framing.

Using a thermal imaging camera in conjunction with a blower door test is strongly recommended for best results in testing for air infiltration and exfiltration. Testing with both a blower door and a thermal imaging camera can show the "exact" location of the building envelope problems. With a blower door in operation, a technician using an infrared thermal imaging camera and a pressure gauge (to verify the pressure differential in various parts of the house) can find areas that contribute to the loss of conditioned air by convection. These losses include heated and humidified air in the winter and cooled and dehumidified air in the summer caused by either infiltration or exfiltration.

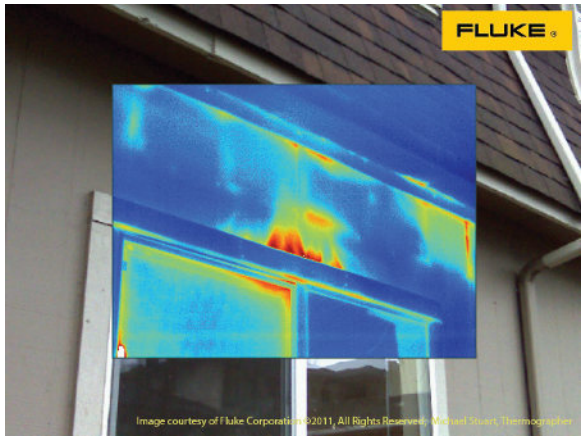
Figure 39.29 A thermal imaging camera showing warm air exfiltrating at the top of a window.



Courtesy Fluke Corporation

Figure 39.27 through **Figure 39.29** show warm air exfiltrating from a residential structure. The most effective thermal imaging work in an energy audit will occur indoors when a living space is being heated in the winter or cooled in the summer, not in the spring or fall. This happens because there are greater temperature differences between the inside and outside of the house in the summer and winter months.

Heating and cooling losses can occur by both conduction and convection. Conduction heat losses can also happen along with convective losses when insulation is missing from an outside wall, **Figure 39.16(B)**. Conductive heat losses and gains can also occur through a process called **thermal bridging**. Thermal bridging is rapid heat being conducted through the residential structure's shell by materials in direct contact with one another that are very thermally conductive, **Figure 39.30**. An example of thermal bridging is a cold aluminum or steel window frame in contact with the window's glass, which will rapidly conduct heat through the building's shell to the outdoors in the winter. The result is rapid heat loss to the outside and a cold interior surface on the window frame and glass for condensate to form. **Figure 39.31(A)** shows a window where condensate that has ran down the glass and rotted the bottom structure of the window because of thermal bridging. *Thermal bridging can be lessened by installing a gasket material made of a poor thermal conductive material between the window frame and the glass.* The gasket material is often referred to as a **thermal break**, **Figure 39.31(B)**.

Figure 39.27 A thermal imaging camera showing warm air exfiltrating around the side of a window.

Courtesy Fluke Corporation

To set up for thermal imaging testing, make sure there is a temperature difference of approximately 18°F from the interior to the exterior surface. For air leakage inspection work, the temperature difference should be 9°F. Make sure these temperature differences have stabilized for a period of 4 hours or more before starting the test. Record the interior and exterior air temperature and relative humidity. Make notes as to wind direction, sun position, precipitation, and

Courtesy Fluke Corporation

any other environmental factor that may affect test results. Close all outside doors, open all inside doors, and make sure the HVAC system has been off for at least 15 minutes.

Install the blower door on an exterior door. The blower door will induce or draw a negative pressure on the inside of the house. As mentioned earlier, this negative pressure should be 20 Pascals for infiltration and exfiltration inspections with a thermal imaging camera. This will pull outside air to the inside of the house through every crack and orifice because of the pressure difference caused by the blower door. The thermal imaging camera can spot these leaks and show them as thermal images of different colors. The thermal imager cannot see the incoming air, but it can detect cool or warm surfaces created as air leaks across them. Some of the more common places for incoming air leakages are

- window sills,
- electrical fixtures,
- windows and doors,
- penetrations in the wall, roof, and floor caused by plumbing, lighting, and electrical outlets,

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- joints around chimneys,
- joints between walls,
- joints between ceilings and floors, and
- joints between top plates and sill plates.

Research has shown that the most serious air leaks occur at the top and bottom of the conditioned envelope, like attics and basements. Large gaps for air to travel are often found around

- plumbing pipes,
- recessed lighting fixtures,
- chimneys,
- eave soffits,
- chaseways,
- basement rim joists where the house foundation meets the wood framing,
- top and bottom of plumbing runs and vents especially in attics and basements,
- utilities such as electrical conduit and TV cables entering the conditioned air space,
- cold floors in the winter, especially above crawl spaces and garages, and
- floor slabs that extend outdoors and have no thermal barrier between the indoor and outdoor portion, which can account for large conduction heat losses.

Figure 39.32(A) illustrates common air leakages within a residential structure. Blue arrows show air leaking into the

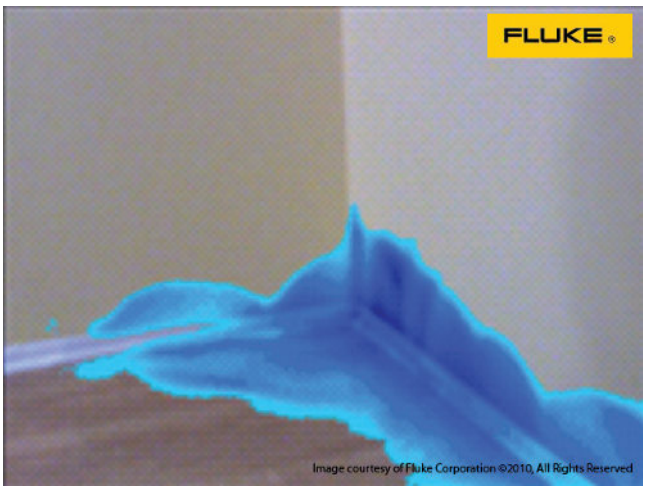
house and red arrows show air leaking out of the house. **Figure 39.32(B)** is a pie chart showing common air leak sources with their respective percentages.

A blower door can also pressurize a house. Once the house is pressurized, a thermal imaging camera can capture where air exfiltrates from a home. Often, air exits from different places than where it enters a home, **Figure 39.27**, **Figure 39.28**, and **Figure 39.29** show air exfiltration leakages.

Thermal imaging cameras can also reveal the presence of moisture and the problems it creates. Thermal imaging cameras can also be used to validate the effectiveness of repairs and improvements, such as caulking, filling voids with spray foams, and adding insulation. **Figures 39.33(A)** and **39.33(B)** show moisture on the floor and wall of a home. Moisture can be caused by leaks, condensate, or flooding. Moisture can be

Figure 39.33 (A) A thermal imaging camera showing moisture on the floor and wall of a home.



Courtesy Fluke Corporation

found in walls, floors, ceilings, and roofs. The resistance value (R-value) of insulation and building materials will significantly decrease when they are wet. Moisture and condensation often go hand-in-hand with air leaks in a structure because air can provide a means for moisture to travel. *Moisture, if not properly remedied, can lead to building damage, reduced insulation effectiveness, and mold growth.* Mold and mildew will start to grow where moisture is present, causing other health-related problems. The effects of evaporative cooling (usually a 2° to 5°F surface temperature difference) helps reveal the extent of moisture damage, even when the surface feels dry to the touch. However, all suspected moisture problems should be validated with a moisture meter. Please refer to Unit 34, "Indoor Air Quality," for more detailed information on mold, moisture, indoor air pollutants, and safety.

39.7 SEALING AIR LEAKS

Warm air leaking into a home during the summer and out of a home during the winter can waste a lot of energy dollars. One of the quickest dollar-saving tasks a homeowner can do is caulk, seal, and weather-strip all seams, cracks, and openings to the outside. Savings on heating and cooling bills can be achieved by reducing the air leaks in a home. Air infiltrates into and out of a home through every hole and crack. About one-third of this air infiltrates through openings in ceilings, walls, and floors. Some main reasons why a homeowner would air-seal their home are listed below:

- Damage control for frozen pipes which may burst and cause water damage
- Preventing pest entry and damage
- Ice dam prevention
- Comfort of the entire home by preventing drafts and cold spots

Figure 39.34 An auditor holding a chemical smoke generator up to a recessed light to find out if there is a possible air path to the outside.

- Preventing water damage in walls and other building materials
- Money savings on heating and cooling
- Reducing outdoor noise and indoor noises between rooms
- Improving indoor air quality by sealing out outside air

First, test the home for air tightness. A certified energy auditor can use a blower door test. The homeowner can perform a simple test themselves using a smoke pen, lit ensconce stick, or other nontoxic chemical smoke-generating device. On a windy day, a lit incense stick or a smoke generator is carefully held next to windows, doors, electrical boxes, plumbing fixtures, electrical outlets, ceiling fixtures, attic hatches, and other locations where there is a possible air path to the outside, **Figure 39.34**. A smoke stream that travels horizontally locates an air leak that may need caulking, sealing, or weather-stripping.

The 2009 International Energy Conservation Code (IECC) and the 2009 International Residential Code (IRC) have several new mandatory requirements for air sealing in new construction and additions, adapted by local jurisdiction. In general, the requirements do not apply to retrofit projects unless the project adds living space to the building or changes the building's energy load. Listed below are important places to seal air leakages.

- *Caulk and weather-strip doors and windows that leak air,* **Figures 39.35(A)** *and* **(B)**.
- *Caulk and seal air leaks where plumbing, ducting, or electrical wiring penetrates through walls, floors, ceilings, and soffits over cabinets,* **Figures 39.36(A)** *and* **(B)**.
- *Install foam gaskets behind outlet and switch plates on walls.*
- *Seal all joints, seams, and penetrations.*
- *Seal rim joists, sill plates, foundations, and floors,* **Figures 39.37(A)** *and* **(B)**.

- *Seal fireplace walls,* **Figure 39.38**.
- *Look for dirty spots in your insulation, which often indicate holes where air leaks into and out of the house. The holes can be sealed with low-expansion spray foam made for this purpose.*
- *Look for dirty spots on the ceiling paint and carpet, which may indicate air leaks at interior wall/ceiling joints and wall/floor joists. These joints can be caulked.*
- *Install storm windows over single-pane windows or replace them with more efficient windows, such as double-pane.*
- *Seal openings between window and door assemblies and their respective jambs and framing.*
- *When the fireplace is not in use, keep the flue damper tightly closed. A chimney is designed specifically for smoke to escape, so until it is closed, warm air escapes—24 hours a day!*
- *For new construction, reduce exterior wall leaks by installing house wrap, taping the joints of exterior sheathing, and comprehensively caulking and sealing the exterior walls.*
- *Seal utility penetrations.*
- *Seal garage/living space walls,* **Figure 39.39**.
- *Seal attic knee walls and attic air sealing,* **Figures 39.40(A)** *and* **(B)**.
- *Use foam sealant around larger gaps around windows, baseboards, and other places where warm air may be leaking out.*
- *Install kitchen exhaust fan covers to keep air from leaking in when the exhaust fan is not in use. The covers typically attach via magnets for ease of replacement.*
- *Replace existing door bottoms and thresholds with ones that have pliable sealing gaskets to prevent conditioned air leaking out from underneath the doors.*
- *Check fireplace flues. Fireplace flues are made of metal, and over time repeated heating and cooling can cause the metal to warp or break, permitting hot or cold air loss.*
- *Seal dropped ceilings/soffit or chases adjacent to the thermal envelope,* **Figure 39.41**.
- *Seal duct shafts/pipe shafts and penetrations,* **Figure 39.42**.
- *Seal staircase framing at exterior wall/attic,* **Figure 39.43**.
- *Seal walls and ceilings separating a garage from conditioned spaces.*
- *Seal exterior walls, electrical outlets, exhaust fans, plumbing penetrations, and tub and shower,* **Figure 39.44**.

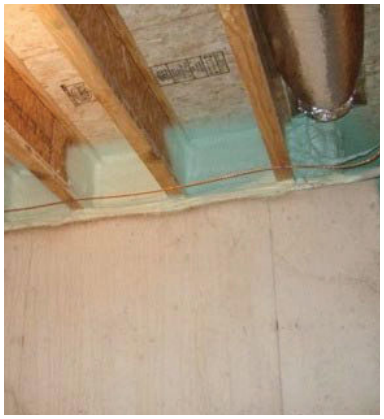

Figure 39.38 Air seal the enclosure and flue.

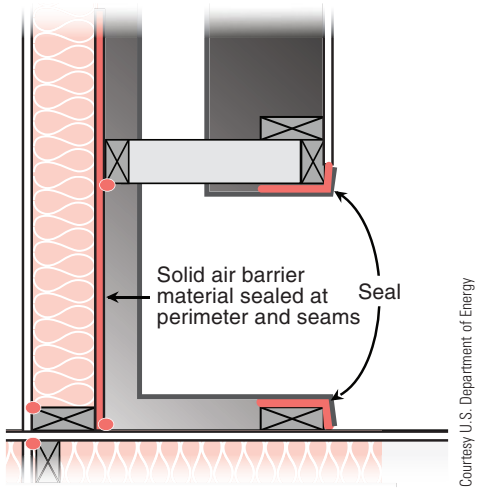

Figure 39.39 Finish the walls that separate the garage from the rest of the home with drywall that is sealed to the top and bottom plate with a bead of caulk.

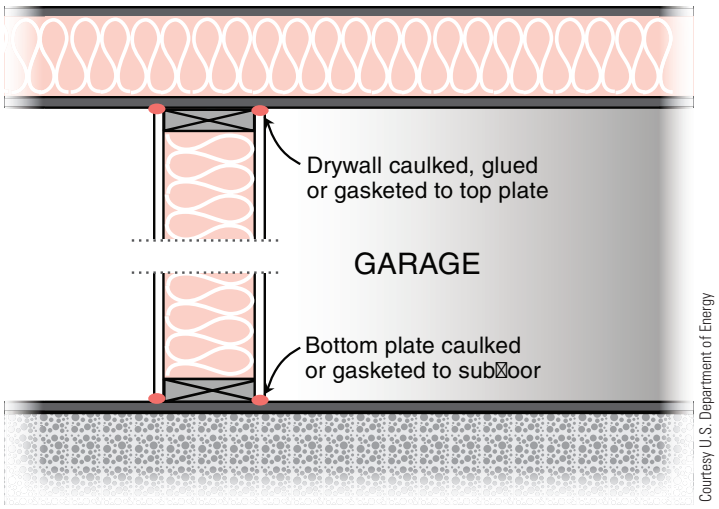


- *Install inflatable chimney balloons beneath a fireplace flue during periods of nonuse. They are made from several layers of durable plastic and can be removed easily and reused hundreds of times. Should the balloon remain in place accidentally before making a fire; the balloon will automatically deflate within seconds of coming into contact with heat.*
- *Seal rim joist junctions.*
- *Seal attic access or pull-down stairs,* **Figure 39.45**.
- *Seal the flue or chimney shaft.*
- *Air-seal recessed lights (can lights) by installing a box around them and air-sealing the box by using caulk or a gasket under the decorative cover,* **Figure 39.3(A)**. *Another option is to replace the recessed fixtures with ones that are rated for insulation contact and air tightness (ICAT).*
- *Seal attic access openings.*
- *Seal return and supply ducts,* **Figure 39.46(A)** *and* **(B)**.
- *Seal drywall and top plate junctions.*

39.8 DUCT LEAKAGE TESTING

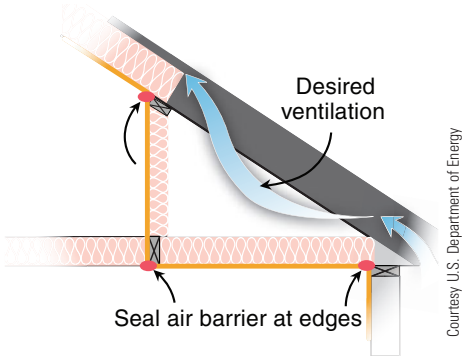
In both new and existing homes, as much as 25% of the total energy losses can often be blamed on air leakage in forced-air duct systems. *Testing and sealing leaky air distribution systems is one of the most cost-effective energy improvements for homeowners.* Because air is invisible, most duct leaks go unnoticed by HVAC contractors and homeowners. Often, ducts are in attics, crawl spaces, or other hard-to-access places. It is usually these hard-to-find-and-access leaky ducts that are the important ones to fix because of their being connected to hot attics or humid crawl spaces. Listed below are a few problems caused by leaky ductwork:

1. Leaks in return ducts draw air into the building from crawl spaces, garages, and attics, bringing with it dust, mold spores, pollen, insulation fibers, and other contaminants.
2. Leaks in supply ducts cause expensive conditioned air to be dumped directly outside, in the attic or crawl space, rather than delivering it to the building.
3. Duct leakage greatly increases the use of electric strip heaters in heat pumps during the heating season.
4. In humid climates, return-air ducts drawing in moist air leaks can overwhelm air-conditioning humidity loads, causing occupants to feel clammy.
5. Unconditioned air pulled in by leaky return-air ducts will reduce both efficiency and capacity of the air-conditioning system.

Duct leaks can be caused by the initial installation, by general wear and tear on the HVAC system over time, and by equipment or material failures, which may include:

- failed taped duct joints,
- holes in the duct run,

Figure 39.40 (A) Insulate and air seal the knee wall itself, or along the roof line.



- plenum joints at the air handler,
- tabbed sleeves,
- panned floor joists,
- poorly fitting seams and joints in ductwork,
- return plenums connected to unsealed building cavities,
- any duct joints,
- poorly fitting air handler doors, filter doors, and cabinets,
- deteriorating duct board facing,
- joints in sectioned elbows,
- poor connections between room air registers and the air register boots,
- poor connections between the room air register's boot and the floor or wall,
- joints at branch takeoffs,

Figure 39.40 (B) Seal the drywall to the top plate and ceiling drywall. Pull back insulation to seal drywall to the top plate with spray foam, caulk, or other sealer.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 39.42 Seal attic and wall penetrations associated with mechanical ventilation systems, electrical chase openings, and dropped soffits.

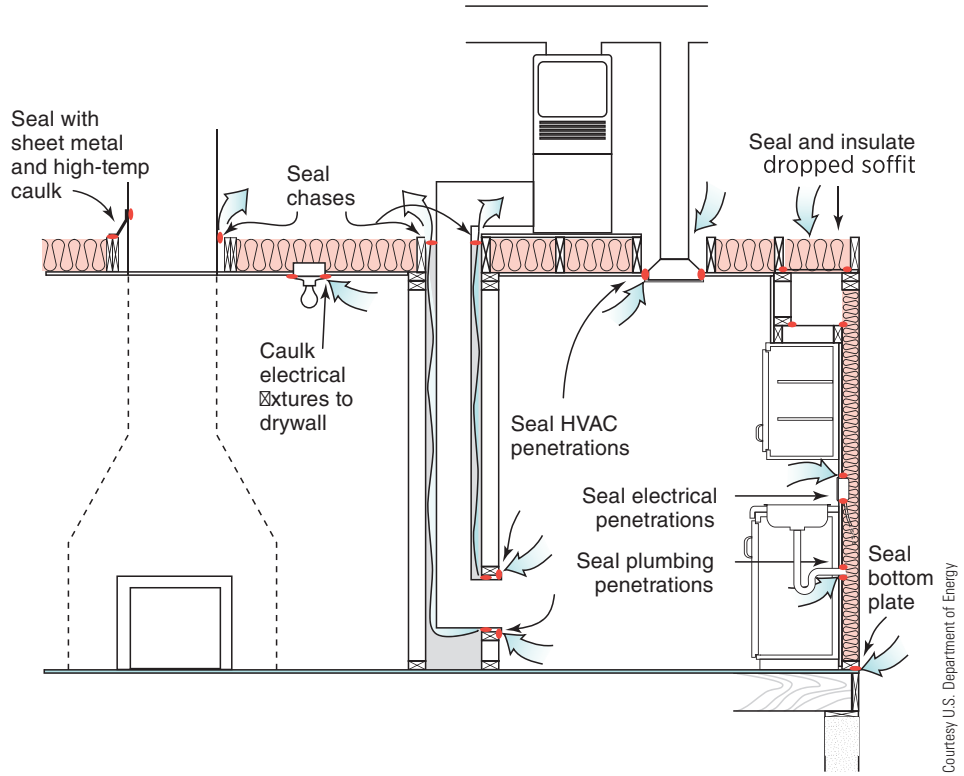

Figure 39.43 Install an air barrier and air sealing on exterior walls behind stairs.

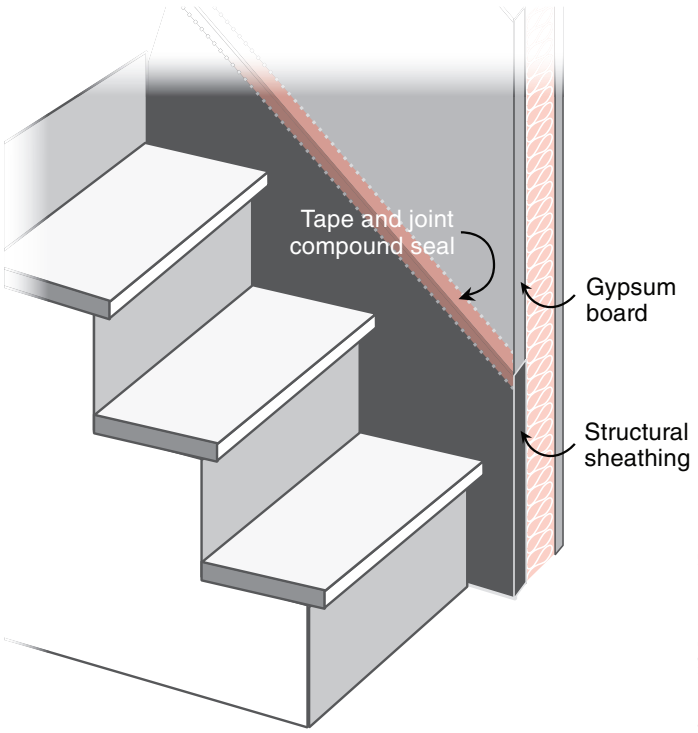

- supply and return registers and flooring,
- disconnected or partially disconnected air register boot connections,
- flexible duct to metal duct connections,
- improperly sealed building cavities for supply or return ducts,
- connections on main duct trunks that usually occur every 48 in.,
- collars attached to the main duct trunk,
- leaky duct intersections, or
- leaks at adjustable joints.

What effect duct leakage will have on a home will depend on

1. whether the leak is connected to an outdoor (unconditioned) space or indoor (conditioned) space.
2. location of the duct leak in relation to the air handler.
3. the size of the duct leak.

Duct leakage to the outside of the conditioned space has a much larger impact on HVAC system performance than duct leakage inside the conditioned space. Duct leakage to the outside usually occurs when leaky duct systems run through attics, garages, or crawl spaces. However, even if leaky ducts are located inside the building envelope in a conditioned space, air leakage to the outside can still occur.

Courtesy U.S. Department of Energy

This happens when leaky ducts passing through walls or floor cavities create a pressure difference between the cavity the ductwork is in and other building cavities indirectly connected to the outside. *All framed cavities should be lined with OSB, plywood, duct board, drywall, or sheet metal and then sealed with mastic at every joint.* When the air handler blower is operating, air can be forced through these leaks. Some building cavities themselves are used as supply or return ducts. Also, the nearer the leak is to the air handler; the higher the pressure will be in the ductwork. This is why leaks nearer the air handler are more important than leaks farther away.

Duct leakage to a conditioned space inside the house does not have as much impact on system performance and has a smaller energy penalty compared to duct leakage to the outside. If the leaky ductwork is located completely within the conditioned living space of a home, leaking air simply enters the already conditioned space. However, air-balance problems may result from too much or too little air released to a conditioned space because of duct leakage.

Duct leakages to conditioned spaces may cause air pressure differences that create air leakages through the house's shell.

Many times, houses have basement return-air systems where panned underfloor joists (joist bays) are used as return ductwork. It is hard to completely seal this type of return-air system, but if the basement is conditioned, the energy loss penalty is very small. However, this may cause the basement to depressurize to the point where combustion products from the water heater and furnace spill into the basement. Moisture leakage and radon gas can also easily enter a house with a depressurized basement. If a basement is conditioned in the winter, it usually is not conditioned in the summer. Supply-duct air leakage during the air-conditioning season will leak cooling air to the unconditioned basement even though the basement has no cooling load.

39.9 DUCT PRESSURIZATION TEST FOR TOTAL AIR LEAKAGE

Measuring the total leakage of air from ducts is accomplished with a **duct blower** test. This test measures the air leakage rate in **cfm** of the entire air handling system, which includes both the supply- and return-air ducts, along with the air handler cabinet. A duct blower is shown in **Figure 39.47**. This test gives the energy auditor the air leakage rate once the air handling system is subjected to a uniform test pressure of +25 Pascals of positive pressure using a duct blower. The test pressure of 25 Pascals has been adopted by the majority of residential duct testing programs in the United States because it is representative of typical duct pressures in a residential environment. The total air leakage test measures air leakage rates to both the outside (attics, crawl spaces, and garages) and the inside of the structure.

Using a duct blower to test the air tightness of duct systems is one of the most accurate and common methods for measuring air leakage rates in duct systems. The duct blower consists of a variable-speed fan, a digital manometer, and a set of reducer plates for measuring different air leakage rates. Following the directions in the operations manual of whichever duct blower is purchased is strongly recommended. Digital manometers need a warm-up period and calibration before each use. They also have to be set to the correct range, fan type, and mode. Below are some general guidelines or steps for measuring "total" (indoors and outdoors) duct leakage of an air handling system using a duct blower:

- Open all windows, doors, and vents of the house, including intermediate zones, to the outdoors. This allows all zones (indoor, outdoor, and intermediate) to be open to each other. (This step assures the test is measuring only the duct system tightness, not the tightness of the ducts plus other air barriers, such as foundations, roofs, garages, and walls.)

Figure 39.48 (B) Tape off all return registers with a duct sealing material such as Duct Mast or a high-quality painter's masking tape and masking paper.

Courtesy Ferris State University. Photo by John Tomczyk

- Install the duct blower in the air handler with tape and cardboard, **Figure 39.47**. The duct blower can also be connected to a large return-air register using its connector duct.
- Remove the air filters from the air handling and duct system.
- Tape off all supply and return registers with a duct sealing material such as Duct Mast or a high-quality painter's masking tape and masking paper, **Figure 39.48(A)** and **Figure 39.48(B)**.
- Drill a ¼-in. hole in the supply duct a short distance away from the air handler and insert a manometer hose. When the manometer is connected, this hose will measure the duct pressure WRT outdoor pressure.
- Connect an airflow manometer hose near the duct blower's fan airflow in cfm.
- Pressurize the duct system to 25 Pascals and record the duct blower's airflow in cfm, **Figure 39.49**.
- While the ducts and air handler cabinet are pressurized to 25 Pascals, the auditor or technician can check for leaks in the ducts, air handler, and duct branches.
- Once leaks are found and testing is complete, seal the leaks, replace all filters, and remove all tape and paper seals from air registers. Sealing leaks will be covered later in this unit.

39.10 DUCT LEAKAGE TO THE OUTDOORS

As mentioned earlier, duct leakage to the outside of the conditioned space has a much larger impact on HVAC system performance than duct leakage to the inside of the conditioned space. Duct leakage to the outside of the structure's conditioned space usually occurs when leaky duct systems run through attics, garages, or crawl spaces. A duct leakage test to the outdoors is a much more meaningful test to the energy auditor than a total duct leakage test because the leakage is directly related to wasted energy and so has much more potential for energy savings than a total duct leakage test.

This test requires the use of both a blower door and a duct blower. Again, following the directions in the operations manual of whichever blower door and duct blower is purchased is strongly recommended. And remember, digital manometers need a warm-up period and calibration before each use. Below are steps or general guidelines for measuring duct air leakage to the outdoors using both a blower door and a duct blower:

- Close all windows and outside doors. Make sure all indoor conditioned areas are opened to one another. This simulates a typical heating or cooling mode inside the home.
- Install a blower door in a configuration to pressurize the home, **Figure 39.50**.
- Connect the duct blower to the air handler or to a return air register, **Figure 39.47** and **Figure 39.50**.
- With the duct blower, pressurize the duct system to 25 Pascals. The variable-speed fan on the duct blower can be adjusted until 25 Pascals is reached.
- Pressurize the house with the blower door until the pressure difference between the house and the ductwork is 0.0 Pascals. This is referred to as the pressure of the house WRT ducts.
- The duct blower will give a digital readout of the airflow in cfm of the duct leakage to the outdoors.

39.11 COMBUSTION EFFICIENCY AND SAFETY TESTING

It is important that energy auditors, contractors, and HVAC/R service technicians know the fundamentals of combustion. They will be checking combustion appliances such as furnaces, wood stoves, water heaters, and

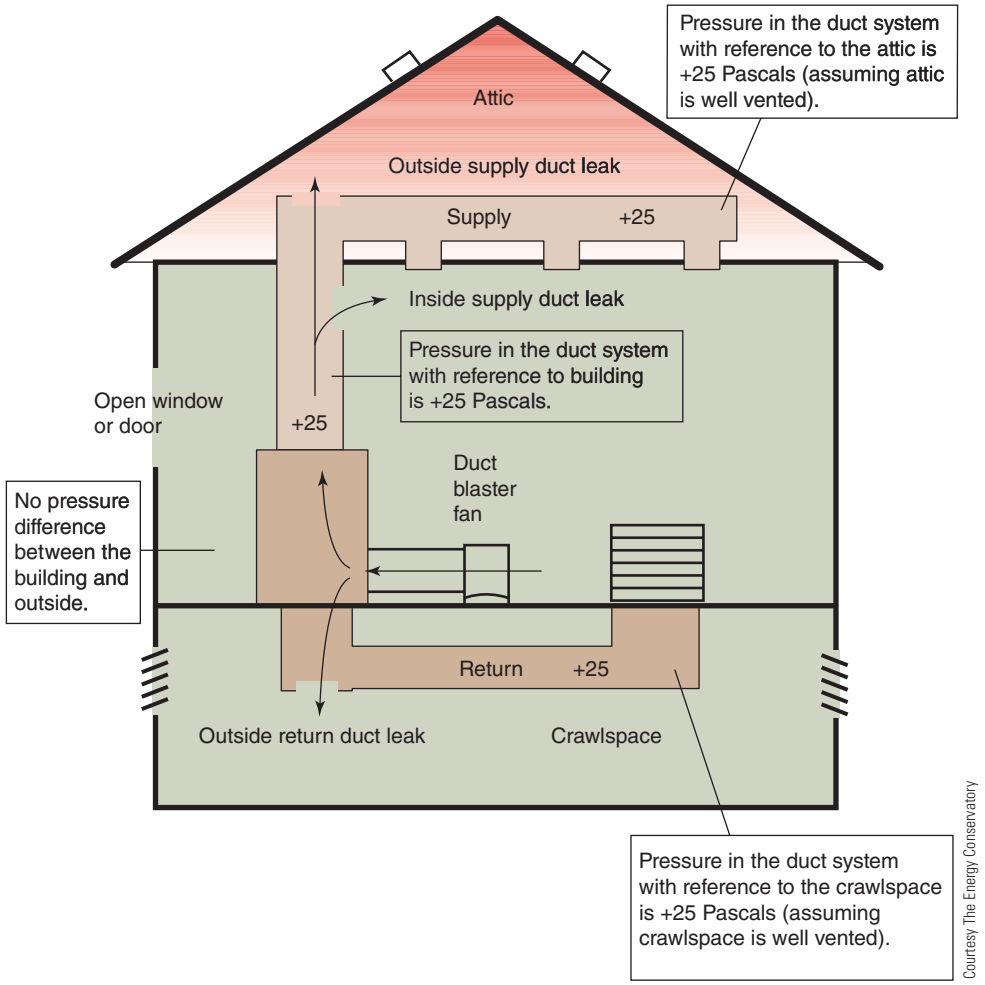
Figure 39.49 Pressurize the duct system to 25 Pascals and record the duct blower's airflow in cfm.



fireplaces for carbon monoxide levels, backdrafting, and other safety hazards such as cracked heat exchangers and gas leakage.

Combustion needs fuel, oxygen, and heat. The reaction of fuel, oxygen, and heat is known as rapid oxidation, or the process of burning. The fuel in this case is natural gas (methane), propane, butane, or fuel oil. The oxygen for combustion comes from the air, which contains approximately 21% oxygen and 79% nitrogen. The heat comes from some type of ignition system, which can be a spark or a hot surface igniter. The fuels contain hydrocarbons that unite with the oxygen when heated to the ignition temperature. Natural gas, propane, butane, and fuel oil are all considered hydrocarbons (HC). Enough air must be supplied to furnish the proper amount of oxygen for the combustion process.

The ignition temperature for natural gas is 1100°F to 1200°F. The ignition source must provide this heat, which is the minimum temperature for burning. When the burning process involves methane, the chemical formula is

Complete or perfect combustion:

$$CH_4 + 2\,O_2 \rightarrow CO_2 + 2\,H_2O + \text{Heat}$$

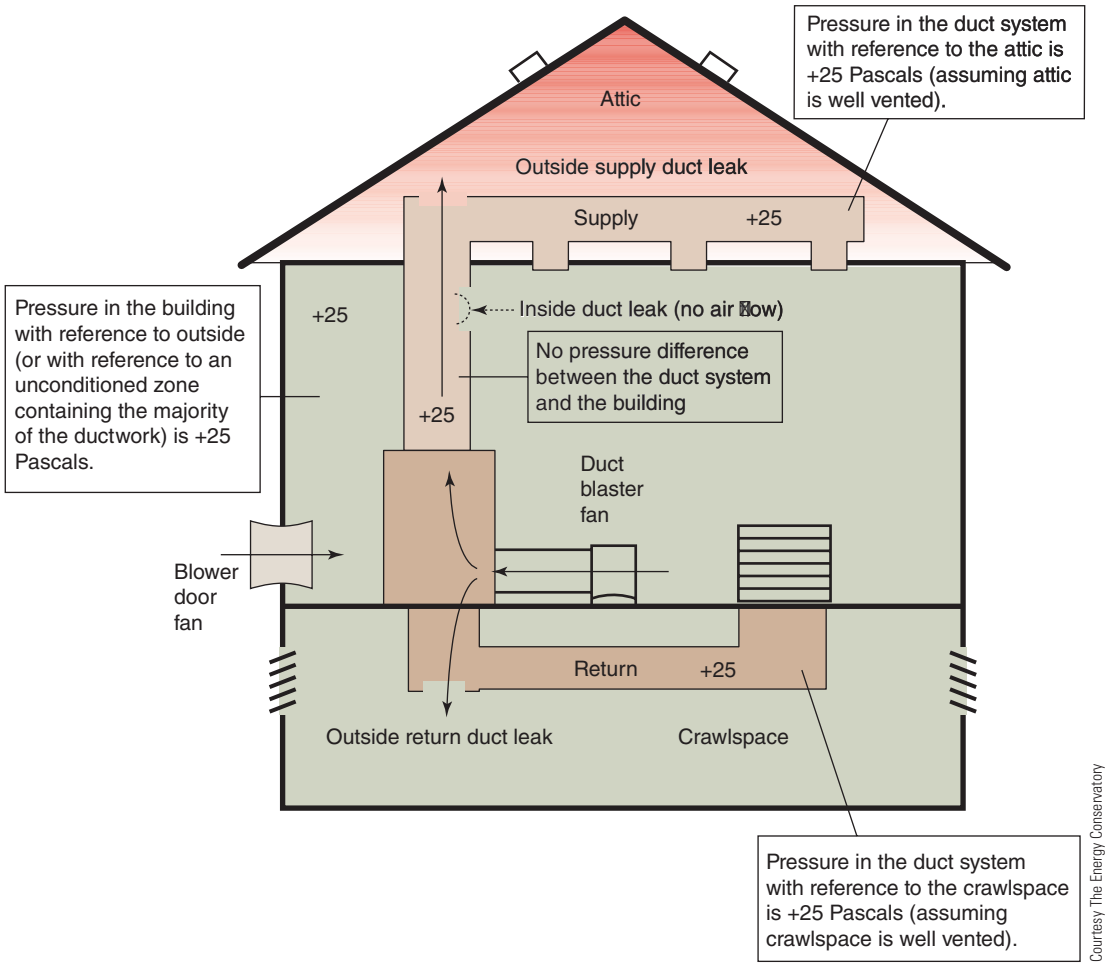
where

CH_4 = methane
O_2 = oxygen
CO_2 = carbon dioxide
H_2O = water vapor

This formula represents perfect combustion. This process produces carbon dioxide, water vapor, and heat. Although perfect combustion seldom occurs, slight variations create no danger. However, large variations away from perfect combustion can be hazardous to human health.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 39.50 Install a blower door in a configuration to pressurize the home, then connect the duct blower to the air handler or to a return-air register.



Incomplete combustion can be represented by the chemical formula:

Incomplete combustion:

$$CH_4 + O_2 \rightarrow CO_2 + H_2O + CO + O_2 + C + \text{Heat}$$

where

CO = carbon monoxide
O_2 = oxygen
C = Unburned carbon or soot

As one can see, carbon monoxide (CO) is a product of incomplete combustion. The oxygen (O_2) at the end of the equation is oxygen that goes through the combustion process without reacting. It is this percentage of excess (unreacted) oxygen that informs us about the fuel–air mixture and directly relates to the completeness of combustion. The (C) at the end of the equation is unburned carbon or soot.

SAFETY PRECAUTION: *The technician must see to it that the combustion is as close to perfect as possible. By-products of poor or imperfect combustion are carbon monoxide—a poisonous gas—soot, and minute amounts of other products like nitrous oxides (NO_x) and sulfur dioxide (SO_2). NO_x is a toxic gas that is formed in the hottest part of the flame. It should be obvious that carbon monoxide production must be avoided. Carbon monoxide (CO) is a very toxic gas that can go unnoticed because it is odorless, colorless, and tasteless. It is deadly at high levels, and at low levels it will make people very sick, cause nagging illnesses that can hide behind other symptoms of illness. Technicians can measure the exhaust gases of combustion appliances with very accurate, sophisticated digital testing instrumentation,* **Figure 39.52**, **Figure 39.55(B)**, *and* **Figure 39.57**, *these instruments can measure carbon monoxide in parts per million (ppm). It is very important for homeowners to install carbon monoxide detectors to protect them from the dangers of carbon monoxide poisoning. Refer to Unit 34, "Indoor Air Quality," for more detailed information on carbon monoxide and other indoor pollutants.*•

39.12 FURNACE EFFICIENCY TESTING

Digital flue gas analysis instrumentation measures

1. carbon monoxide (CO),
2. oxygen (O_2),
3. draft, and
4. flue gas temperature.

These digital flue gas analyzers will calculate combustion efficiency in a percentage and in **steady-state efficiency (SSE)**. The term *steady-state efficiency* refers to combustion efficiency when the flue gas temperature (stack temperature) has stabilized and the flue gas samples reach equilibrium. Combustion efficiency is the ability of the combustion appliance to convert fuel into heat energy. Today, technicians and/or auditors can quickly test the efficiency of furnaces, **Figure 39.51**.

Some common efficiency problems are low fuel input pressure and high O_2. This will result in very poor heat transfer. Only by performing a flue gas analysis with combustion analyzer instrumentation can an auditor or technician detect this problem. The remedy is to optimize the fuel–air mixture, which can increase the SSE up to 10% and reduce O_2 emissions. Another common problem is a too low flue gas temperature. Low flue gas temperatures are usually an indicator of good efficiency. However, if flue gas temperatures are too low, especially in older conventional furnaces, condensation will form in the vent pipe. This happens because the flue gas has cooled below its dew point temperature (DPT). This condensation has been known to be a bit acidic and can rust metal vent pipes and damage masonry chimneys.

Certain furnace parameters are very important for indicating how efficiently the furnace is performing. These parameters also tell the auditor or technician how safely the furnace is operating.

Figure 39.51 A technician testing the combustion efficiency of a furnace.

Courtesy Ferris State University. Photo by John Tomczyk

- **Percent oxygen (O_2)**—Indicates whether the fuel–air mixture is correct. Percent O_2 indicates the percentage of excess air and is indirectly related to furnace efficiency. As the percent O_2 increases, the furnace efficiency decreases along with the percentage of carbon dioxide.
- **Stack (flue gas) temperature**—**Stack temperature** or flue gas temperature is indirectly related to furnace efficiency. As flue gas temperature increases, furnace efficiency decreases. Stack temperature is a major indicator of combustion efficiency; it reflects the heat that did not transfer from the combustion gases to the heating medium (air, water, or steam). A high flue gas temperature means a lot of heat is escaping out the vent of the furnace, making it less efficient. A too low flue gas temperature also may cause inadequate drafting of the furnace. Low flue gas temperatures can also cause condensation in the vent pipe when the flue gas cools enough to reach its dew point temperature. Stack temperature must be measured before the introduction of dilution air, which means before the draft diverter or draft hood of the combustion appliance, if one is used. **Net stack temperature** is the stack temperature minus the room's combustion air (ambient) temperature. For example, if the actual measured stack temperature is 300°F and the ambient around the furnace is 70°F, then the net stack temperature is 230°F (300 − 70)°F. Modern combustion analyzers usually measure the room's ambient temperature during the warm-up period. Always follow the combustion analyzer's instructions for proper operating procedures when combustion air is piped from the outdoors directly to the combustion appliance.
- **Carbon monoxide (CO)**—Incomplete combustion will create CO. The target is not to exceed 100 ppm of CO in the combustion gases. Adjustments to the primary air, gas pressure, and burner maintenance can usually achieve less than 100 ppm of CO, **Figure 39.52**.

Figure 39.52 A technician testing the ppm carbon monoxide (CO) in a furnace's flue gases.

- **Airflow**—Airflow through the furnace is indirectly related to the temperature rise through the furnace. The more airflow in cubic feet per minute (cfm), the smaller the temperature rise. The temperature rise is a measurement of the supply-air temperature minus the return-air temperature. **Figure 39.53** illustrates how to measure the temperature rise across a furnace. Airflow in cfm has a large impact on flue gas temperature, temperature rise, and furnace output in btu/h. The higher the cfm, the lower the flue gas temperature and temperature rise, but the higher the capacity of the furnace in btu/h.

As mentioned earlier, CO_2 is a product of complete combustion. The higher the percentage of CO_2, the greater the steady-state efficiency (SSE). CO_2 will range usually between 3% to 14%. Oxygen (O_2) is an indicator of the amount of excess air in the combustion gases. As the O_2 gets higher, the SSE will decrease. Oxygen will also range from 3% to 14%. Generally, the SSE will decrease as the stack temperature increases. However, to determine SSE, the stack temperature must be compared and analyzed with O_2 or CO_2 levels. Refer to **Figure 39.54** for general guidelines on combustion standards for gas furnaces.

Furnace heat exchangers are made of sheet steel or aluminized steel and are designed to provide rapid transfer of heat from the hot combustion products through the steel to the air that will be distributed to the space to be heated. Heat exchangers must have the correct airflow across them or problems will occur. If too much air flows across a heat exchanger, the flue gas will become too cool and the products of combustion may condense and run down the flue pipe. These products are slightly acidic and will deteriorate the flue system if not properly removed. However, high-efficiency condensing gas furnaces and their venting systems are equipped to handle the condensation of flue gases. If there is not enough airflow, the combustion chamber will overheat, and stress will occur.

Generally, too much airflow will decrease the temperature rise across the furnace. This happens because the air is in contact with the heat exchanger for only a short time. Too little airflow will increase the temperature rise

Figure 39.53 How to measure the temperature rise across a furnace.

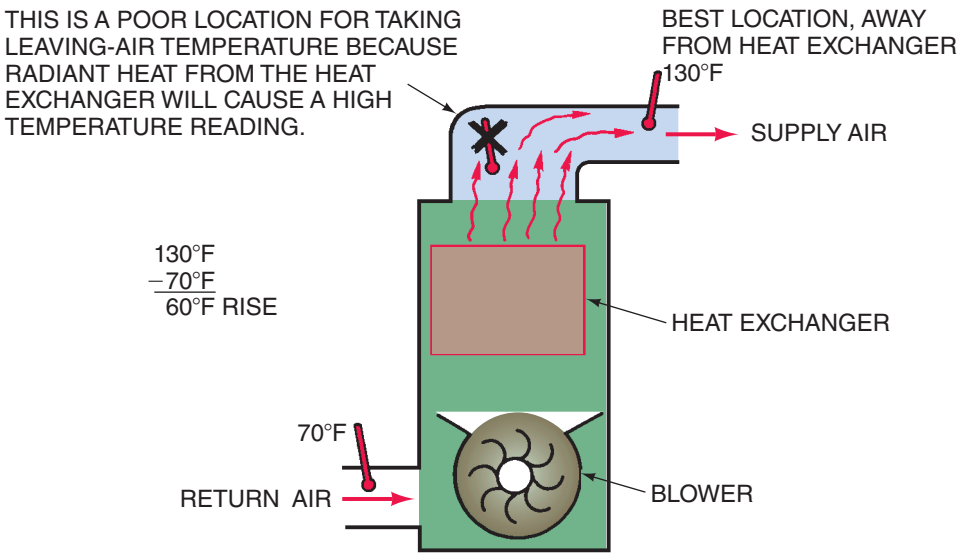

Figure 39.54 General combustion guideline standards for gas furnaces.

PERFORMANCE INDICATORS	SSE 70+	SSE 80+	SSE 90+
Carbon Monoxide (CO) ppm	Less than 100 ppm	Less than 100 ppm	Less than 100 ppm
Temperature Rise (°F)	60°–90° *	45°–75° *	35°–65° *
Stack Temperature (°F)	350°–450°	275°–350°	110°–120°
Oxygen (% O_2)	5–10%	4–9%	4–9%
Gas Pressure (in. WC)	3–4 *	3–4 *	3–4 *
Draft in. WC	−0.02 to −0.04 in. WC	−0.02 to −0.04 in. WC	
(Pascals) Pa	(−5 to −10 Pa)	(−5 to −10 Pa)	+20 to 60 Pa
Steady State Efficiency (SSE) %	73–78%	79–82%	91–97%

*Follow manufacture's instructions.

across the furnace because the air is in contact with the heat exchanger for a longer time period. Furnace manufacturers print the recommended air temperature rise for most furnaces on the furnace nameplate. Normally, for a gas furnace it is between 40°F and 70°F. However, the nameplate-rated temperature rise is dependent on whether the furnace is standard-, mid-, or high-efficiency. (This will be explained later in this unit.) The temperature rise of the furnace decreases as the efficiency increases. This can be verified by taking the return-air temperature and subtracting it from the leaving-air temperature, **Figure 39.53**. Be sure to use the correct temperature probe locations. Radiant heat can affect the temperature readings.

The following formula may be used to calculate the exact airflow across a gas furnace:

$$\text{cfm} = Q_s \div (1.08 \times \text{TD})$$

where

Q_s = Sensible heat in Btu/h
cfm = Cubic feet of air per minute
1.08 = A constant
TD = Temperature difference between supply and return air

This requires some additional calculations because gas furnaces are rated by the input. If a gas furnace is 80% efficient during steady-state operation, you may multiply the input times the efficiency to find the output. For example, if a gas furnace has an input rating of 80,000 Btu/h and a temperature rise of 55°F, how much air is moving across the heat exchanger in cfm? The first thing to do is to find out what the actual heat output to the airstream is: 80,000 × 0.80 (80% estimated furnace efficiency) = 64,000 Btu/h. Use this formula:

$$\text{cfm} = Q_s \div (1.08 \times \text{TD})$$
$$\text{cfm} = 64{,}000 \div (1.08 \times 55)$$
$$\text{cfm} = 1077.4$$

The answer's accuracy will be increased by taking several temperature readings at both the supply- and return-air ducts and averaging them. The more readings taken, the more accurate the answer will be. A good digital thermometer will also increase accuracy.

39.13 FURNACE EFFICIENCY RATINGS

Furnace efficiency ratings are determined by the amount of heat that is transferred to the heated medium, which is usually water or air. The following factors determine the efficiency of the furnace:

1. Type of draft (natural atmospheric injection, induced, or forced)
2. Amount of excess air used in the combustion chamber
3. Delta-T, or temperature difference, of the air or water entering versus leaving the heating medium side of the heat exchanger
4. Flue stack temperature

The following are furnace classifications and approximate **Annual Fuel Utilization Efficiency (AFUE)** ratings:

Conventional, or Standard-Efficiency, Furnace (78% to 80% AFUE)

- Atmospheric injection or draft hood
- 40% to 50% excess air usage
- Delta-T of 70°−100°F (lowest cfm airflow of furnaces)
- Stack temperatures of 350°−450°F
- Noncondensing
- One heat exchanger

Mid-Efficiency Furnace (78% to 83% AFUE)

- Usually induced or forced draft
- No draft hoods
- 20% to 30% excess air
- Delta-T of 45°−75°F (more cfm airflow than conventional units)
- Stack temperatures of 275°−300°F
- Noncondensing
- One heat exchanger

High-Efficiency Furnace (87% to 97% AFUE)

- Usually induced or forced draft
- No draft hoods
- 10% excess air
- Delta-T of 35°−65°F (highest cfm of all furnaces)
- Stack temperatures of 110°−120°F
- Two or three heat exchangers
- Condensing furnace (reclaims the latent heat of condensation by condensing flue-gas water vapors to liquid water)
- Use of PVC pipe for appliance venting to avoid corrosion

As excess air decreases, the DPT increases. This is the main reason high-efficiency condensing gas furnaces require very little excess air in the combustion processes. High-efficiency condensing furnaces operate below the DPT of the combustion gases in order for condensation to happen. The reason for the low Delta-T for high-efficiency furnaces is the increased amount of air (cfm) through their heat exchangers. This keeps the air in contact with the heat exchanger for a shorter period of time.

39.14 FLAME COLOR

A good flame has an inner and outer mantle and is hard and blue. Orange streaks in the flame are not to be confused with yellow streaks. Orange streaks are dust particles burning. Other than pressure to the gas orifice, the primary air is often the only

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

adjustment that can be made to the flame. Modern furnaces have very little adjustability. This is intentional in order to maintain minimum standards of flame quality. The only thing that will change the furnace combustion characteristics to any extent, other than primary air and gas pressure adjustments, is dirt or lint drawn in with the primary air. If the flame begins to burn yellow, primary air restriction should be suspected. For a burner to operate efficiently, the gas flow rate must be correct, and the proper quantity of air must be supplied.

SAFETY PRECAUTION: *Yellow tips indicate an air-starved flame emitting poisonous carbon monoxide.*•

Cooling the flame will cause inefficient combustion. This happens when the flame strikes the sides of the combustion chamber (due to burner misalignment), which is called flame impingement. When the flame strikes the cooler metal of the chamber, the temperature of that part of the flame is lowered below the ignition temperature. This results in poor combustion, which produces carbon monoxide and soot. Soot, which is basically unburned carbon, lowers furnace efficiency because it collects on the heat exchanger and acts as an insulator, so it also must be kept at a minimum. Refer to Unit 31, "Gas Heat," for more detailed information on furnace efficiency ratings and correct flame color.

39.15 FURNACE PREVENTIVE MAINTENANCE

Gas equipment preventive maintenance consists of servicing the air-side components: filter, blower, belt and drive, and the burner section. Air-side components are the same for gas as for electric forced-air heat, so only the burner section will be discussed here.

The burner section consists of the burner, the heat exchanger, and the venting system for the products of combustion. The burner section of the modern gas furnace does not need adjustment from season to season. *It will burn efficiently and be reliable if it is kept clean. Rust, dust, or scale must be kept from accumulating on top of the burner where the secondary air supports combustion, or in the actual burner tube where primary air is induced into the burner. When a burner is located in a clean atmosphere (no heavy particles in the air as in a manufacturing area) most of the dust particles in the air will burn and exit through the venting system. The burner may not need cleaning for many years.* A vacuum cleaner with a crevice tool may be used to remove small amounts of scale or rust deposits. The burner and manifold may be removed for more extensive cleaning inside the burner tube where deposits may be located. Each burner may be removed and tapped lightly to break the scale loose. An air hose should be used to blow down through the burner ports while the burner is out of the system. The particles will blow back out the primary air shutter and out of the system. **SAFETY PRECAUTION:** *Wear goggles when using compressed air for cleaning.*•

Cleaning cannot be accomplished while the burners are in the furnace. When reinstalling the burner, the alignment should be checked to make sure that no flame impingement to the heat exchanger will occur. The burners should set straight and feel secure while in place. Large deposits of rust scale may cause flame impingement and must be removed.

A combustion analysis is not necessary as routine maintenance on the modern gas furnace. On new furnaces the primary air is sometimes the only adjustment. Many times, even primary air cannot be adjusted because the burners are inshot burners. All gas burners should burn with a clear flame, with only occasional orange streaks in the flame. The flame should be hard and blue with a distinct inner and outer mantle. There should never be any yellow or yellow tips on the flame. If yellow tips cannot be adjusted from the flame, the burner contains dirt or trash, and it should be removed for cleaning. Observe the burner for correct ignition as it is lit. Often, the crossover tubes that carry the burner flame from one burner to the next get out of alignment and the burner lights with an irregular pattern. Sometimes it will "puff" when one of the burners is slow to ignite.

The venting system should be examined for obstructions. Birds may nest in the flue pipe, or the vent cap may become damaged. Visual inspection is the first procedure. Then, with the furnace operating, the technician should use a chemical smoke generator or smoke stick in the vicinity of the draft diverter on standard-efficiency furnaces to look for smoke pulling into the diverter and drafting upward, **Figure 39.55(A)**. This is a sign that the furnace is drafting correctly.

Observe the burner flame with the furnace blower running. A flame that blows with the blower running indicates a crack in the heat exchanger. This would warrant further examination of the heat exchanger. It is difficult to find a small crack in a heat exchanger and one may only be seen with the heat

exchanger out of the furnace housing. **Figure 39.55(B)** shows a technician checking a water heater with a digital carbon monoxide sensing meter. The meter will sense ppm CO coming into the home from backdrafting.

High-efficiency condensing furnaces require maintenance of the forced-draft blower motor if it is designed to be lubricated. The condensate drain system should be checked to be sure it is free of obstructions and that it drains correctly. *Manufacturers of condensing furnaces sometimes locate the condensing portion in the return-air section, where all air must move through the coil. The coil is finned and will collect dirt if the filters are not cleaned. Routine inspection of this condensing coil for obstruction is a good idea.*

All installations should be checked by setting the room thermostat to call for heating and by making sure the proper sequence of events occurs. Always know the sequence of operation for the furnace. Some technicians disconnect the circulating fan motor and allow the furnace to operate until the high-limit control shuts it off, which proves the safety device will shut off the furnace. Technicians will often perform a combustion analysis test to check furnace efficiency and then make air shutter adjustments. For more detailed information on gas and oil furnaces, refer to Unit 31, "Gas Heat," and Unit 32, "Oil Heat."

SAFETY PRECAUTION: *With the furnace operating, the technician should strike a match or use a smoke generator in the vicinity of the draft diverter and look for the flame to pull into the diverter. This is a sign that the furnace is drafting correctly.*•

SAFETY PRECAUTION: *All gas burners should burn with a clear flame, with only occasional orange streaks in the flame. The flame should be hard and blue with a distinct inner and outer mantle. There should never be any yellow or yellow tips on the flame. Yellow is an indication of an air-starved flame.*•

SAFETY PRECAUTION: *Observe the burner flame with the furnace fan running. A flame that blows with the fan running indicates a crack in the heat exchanger. This would warrant further examination of the heat exchanger.*•

39.16 SPILLAGE AND BACKDRAFTING

As mentioned earlier, carbon monoxide (CO) is a colorless and odorless gas which can sicken or kill persons residing in the home. Carbon monoxide can enter the homes living spaces by

- backdrafting,
- spillage, or
- cracked heat exchangers.

Backdrafting can be caused by pressure differences. When the pressure is lower in the living space of the home with respect to the pressure in the vent or chimney for the combustion appliances, backdrafting will occur. The pressure difference will draw combustion by-products down the chimney or vent pipe and often over the flame, causing a suffocated flame and carbon monoxide, **Figure 39.58(B)**. **Figure 39.55(A)** shows a technician testing for backdrafting or downdrafting with a chemical smoke generator at the draft diverter of a residential furnace. **Figure 39.55(B)** shows a technician testing for backdrafting on a water heater by checking the ppm carbon monoxide (CO) with a digital meter. In **Figure 39.55(C)**, a technician is checking for backdrafting in a residential fireplace

Courtesy The Energy Conservatory

using a chemical smoke generator. **Figure 39.55(D)** shows a technician measuring the airflow from an exhaust fan using an exhaust fan flow meter and digital gauge. Exhaust fans can cause a negative pressure in the home because they exhaust inside conditioned air, which must be made up or a negative pressure will result. Backdrafting can be caused by

- high winds,
- combustion using inside air,
- open fireplaces,
- clothes dryers,
- exhaust fans,
- leaky return-air ducts in the combustion appliance zone (CAZ),
- a poorly designed chimney, or
- a poorly designed venting system.

Some remedies for backdrafting problems include sealing all leaky ducts, especially return-air ducts in the CAZ; eliminating all sources of depressurization (clothes dryers and exhaust fans) near the vent or chimney; and providing outdoor air for all combustion appliances. Large, open fireplaces are especially a hazard because their draft is so powerful it will bring the inside living space of a residence into a negative pressure real fast. Make sure all fireplaces have sealed combustion chambers where outside air is used for the combustion process. This will prevent depressurization of the inside of the home and backdrafting of other combustion appliances. In all cases, bring outdoor air into the CAZ and replace open-combustion, atmospheric (non-direct-vented) appliances with sealed-combustion (direct-vented) power-drafted, high-efficiency appliances, **Figure 39.56(A)** and **Figure 39.56(B)**. The Building Performance Institute (BPI) considers naturally drafting appliances and venting systems antiquated and both unsafe and inefficient. It recommends replacing them with modern, direct-vented power-draft-assisted appliances.

Spillage is not as serious as backdrafting, but it is an unhealthy situation and can cause sickness in households if not controlled. Spillage is a temporary flow of combustion by-products into the living space. Spillage usually happens when a furnace (combustion appliance) has just started up and the chimney or vent has a weak draft. The weak draft is caused by a cool chimney or vent pipe. Spillage usually stops once the chimney or vent warms up. **Figure 39.57** shows a technician checking a furnace for ppm CO caused by spillage.

Cracked heat exchangers can allow combustion products to mix with the heating air that enters the living spaces of the house and cause serious health effects. Heat exchangers can become cracked by

- failed weld joints,
- rust from condensation,
- stress cracks from excessive heat, or
- old age.

Heat exchangers can be inspected for cracks by probing the combustion chamber with a modern miniature camera. Using lights, chemicals, and smoke generators in the combustion chamber can also search out leaky heat exchangers. Detection devices placed at the supply registers in living areas can detect the, light, chemicals, or smoke. And a light placed in the heat exchanger can often be seen from the outside if there is a crack. If there is any variation in color, size, or motion of the flame when the furnace's blower turns on, the heat exchanger is probable cracked.

39.17 FLAME SAFEGUARD CONTROLS

Flame safeguard controls protect against unignited fuel that enters the combustion chamber. The build-up of such fuel can quickly become a serious fire and explosion hazard. The three most common types of flame safeguard controls are

1. thermocouples,
2. flame rectification, and
3. a cadmium sulfide (Cad) cell or photo cell.

Thermocouples are found mainly on older gas furnaces. This control consists of two dissimilar metals welded together at one end, called the "hot junction." When this junction is heated, it generates a small voltage (approximately 15 mV with load; 30 mV without load) across two wires at the other end. As long as the electrical current in the thermocouple energizes a coil, the gas can flow. If the flame goes out, the thermocouple will cool off in about 30 to 120 sec, no current will flow, and the gas valve will close.

Most older gas furnaces use thermocouple systems, but they are gradually being phased out and replaced with more efficient furnace models incorporating flame rectification safeguard controls. However, many water heaters still use thermocouples as flame safeguard controls.

Flame rectification is based on the fact that the pilot flame or main flame can conduct electricity because it contains ionized combustion gases, which are made up of positively and negatively charged particles. The flame is located between two electrodes of different sizes. The electrodes are fed with an alternating current (AC) signal from the furnace's electronic module. Because the electrodes are of different sizes, current will flow better in one direction than in the other with the flame acting as a switch. If there is no flame, the "switch" is open and electricity will not flow. When the flame is present, the switch is closed and will conduct electricity. The two electrodes in a spark-to-pilot (intermittent pilot) ignition system are the pilot hood (earth ground) and a flame rod or flame sensor.

As AC switches the polarity of the electrodes 60 times each second, the positive ions and negative electrons move to the different-size electrodes. The particles move at different speeds because the positively charged particles (ions) are relatively larger, heavier, and slower than the negatively charged particles (electrons). In fact, the electrons are about 100,000 times lighter than the ions. This produces a rectified AC signal, which looks much like a pulsating DC signal. It is the DC signal that the electronics of the furnace recognize. It is proof that a flame exists and is not a short resulting from humidity or direct contact between the electrodes. Humidity or direct contact would cause an AC current to flow, which the furnace's electronic module would not recognize. An AC signal would prevent the main gas valve from opening in a spark-to-pilot system. In a DSI system it would shut down the main gas once the trial for ignition timing had elapsed and might put the furnace in a lockout mode. The DC signal can be measured with a microammeter in series with one of the electrode leads and usually ranges between 1 and 25 microamps. The magnitude of the microamp signal may depend on the quality, size, and stability of the flame and on the electronic module and electrode design. Refer to Unit 31, "Gas Heat," for more detailed information on thermocouple and flame rectification operation.

Cad cells, or photo cells, are usually used in conjunction with a primary control and are most often found on oil-fired furnaces. The main component of the relay is the **cad cell**, which is made from a chemical compound called cadmium sulfide that changes its resistance in response to the amount of light the material is exposed to. The cad cell is made up of cadmium sulfide, a ceramic disc, a conductive grid, and electrodes. The entire assembly is encased in glass. The cell is positioned in the oil burner so that it can sense the light produced when the air-oil mixture is ignited. When the burner is off, no light is being generated and the resistance of the cad cell is very high, about 100,000 ohms. When the burner is firing, the resistance of the cad cell drops to under 1000 ohms. The primary control will shut the burner down in a preset amount of time if no light is sensed by the cad cell and its resistance remains high. Refer to Unit 32, "Oil Heat," for more detailed information on cad cell operation.

39.18 EXCESS AIR

Excess air consists of (1) combustion air and (2) dilution air. **Combustion air** is primary and/or secondary air. Primary air enters before combustion takes place. It mixes with raw gas in the burner before a flame has been established. Too much primary air can cause the flame to "lift off" the burner and be noisy or unsettled. Too little primary air can cause a very lazy flame that looks like it is searching for air. A good flame has an inner and outer mantle and is hard and blue. Secondary air enters after combustion and supports it. **Dilution air** is excess air that enters after combustion, usually at the end of the heat exchanger. It is brought in by the draft hood of the furnace, **Figure 39.58(A)**.

As **excess air** decreases, the dew point temperature (DPT) increases. The DPT for undiluted flue gas is around 140°F. In diluted flue gas, the temperature may drop to about 105°F. This is the main reason high-efficiency condensing furnaces require very little excess air for combustion. They operate below the DPT of the combustion gases to promote condensation.

Gas furnaces with high efficiency ratings are being installed in many homes and businesses. The U.S. Federal Trade Commission requires manufacturers to provide an Annual Fuel Utilization Efficiency (AFUE) rating. All forced-air gas furnaces have efficiency ratings. This rating allows the consumer to compare furnace performance before buying. Annual efficiency ratings have been increased in some instances from 65% to 97% or higher. A part of this increase in efficiency is accomplished by keeping too much heat from being vented to the atmosphere. In conventional furnaces stack temperatures are kept high to provide a good draft for proper venting. High temperatures also prevent condensation and therefore corrosion in the vent. But because of the high stack temperatures, excess heat is allowed to escape to the atmosphere, thus reducing efficiency.

39.19 VENTING

Conventional gas furnaces use hot vent gas temperatures and natural convection to vent the products of combustion (flue gases). Flue gases contain approximately 1 ft^3 of oxygen (O_2), 12 ft^3 of nitrogen (N_2), 1 ft^3 of carbon dioxide (CO_2), and 2 ft^3 of water vapor (H_2O). The hot gas is vented quickly, primarily to prevent cooling, which produces condensation and other corrosive activity. As mentioned, conventional non-direct-vented furnaces lose some efficiency

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

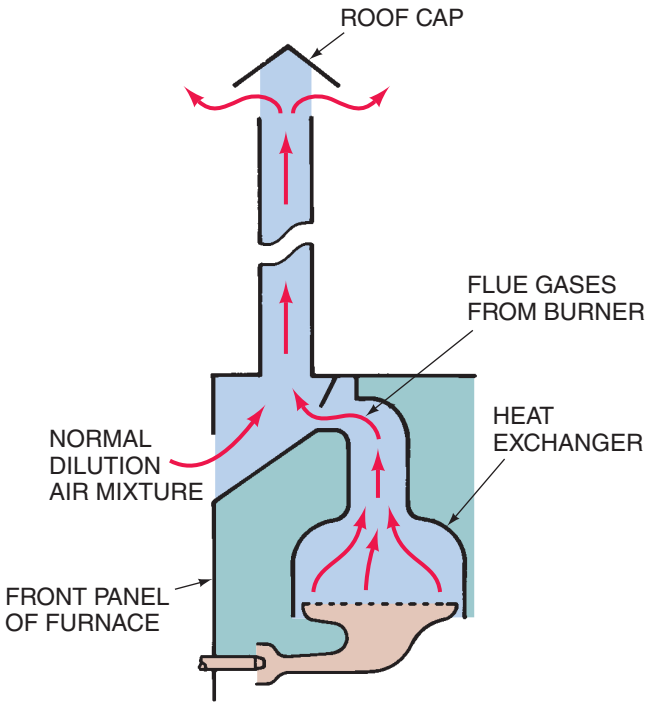
because considerable heat is lost up the flue. High-efficiency furnaces (90% and higher) recirculate the flue gases through a special extra heat exchanger to keep more of the heat available for space heating in the building. The gases are then pushed out of the flue by a small fan. There is some condensation and thus corrosion in the flue, so plastic pipe is used because it is not damaged by the corrosive materials. **SAFETY PRECAUTION:** *Regardless of the type, combustion appliances must be properly vented so that the by-products of combustion will all be dissipated into the atmosphere.*•

A venting system must provide a safe and effective means of moving the flue gases to the outside air. With a conventional furnace, it is important for the flue gases to be vented as quickly as possible. They are equipped with a draft hood that blends some room air with the rising flue gases, **Figure 39.58(A)** and **Figure 39.58(B).** The products of combustion enter the draft hood and are mixed with air from the area around the furnace. Approximately 100% additional air (called dilution air) enters the draft hood at a lower temperature than the flue gases. The heated gases rise rapidly and create a draft, bringing the dilution air in to mix and move up the vent.

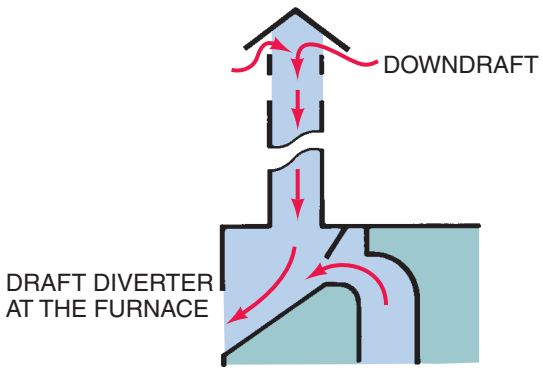
Figure 39.58 (A) Dilution air is excess air after combustion and usually enters at the end of the heat exchanger. It is brought in by the draft hood of the furnace.

Courtesy Ferris State University. Photo by John Tomczyk

Figure 39.58 (B) Conventional furnaces are equipped with a draft diverter or draft hood that blends some room air with the rising flue gases. The diverter or hood also prevents downdraft air from blowing out the burner flame and pilot light, if the furnace has one.



(B-1)



(B-2)

All furnaces must be supplied with the correct amount of excess air. As mentioned earlier, excess air consists of combustion air and dilution air. Combustion air consists of both primary and secondary air. This amount of air for gas-burning appliances is determined by the appliance size and is mandated by local codes or the National Fuel Gas code, which is considered the standard by many states. Obviously, the larger the furnace, the more excess air is needed. One rule of thumb is that a grill with a free area of 1 in^2 per 1000 Btu/h must be provided below the furnace (if the structure is over a crawl space) and above the furnace (to the attic space) to provide adequate air for combustion. For a 100,000-Btu/h furnace,

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

this would be 100 in² of free area. The grill must be larger than 10 in. × 10 in. = 100 in² because of the space the louvers take up. (Approximately 30% of the grill area is louvers.) So the grill would have to be 100/0.70 = 142.9 in², or 12 in. × 12 in. The vent above the furnace is for dilution air. The vent below is for combustion air.

This example of figuring out what adequate ventilation air should be is only one possibility. In the past, excess air was merely extracted from the volume of air in the structure. Structures today are built tighter with less infiltration air entering around the windows and doors, so makeup air for the furnace must be considered. Even old structures are being tightened by the use of storm windows, weather stripping, and other weatherization methods, so there is less air infiltration and exfiltration. A furnace installed in an older structure that has been tightened may have venting problems as evidenced by flue gases spilling out of the draft diverter rather than exiting out the flue. If wind conditions produce a downdraft, the opening in the draft hood provides a place for the gases and air to go, diverting it away from the pilot and main burner flame. The draft diverter helps reduce the chance of the pilot flame being blown out and the main burner flame altered, **Figure 39.58(B)**.

Venting categories were created when high-efficiency furnaces were introduced. Following are the four venting categories listed by the American National Standards Institute (ANSI). Based on ANSI Standard Z21.47A-1990, they set venting standards for temperature and pressure for the proper venting of gas furnaces.

- **Category I**—Furnace has a nonpositive vent pressure and operates with a vent gas temperature at least 140°F above its dew point (conventional or standard-efficiency furnace).
- **Category II**—Furnace has a nonpositive vent pressure and operates with a vent gas temperature less than 140°F above its dew point (no longer manufactured because of condensate problems at start-up).
- **Category III**—Furnace has a positive vent pressure and operates with a vent gas temperature at least 140°F above its dew point (mid-efficiency furnace).
- **Category IV**—Furnace has a positive vent pressure and operates with a vent gas temperature less than 140°F above its dew point (high-efficiency condensing furnace).

SAFETY PRECAUTION: *Make sure replacement air is available in the CAZ.*•

It takes 10 ft³ of air to support combustion for each 1 ft³ of natural gas. To this is added 5 ft³ more to ensure enough oxygen. Another 15 ft³ is added at the draft hood, making a total of 30 ft³ of air for each 1 ft³ of gas. A 100,000-Btu/h furnace would require 2857 ft³/h of fresh air (100,000 btu/h) divided by (1050 btu/ft³) × (30) = 2857 ft³/h. All of this air must be replaced in the furnace area and also must be vented as flue gases rise up the vent. If the air is not replaced, the furnace area will become a negative pressure area and air will be pulled down the flue. Products of combustion will then fill the area.

Type B vent or approved masonry materials are required for conventional gas furnace installations. Type B venting systems consist of metal vent pipe of the proper thickness, which is approved by a recognized testing laboratory. The venting system must be continuous from the furnace to the proper height above the roof. Type B vent pipe is usually of a double-wall construction with air space between. The inner wall may be made of aluminum and the outer wall may be constructed of steel or aluminum. The vent pipe should be at least the same diameter as the vent opening at the furnace. The horizontal run should be as short as possible; long runs lower the temperature of the flue gases before they reach the vertical vent or chimney and they reduce the draft. The run should always be sloped upward as the vent pipe leaves the furnace. A slope of ¼ inch per foot of run is the minimum recommended, **Figure 39.59**. As few elbows as possible should be used. The vent connector should not be inserted beyond the inside of the chimney wall, and there should be no obstructions in the chimney when venting into a masonry-type chimney, **Figure 39.60**. If two or more gas appliances are vented into a common flue, the common flue size should be calculated based on recommendations from the National Fire Protection Association (NFPA) or local codes. The top of each gas furnace vent should have an approved vent cap to prevent the entrance of rain and debris and to help prevent wind from blowing the gases back into the building through the draft hood.

Metal vents reach operating temperatures quicker than masonry vents do. Masonry chimneys tend to cool the flue

Figure 39.59 The horizontal run should be as short as possible. Horizontal runs should always be sloped upward as the vent pipe leaves the furnace. A slope of ¼ inch per foot of run is the minimum recommended.

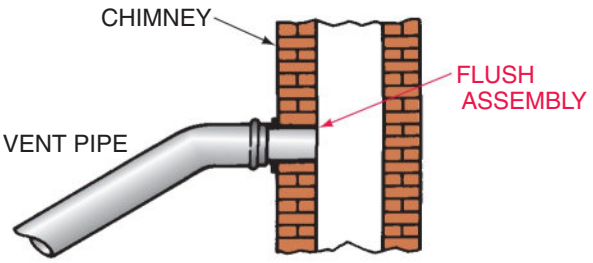
Figure 39.60 The vent connector should not be inserted beyond the inside of the wall of the chimney, and there should be no obstructions in the chimney when venting into a masonry-type chimney.



gases. They must be lined with a glazed-type tile or vent pipe. If an unlined chimney is used, the corrosive materials from the flue gas will destroy the mortar joints. It takes a long running cycle to heat a heavy chimney. Condensation occurs at start-up and during short running times in mild weather. The warmer the gases, the faster they rise and the less damage there is from condensation and other corrosive actions. Vertical vents can be lined and glazed masonry or prefabricated metal chimneys approved by a recognized testing laboratory. When an unlined chimney must be used, a special corrosion-resistant flexible liner often can be installed. It is worked down into the chimney and connected at the bottom to the furnace vent. This provides a corrosion-proof vent system.

When the furnace is off, heated air can leave the structure through the draft hood. Automatic vent dampers that close when the furnace is off and open when the furnace is started can be placed in the vent to prevent air loss. Several types of dampers are available. One uses a helical bimetal strip with a linkage to the damper. When the bimetal expands, it turns the shaft fastened to the helical strip and opens the damper, **Figure 39.61**. Another type uses damper blades constructed of bimetal. When the system is off, the damper is closed. When the vent is heated by the flue gases, the bimetal action on the damper blades opens them, **Figure 39.62**. Other automatic vent dampers are controlled by a small electric motor. For safety reasons, the motors are electrically linked to the burner controls, which prevent the furnace from operating when the damper is closed and causing an unwanted health hazard from combustion by-product spillage into the structure.

39.20 DRAFT

Draft is the force that allows air to travel into the combustion chamber of a **combustion appliance** and pulls the combustion gases out through a vent or chimney. Correct **draft** is essential for efficient burner operation. The draft determines the rate at which combustion gases pass through the furnace. Draft also governs the amount of air supplied for combustion. *The correct draft is essential for efficient operation of the furnace and for the safety of the people living in the residence or structure.* Relative to the atmosphere, correct draft is a negative pressure and

Figure 39.63 Barometric dampers are used to maintain constant over-the-fire drafts regardless of chimney or vent system draft conditions.

Courtesy Ferris State University. Photo by John Tomczyk

is referred to as an **updraft** because it travels up the vent or chimney. Insufficient draft may cause pressure in the combustion chamber, resulting in smoke and odor around the furnace (combustion appliance). Excessive draft can increase the stack temperature and reduce the amount of carbon dioxide in the flue gases.

Atmospheric-draft heating appliances are often referred to as **open combustion devices**. They draw combustion air from the surrounding room. Some older models draw indoor air into their chimney or vents through a **dilution air** device. In gas furnaces and boilers, the dilution air device is often referred to as a **draft diverter** or **draft hood**. In oil-fired furnaces and boilers, the dilution device is referred to as a **barometric damper**. Barometric dampers are used to maintain constant **over-the-fire drafts** regardless of chimney or vent system draft conditions, **Figure 39.63**. Double-acting barometric damper controls allow the control damper to swing open to introduce air into the vent system when the draft is too high. They also allow the damper to swing open to relieve downdrafts. Draft diverters, draft hoods, and barometric dampers are also used to provide draft control and introduce dilution air into the venting system to reduce the possibility of condensation in the vent system. High-efficiency combustion appliances (Category IV) do not use draft controls. Their vent pressures are positive all the way to the terminal end of the vent.

In natural- or **atmospheric-draft** appliances, the combustion gases are less dense than the air around the furnace and in the chimney or vent piping. Because of this, the hot combustion gases are more buoyant. The added buoyancy causes the gases to rise and induce a draft. Factors that determine the strength of the draft are

- temperature of the flue gases,
- chimney or vent height, or
- chimney or vent cross-sectional area.

The hotter the flue gases, the stronger the draft. Also, the higher the chimney or vent piping, the stronger the draft will be. However, as the cross-sectional area of the chimney or vent increases, the draft will decrease. The draft will be stronger with a narrower vent or chimney as long as the vent or chimney is not undersized for the heating appliance. It will take a longer time to heat up a chimney or vent that has a large cross-sectional area and induce a good draft compared to one with a smaller cross-sectional area. Atmospheric-draft heating appliances are those in which the air for the combustion process is at atmospheric pressure; they rely solely on the buoyancy of their combustion gases for draft, **Figure 39.58(A)**.

Today, most modern furnaces are **power drafted** using a **combustion blower motor** and a fan. These systems are sometimes referred to as fan-assisted draft. Power drafting can be either (1) **induced draft** or (2) **forced draft**, **Figure 39.64**. Neither system has a device that allows dilution air into the venting system. This is because their fans control the strength of the **over-the-fire draft** and create a regulated flow of combustion air and combustion gases, which minimizes the use of **excess air**. Induced-draft systems have a combustion blower motor located at the outlet of the heat exchanger. They pull or suck combustion gases through the heat exchanger, usually causing a slight negative pressure in the heat exchanger itself. Forced-draft systems push or blow combustion gases through the heat exchanger and cause a positive pressure in the exchanger. Forced-draft systems have the combustion blower motor at the inlet of the heat exchanger.

SAFETY PRECAUTION: *The most dangerous hazards in terms of air pollution and fire danger in residential homes are combustion appliances. It is of utmost importance that the combustion appliance is installed and vented correctly.*•

Figure 39.64 Both induced-draft and forced-draft systems have a combustion blower motor, fan, and housing.

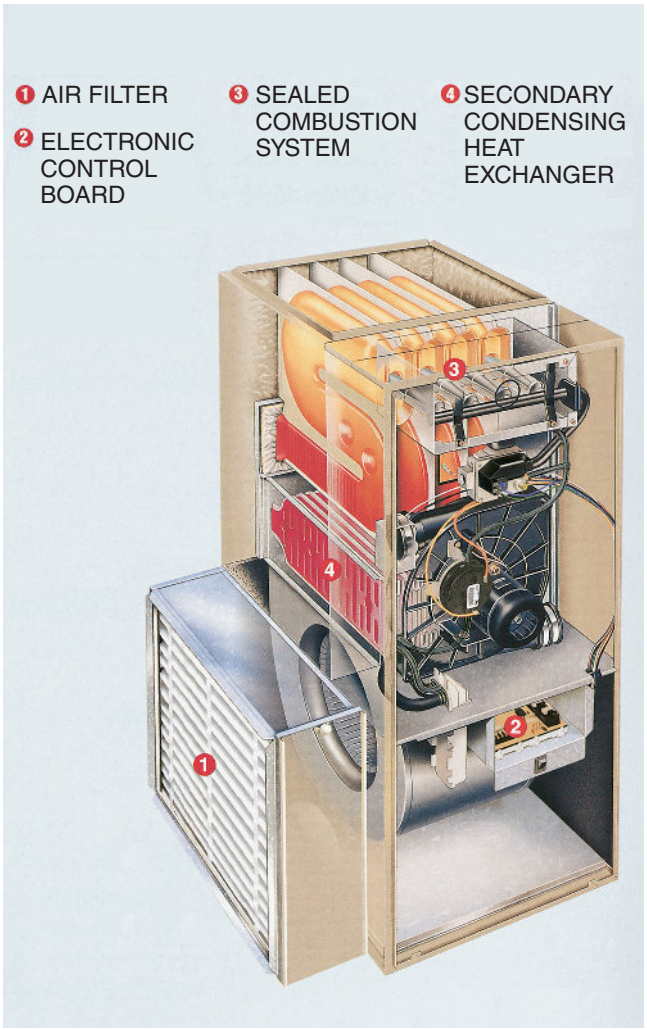
Figure 39.65 The burners of a modern, high-efficiency combustion appliance are located at the top of the furnace in a sealed combustion chamber.



Source: Bryant Heating and Cooling Systems

The burners for modern high-efficiency combustion appliances are located at the top of the furnace in a sealed combustion chamber, **Figure 39.65**. The combustion gases are pulled or sucked through the heat exchanger and when they reach the dew point, liquid condensate forms and drains by gravity to a condensate sump or drain trap. The burners are located on top to allow the draining of condensate by gravity. High-efficiency furnaces will be covered in detail later in this unit.

Draft can be divided into two categories: (1) over-the-fire draft and (2) stack (chimney) draft. Over-the-fire draft is the draft over the fire and will be a lower reading—lower than chimney draft. If the combustion appliance allows this draft to be read, there will be a place to take the reading located just over the burners, **Figure 39.66**. Over-the-fire draft does not apply to atmospheric combustion devices.

Figure 39.66 A technician taking an over-the-fire draft reading.

Courtesy Ferris State University, Photo by John Tomczyk

The reading for **chimney** or **stack draft** is taken in the vent stack between the combustion device and the draft diverter, **Figure 39.51**. Stack or chimney draft is often referred to as **flue draft**. The stack draft is typically between −0.02 in. WC and −0.04 in. WC. Combustion devices with power burners usually have over-the-fire drafts of −0.02 in. WC, and the stack draft is usually between −0.02 in. WC to −0.04 in. WC. **SAFETY PRECAUTION:** *Always consult the combustion appliance manufacturer's specifications or the unit nameplate for specific draft requirements.*•

39.21 HIGH-EFFICIENCY GAS FURNACE ANATOMY

Unlike conventional and mid-efficiency gas furnaces, high-efficiency gas furnaces have some unique characteristics:

- A "recuperative" or "secondary" (and sometimes "tertiary") heat exchanger with connecting piping for flue-gas passage from the primary heat exchanger.
- A flue-gas condensate disposal system, which includes a drain, taps, drain lines, and drain traps.
- A venting system that is either induced draft or forced power draft.

A direct-vented high-efficiency gas furnace has a sealed combustion chamber. This means that the combustion air is brought in from the outside through an air pipe, which is usually made of PVC plastic, **Figure 39.56(A)**. *The combustion chamber never receives conditioned room air. Combustion gases are then exhausted to the outside through a separate, dedicated vent pipe. The exhaust gases are sealed within the system to prevent backdrafting—exhaust fumes coming back down the flue into the living space. Since conditioned room air is not used for combustion, it does not have to be replaced. Using outside air instead of room air prevents the conditioned room from being depressurized or pulled into a*

slight vacuum. This cuts down on the amount of infiltration entering the room and of cold, infiltrated air that has to be reheated.

Direct venting also minimizes the interaction of the furnace with other combustion appliances. Depressurization of a building or home may lead to combustion products entering from the vent systems of water heaters and clothes driers and from exhaust products in attached garages. When a conditioned space is depressurized, even toxic fumes and particulates from a connecting or attached garage or building can infiltrate. These are reasons why direct venting a furnace is an added safety feature. As mentioned earlier, a non-direct-vented high-efficiency furnace uses indoor air for combustion and can depressurize a room. Both direct-vented and non-direct-vented systems are positive pressure systems and can be vented vertically or through a sidewall. Such a system's flue pipe pressure is positive the entire distance to its terminal end. However, it is possible for a system to be direct vented and still not be a positive pressure system.

In high-efficiency systems a small combustion blower is installed in the vent system near the heat exchanger. This blower mainly operates when the furnace is on so that heated room air is not being vented 24 hours a day. Heated room air will only be vented if the furnace is non-direct-vented, because non-direct-vented furnaces get their combustion air from the conditioned space. However, if the furnace is direct-vented, it will have a sealed combustion chamber and will get its combustion air from the outside through an air pipe, **Figure 39.56(A)**. There is no possible way for conditioned room air to be vented because the combustion chamber never receives room air. Since room air is not used for combustion, it prevents the conditioned room from being depressurized, or being pulled into a slight vacuum. This will cut down on the amount of infiltration entering the room, and less cold, infiltrated air will have to be reheated. Direct venting also minimizes the interaction of the furnace with other combustion appliances.

As mentioned earlier in this unit, combustion blowers can be forced- or induced-draft. An induced-draft system places the combustion blower at the outlet of the heat exchangers, causing a negative pressure that actually sucks the combustion gases out of the exchangers. In a forced-draft system, the combustion blower is before the heat exchangers and creates a positive pressure that blows the combustion gases through the exchangers. Forced-draft blowers will vent gases at a lower temperature than is possible with a natural draft, allowing the heat exchanger to absorb more of the heat from the burner for distribution to the conditioned space. When combustion blowers are used for furnace venting, the room thermostat normally energizes the blower. Blower air can be operated by airflow switches, a centrifugal switch on the motor, or a diaphragm-type pressure switch designed to sense either negative or positive pressure. Some direct-vented designs need stronger flue fan or combustion blower systems to overcome the additional pressure drop created by the sealed combustion chamber and added combustion air pipe. In fact, the combustion blower must overcome three system pressure drops:

1. The heat exchangers' system pressure drops
2. The vent system (vent and combustion air pipe) pressure drop
3. Vent termination wind resistance pressure

Combustion blower motors use an air-proving switch or pressure switch to prove that the mechanical draft has been established before allowing the main burner to light, **Figure 39.67**. The pressure switches are connected to the combustion blower housing or heat exchanger (burner box) by rubber tubing. The pressure switches have diaphragms that are sensitive to pressure differentials. Some furnaces use a single-port pressure switch that senses the negative pressure inside the heat exchanger caused by an induced-draft combustion blower. Others use a dual-port, or differential, pressure switch that senses the difference in pressure between the combustion blower and the burner box. When the venting system is operating properly, sufficient negative pressure is created by the combustion blower to keep the pressure switch closed and the furnace operating. However, if the heat exchanger has a leak or the furnace vent pipe is blocked, the pressure switch will open due to insufficient negative pressure and interrupt the operation of the main burners. Different furnace manufacturers use various pressure settings for their pressure switches. The settings are usually measured in inches of water column and are sometimes indicated on the pressure switch housing. The pressures can be measured using a digital or liquid-filled manometer. **SAFETY PRECAUTION:** *Never replace a pressure switch with another pressure switch without knowing its operating pressures. Always consult with the furnace manufacturer or use a factory-authorized substitute pressure switch.*

Figure 39.67 Combustion blower motors use an air-proving pressure switch to prove that the mechanical draft has been established before allowing the main burner to light.

39.22 HVAC/R SYSTEM TESTING

The proper and efficient operation of the heating, cooling, refrigeration, water heating, and humidification systems all greatly affect the energy usage of a residence. *Routine maintenance and sporadic testing of this equipment can assure the homeowner that the equipment is working efficiently. HVAC/R diagnostics include refrigerant charge checks, equipment and duct airflow and pressure measurements, along with specific temperature measurements.*

Listed here are some routine maintenance and tests for cooling equipment, some of which can be performed by the homeowner and some by service technicians and/or residential energy auditors.

- *Clean the condenser and evaporator coil annually.*
- *Clean the blower fan blades.*
- *Check airflow quantities (cfm),* **Figure 39.68.**
- *Straighten fins on condenser and evaporator.*
- *Replace air handler filters often.*
- *Keep all supply and return registers clear and clean.*
- *Check low-side superheat and condenser subcooling for proper charge.*
- *Replace compressor contactor every 3–4 years.*
- *Make sure the suction line is insulated.*
- *Make sure air ducts do not leak.*

Listed here are some routine maintenance and tests for heating equipment. Some can be performed by the homeowner and some by a service technician.

- *Replace air handler filters often.*
- *Keep all supply and return registers clear and clean.*
- *Clean the blower fan blades.*
- *Check flame characteristics.*
- *Perform a combustion efficiency test annually.*
- *Inspect thermostat and heat anticipator settings.*
- *Test for carbon monoxide.*
- *Check the heat exchanger for cracks.*
- *Make sure air ducts do not leak.*
- *Check airflow quantities (cfm).*
- *Test for proper draft.*
- *Test high-limit control.*
- *Inspect burners for dirt, rust, and other debris.*
- *Adjust air and water temperature according to outdoor temperature.*
- *Look for any vent or chimney blockages.*
- *Walk the appliance through the sequence of operation.*
- *Set the controls for highest efficiency.*

Figure 39.68 A residential energy auditor using a flow hood to measure the airflow (cfm) out of a ceiling diffuser in a residence.

Courtesy Ferris State University. Photo by John Tomczyk

Listed next are some routine maintenance and tests for oil-fired combustion appliances that should be performed by a service technician.

- *Test the oil pump pressure.*
- *Clean the oil strainer.*
- *Perform a combustion efficiency test annually.*
- *Replace the oil nozzle annually.*
- *Test the cad cell flame sensor.*
- *Test the high-limit control.*
- *Check electrode placement and gap.*
- *Adjust the air shutter for best efficiency.*
- *Adjust the barometric damper.*
- *Test for carbon monoxide.*
- *Check flame characteristics.*
- *Check airflow quantities (cfm).*
- *Check the heat exchanger for cracks.*
- *Clean the blast tube and blower.*
- *Check for oil leaks.*

For more detailed information on testing, routine maintenance, venting, installation, typical operating conditions, troubleshooting, and charging of domestic refrigerators, freezers, room air conditioners, home air conditioners, stoves and fireplaces, gas and oil furnaces, geothermal heat pumps, air source heat pumps, hydronic heating system and boilers, heat gains and heat losses in structures, and solar heating systems, please refer to the following appendices and units contained elsewhere in this text:

39.23 NUMERICAL ANALYSIS AND REPORTING

Energy auditors use powerful computer programs and other electronic tools to model energy usage within a residence. Computer programs containing energy algorithms help auditors produce analytical reports and report summaries. Worksheets and spreadsheets also assist both the energy auditor and the homeowner in the actual audit and with their decision making after the audit is completed and a summary report is generated. Remember, one of the most important purposes of an energy audit is to determine where energy is used and/or wasted. Homes with the highest energy usage have the greatest potential for energy savings. Decision making encompasses what energy conservation measure (ECM) to choose and apply to the residence, usually according to their potential for saving energy. This decision-making process is also dependent on a solid understanding on how residential structures use energy.

An energy auditor will analyze and report the findings both manually and with reputable simulation software. The detailed written report of the findings prepared and presented to the homeowner should include a numerical analysis of where energy is being used, lost, or wasted and how to fix any energy-related problems. The report should also suggest any human behavioral changes that will help with energy conservation measures. In addition, the report should include recommendations on what fixes or changes will be of benefit by saving the most money and/or energy. The report should also educate the homeowner on how to maximize the payoffs from the energy audit's findings by tapping potential financial support from federal, state, and local sources and/or utility companies. It should include information on tax incentives, grants, and rebates that may help cover the cost of the audit.

WORKSHEETS FOR REPORTING

Following are examples of some common topics used for compiling worksheet data in home energy audits:

1. Building Occupant and Information Sheet
2. Health Safety and Structural Worksheet
3. Heating/Air Handler Equipment Worksheet
4. Cooling and Water Heating Equipment Worksheet
5. CAZ and Blower Door Testing
6. Duct Testing and Audit Diagnostics
7. House Diagrams
8. Postinspection Worksheet
9. Postinspection (Infiltration, Health, Safety) Worksheet

REPORTING BASE LOAD VERSUS SEASONAL USE

As mentioned earlier in this unit, LAMEL is an acronym for lighting, appliance, and miscellaneous electrical loads. Energy used in a residential structure can be categorized into two types: (1) base loads (LAMELS) and (2) seasonal energy usages. Typical residential base loads or LAMELs are the following:

- Lights
- Refrigerators
- Freezers
- Water heaters
- Clothes dryers
- Computers
- Printers
- Copiers
- Cell phone chargers

On the other hand, seasonal energy usages include only heating and cooling energy. It is important that the energy auditor understand whether base loads or seasonal energy usages are the dominant energy usage in the home. Often, homes are serviced with both combustion fuel and electricity. Electricity is usually too expensive to handle both base loads and seasonal energy usages, but in some regions of the country nothing else is available. Auditors must know which energy loads in the home are serviced by electricity, by combustion fuels, or both.

Figure 39.69(A) and **(B)** are examples of seasonal-dominated and base load-dominated energy usage. Notice in **Figure 39.69(A)** that the home has a small energy base load but high seasonal energy usage. This is typical of homes with poorly insulated structures or shells, defined as the floors, roof, and walls of a building, or, in other words, the exterior envelope of the building. The home could also be located in a very cold climate, or both. **Figure 39.69(B)** illustrates a home with a large energy base load usage, but smaller seasonal energy usage. Homes like these are either geographically located where weather conditions are less severe, or constructed much more efficiently.

ENERGY INDEX REPORTING

A way to compare one home to another and to characterize their energy efficiency is through an **energy index**. One of the simplest methods of determining an energy index is to divide the home's energy usage in BTUs/h by the square footage of the conditioned space. Another way is to divide the energy usage in kilowatt-hours by the square footage of the conditioned space. An energy index that takes into account the severity of the climate where the house is located also uses the heating degree days. The energy

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Figure 39.69 (A) Heavily seasonal-weighted energy usage. (B) Heavily baseload-weighted energy usage.

usage in BTUs/h is divided by both the square footage of the conditioned space and the heating degree days for that geographical location.

The most popular energy index is the **HERS index**. HERS is an acronym for Home Energy Rating Systems, a standardized rating procedure administered by the **Residential Energy Services Network (RESNET)**. The HERS index score is determined by computer modeling of the home with **Residential Energy Analysis and Rating Software (REM/Rate)**. The score provides a "miles-per-gallon" type of rating for expected energy consumption. Each home receives a score that can be compared with those of other new or existing homes. The lower the HERS score, the more efficient the home. **Figure 39.70** is an example of a HERS Home Energy Rating Certificate. This home has a HERS index of 60. An index of 85 or lower earns the home an Energy Star label. An index of 100 is a reference home built to the International Energy Conservation Code (IEEC) standards. An index can be over 100. An index of 0.0 (zero) would mean the home was a "net-zero" energy home. This means the home uses energy but also either generates and/or captures energy to negate its energy usage. The capture and/or generation of energy could be through wind power, solar heat capture for heating household air or water, or photovoltaic electricity generation, to mention a few.

The Home Energy Rating Certificate is a summary of

1. general information,
2. mechanical system features,
3. building shell features, including infiltration rates (ACH) for heating and cooling using the blower door test,
4. lights and appliance features, and
5. estimated energy costs.

Notice in **Figure 39.70** that the estimated annual energy cost category consists of

- heating,
- cooling,
- hot water,
- lights/appliances,
- photovoltaics, and
- service charges.

As mentioned earlier, residential energy audits not only provide homeowners with an opportunity to lower their monthly utility bills, they also can help our nation become less dependent on foreign oil by conserving energy. The ability to conserve natural resources is an added attraction to many homeowners for getting an energy audit performed on their home. It is important that we all do our part to make this world a better place to live.

SUMMARY

- Four organizations that offer certifications for home auditors and contractors include: Association for Energy Engineers (AEE), Building Performance Institute (BPI), Green Mechanical Council, and Residential Energy Services Network (RESNET).
- The home energy audit can be divided into three broad categories: screening, visual inspections and measurements, diagnostic testing, and numerical analysis with reporting.
- Base loads are consistent, everyday consumptions of energy within a residential structure.
- Energy audits and weatherization often identify and interact with a home's indoor air quality.
- Diagnostic testing and evaluation of the home and its systems that consume energy is probably the most important phase of the energy audit. These diagnostic tests bring out many of the building's "hidden unknowns."
- The most common diagnostic tests performed during a residential energy audit are blower door testing, infrared scanning testing (thermal imaging camera), duct leakage testing, combustion efficiency and safety testing, and HVAC/R system testing.
- Blower door infiltration tests give the auditor insight into how tight or leaky the home's building envelope is overall.
- Using a thermal imaging camera in conjunction with a blower door test is strongly recommended for best results in testing for air infiltration and exfiltration.
- Warm air leaking into the home during the summer and out of the home during the winter can waste a lot of energy dollars.
- In both new and existing homes, as much as 25% of the total energy losses can often be blamed on air leakage in forced-air duct systems.
- Duct leakage to the outside of the conditioned space has a much larger impact on HVAC system performance than duct leakage inside the space.
- Combustion efficiency is the ability of the combustion appliance to convert fuel into heat energy.
- Digital flue-gas analysis instrumentation measures carbon monoxide (CO), oxygen (O_2), draft, and flue-gas temperature.
- Carbon monoxide (CO) production must be avoided, as it is a colorless, odorless, poisonous gas.
- Furnace efficiency ratings are determined by the amount of heat that is transferred to the heated medium, which is usually water or air.
- Orange streaks in the gas flame are not to be confused with yellow streaks. Orange streaks are dust particles burning.
- Cooling the gas flame will cause inefficient combustion.
- Backdrafting can be caused by pressure differences. When the pressure is lower in the living space of the home with respect to the vent or chimney for the combustion appliances, backdrafting will occur.
- Spillage is not as serious as backdrafting, but it is an unhealthy situation and can cause sickness in households if not controlled. Spillage is a temporary flow of combustion by-products into the living space.
- Cracked heat exchangers can allow combustion products to mix with the heating air that enters the living spaces of the house and cause serious health effects.
- Flame safeguard controls protect against unignited fuel that enters the combustion appliance's combustion chamber.
- Excess air consists of combustion air and dilution air for a gas furnace. Combustion air is primary and/or secondary air. Primary air enters before combustion takes place. Dilution air is excess air after combustion and usually enters at the end of the heat exchanger. It is brought in by the draft hood of the gas furnace.
- All combustion appliances must be properly vented so that the by-products of combustion will all be dissipated into the atmosphere.
- When high-efficiency gas furnaces were introduced, four venting categories were created by the American National Standards Institute (ANSI).
- Draft is the force that allows air to travel into the combustion chamber of a combustion appliance and expels the combustion gases out through a vent or chimney.
- Atmospheric-draft heating appliances are often referred to as open combustion devices. They draw combustion air from the surrounding room.
- Oil-fired furnaces and boilers refer to their dilution device as a barometric damper.
- Draft diverters, draft hoods, and barometric dampers are also used to provide draft control and introduce dilution air into the venting system to reduce the possibility of condensation in the vent system.
- High-efficiency combustion appliances (Category IV) do not use draft controls. Their vent pressures are positive all the way to the terminal end of the vent.
- Induced-draft systems have a combustion blower motor located at the outlet of the heat exchanger. Forced-draft systems push or blow combustion gases through the heat exchanger and cause a positive pressure.
- Neither induced-draft nor forced-draft systems have devices that allow dilution air into the venting system.
- The burners of modern, high-efficiency combustion appliances are located at the top of the furnace in a sealed combustion chamber. The combustion gases are pulled or sucked through the heat exchanger.
- Draft can be divided into two categories: over-the-fire draft and stack (chimney) draft. Over-the-fire draft is the draft reading that is taken over the fire; it will be a lower reading lower than chimney draft.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- A chimney or stack draft reading is taken in the vent stack between the combustion device and the draft diverter. Stack or chimney draft is often referred to as flue draft.
- A direct-vented, high-efficiency gas furnace has a sealed combustion chamber. This means that the combustion air is brought in from the outside through an air pipe, which is usually made of PVC plastic.
- Using outside air instead of room air for combustion purposes prevents the conditioned room from being depressurized or pulled into a slight vacuum.
- Some direct-vented designs need stronger flue fan or combustion blower systems to overcome the additional pressure drop created by the sealed combustion chamber and added combustion air pipe.
- High-efficiency condensing furnaces operate below the DPT of the combustion gases in order to allow condensation to happen. The flue gas is intentionally cooled below the DPT to promote condensation.
- Homes with the highest energy usage have the greatest potential for energy savings. Decision making encompasses what energy conservation measure (ECM) to choose and apply to the residence.
- The energy audit report should include recommendations on what fixes or changes will benefit the homeowner by saving the most money and/or energy.
- Home energy usage can be divided into two categories: base loads (LAMELS) and seasonal energy usages.
- A way to compare one home to another and to characterize their energy efficiency is through an energy index. The most popular energy index is the HERS index.

REVIEW QUESTIONS

1. Define a residential energy audit.
2. Name and briefly explain the three broad categories of a residential energy audit.
3. Name four nationally recognized energy certifications for home auditors and contractors.
4. Performing a home energy audit starts with a visual inspection of a home and its energy systems which include: _____, _____, _____, and _____.
5. Name seven base loads, or LAMEL loads, as they apply to a residential energy audit.
6. Name and briefly explain the five most common diagnostic tests performed during a residential energy audit.
7. One Pascal (Pa) is equal to how many inches of water column (in. WC)?
8. One inch of water column (in. WC) is equal to how many Pascals (Pa)?
9. Briefly describe a blower door test.
10. What can an infrared scanning camera do for an auditor that the blower door test cannot?
11. Briefly describe what a duct blower's function is as it applies to residential energy audits.
12. Briefly describe how to check for duct leakage to the outdoors using a duct blower and a blower door.
13. Briefly describe and write the equation for perfect (complete) combustion.
14. Briefly describe and write the equation for incomplete combustion.
15. When performing a combustion efficiency test, digital flue gas will measure what four parameters? _____, _____, _____, and _____.
16. Briefly define draft as it applies to a combustion appliance.
17. Briefly define backdrafting as it applies to a combustion appliance.
18. Briefly define spillage as it applies to a combustion appliance.
19. Name four causes for backdrafting. _____, _____, _____, and _____.
20. What will a cracked heat exchanger cause in a combustion appliance?
21. What is the function of flame safeguard controls?
22. Name three common flame safeguard controls. _____, _____, and _____.
23. Define primary air as it applies to a combustion appliance.
24. Define secondary air as it applies to a combustion appliance.
25. Define dilution air as it applies to a combustion appliance.
26. Define excess air as it applies to a combustion appliance.
27. What is the difference between an induced-draft and a forced-draft combustion appliance?
28. What is the difference between over-the-fire draft and stack (chimney) draft?
29. What is meant by a direct-vented, sealed-combustion, high-efficiency furnace?
30. What is meant by an energy conservation measure (ECM)?
31. What is the difference between a base load and seasonal energy usage as they apply to a residential home?
32. Define a home energy index.

TYPICAL OPERATING CONDITIONS

OBJECTIVES

After studying this unit, you should be able to

- explain what conditions will vary the evaporator pressures and temperatures.
- define how the various conditions in the evaporator and ambient air affect condenser performance.
- state the relationship of the evaporator to the rest of the system.
- describe the relationship of the condenser to the total system performance.
- *compare high-efficiency equipment and standard-efficiency equipment.*
- establish reference points when working on unfamiliar equipment to know what the typical conditions should be.
- describe how humidity affects equipment suction and discharge pressure.
- *explain three methods that manufacturers use to make air-conditioning equipment more efficient.*

SAFETYCHECKLIST

- ☑ The technician must use caution while observing equipment operating conditions. Electrical, pressure, and temperature readings must be taken while the technician observes the equipment, and many times the readings must be taken while the equipment is in operation.
- ☑ Wear goggles and gloves when attaching gauges to a system.
- ☑ Observe all electrical safety precautions. Be careful at all times and use common sense.

Air-conditioning technicians must be able to evaluate both mechanical and electrical systems. The mechanical operating conditions are determined or evaluated with gauges and thermometers; electrical conditions are determined with electrical instruments.

40.1 MECHANICAL OPERATING CONDITIONS

Air-conditioning equipment is designed to operate at its rated capacity and efficiency at one set of design conditions. The design conditions are generally considered to be an outside temperature of 95°F and an inside temperature of 80°F with humidity at 50%. This rating is established by the Air-Conditioning, Heating and Refrigeration Institute (AHRI). Not only must equipment have a rating as a standard from which estimators and buyers can work, but it is also rated so that the buyer will have a common basis on which to compare one piece of equipment with another. All equipment in the AHRI directory is rated under the same conditions—80°F dry-bulb and 50% humidity indoors and 95°F dry-bulb outdoors.

A piece of equipment rated at 3 tons will perform at a 3-ton capacity, or 36,000 Btu/h, under the stated conditions. Under different conditions, the equipment will perform differently. Many occupants might not be comfortable at 80°F with a relative humidity of 50% and so will normally operate their system at about 75°F with the relative humidity in the conditioned space close to 50%. The equipment will not have quite the capacity at 75°F that it has at 80°F. If the designer wants the system to have a capacity of 3 tons at 75°F and 50% relative humidity, the manufacturer's literature should be consulted to choose other equipment. **The 75°F, 50% humidity condition will be used as the design condition in this unit because it is a common operating condition of equipment in the field.**

AHRI rates condensers on the basis of 95°F air passing over them. With 95°F air passing over it, a new standard-efficiency condenser will condense refrigerant at about 125°F. As the condenser ages, dirt accumulates on the outdoor coil and the efficiency decreases. The refrigerant will then condense at a higher temperature, which can easily approach 130°F, a value often found in the field. However, the unit uses a 125°F condensing temperature, assuming that equipment has been properly maintained. It is not easy to see the change in load conditions on gauges and instruments used in the field. An increase in humidity is not followed by a proportional rise in suction pressure and amperage. Perhaps the most noticeable aspect of an increase in humidity is an increase in the condensate accumulated in the condensate drain system.

40.2 RELATIVE HUMIDITY AND THE LOAD

The inside relative humidity adds a significant load to the evaporator coil and has to be considered as part of the load. When conditions vary from the design conditions, the capacity of the equipment will vary. The pressures and temperatures will also change.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

40.3 RELATIONSHIPS OF SYSTEM COMPONENT UNDER LOAD CHANGES

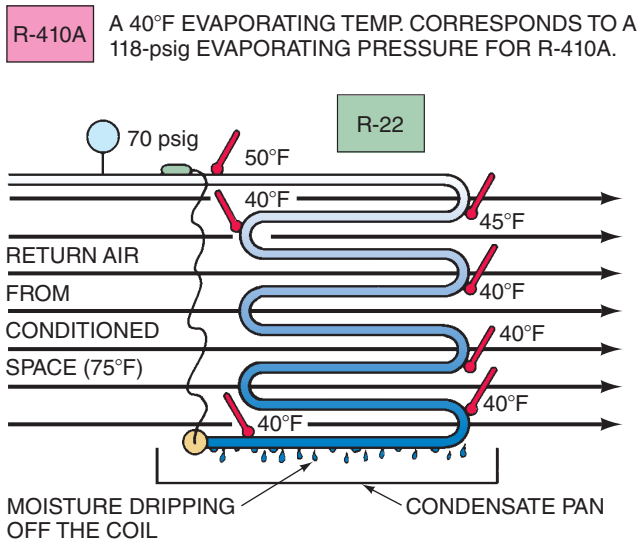
If the outside temperature increases from 95°F to 100°F, the equipment will be operating at a higher head pressure and will not have as much capacity. The capacity also varies when the space temperature goes up or down or when the humidity varies. The relationship among the various components in the system also varies. The evaporator absorbs heat. When anything happens to increase the amount of heat absorbed into the system, the system pressures will rise. The condenser rejects heat. If anything happens to prevent the condenser from rejecting heat from the system, the system pressures will rise. The compressor pumps heat-laden vapor. Vapor at different pressure levels and saturation points (in reference to the amount of superheat) will hold different amounts of heat and will require different energy inputs.

40.4 EVAPORATOR OPERATING CONDITIONS

The evaporator normally will operate at a 40°F boiling temperature when operating at the 75°F, 50% humidity condition. This will cause the suction pressure to be 70 psig for R-22. (The actual pressure corresponding to 40°F is 68.5 psig; for our purposes, we will round this off to 70 psig.) If R-410A is used as the refrigerant, the suction pressure would be 118 psig for a 40°F evaporating temperature at design conditions and under a steady-state load. Under these conditions the evaporator is boiling the refrigerant exactly as fast as the expansion device is metering it into the evaporator. As an example, suppose that the evaporator has a return-air temperature of 75°F and the air has a relative humidity of 50%. The liquid refrigerant goes nearly to the end of the coil, and the coil has a superheat of 10°F. This coil is operating as intended at this typical condition, **Figure 40.1**.

Late in the day, after the sun has been shining on the house, the heat load inside becomes greater. A new condition is being established. The example evaporator in **Figure 40.2** has a fixed-bore metering device that will feed only a certain amount of liquid refrigerant. The space temperature in the house has climbed to 77°F and is causing the liquid refrigerant in the evaporator to boil faster, **Figure 40.3**. This causes the suction pressure and the superheat to go up slightly. The new suction pressure is 73 psig, and the new superheat is 13°F. This is well within the range of typical operating conditions for an evaporator. The system actually has a little more capacity at this point if the outside temperature is not too much above design. If the head pressure goes up because the outside temperature is 100°F, for example, the suction pressure will even go higher than 73 psig, because head pressure will influence it, **Figure 40.4**.

Figure 40.1 An evaporator operating at typical conditions. The refrigerant is boiling at 40°F in the coil. This corresponds to 68.5 psig (typically rounded off to 70 psig) for R-22 and 118 psig for R-410A.



Many different conditions will affect the operating pressures and air temperatures to the conditioned space. There can actually be as many different pressures as there are different inside and outside temperature and humidity variations. This can be confusing, particularly to the new service technician. However, the service technician can use some common conditions when troubleshooting. The technician rarely has a chance to work on a piece of equipment when the conditions are perfect. Most of the time when the technician is assigned a job, the system has been off for some time or not operating correctly for long enough that the conditioned space temperature and humidity are higher than normal, **Figure 40.5**. After all, a rise in space temperature is what often prompts a customer to call for service.

40.5 HIGH EVAPORATOR LOAD AND A COOL CONDENSER

A high temperature in the conditioned space is not the only thing that will cause the pressures and capacity of a system to vary. The reverse can happen if the inside temperature is warm and the outside temperature is cooler than normal, **Figure 40.6**. For example, before going to work, a couple may turn the air conditioner off to save electricity. They may not get home until after dark to turn the air conditioner back on. By this time it may be 75°F outside but still be 80°F inside the structure. The air passing over the condenser is now cooler than the air passing over the evaporator. The evaporator may also have a large humidity load. The condenser becomes so efficient that it will hold some of the charge because it starts to condense refrigerant in the first part of the condenser. Thus, more of the refrigerant charge is in the condenser tubes, and this will slightly starve the evaporator.

Figure 40.5 This system has been off long enough that the temperature and the humidity have gone up inside the conditioned space. Notice the excess moisture forming on the coil and going down the drain.

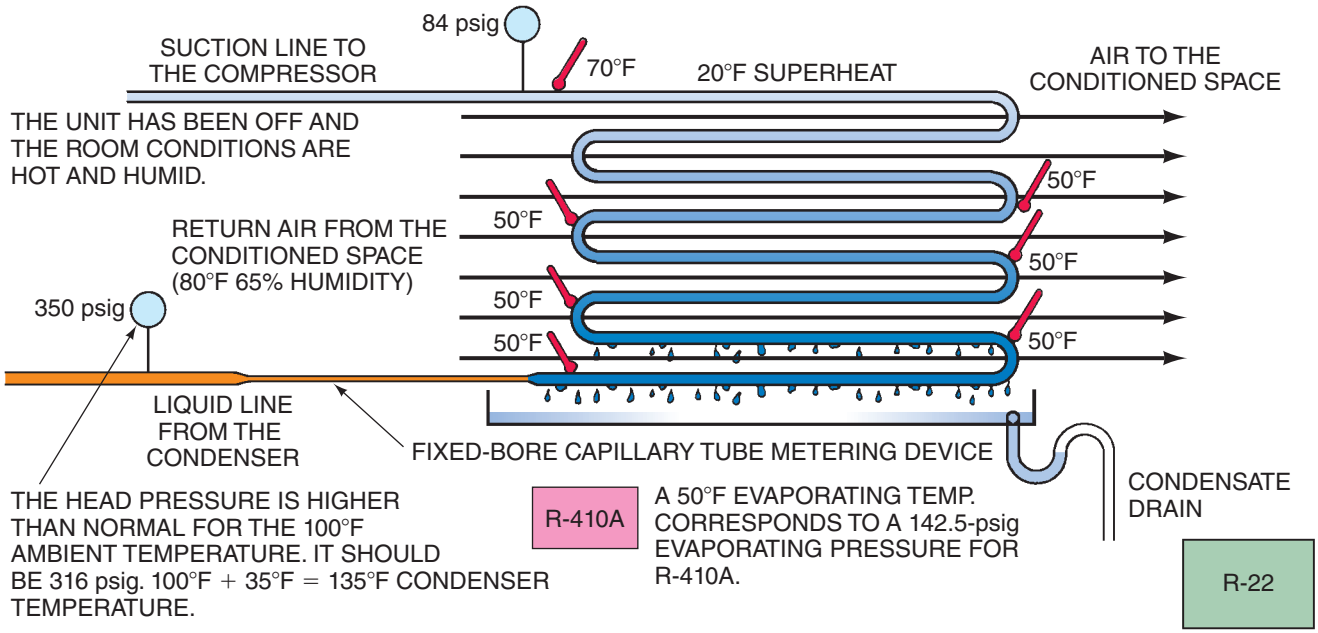

Figure 40.6 A system operating when the outside ambient air is cooler than the inside space temperature air. As the return air cools down, the suction pressure and boiling temperature will decrease.

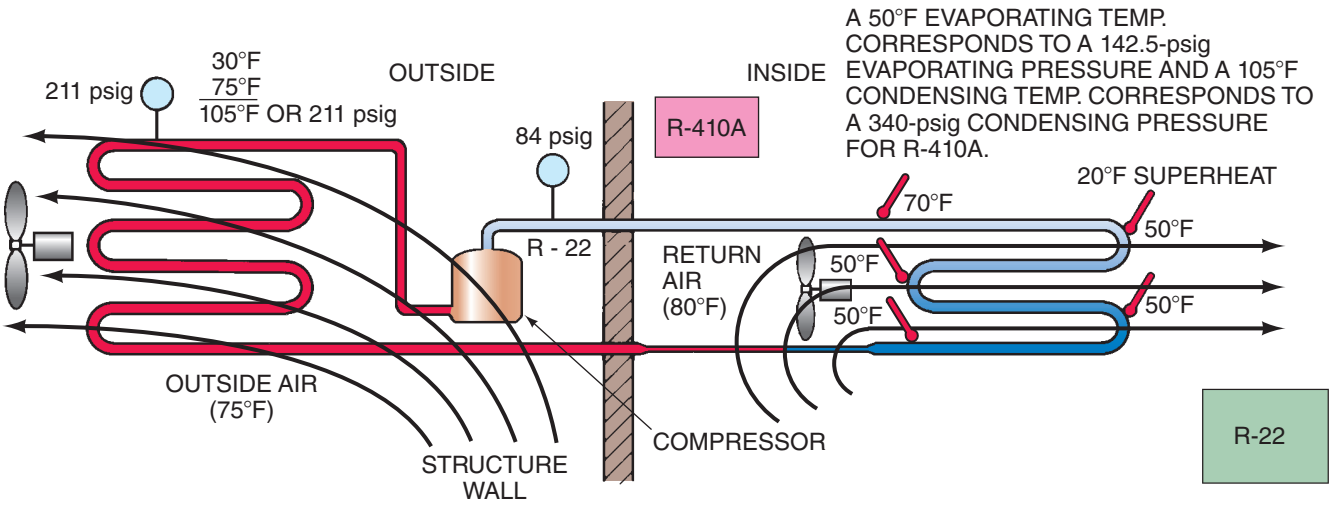

The system may not have enough capacity to cool the home for several hours. The condenser may hold back enough refrigerant to cause the evaporator to operate below freezing and freeze up before it can cool the house and satisfy the thermostat.

This condition has been improved by some manufacturers by means of a variable-speed fan operated through an inverter or by two-speed operation for the condenser fan. The fan is controlled by a modulating controller and fan motor or a single-pole–double-throw thermostat that operates the fan at both high speeds (when the outdoor temperature is high) and low speeds (in mild temperatures). Typically, the fan will run on high speed when the outdoor temperature is above 85°F and at low speed below 85°F. When the fan is operating at low speed in mild weather, the head pressure is increased, reducing the chances of the evaporator condensate freezing.

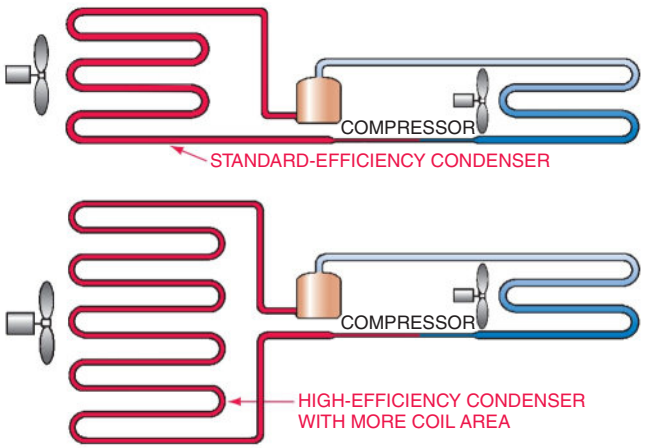
40.6 GRADES OF EQUIPMENT

Manufacturers have worked continuously to make air-conditioning equipment more efficient. There are three grades of equipment: economy, standard-efficiency, and high-efficiency grade. Some companies manufacture all three grades. Some offer only one grade and may take offense if someone calls their equipment the lower grade. Economy grade and standard-efficiency grade are about equal in efficiency, but they differ in the materials used in their manufacture and their appearance. *High-efficiency equipment may be much more efficient and will not have the same operating characteristics,* **Figure 40.7**.

A condenser normally will condense refrigerant at a temperature of about 30°F to 35°F higher than the ambient temperature. For example, when the outside temperature is 95°F, the average condenser will condense the refrigerant at 125°F to 130°F, and the head pressure for these condensing temperatures would be 278 to 297 psig for R-22 or 446 to 475 psig for R-410A. *High-efficiency air-conditioning equipment may have a much lower operating head pressure. The high efficiency is gained by using a larger condenser surface or by using more modern alloys with more extended surfaces or fins. The condensing temperature may be as low as 20°F greater than the outdoor ambient temperature. This would bring the head pressure down to a temperature corresponding to 115°F, or 243 psig for R-22 and 390 psig for R-410A. The compressor will not use as much power under this condition because of the lower compression ratio,* **Figure 40.8**. *When large condensers are used, the head pressure is reduced. Lower power requirements are a result. More efficient condensers require some means of head pressure control, such as that mentioned previously. High efficiency equipment will also incorporate TXV metering devices to keep the evaporator active under all heat load conditions. Electrically commutated motors (ECMs) for evaporators and condensers will also usually accompany high efficiency equipment. Refer to Unit 10, "System Charging," when charging a TXV system.*

Figure 40.7 A standard-efficiency condenser and a high-efficiency condenser. The high-efficiency condenser will have more surface area and may be made of a different metal or alloy with more extended surfaces or fins.



This description of condensers and their typical operating conditions holds true when the air-conditioning system is operating under a typical load. However, under high evaporator heat loads, the temperature difference between the condenser and the ambient will be much higher. The reason for this is simple. As the evaporator absorbs heat, it must reject that heat in the condenser, and as more heat is absorbed in the evaporator, more heat must be rejected in the condenser. However, a fixed-sized condenser operating under a relatively constant outside ambient cannot accomplish this amount of heat rejection at a 20°F temperature difference (for a high-efficiency

Figure 40.8 A standard-efficiency unit and a high-efficiency unit.

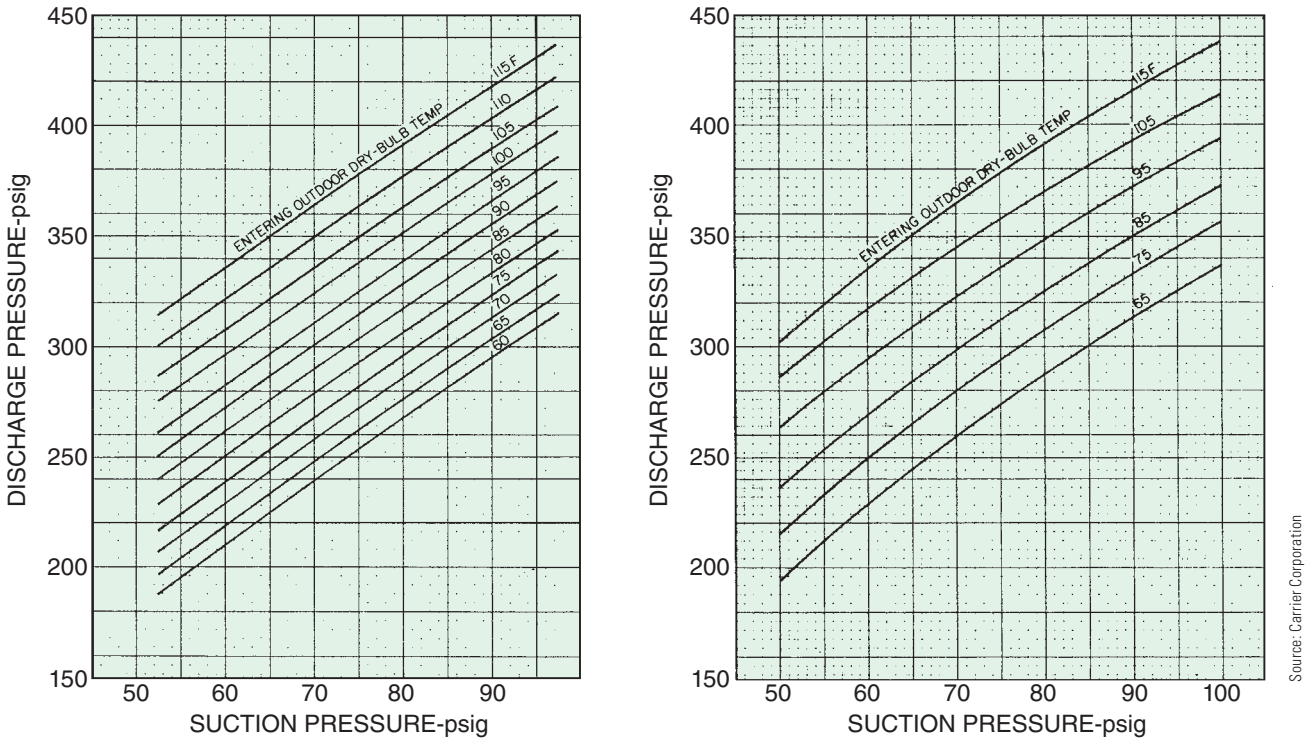
Figure 40.9 Charts are furnished by some manufacturers to monitor unit performance.

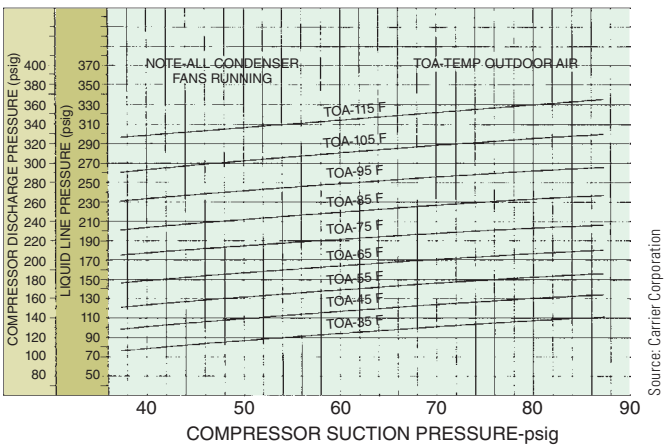


condenser) or at a 30°F temperature difference (for a standard condenser). So excess heat starts to accumulate in the condenser and the condensing temperature increases. After the condensing temperature increases, there exists a greater temperature difference between the ambient and the condensing temperature. This temperature difference increases the heat transfer between the condenser and the ambient, and the condenser will then be able to reject the higher evaporator loads. However, it will be rejecting this higher heat load at a higher condensing temperature and higher compression ratio. The same is true under low evaporator loads. However, the condenser will operate at a lower temperature difference between itself and the ambient because of the reduced load.

40.7 DOCUMENTATION WITH THE UNIT

The technician needs to know what the typical operating pressures should be under different conditions. Some manufacturers furnish a chart that tells what the suction and discharge pressures should be at various conditions, **Figure 40.9** and **Figure 40.10**. Some publish a bulletin listing all of their equipment along with the typical operating pressures and temperatures. Others furnish this information with the unit in the installation and start-up manual, **Figure 40.11**. The homeowner may have this booklet, which may be helpful to the technician.

Figure 40.10 *A page from a manufacturer's bulletin explaining how to charge one model of equipment.*



Three things must be considered along with the manufacturer's published list of typical operating conditions:

1. The load on the outdoor coil, which is influenced by the outdoor temperature and the evaporator heat loading.
2. The sensible-heat load on the indoor coil, which is influenced by the indoor dry-bulb temperature.
3. The latent-heat load on the indoor coil, which is influenced by the humidity. The humidity is determined by taking the wet-bulb temperature of the indoor air.

Figure 40.11 *A chart furnished by a manufacturer in the installation and start-up literature.*

REFRIGERANT CHARGING

SAFETY PRECAUTION: To prevent personal injury, wear safety glasses and gloves when handling refrigerant. Do not overcharge system. This can cause compressor flooding.

1. Operate unit a minimum of 15 minutes before checking charge.
2. Measure suction pressure by attaching a gage to suction valve service port.
3. Measure suction line temperature by attaching a service thermometer to unit suction line near suction valve. Insulate thermometer for accurate readings.
4. Measure outdoor coil inlet air dry-bulb temperature with a second thermometer.
5. Measure indoor coil inlet air wet-bulb temperature with a sling psychrometer.
6. Refer to table. Find air temperature entering outdoor coil and wet-bulb temperature entering indoor coil. At this intersection note the superheat.
7. If unit has higher suction line temperature than charted temperature, add refrigerant until charted temperature is reached.
8. If unit has lower suction line temperature than charted temperature, recover refrigerant until charted temperature is reached.
9. If air temperature entering outdoor coil or pressure at suction valve changes, charge to new suction line temperature indicated on chart.
10. This procedure is valid, independent of indoor air quantity.

The technician needs to record these temperatures and plot them against the manufacturer's graph or table to determine the performance of the equipment.

40.8 ESTABLISHING A REFERENCE POINT ON UNKNOWN EQUIPMENT

When a technician has no literature on the equipment and cannot obtain any, what should be done? The first thing is to try to establish some known condition as a reference point. For example, is the equipment standard-efficiency or high-efficiency? This will help establish a reference point for the suction and head pressures mentioned earlier. High-efficiency equipment is often larger than normal. It is not always identified as high-efficiency, and the technician may have to compare the size of the condenser to another one to determine the head pressure. It should be obvious that a larger or oversized condenser would have a lower head pressure. For example, a 3-ton compressor will have a full-load amperage (FLA) rating of about 17 A at 230 V. The amperage rating of the compressor may help to determine the rating of the equipment, **Figure 40.12**. Although a 3-ton high-efficiency piece of equipment will have a lesser amperage rating than standard equipment, the ratings will be close enough to compare and

Figure 40.12 A table of current ratings for different-sized motors at different voltages.

APPROXIMATE FULL-LOAD AMPERAGE VALUES FOR ALTERNATING-CURRENT MOTORS

Motor	Single Phase		3-Phase-Squirrel Cage Induction		
HP	115 V	230 V	230 V	460 V	575 V
$\frac{1}{6}$	4.4	2.2			
$\frac{1}{4}$	5.8	2.9			
$\frac{1}{3}$	7.2	3.6			
$\frac{1}{2}$	9.8	4.9	2	1.0	0.8

to determine the capacity of the equipment. If the condenser is very large for an amperage rating that should be 3 tons, the equipment is probably high-efficiency and the head pressure will not be as high as in a standard piece of equipment. *In addition, high-efficiency air-conditioning equipment often uses a thermostatic expansion valve rather than a fixed-bore metering device to gain a certain amount of efficiency.* The evaporator may also be larger than normal, which will add to the efficiency of the system. It is more difficult, however, to determine the evaporator size because, being enclosed in a casing or the ductwork, it is not as easy to see.

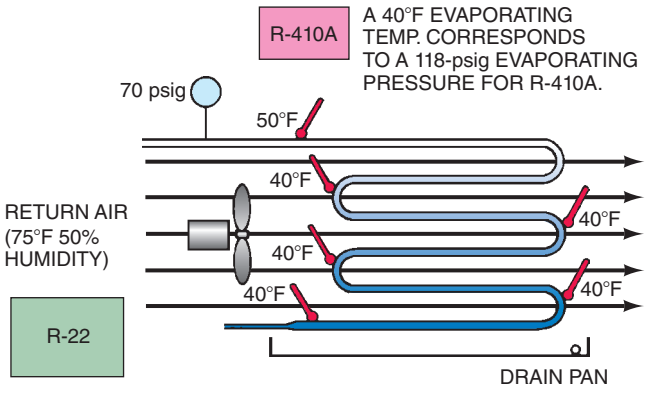
40.9 SYSTEM PRESSURES AND TEMPERATURES FOR DIFFERENT OPERATING CONDITIONS

The operating conditions of a system can vary so much that this unit cannot cover all possibilities; however, a few general statements committed to memory may help. Standard-efficiency equipment and high-efficiency equipment will operate along the lines of the general conditions listed in the following subsections.

OPERATING CONDITIONS NEAR DESIGN SPACE CONDITIONS FOR STANDARD-EFFICIENCY EQUIPMENT

1. The suction temperature is 40°F (70 psig for R-22 and 118 psig for R-410A), **Figure 40.13**.

Figure 40.13 An evaporator operating at close-to-design conditions.

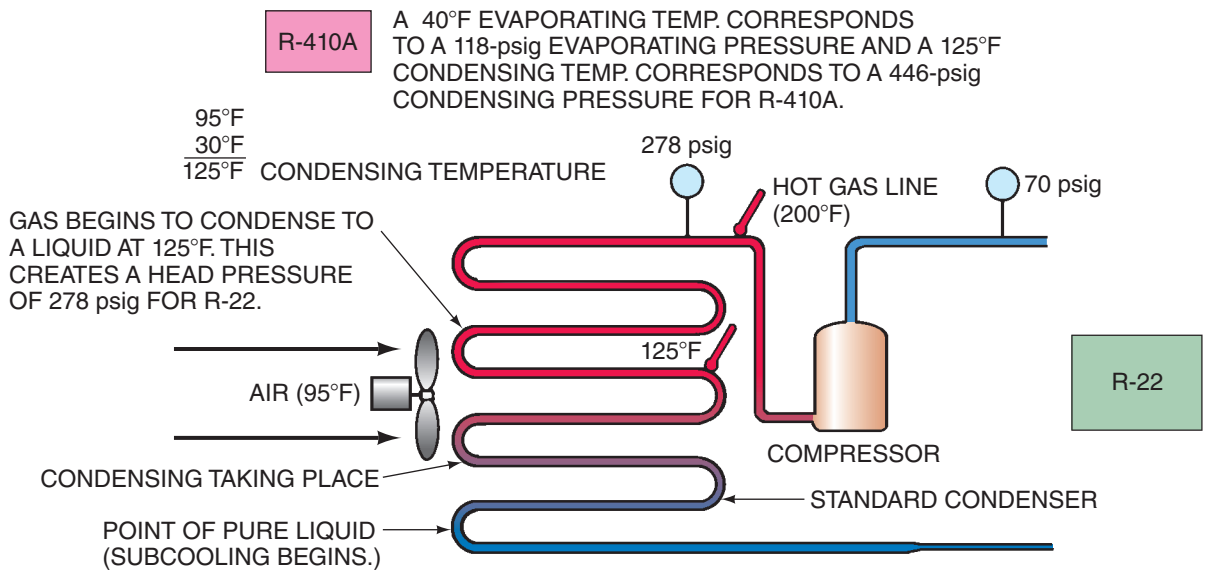


2. The head pressure should correspond to a temperature of no more than 35°F above the outside ambient temperature. This would be 297 psig for R-22 and 475 psig for R-410A when the outside temperature is 95°F (95°F + 35°F = 130°F condensing temperature). A typical condition would be condensing at 30°F above the ambient, or 95°F + 30°F = 125°F, **Figure 40.14**. The head pressure would be 278 psig for R-22 and 446 psig for R-410A.

SPACE TEMPERATURE HIGHER THAN NORMAL FOR STANDARD-EFFICIENCY EQUIPMENT

1. The suction pressure will be higher than normal. Normally, the refrigerant boiling temperature is about 35°F

Figure 40.14 The normal conditions of a standard condenser operating on a 958F day.



Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

cooler than the entering-air temperature. (Recall the relationship of the evaporator to the entering-air temperature described in the refrigeration section.) When the conditions are normal, the refrigerant boiling temperature would be 40°F when the return air temperature is 75°F. This is true when the humidity is normal. When the space temperature is higher than normal because the equipment has been off for a long time, the return-air wtemperature may go up to 85°F and the humidity may be high also. The suction temperature may then go up to 50°F, with a corresponding pressure of 84 to 93 psig for R-22 and 142 to 156 psig for R-410A, **Figure 40.15**. This higher-than-normal suction pressure may cause the discharge pressure to rise also.

2. The discharge pressure is influenced by the outside temperature and the suction pressure. For example, the discharge pressure is supposed to correspond to a temperature of no more than 30°F higher than the ambient temperature under normal conditions. When the suction pressure is 80 psig, the discharge pressure is going to rise accordingly. It may move up to a new condensing temperature 10°F higher than normal. This would mean that the discharge pressure for R-22 could be 317 psig (95°F + 30°F + 10°F = 135°F) or 506 psig for R-410A while the suction pressure is high, **Figure 40.16.** When the unit begins to reduce the space temperature and humidity, the evaporator pressure will begin to come down. The load on the evaporator is reduced. The head pressure will come down also.

Figure 40.15 Pressures and temperatures as they may occur with an evaporator when the space temperature and humidity are above design conditions.

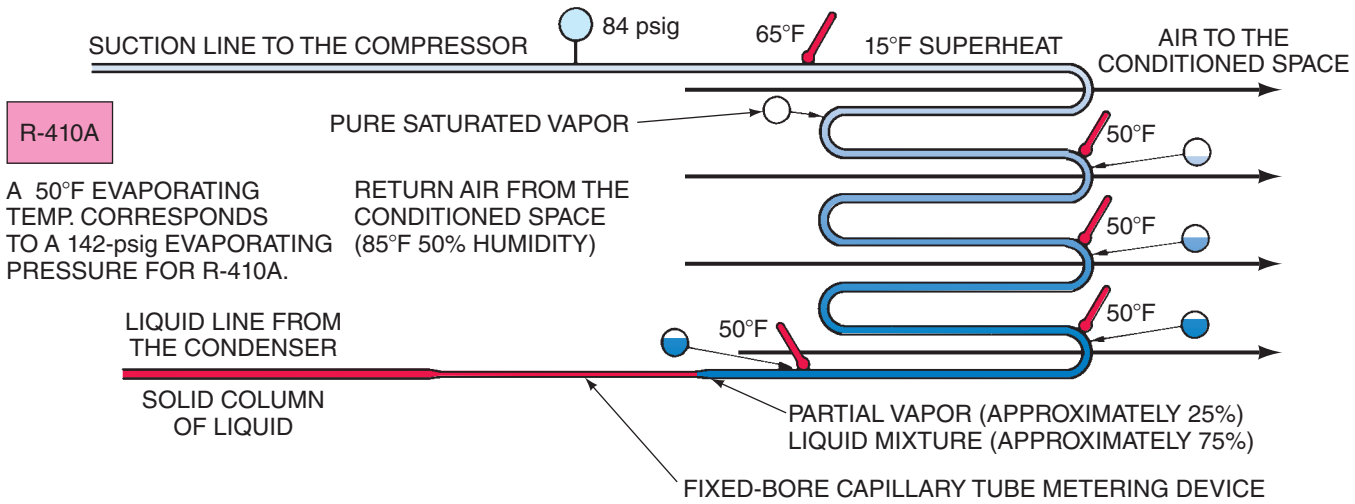


Figure 40.16 The condenser is operating at the design condition as far as the outdoor ambient air is concerned, but the pressure is high because the evaporator is under a load that is above design.

OPERATING CONDITIONS NEAR DESIGN CONDITIONS FOR HIGH-EFFICIENCY EQUIPMENT

1. The evaporator design temperature may in some cases operate at a slightly higher pressure and temperature on high-efficiency equipment because the evaporator is larger. The boiling refrigerant temperature may be 45°F at design conditions, and this would create a normal suction pressure of 76 psig for R-22 and 130 psig for R-410A, **Figure 40.17**. The evaporator will employ a TXV metering device to keep the entire evaporator active under all heat load conditions. Refer to Unit 10, "System Charging," when charging a TXV system.
2. The refrigerant may condense at a temperature as low as 20°F more than the outside ambient temperature. For a 95°F day with R-22, the head pressure may be as low as 243 psig, and as low as 390 psig for R-410A, **Figure 40.17**. If the condensing temperature is as high as 30°F above the ambient temperature, the technician should suspect a problem. For example, the head pressure should not be more than 277 psig on a 95°F day for R-22 and 446 psig for R-410A.

OTHER-THAN-DESIGN CONDITIONS FOR HIGH-EFFICIENCY EQUIPMENT

1. When the unit has been off long enough for the load to build up, the space temperature and humidity are above design conditions and the high-efficiency system pressures will be higher than normal, as they would in the standard-efficiency system. With standard equipment, when the return-air temperature is 75°F and the humidity is approximately 50%, the refrigerant boils at about 40°F. This is a temperature difference of 35°F. A high-efficiency evaporator is larger, and the refrigerant may boil at a temperature difference of 30°F, or around 55°F when the space temperature is 85°F, **Figure 40.18**. The exact boiling temperature relationship depends on the manufacturer's design and how much coil surface area was selected. The TXV metering device will keep the evaporator active under all heat load conditions. Refer to Unit 10, "System Charging," when charging a TXV system.
2. The high-efficiency condenser, like the evaporator, will operate at a higher pressure when the load is increased. The head pressure will not be as high as it would with a standard-efficiency condenser because the condenser has extra surface area.

The capacity of high-efficiency systems is not up to the rated capacity when the outdoor temperature is much below design. The conditions in the earlier example of the couple that shut off the air-conditioning system before going to work and then turned it back on when they came home will be much worse with a high-efficiency system. The fact that the standard condenser became too efficient at night when the air was cooler will be much more evident with the larger, high-efficiency condenser. Most manufacturers produce variable-speed or two-speed condenser fans so that lower fan speeds can be used in mild weather to help compensate for this temperature difference. The service technician who tries to analyze a component of high-efficiency equipment on a mild day will find the head pressure low. This

Figure 40.17 *High-efficiency system operating conditions—45°F evaporator temperature and 115°F condensing temperature.*

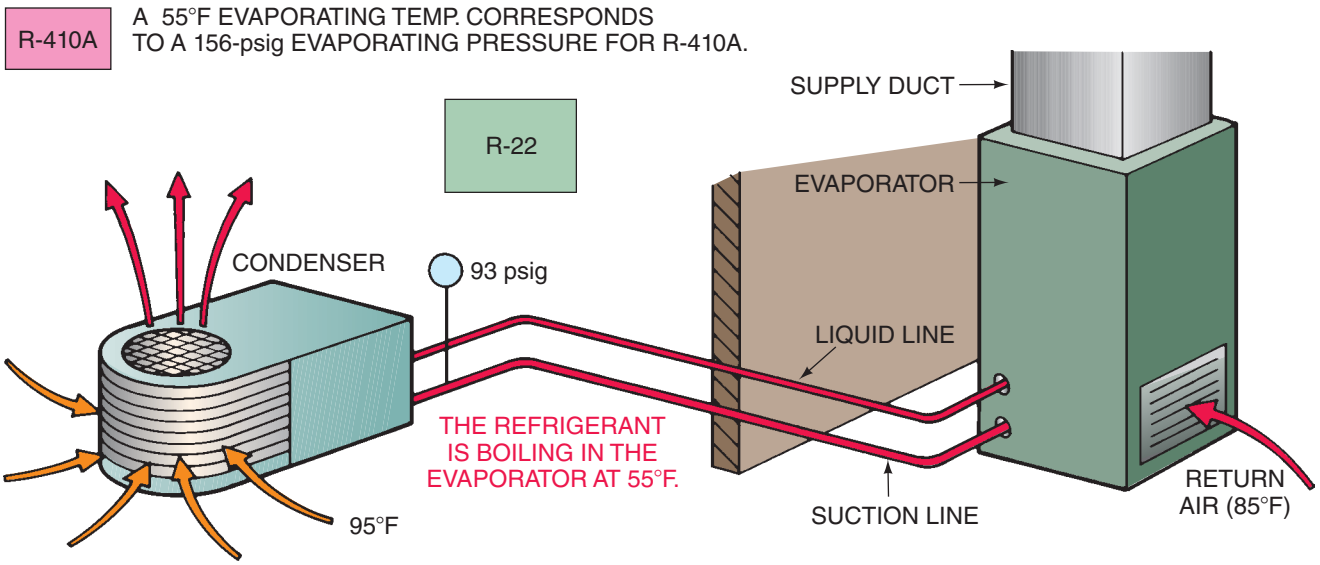
Figure 40.18 An evaporator in a high-efficiency system with a load above design conditions.



will also cause the suction pressure to be low. Using the coil-to-air relationships for the condenser and the evaporator will help determine the correct pressures and temperatures.

Remember these two statements:

1. The evaporator absorbs heat, which is related to its operating pressures and temperatures.
2. The condenser rejects heat and has a predictable relationship to the evaporator load and outdoor ambient temperature.

40.10 EQUIPMENT EFFICIENCY RATING

Manufacturers have a method of rating equipment so that the designer and the owner can tell high efficiency from low efficiency at a glance. This rating was originally called the EER rating, which stands for energy efficiency ratio and is actually the output in Btu/h divided by the input in watts of power used to produce the output. For example, a system may have an output of 36,000 Btu/h with an input of 4000 W:

$$\frac{36{,}000 \text{ Btu/h}}{4000 \text{ W}} = \text{an EER of 9}$$

The larger the EER rating, the more efficient the equipment. For example, suppose that the 36,000 Btu/h air conditioner required only a 3600-W input:

$$\frac{36{,}000 \text{ Btu/h}}{3600 \text{ W}} = \text{an EER of 10}$$

The customer is getting the same capacity using less power. The equipment is more efficient. **The larger the EER rating, the more efficient the equipment.**

The EER rating is a steady-state rating and does not account for the time the unit operates before reaching peak efficiency. This operating time has an unknown efficiency. It also does not account for shutting the system down at the end of the cycle (when the thermostat is satisfied), leaving a cold coil in the duct. The cold coil continues to absorb heat from the surroundings, not the conditioned space. Refrigerant pressures equalize to the cold coil that must be pumped out at the beginning of the next cycle. This accounts for some of the inefficiency at the beginning of the cycle. Some manufacturers include controls that keep the fan running at the end of the cycle to take advantage of this cold-coil heat exchange. The indoor fan will run for several minutes after the compressor shuts off. This is accomplished with the electronic circuit board that controls the fan operation.

The EER rating system does not give the complete picture, so a rating of seasonal efficiency has been developed, called the seasonal energy efficiency ratio (SEER). This rating is tested and verified by a rating agency and includes the start-up and shutdown cycles. The rating agency is the Air Conditioning, Heating, and Refrigeration Institute (AHRI), which publishes ratings of manufacturers' equipment that they list in their catalogs. A typical rating may look like **Figure 40.19.** *The government has been encouraging industry to go to equipment ratings of 13 SEER. In fact, 13-SEER equipment is now mandatory. Equipment manufactured with an efficiency rating of 12 SEER is common. SEER ratings in the mid-20s are not uncommon today for high-efficiency air-conditioning equipment incorporating variable-frequency drives (VFDs).* High SEER equipment has a higher initial cost; not everyone will make this kind of investment, so lower-efficiency equipment is still popular. Speculative home builders have a tendency to install the lower-price and lower-efficiency equipment for quicker sale of the home.

Figure 40.19 Examples of SEER ratings.

MODEL	CAPACITY (Btu/x)	SEER
A	24,000	9.00
B	24,000	10.00
C	24,000	10.50
D	24,000	11.00
E	24,000	11.50
F	24,000	12.00
G	24,000	15.00
H	24,000	17.00
I	24,000	19.00
J	24,000	22.00
K	24,000	24.00

40.11 TYPICAL ELECTRICAL OPERATING CONDITIONS

The electrical operating conditions are measured with a volt-ohmmeter and an ammeter. Three major power-consuming devices may have to be analyzed from time to time: the indoor fan motor, the outdoor fan motor, and the compressor. The control circuit is considered a separate function.

The starting point for evaluating electrical operating conditions is knowing what the system supply voltage is supposed to be. For residential units, 230 V single-phase is typical. Light-commercial equipment will nearly always use 208 V or 230 V single-phase or three-phase. Single- and three-phase power may be obtained from a three-phase power supply. An equipment rating may be 208/230 V. The reason for the two different ratings is that some power companies provide 208 V and others provide 230. Some light-commercial equipment may have a supply voltage of 460 V three-phase if it is installed at a large commercial complex. For example, an office may have a 3- or 4-ton air-conditioning unit that operates separately from the main central system. If the supply voltage is 460 V three-phase, the small unit may operate from the same power supply. When 208/230-V equipment is used at a commercial installation, the compressor may be three-phase and the fan motors single-phase. The number of phases that the power company furnishes makes a difference in the method of starting the compressor. Single-phase compressors may have a start assist, such as the positive temperature coefficient device or a start relay and start capacitor. Three-phase compressors will have no start-assist accessories.

40.12 MATCHING THE UNIT TO THE CORRECT POWER SUPPLY

The typical operating voltages for any air-conditioning system must be within the manufacturer's specifications. This is ±10% of the rated voltage. For the 208/230-V motor, the minimum allowable operating voltage would be $208 \times 0.90 = 187.2$ V. The maximum allowable operating voltage would be $230 \times 1.10 = 253$ V. Notice that because this application is 208/230 V, the calculations used the 208-V rating as the base for figuring the low voltage and the 230-V rating for calculating the highest voltage. If the motor is rated at 208 V or 230 V alone, that value (208 V or 230 V) is used for evaluating the voltage.

Equipment may be started under some conditions that are beyond the rated conditions. The technician must use some judgment. For example, if 180 V is measured, the equipment should not be started because the voltage will drop further with the current draw of the motor. If the voltage reads 260 V, the equipment may be started because the voltage may drop slightly when the motor is started. If the voltage drops to within the limits, the motor is allowed to run.

40.13 STARTING THE EQUIPMENT WITH THE CORRECT DATA

When the correct rated voltage is known and the minimum and maximum voltages are determined, the equipment may be started if the voltages are within the limits. The three motors—indoor fan, outdoor fan, and the compressor—can be checked for the correct current draw.

The indoor fan builds the air pressure to move air through the ductwork, filters, and grilles to the conditioned space. By law, the voltage characteristics must be printed on the fan motor in such a way that they will not come off. However, the motor might be mounted so that the data cannot be easily seen. In some cases the motor may be inside the squirrel cage blower. If so, removing the motor is the only way of determining the fan current. If the supplier can be easily contacted, the technician may obtain the information in that way. If the electrical characteristics of the motor cannot be obtained from the nameplate, they might be available on the unit nameplate. The fan motor may have been changed to a larger motor for more fan capacity, however.

40.14 FINDING A POINT OF REFERENCE FOR AN UNKNOWN MOTOR RATING

When a motor is mounted so that the electrical characteristics cannot be determined, the technician must improvise. We know that air-conditioning systems normally move about 400 cfm of air per ton. This can help determine the amperage of the indoor fan motor—the fan amperage on an unknown system can be compared with the amperage of a known system. All that is needed is the approximate system capacity. As discussed earlier, compressor amperages of the unit in

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s).
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

question can be compared to a known unit. For example, the compressor amperage of a 3-ton system is about 17 A when operating on 230 V. If the amperage of the compressor in the system being checked is 17 A, the technician can assume that the system is close to 3 tons. The indoor fan motor for a 3-ton system should be about 1/3 hp for a typical duct system. The fan motor amperage for a 1/3-hp permanent split-capacitor motor is 3.6 A at 230 V. If the fan in question is pulling 5 A, the technician should suspect a problem. Fan motors shipped in a warm-air furnace may have been changed if air-conditioning was added at a later date. In this case, the furnace nameplate may not give the correct fan motor data. The condensing unit will have a nameplate for the condenser fan motor. This motor should be sized fairly close to its actual load and should pull close to nameplate amperage.

40.15 DETERMINING THE COMPRESSOR RUNNING AMPERAGE

The compressor current draw may not be as easy to determine as the fan motor current draw because not all compressor manufacturers stamp the compressor run-load amperage (RLA) rating on the compressor nameplate. Running-load amperage is an older term that is being replaced with rated-load amperage (RLA). Because there are so many different compressor sizes, it is hard to state the correct full-load amperage. For example, motors normally come in the following increments: 1, 1½, 2, 3, and 5 hp. A unit rated at 34,000 Btu/h is called a 3-ton unit, although a 3-ton unit actually takes 36,000 Btu/h. Ratings that are not completely accurate are known as **nominal ratings**. They are rounded off to the closest rating. A typical 3-ton air-conditioning unit would have a 3-hp compressor motor. A unit with a rating of 34,000 Btu/h does not need a full 3-hp motor, but it is supplied with one because there is no standard horsepower motor to meet its needs. If the motor amperage for a 3-hp motor were stamped on the compressor, it could cause confusion because the motor may never operate at that amperage. A unit nameplate lists electrical information, **Figure 40.20**.

NOTE: *The manufacturer may stamp the compressor RLA on the unit nameplate. Please refer to Unit 18, "Application of Motors," when referring to full-load amperage (FLA), rated-load amperage (RLA), service-factor amperage (SFA), and lock-rotor amperage (LRA).* •

40.16 COMPRESSORS OPERATING AT FULL-LOAD CURRENT

It is rare for a compressor motor to operate at its RLA rating. If design or above-design conditions were in effect, the compressor would operate at close to full load. When the unit is operating at a condition greater than design, such as when the unit has been off for some time in very hot weather, it might appear that the compressor is operating at more than RLA. However, other conditions usually keep the compressor from drawing too much current. The compressor is pumping vapor, and vapor is very light. It takes a substantial increase in pressure difference to create a significantly greater workload. Please refer to Unit 18, "Application of Motors," when referring to full-load amperage (FLA), rated-load amperage (RLA), service-factor amperage (SFA), and lock-rotor amperage (LRA).

Figure 40.20 A condensing unit nameplate.

40.17 HIGH VOLTAGE, THE COMPRESSOR, AND CURRENT DRAW

A motor operating at a voltage higher than its voltage rating will be prevented from drawing too much current. A motor rated at 208/230 V has an amperage rating at some value between the amperage at 208 and 230 V. Therefore, if the voltage is 230 V, the amperage may be lower than the nameplate amperage even during overload. The compressor motor may be larger than needed most of the operating time and may not reach its rated horsepower until it gets to the maximum design rating for the system. It may be designed to operate at 105°F or 115°F outdoor ambient for very hot regions,

but when the unit is rated at 3 tons, it would be rated down at the higher temperatures. The unit nameplate may contain the compressor amperage at the highest operating condition for which the unit is rated, 115°F ambient temperature.

40.18 CURRENT DRAW AND THE TWO-SPEED COMPRESSOR

Some air-conditioning manufacturers use two-speed compressors to achieve better seasonal efficiencies. These compressors may use a motor capable of operating as a two-pole or a four-pole motor. A four-pole motor runs at 1800 rpm; a two-pole motor runs at 3600 rpm. A motor control circuit will slow the motor to reduced speed for mild weather.

Variable speed may be obtained with electronic circuits. This greatly improves the system's efficiency because there is no need to stop the compressor and restart it at the beginning of the next cycle. However, this means more factors for which a technician must establish typical running conditions under other-than-design conditions. The equipment should perform just as typical high-efficiency equipment would when operating at design conditions.

SAFETY PRECAUTION: *The technician must use caution while observing equipment to determine the operating conditions. Electrical, pressure, and temperature readings must be taken while the technician observes the equipment. Many times, the readings must be made while the equipment is in operation.*

SUMMARY

- The inside conditions that vary the load on the system are the space temperature and humidity.
- When the discharge pressure rises, the system capacity decreases.
- *High-efficiency systems often use larger or oversized evaporators, and the refrigerant will boil at a temperature of about 45°F under typical operating conditions. This is a temperature difference of 30°F compared with the return air. High efficiency equipment will also incorporate TXV metering devices to keep the evaporator active under all heat load conditions. Electrically commutated motors (ECMs) for evaporators and condensers will also usually accompany high efficiency equipment. Refer to Unit 10, "System Charging," when charging a TXV system.*
- *High-efficiency equipment has a lower operating head pressure than standard-efficiency equipment partly because the condenser is larger. It has a different relationship to the outside ambient temperature, normally 20°F to 25°F.*
- The first thing that the technician needs to know for electrical troubleshooting is what the operating voltage for the unit is supposed to be.
- Equipment manufacturers require that operating voltages of ±10% of the rated voltage of the equipment be maintained.
- The unit nameplate may have the compressor's RLA printed on it. It should not be exceeded.
- Some manufacturers are now using two-speed motors and variable-speed motors for variable capacity.

REVIEW QUESTIONS

1. The standard design conditions for air-conditioning systems established by the Air-Conditioning, Heating and Refrigeration Institute (AHRI) are outside temperature _____°F, inside temperature _____°F, with a humidity of _____%.
2. The typical temperature relationship between a standard-efficiency air-cooled condenser and the ambient temperature is
   A. 50°F.
   B. 40°F.
   C. 30°F.
   D. 20°F.
3. The evaporator will normally operate at a(n) _____°F boiling temperature when the indoor temperature is 75°F with a 50% humidity condition.
   A. 40
   B. 50
   C. 60
   D. 70
4. A typical temperature relationship between a high-efficiency condenser and the ambient temperature is
   A. 10°F.
   B. 20°F.
   C. 30°F.
   D. 40°F.

5. How is condenser high efficiency obtained?
6. High-efficiency air-conditioning systems may use a(n) _____ rather than a fixed-bore metering device.
7. What does the head pressure do if the suction pressure rises?
8. What will cause the suction pressure to rise?
9. The evaporator design temperature may in some cases operate at a slightly _____ (higher or lower) pressure and temperature on high-efficiency equipment because the evaporator is larger.
10. The seasonal energy efficiency ratio (SEER) includes the energy used in the _____ and _____ cycles.
11. The electrical operating conditions are measured with a(n) _____ and a(n) _____.
12. The three major power-consuming devices on an air-conditioning system that may have to be analyzed are the _____, _____, and the _____.
13. Air-conditioning systems normally move about _____ cfm of air per ton.
14. The compressor amperage of a 3-ton system operating on 230 V is approximately _____A.
15. Many ratings for components of an air-conditioning system are not completely accurate due to many different operating conditions and are called _____ ratings.
    A. nominal
    B. SEER
    C. high-efficiency
    D. standard-efficiency

UNIT 41

TROUBLESHOOTING

OBJECTIVES

After studying this unit, you should be able to

- select the correct instruments for checking an air-conditioning unit with a mechanical problem.
- calculate the correct operating suction pressures for both standard and high-efficiency air-conditioning equipment under various conditions.
- calculate the standard operating discharge pressures at various ambient conditions.
- select the correct instruments for troubleshooting electrical problems in an air-conditioning system.
- check the line and low-voltage power supplies.
- troubleshoot basic electrical problems in an air-conditioning system.
- use an ohmmeter to check the various components of the electrical system.

SAFETY CHECKLIST

- ☑ Be extremely careful when installing or removing gauges. Escaping refrigerant can injure your skin and eyes. Wear gloves and goggles. If possible, turn off the system to install a gauge on the high-pressure side. Most air-conditioning systems are designed so that the pressures will equalize when turned off.
- ☑ *Wear goggles and gloves when transferring refrigerant from a cylinder to a system or when recovering refrigerant from a system. Do not recover refrigerant into a disposable cylinder. Use only tanks or cylinders approved by the Department of Transportation (DOT).*
- ☑ Be very careful when working around a compressor discharge line. The temperature may be as high as 300°F.
- ☑ All safety practices must be observed when troubleshooting electrical systems. Often, readings must be taken while the power is on. Only let the contact tips on the insulated meter leads touch the hot terminals. Never use a screwdriver or other tools around terminals that are energized. Never use tools in a hot electrical panel.
- ☑ Turn the power off whenever possible when working on a system. Lock and tag the disconnect panel and keep the only key on your person.
- ☑ Do not stand in water when making any electrical measurements.
- ☑ Short capacitor terminals with a 20,000-Ω resistor before checking with an ohmmeter.
- ☑ Students and other inexperienced persons should perform troubleshooting tasks only under the supervision of an experienced person.

41.1 INTRODUCTION

Troubleshooting air-conditioning equipment involves troubleshooting both mechanical and electrical systems; they may have symptoms that overlap. For example, if an evaporator fan motor capacitor fails, the motor will slow down and begin to get hot. It may even get hot enough for the internal overload protector to stop it. While it is running slowly, the suction pressure will go down and give symptoms of a restriction or low charge. If the technician diagnoses the problem based on suction pressure readings only, a wrong decision may be made.

41.2 MECHANICAL TROUBLESHOOTING

Gauges and temperature-testing equipment are used when performing mechanical troubleshooting. The gauges used are those on the gauge manifold as shown in **Figure 41.1(A)** and **(B)**. The suction or low-side gauge is on the left side of the manifold, and the discharge, or the high-side, gauge is on the right side. The most common refrigerants used in air conditioners are R-22 and R-410A. However, because of ozone depletion and global warming concerns, more environmentally safe refrigerants have entered the market and may be used instead. Refer to Unit 9, "Refrigeration and Oil Chemistry and Management," for more detailed information on newer refrigerants and their compatible oils. An R-22 temperature chart is printed on many gauges for determining the saturation temperature for the low- and high-pressure sides of the system. The production of R-22 will be banned starting in the year 2020. As of 2020, no new R-22 can be produced. Because these same gauges are often used for refrigeration, temperature scales for refrigerants used in refrigeration temperature ranges are also printed on most gauges, **Figure 41.2(A)**. The R-12 scale is not used for residential air-conditioning unless the equipment is old enough for R-12 to have been used. *The common refrigerant for automobile air-conditioning starting in 1992 is R-134a.* However, because R-134a has a relatively high global warming potential, it too will soon be replaced with a more environmentally safe refrigerant. Older automobiles normally would use R-12. Many newer gauges are more universal and may not have a temperature relationship printed on them, or they may have a printed temperature relationship for a specific refrigerant, **Figure 41.2(B)**.

(B)

Many manufacturers use R-410A as a refrigerant. It is a popular refrigerant blend that is replacing R-22 in new equipment. This refrigerant has a much higher working pressure than R-22. Gauges have to be built to handle the higher pressures of R-410A or injury can occur. The gauge ports are the same size, 1/4 in., as for R-22, and either gauge manifold will attach to the R-410A system, but gauges rated for R-22 will be overpressurized if attached to an R-410A system. If R-22 gauges are used on an R-410A system, they will read at the highest point on the gauge. Gauges are most accurate in the middle of their scale range. The technician should make sure what the refrigerant is and apply the correct gauge manifold and hoses. **Figure 41.2**(C) illustrates a gauge built to handle both R-410(A) and R-22. As newer refrigerants and refrigerant blends enter the market, the pressure and temperature scales printed on them will differ.

A wireless digital pressure/temperature gauge with clamp-on temperature probes can provide wireless connection to your

for R-410A, which correlates to a low-side saturated vapor temperature of 37.6°F. The P/T conversion is done by the app. The clamp-on temperature probe reads a low-side compressor in temperature of 53.4°F. These temperatures and pressures are all shown on the right side of the smart device in the service technician's hand. The difference between the two temperatures of 53.4° and 37.6° is 15.8° of total (compressor) superheat, which is automatically calculated by the app.

The smart device also shows a high-side pressure reading of 296.4 psig for R-410A, which correlates to a high-side saturation temperature of 94.9°. The clamp-on probe on the liquid line at the condenser outlet reads 84.2°. The difference between these two temperatures is 10.7° of liquid subcooling in the condenser.

The service technician can also use a screenshot feature which allows them to save pressure, temperature, subcooling, and superheat readings via e-mail. This data can now be organized by location and unit being serviced for easy tracking and storage history. The Bluetooth radio has a range of up to 400 feet with a 10-hour rechargeable battery life. There are 98 refrigerant profiles within the app, which can be upgraded. The wireless digital pressure/temperature gauge with clamp-on temperature probe can be bought individually for individual temperature and pressure measurements, or for dual pressure and temperature readings, **Figure 41.2(D)**. Superheat and subcooling are probably two of the HVAC/R service technician's most important measurements and calculations when troubleshooting a system. Using the most recent state-of-the-art digital tools can save time and money, automate measurements, and permit technicians to share data.

An iPhone-, iPad-, and Android-compatible smart manifold is shown in **Figure 41.2(F)**. This digital manifold technology

has remote monitoring along with data reporting. The smart manifold wirelessly displays the system's actual pressures, temperatures, superheat, and subcooling while simultaneously calculating performance targets, **Figure 41.2(G)**. This smart manifold replaces traditional analog gauges with real-time graphical feedback. By using electronic pressure transducers and various wired or wireless probes, the manifold can collect, organize, and present system performance in a detailed and concise way. The system utilizes a smart phone or tablet to communicate system diagnostics wirelessly and capitalize on GPS, video, and communications platforms already available in smart devices. This manifold is engineered and constructed to withstand the abuse of everyday use while still holding the accuracy of measurement that is required for the industry. The app includes an easy-to-read display; target pressures calculated and displayed; over 40 refrigerants; equipment profiling; calculated target zones for superheat, subcooling, and discharge line temperature; and troubleshooting. The app can be downloaded from the App Store® or Google Play®.

Service technicians often multi-task and work on more than one refrigeration or air-conditioning system at a time. Many times with today's digital service tools, a technician will remotely monitor the system for the proper operating parameters like evaporator and condensing pressures, evaporator superheat, and condenser subcooling after servicing the system. **Figure 41.2(H)** shows a student service technician setting up an ammeter and Bluetooth high- and low-side pressure gauges on a compressor, after fixing a leak near the liquid line solenoid valve and charging refrigerant to a glass door reach-in freezer. **Figure 41.2(I)** shows the service technician's partner remotely monitoring system pressures with a tablet and appropriate downloaded application or "App" from an outside unit two hours after refrigerant was added and

freezing temperatures were achieved. This same service technician is currently working on an outdoor heat pump that is servicing a computer room for the university. The Bluetooth gauge technology allows this kind of multi-tasking of serviced units without going in and out of the building, saving time and money. Many times in the hot summer months, a service technician can remotely monitor system pressures from an air-conditioned service van while simultaneously doing needed paperwork for their company and the customer.

Unlike radios and mobile phones, which send information wirelessly over many miles, Bluetooth technology exchanges data wirelessly over short distances (10 meters) using radio waves. Bluetooth technology is built into many products like computers, mobile phones, and medical devices. The name "Bluetooth" comes from the tenth-century Danish king Harold Bluetooth who helped unite parties at war in Denmark, Sweden, and Norway. Thus, Bluetooth technology was created as an open standard to allow connectivity and collaboration between different products within different industries. Bluetooth technology is a combination of hardware and software. Bluetooth products contain a computer chip containing a Bluetooth radio, **Figure 41.2(J)**.

Figure 41.2 (J) A Bluetooth product containing a computer chip containing a Bluetooth radio.

Courtesy Appion Inc.

However, software (an application or App) is also needed to connect or interface to other products using Bluetooth wireless technology. Many of these Apps can be downloaded free from the App Store® or Google Play®. Bluetooth technology is bringing everyday devices into the digital world, which allows them to connect to one another without wires. Today, just about all top-selling tablets, personal computers, headsets, computer mice, keyboards, and smart phones incorporate Bluetooth technology.

41.3 APPROACH TEMPERATURE AND TEMPERATURE DIFFERENCE

Many technicians use the terms **approach temperature** or *temperature split* to describe the difference in temperature between heat exchange mediums. For example, the difference in temperature between the indoor coil and the return air for a central air-conditioning system is 35°F for standard air-conditioning equipment, **Figure 41.3**. The condenser also has an approach, or split, temperature, **Figure 41.4**. These temperatures are used by the technician to determine when a heat exchanger is functioning correctly. For example, when an air-cooled condenser approach temperature begins to increase, it is a sign that the condenser is not condensing efficiently. This tells the technician that the coil is dirty or that there is not enough air passing over the coil.

Temperature difference (TD) is another term that is used by technicians but it has a different meaning. Temperature

Figure 41.3 The difference between the entering-air temperature and the refrigerant boiling temperature is known as the "approach temperature," or "temperature split."

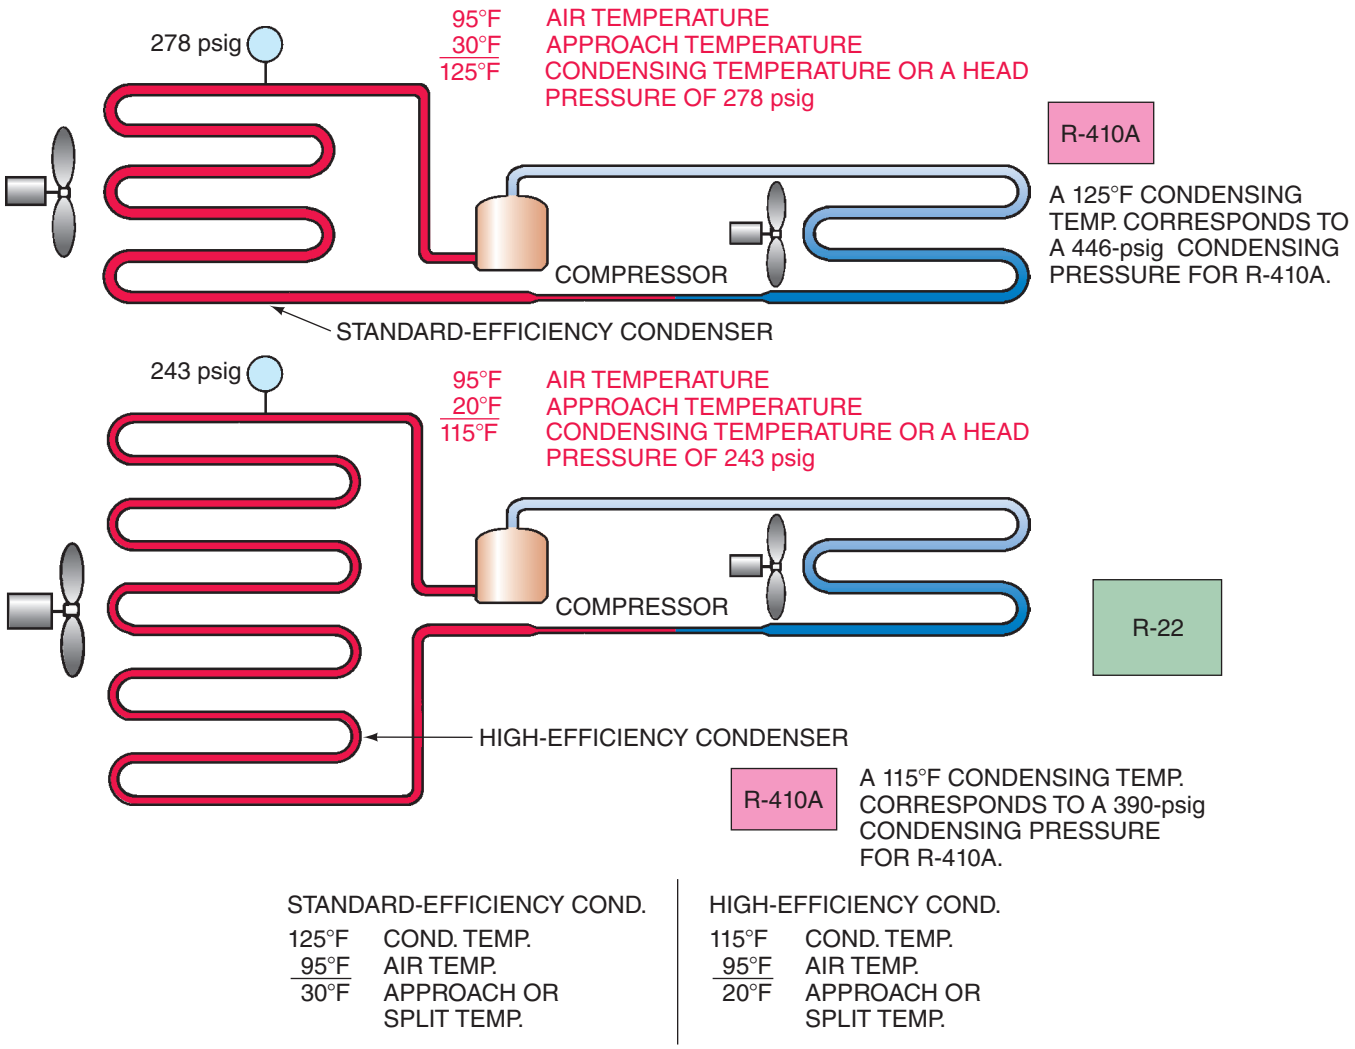
Figure 41.4 The "approach temperature," or "temperature split," works the same for the condenser.



difference applies to the inlet versus the outlet temperature of the same medium. For example, the air entering an evaporator may be 75°F and the leaving-air temperature may be 55°F; the temperature difference is 20°F. The term applies only to the difference in the temperature of the air; the approach temperature example mentioned above, the temperature difference was measured between the refrigerant and the air temperature.

41.4 GAUGE MANIFOLD USAGE

The gauge manifold displays the low- and high-side pressures while the unit is operating. These pressures can be converted to the saturation temperatures for the evaporating (boiling) refrigerant and the condensing refrigerant by using the pressure and temperature relationship. The low-side pressure can be converted to the boiling temperature. If the boiling temperature for a system should be close to 40°F, it can be converted to 70 psig for R-22 and 118 psig for R-410A. The superheat at the evaporator should be close to 10°F at this time. It is difficult to read the suction pressure at the evaporator because it normally has no gauge port. Therefore, the technician takes the pressure and temperature readings at the condensing unit suction line to determine the system performance. (Guidelines for checking the superheat at the condensing unit will be discussed later in this unit.) If the suction pressure were 48 psig for R-22, the refrigerant would be boiling at about 24°F, which is cold enough to freeze the condensate on the evaporator coil and too low for continuous operation. The probable causes of low boiling temperature are low charge or restricted airflow, **Figure 41.5**.

SAFETY PRECAUTION: *The technician must be extremely careful while attaching manifold gauges. High-pressure refrigerant will injure your skin and eyes. Wearing goggles and gloves is necessary. The danger from attaching the high-pressure gauges*

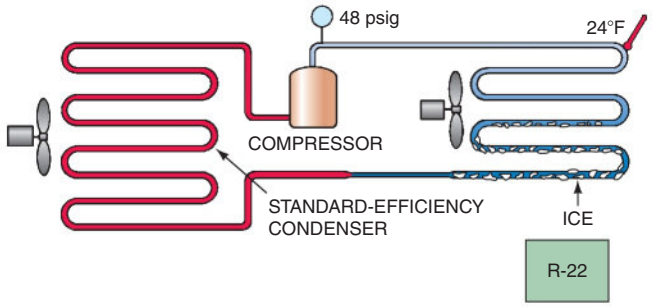
Figure 41.5 This coil was operated below freezing until the condensate on the coil froze.



can be reduced by shutting off the unit and allowing the pressures to equalize to a lower pressure. Liquid R-22 can cause serious frostbite because it boils at −42°F at atmospheric pressure, while R-410A boils at −60°F.•

The high-side gauge may be used to convert pressures to condensing temperatures. For example, if the high-side gauge reads 278 psig for R-22 and the outside ambient temperature is 80°F, the head pressure may seem too high. The gauge manifold chart shows that the refrigerant is condensing at 125°F. However, the refrigerant should not condense at a temperature more than 30°F higher than the ambient temperature. Adding 30°F to the ambient temperature of 80°F = 110°F, so the condensing temperature is actually 15°F too high. Probable causes are a dirty condenser, an overcharge of refrigerant, or noncondensables in the system.

The gauge manifold is used whenever the pressures need to be known. Two types of pressure connections are used with air-conditioning equipment: the Schrader valve and the service valve, **Figure 41.6**. The **Schrader valve** is a pressure connection only. The **service valve** can be used to isolate the system for service. The system may have a Schrader connection for the gauge port and a service valve for isolation, **Figure 41.7**.

41.5 WHEN TO CONNECT THE GAUGES

For small systems, the technician should not connect a gauge manifold every time the system is serviced. A small amount of refrigerant escapes each time a gauge is connected, and some residential and small commercial systems have a critical refrigerant charge. When the high-side line is connected, high-pressure refrigerant will condense in the gauge line. The refrigerant will escape when the gauge line is disconnected from the Schrader connector. A gauge line full of liquid refrigerant lost while checking pressures may be enough to affect the system charge. A short gauge line connector for the high side will help prevent refrigerant loss, **Figure 41.8**. This can be used only to check pressure. It cannot be used to transfer refrigerant out of the system because it is not a manifold.

Figure 41.6 Two valves commonly used when taking pressure readings on modern air-conditioning equipment. (A) A Schrader valve. (B) Two service valves.

Figure 41.7 This service valve has a Schrader port instead of a back seat like a refrigeration service valve.

Photo by Bill Johnson

Another method of connecting the gauge manifold to the Schrader valve service port is with a small hand valve, which has a depressor for depressing the stem in the Schrader valve, **Figure 41.9**. The hand valve can be used to keep the refrigerant in the system when disconnecting the gauges. Follow these steps: (1) Turn the stem on the valve out; this allows the Schrader valve to close; (2) make sure there is a plug in the center line of the gauge manifold;

(3) open the gauge manifold valves. This procedure will cause the gauge lines to equalize to the low side of the system. The liquid refrigerant will move from the high-pressure line to the low side of the system. The only refrigerant that will be lost is an insignificant amount of vapor in the three gauge lines. This vapor is at the suction pressure while the system is running and should be about 70 psig for R-22 air-conditioning systems. The hand valve can also be used to remove Schrader valves while pulling a vacuum on a system. Removing the Schrader valve while pulling a vacuum causes less restriction and a faster and more effective evacuation process. **NOTE:** *This procedure should only be done with a clean and purged gauge manifold,* **Figure 41.10.**•

41.6 LOW-SIDE GAUGE READINGS

When using the gauge manifold on the low side of the system, the technician can compare the actual evaporating pressure to the normal evaporating pressure. This verifies that the refrigerant is boiling at the correct temperature for the low side of the system at some load condition. High-efficiency systems often have oversized evaporators. This makes the suction pressure slightly higher than normal. A standard-efficiency system usually has a refrigerant boiling temperature of about 35°F cooler than the entering-air temperature at the standard operating condition of 75°F return air with a 50% humidity.

If the space temperature is 85°F and the humidity is 70%, the evaporator has an oversized load. It is absorbing an extra heat load, both sensible heat and latent heat, from the moisture in the air. The technician needs to wait a sufficient time for the system to reduce the load to determine whether the equipment is functioning correctly. Gauge readings before this time will not reveal the kind of information that will verify the system performance unless a manufacturer's performance chart is available.

It is good practice to start the unit and check for problems. If none are apparent, the technician can let the unit run for the rest of the day and come back the next morning before evaluating system performance. There may be a larger-than-normal volume of condensate pouring from the drain line. The moisture content in the form of condensate must be removed before the actual air temperature will begin to drop significantly.

41.7 HIGH-SIDE GAUGE READINGS

Gauge readings obtained on the high-pressure side of the system are used to check the relationship of the condensing refrigerant to the ambient air temperature. Standard air-conditioning equipment condenses the refrigerant at no more than 30°F higher than the ambient temperature. For a 95°F entering-air temperature, the head pressure should correspond to 95°F + 30°F = 125°F for a corresponding head pressure of 278 psig for R-22; the head pressure should be 169 psig for R-12 and 445 psig for R-410A. If the head pressure shows that the condensing temperature is higher than this, something is wrong.

When checking the condenser air temperature, be sure to check the actual temperature. Do not use the weather report as the ambient temperature. Air-conditioning equipment located on a black roof is influenced by solar heating of the air being pulled across the roof, **Figure 41.11**. If the condenser is located close to any obstacles, such as below a sundeck, air may be circulated back through the condenser and cause the head pressure to be higher than normal, **Figure 41.12**.

High-efficiency condensers perform in the same way as standard-efficiency condensers except that they operate at lower pressures and condensing temperatures.

Figure 41.10 A method of pumping refrigerant condensed in the high-pressure line over into the suction line. (A) Purging a manifold. (B) Taking pressure readings. (C) Removing liquid refrigerant from the high-side gauge line.

Figure 41.11 A condenser located low on a roof. Hot air from the roof level enters it. A better installation would be to have the condenser mounted up about 20 in. so that air could at least mix with the roof ambient air. The ambient air could be 95°F and the air off the roof 105°F.

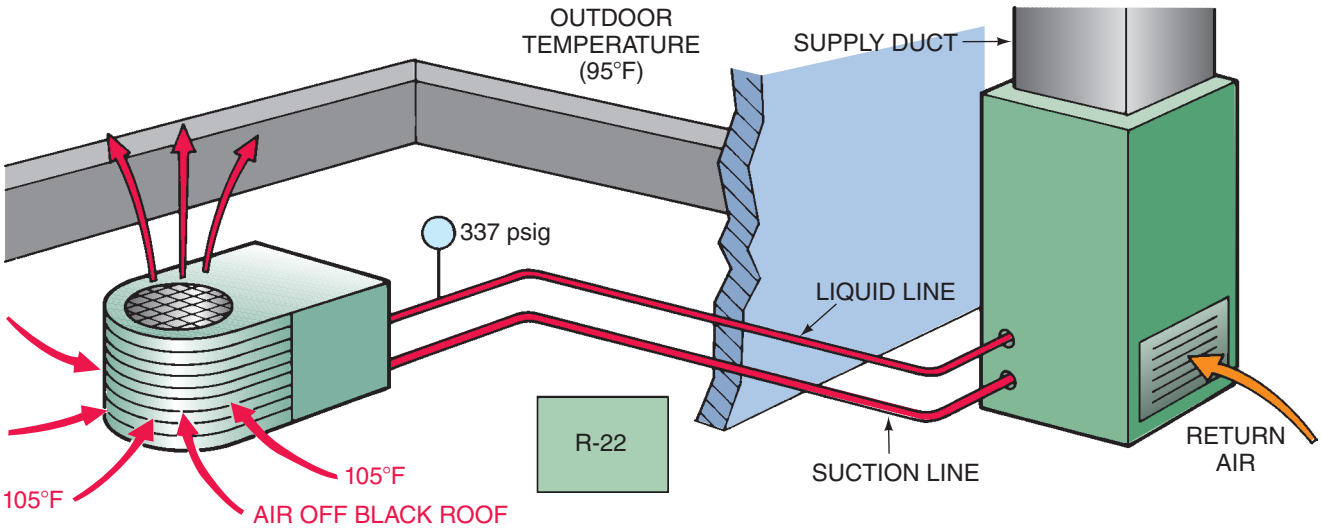

Figure 41.12 A condenser installed so that the outlet air is hitting a barrier in front of it and recirculating to the condenser inlet.

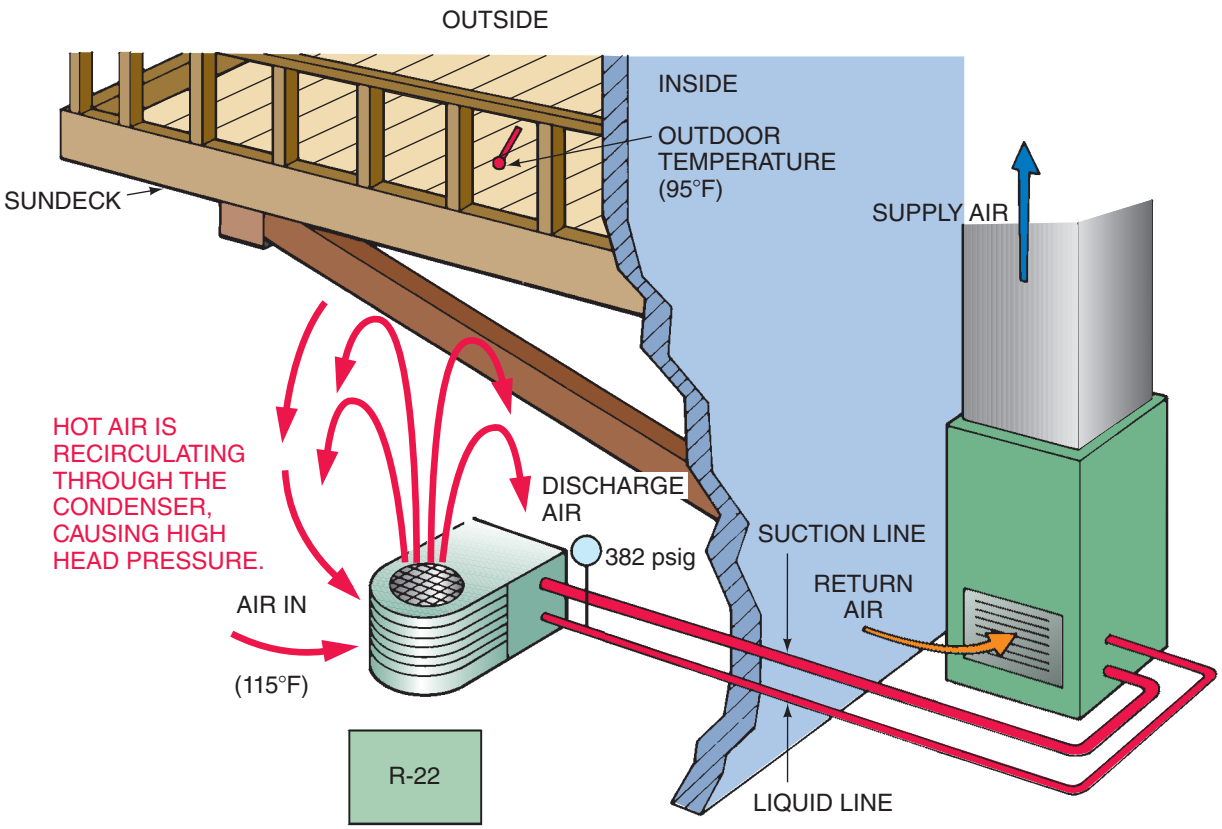

High-efficiency condensers normally condense the refrigerant at a temperature as low as 20°F higher than the ambient temperature. On a 95°F day, the head pressure corresponds to a temperature of 95°F + 20°F = 115°F, which is a pressure of 243 psig for R-22 and 390 psig for R-410A.

41.8 TEMPERATURE READINGS

Temperature readings also can be useful. An electronic thermometer performs very well as a temperature-reading instrument, **Figure 41.13.** It has small temperature leads that respond

Figure 41.13 An electronic thermometer.

Photo by Bill Johnson

quickly to temperature changes. The leads can be attached easily to the refrigerant piping with electrical tape and insulated from the ambient temperature with short pieces of foam line insulation, **Figure 41.14**. It is important that the lead be insulated from the ambient if the ambient temperature is different from the line temperature. The temperature lead is better and easier to use than the glass thermometers used in the past. It was almost impossible to get a true line reading by strapping a glass thermometer to a copper line, **Figure 41.15**.

Temperatures vary from system to system. The technician must be prepared to accurately record these temperatures

Figure 41.14 A temperature lead attached to a refrigerant line in the correct manner. It must also be insulated.

Photo by Bill Johnson

Figure 41.15 A glass thermometer strapped to a refrigerant line.

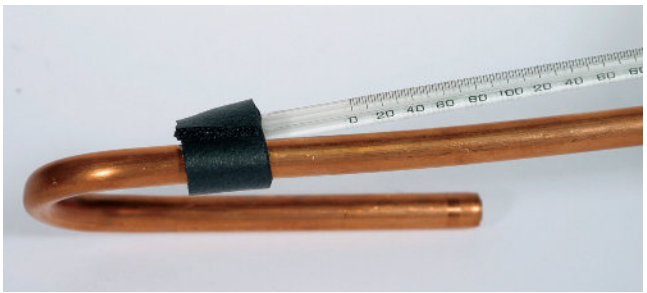

Photo by Bill Johnson

Figure 41.16 This electronic thermometer temperature lead has a damp cotton cloth wrapped around it to convert it to a wet-bulb lead.

Photo by Bill Johnson

to evaluate the various types of equipment. Some technicians record temperature readings under different conditions for future reference. The common temperatures used are inlet air wet- and dry-bulb, outdoor air dry-bulb, and the suction-line temperature. Sometimes, the compressor discharge temperature needs to be known. A thermometer with a range from −50°F to +250°F is commonly used for all of these tests.

INLET AIR TEMPERATURES

It may be necessary to know the inlet air temperature to the evaporator for a complete analysis of a system. A wet-bulb reading to determine the humidity may be necessary. Such a reading can be obtained by using one of the temperature leads with a cotton sock that is saturated with pure water. A wet-bulb and a dry-bulb reading may be obtained by placing a dry-bulb temperature lead next to a wet-bulb temperature lead in the return airstream, **Figure 41.16**. The velocity of the return air will be enough to accomplish the evaporation for the wet-bulb reading.

EVAPORATOR OUTLET TEMPERATURES

The evaporator outlet air temperature is seldom important. It may be obtained, however, in the same manner as the inlet air temperature. The outlet air dry-bulb temperature will normally be about 20°F less than the inlet air temperature. The temperature drop across an evaporator coil is about 20°F when it is operating at typical operating conditions of 75°F and 50% relative humidity return air. If the conditioned space temperature is high with a high humidity, the temperature drop across the same coil will be much less because of the latent-heat load of the moisture in the air.

If a wet-bulb reading is taken, there will be approximately a 10°F wet-bulb drop from the inlet to the outlet during standard operating conditions. The outlet humidity will be almost 90%. This air is going to mix with the room air and will soon drop in humidity because it will expand to the room air temperature. It is very humid because it has been contracted or shrunk during the cooling process. **SAFETY PRECAUTION:** *The temperature lead must not be allowed to touch the moving fan while taking air temperature readings.*•

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

SUCTION-LINE TEMPERATURES

The temperature of the suction line returning to the compressor and the suction pressure will help the technician understand the characteristics of the suction gas. The suction gas may be part liquid if the return-air filters are stopped up or if the evaporator coil is dirty, **Figure 41.17**. The suction gas may have a high superheat if the unit has a low charge or if there is a refrigerant restriction, **Figure 41.18**. The combination of suction-line temperature and pressure will help the service technician decide whether the system has a low charge or a stopped-up air filter in the air handler. For example, if the suction pressure is too low and the suction line is warm, the evaporator is starved, **Figure 41.19**. If the suction-line temperature is cold and the pressure indicates that the refrigerant is boiling at a low temperature, the coil is not absorbing heat as it should. The coil may be dirty or the airflow may be insufficient, **Figure 41.20**. The cold suction line indicates that the unit has enough charge because the evaporator must be full for the refrigerant to get back to the suction line, **Figure 41.21**.

DISCHARGE-LINE TEMPERATURES

The temperature of the discharge line may tell the technician that something is wrong inside the compressor. If there is an internal refrigerant leak from the high-pressure side to the low-pressure side, the discharge gas temperature will go up, **Figure 41.22**. Normally the discharge-line temperature at the compressor would not exceed 220°F for an air-conditioning application even in very hot weather. When a high discharge-line temperature is discovered, the probable cause is an internal leak. The technician can prove this by building up

Figure 41.17 An evaporator flooded with refrigerant.

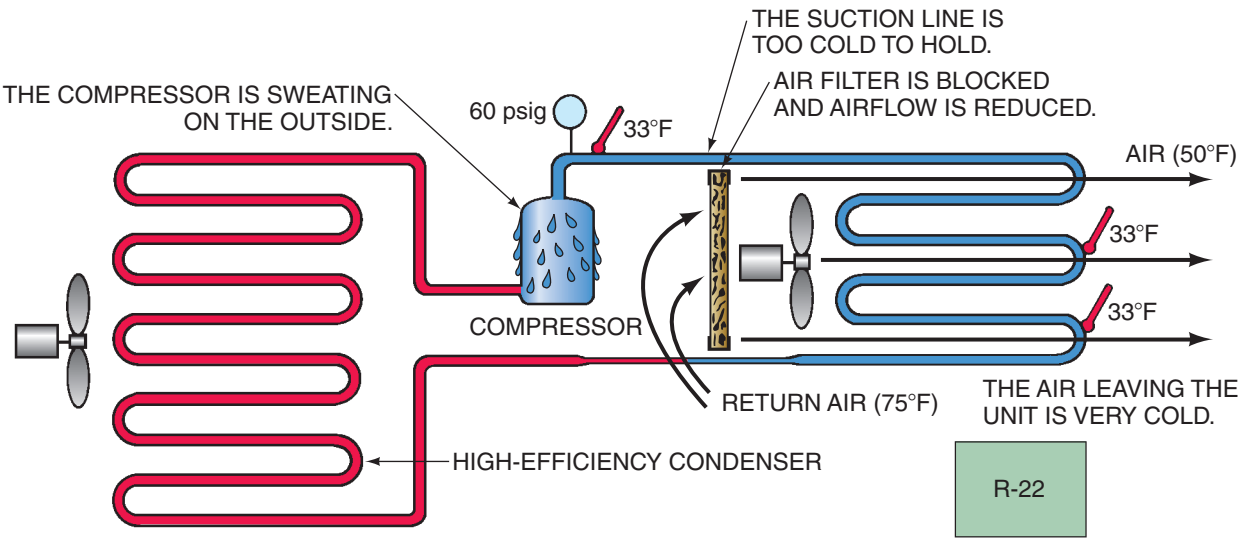

Figure 41.18 The evaporator is starved for refrigerant because of a low refrigerant charge.

Figure 41.19 If the suction pressure is too low, and the suction line is not as cool as normal, the evaporator is starved for refrigerant. The unit refrigerant charge may be low.

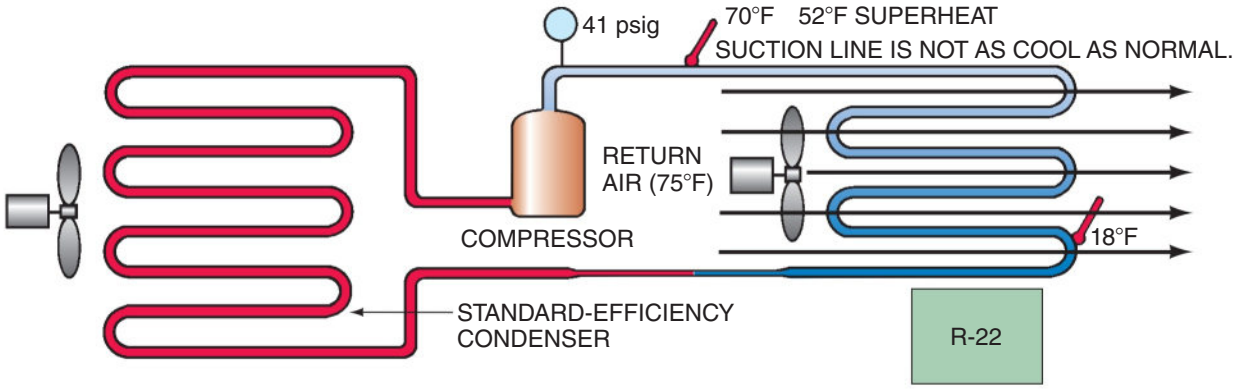

Figure 41.20 When the suction pressure is too low and the superheat is low, the unit is not boiling the refrigerant in the evaporator. The coil is flooded with refrigerant.

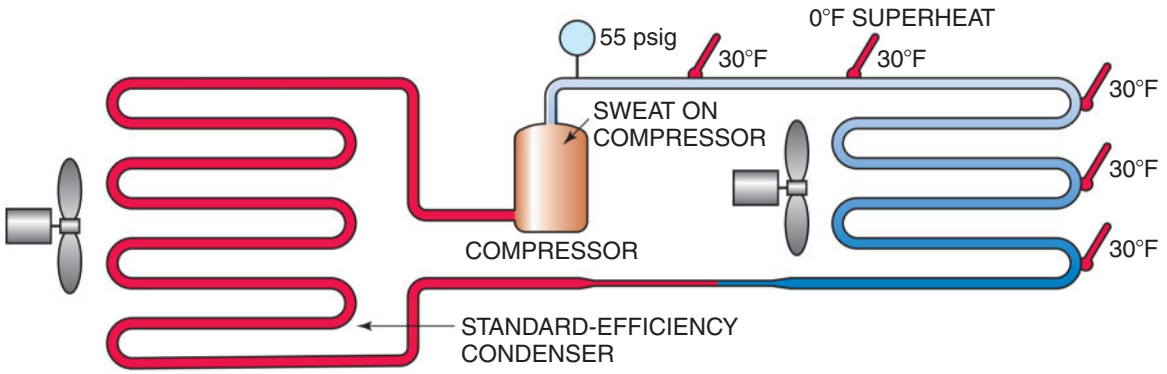

Figure 41.21 The evaporator is full of refrigerant.

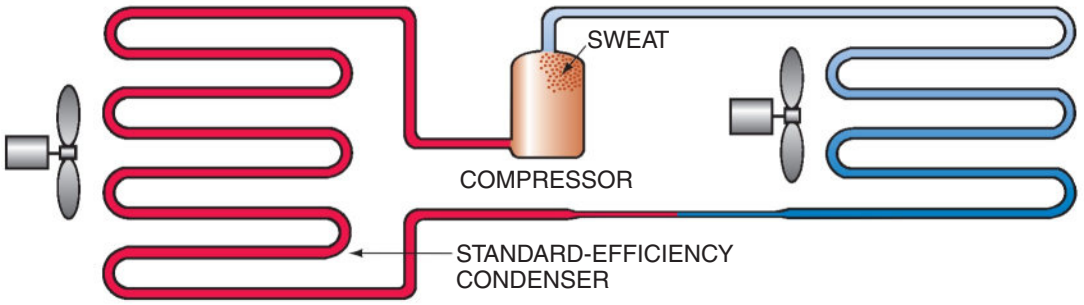
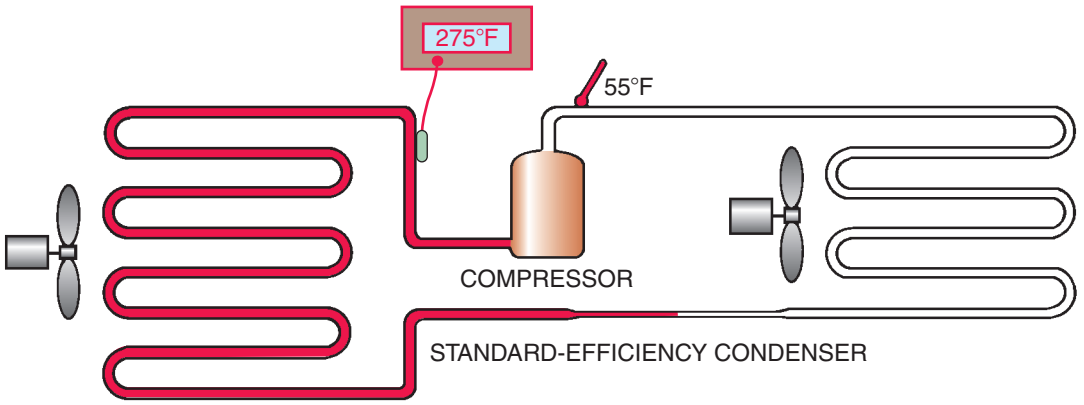


the head pressure as high as 300 psig for R-22 and then shutting off the unit. If there is an internal leak, this pressure difference between the high and the low sides can often be heard (as a whistle) equalizing through the compressor. If the suction line at the compressor shell starts to warm up immediately, the heat is coming from the discharge of the compressor.

High discharge temperatures also can be created by high compression ratios. High compression ratios can be the result of low suction pressures, high condensing pressures, or a combination of both. High discharge temperatures also can be caused from high superheats coming back to the compressor, which is the result of an undercharge of refrigerant, a restricted filter drier, or a metering device starving the system. **SAFETY PRECAUTION:** *The discharge line of a compressor may be as hot as 220°F under normal conditions, so be careful while attaching a temperature lead to this line.*•

Figure 41.22 A thermometer is attached to the discharge line on this compressor. If the compressor has an internal leak, the hot discharge gas will circulate back through the compressor. The discharge gas will be abnormally hot. When a compressor is cooled by suction gas, a high superheat will cause the compressor discharge gas to be extra hot.

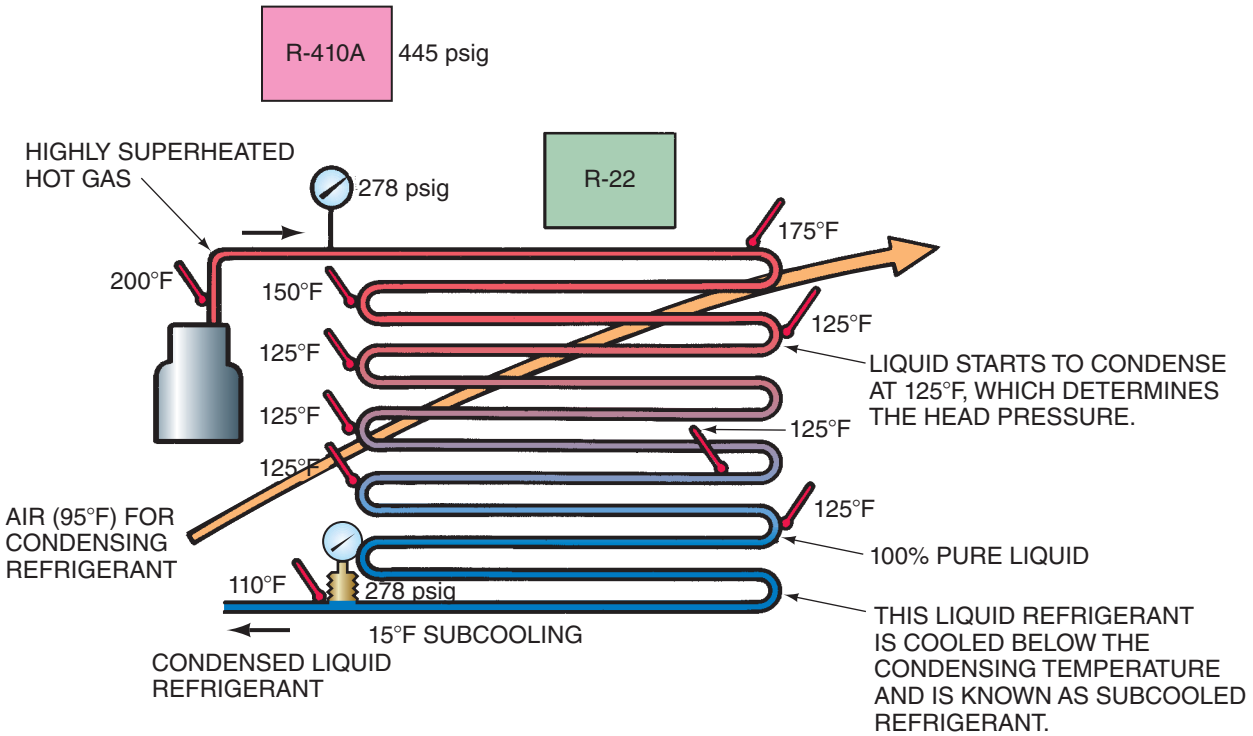


LIQUID-LINE TEMPERATURES

Liquid-line temperature may be used to check the subcooling efficiency of a condenser. Most condensers will subcool the refrigerant to between 10°F and 20°F below the condensing temperature of the refrigerant. If the condensing temperature is 125°F on a 95°F day, the liquid line leaving the condenser may be 105°F to 115°F when the system is operating normally. If there is a slight low charge, there will not be as much subcooling, and the system efficiency therefore will not be as good. The condenser performs three functions: (1) it removes the superheat from the discharge gas, (2) condenses the refrigerant to a liquid, and (3) subcools the liquid refrigerant below the condensing temperature. All three of these functions must be successfully accomplished for the condenser to operate at its rated capacity.

It is a good idea for a new technician to take the time to completely check out a working system operating at the correct pressures. Apply the temperature probes and gauges to all points to verify the readings. This will provide reference points to remember, **Figure 41.23**.

Figure 41.23 This condenser is operating at normal conditions. A technician can use these readings as points of reference for a condenser operating at full-load normal conditions.



41.9 CHARGING PROCEDURES IN THE FIELD

While performing charging procedures in the field, the technician should keep in mind what the designers of the equipment intended and how the equipment should perform. The charge consists of the correct amount of refrigerant in the evaporator, the liquid line, the discharge line between the compressor and the condenser, and the suction line. The discharge line and the suction line do not hold as much refrigerant as the liquid line because the refrigerant is in the vapor state. Actually, the liquid line is the only interconnecting line that contains much refrigerant. When a system is operating correctly, under design conditions, a prescribed amount of refrigerant should be in the condenser, the evaporator, and the liquid line. Understanding the following statements is important for the technician in the field:

1. The amount of refrigerant in the evaporator can be measured by the superheat method.
2. The amount of refrigerant in the condenser can be measured by the subcooling method.
3. The amount of refrigerant in the liquid line may be determined by measuring the length and calculating the refrigerant charge. However, in field service work, if the evaporator is performing correctly, the liquid line has the correct charge.

When the preceding statements are understood, the technician can check for the correct refrigerant level to determine the correct charge.

A field charging procedure may be used to check the charge of most typical systems. The technician sometimes needs typical reference points when adding small amounts of vapor refrigerant to adjust the amount of refrigerant in equipment that has no charging directions. **NOTE:** *Remember, if the refrigerant is a zeotropic blend that may fractionate when vapor-charged, the refrigerant must be throttled in the low side of the system as a liquid to avoid fractionation.* Often the technician finds that the system charge needs adjusting. This can occur due to an over- or undercharge in the factory or from a previous technician's work. It can also occur because of system leaks. *System leaks should always be repaired to prevent further loss of charge to the atmosphere.*

The technician must establish charging procedures to use in the field for all types of equipment. These procedures will help get the system back on line under emergency situations. Following are some methods used for different types of equipment.

FIXED-BORE METERING DEVICES—CAPILLARY TUBE AND ORIFICE TYPE

Fixed-bore metering devices like the capillary tube do not throttle the refrigerant as the *thermostatic expansion valve* (TXV) does. They allow refrigerant flow based on the difference in the inlet and the outlet pressures. The one time when the system can be checked for the correct charge and produce normal readings is at the typical operating condition of 75°F and 50% humidity return air and 95°F outside ambient air. Other conditions will produce different pressures and different superheat readings. The condition that most affects the readings is the outside ambient temperature. When it is lower than normal, the condenser will become more efficient and will condense the refrigerant sooner in the coil. This will have the effect of partially starving the evaporator of refrigerant. Refrigerant in the condenser that should be in the evaporator starves the evaporator.

When a technician needs to check the system for correct charge or to add refrigerant, the best method to follow is the manufacturer's instructions. Please refer to Unit 10, "System Charging" for detailed instructions on charging refrigerant into air conditioning systems with different types of metering devices. If they are not available, the typical operating condition may be simulated by reducing the airflow across the condenser to cause the head pressure to rise. On a 95°F day, the highest condenser head pressure is usually 278 psig for R-22 (95°F ambient + 30°F added condensing temperature difference = 125°F condensing temperature, or 278 psig). The pressure for R-410A would be 445 psig. Because the high pressure pushes the refrigerant through the metering device, no refrigerant held back in the condenser when the head pressure is up to the high-normal end of the operating conditions.

When the condenser is pushing the refrigerant through the metering device at the correct rate, the remainder of the charge must be in the evaporator. A superheat check at the evaporator is not always easy with a split air-conditioning system; instead, a superheat check at the condensing unit can be done. The suction line from the evaporator to the condensing unit may be long or short. For a test comparison, we will use two different lengths: up to 30 ft and from 30 to 50 ft. When the system is correctly charged, the superheat should be 10°F to 15°F at the condensing unit with a line length of 10 to 30 ft. The superheat should be 15°F to 18°F when the line is 30 to 50 ft long. Both of these conditions are with a head pressure of 278 psig for R-22 and 445 psig for R-410A ± 10 psig. At these conditions the actual superheat at the evaporator will be close to the correct superheat of 10°F. When using this method, be sure to allow enough time for the system to settle down after adding refrigerant before drawing any conclusions, **Figure 41.24**.

Superheat temperature taken at the compressor will vary when typical operating conditions are not met. Factors that cause this variation are outside ambient temperatures and inside dry- and wet-bulb temperatures. An air-conditioning system may be operating normally at 30°F superheat at the compressor if the evaporator is seeing a high latent- and sensible-heat load. On the other hand, superheats of 8°F to 15°F may be normal if outside ambient temperatures are high. This is because refrigerant is being forced through the capillary tube at a higher rate.

The manufacturer's superheat charging information should be used, if available. It will take into account all of the varying conditions that affect superheat at the compressor.

Orifice-type metering devices have a tendency to hunt while reading steady-rate operation. This hunting can be observed by watching the suction pressure rise and fall accompanied by the superheat as the suction-line temperature changes. When this occurs, the technician will have to use averaging to arrive at the proper superheat for the coil. For example, if it is varying between 6°F and 14°F, the average value of 10°F superheat may be used.

FIELD CHARGING THE TXV SYSTEM

The TXV system can be charged in much the same way as the fixed-bore system, with some modifications. Please refer to Unit 10, "System Charging" for detailed instructions on charging refrigerant into air conditioning systems with different types of metering devices. The condenser on a TXV system will also hold refrigerant back in mild ambient conditions. This system always has a refrigerant reservoir or receiver to store refrigerant and will not be affected as much as the capillary tube by lower ambient conditions. To check the charge, restrict the airflow across the condenser until the head pressure simulates a 95°F ambient, 278 psig head pressure for R-22 or 445 psig for R-410A. Using the superheat method will not work for this valve because if there is an overcharge, the superheat will remain the same. Superheats of 15°F to 18°F measured at the compressor's inlet are not uncommon for air conditioning systems incorporating TXVs as metering devices. If the sight glass is full, the unit has at least enough refrigerant, but it may have an overcharge. If the unit does not have a sight glass, a measure of the subcooling of the condenser may reveal the amount of charge. For example, a typical subcooling circuit will subcool the liquid refrigerant from 10°F to 20°F cooler than the condensing temperature. A temperature lead attached to the liquid line should read 115°F to 105°F, or 10°F to 20°F cooler than the condensing temperature of 125°F, **Figure 41.25**. If the subcooling temperature is 20°F to 25°F cooler than the condensing temperature, the unit has an overcharge of refrigerant, and the bottom of the condenser is acting as a large subcooling surface.

The charging procedures just described will also work for high-efficiency equipment. The head pressure does not need to be operated quite as high. A head pressure of 250 psig will be sufficient for an R-22 system, and 390 psig for R-410A, when charging. **SAFETY PRECAUTION:** *Refrigerant in cylinders and in the system is under great pressure (as high as 300 psi for R-22 and 500 psig for R-410A). Use proper safety precautions when transferring refrigerant, and be careful not to overfill tanks or cylinders when recovering refrigerant. Do not use disposable cylinders by refilling them. Use only DOT-approved tanks or cylinders. The high-side pressure may be reduced for attaching and removing gauge lines by shutting off the unit and allowing the unit pressures to equalize.*•

Figure 41.25 A unit with a TXV cannot be charged using the superheat method because the TXV controls superheat. The head pressure is raised to simulate a 95°F day, and the temperature of the liquid line is checked for the subcooling level. A typical system will have 10°F to 20°F of subcooling when the condenser contains the correct charge.

41.10 ELECTRICAL TROUBLESHOOTING

Electrical troubleshooting is often required at the same time as mechanical troubleshooting. The volt-ohm-milliammeter (VOM) and the clamp-on ammeter are the primary instruments used, **Figure 41.26**. Knowledge of what the readings should be is required to know whether the existing readings on a particular unit are correct. This is often not easy to determine because the desired reading may not be furnished. **Figure 41.27** shows typical horsepower-to-amperage ratings. It is a valuable tool for determining the correct amperage for a particular motor.

For a residence or small commercial building, one main power panel will normally serve the building. This panel is divided into many circuits. For a split-system type of cooling system, the main panel usually has separate breakers (or fuses) for the air handler or furnace for the indoor unit and for the outdoor unit. For a package or self-contained system, usually one breaker (or fuse) serves the unit, **Figure 41.28**. The power supply voltage is stepped down by the control transformer to the control voltage of 24 V.

Begin any electrical troubleshooting by verifying that the power supply is energized and that the voltage is correct. One way to do this is to see whether the indoor fan will start with the room thermostat FAN ON switch. See **Figure 41.29** for a wiring diagram of a typical split-system air conditioner. The air handler or furnace, where the low-voltage transformer is located, is frequently under the house or in the attic. This quick check with the FAN ON switch can save a trip under the house or to the attic. If the fan will start with the fan relay, several things are apparent: (1) the indoor fan operates, (2) there is control voltage, and (3) there is line voltage to the unit because the fan will run. When taking a service call over the phone, ask the homeowner whether the indoor fan will run. If it does not, bring a transformer. This could save a trip to the supply house or the shop. **SAFETY PRECAUTION:** *All safety practices must be observed while troubleshooting electrical systems. Many times, the system must be inspected while power is on. Let only the insulated meter lead contact probes touch the hot terminals. Special care should be taken while troubleshooting the main power supply because the fuses may be correctly sized large enough to allow great amounts of current to flow before they blow (e.g., when a screwdriver slips in the panel and shorts across hot terminals). Never use a screwdriver in a hot panel.*•

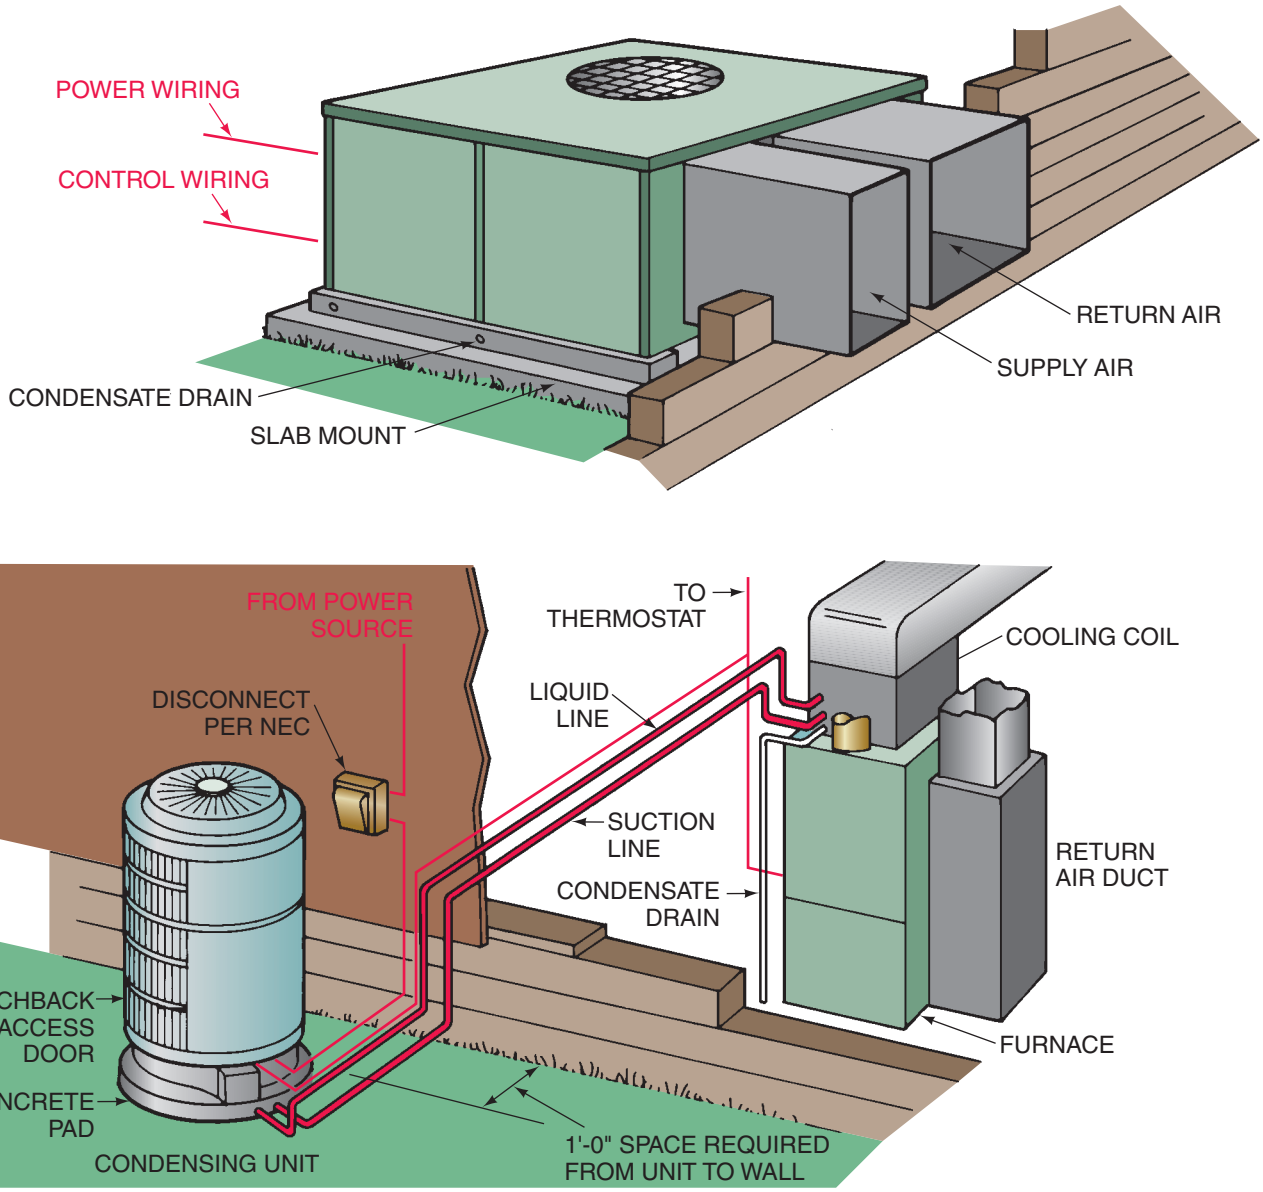
Figure 41.28 A typical package and split-system installation.



If the power supply voltages are correct, move on to the various components. The path to the load may be the next item to check. When trying to get the compressor to run, remember that the compressor motor is operated by the compressor contactor. Is the contactor energized? Are the contacts closed? See **Figure 41.30** for a diagram. Note that in the diagram the only thing that will keep the contactor coil from being energized is the thermostat, the path, or the low-pressure control. If the outdoor fan is operating and the compressor is not, the contactor is energized because it also starts the fan. If the fan is running and the compressor is not, either the path (wiring or terminals) is not making good contact or the compressor internal overload protector is open.

41.11 COMPRESSOR OVERLOAD PROBLEMS

When the compressor overload protector is open, if you cannot hold your hand on the compressor shell, the motor is too hot. Ask these questions: Can the charge be low (this compressor is suction-gas-cooled)? Can the start-assist circuit not be working and the compressor not starting?

Allow the compressor to cool before restarting it. It is best to fix the unit so that it will not come back on for several hours. The best way to do this is to remove a low-voltage wire. If the disconnect switch is pulled, by the next day the refrigerant charge may have migrated to the crankcase

because there was no crankcase heat. To start the unit within the hour rather than waiting, pull the disconnect switch and run a small amount of water through a hose over the compressor. **SAFETY PRECAUTION:** *The standing water poses a potential electrical hazard. Be sure that all electrical components are protected with plastic or other waterproof covering. Do not come in contact with the water or electrical current when working around live electricity.* It will take about 30 min to cool. Have the gauges and a cylinder of refrigerant connected on the unit because when the compressor is started up by closing the disconnect, it may need refrigerant. If the system has a low charge, taking the time to set up to charge after starting the system may allow the compressor to cut off again from overheating before the gauges are connected.

41.12 COMPRESSOR ELECTRICAL CHECKUP

Manufacturers report that a fairly high percentage of compressors returned to them under warranty are actually not defective but were reported by the technician as defective. The technician should use great care when condemning a compressor, as it costs a lot of money in labor and materials to reclaim the refrigerant, ship in a new compressor, and ship the defective compressor back to the manufacturer for in-warranty work. When the compressor is out of warranty, the owner must bear that burden. The technician must be correct with the diagnosis.

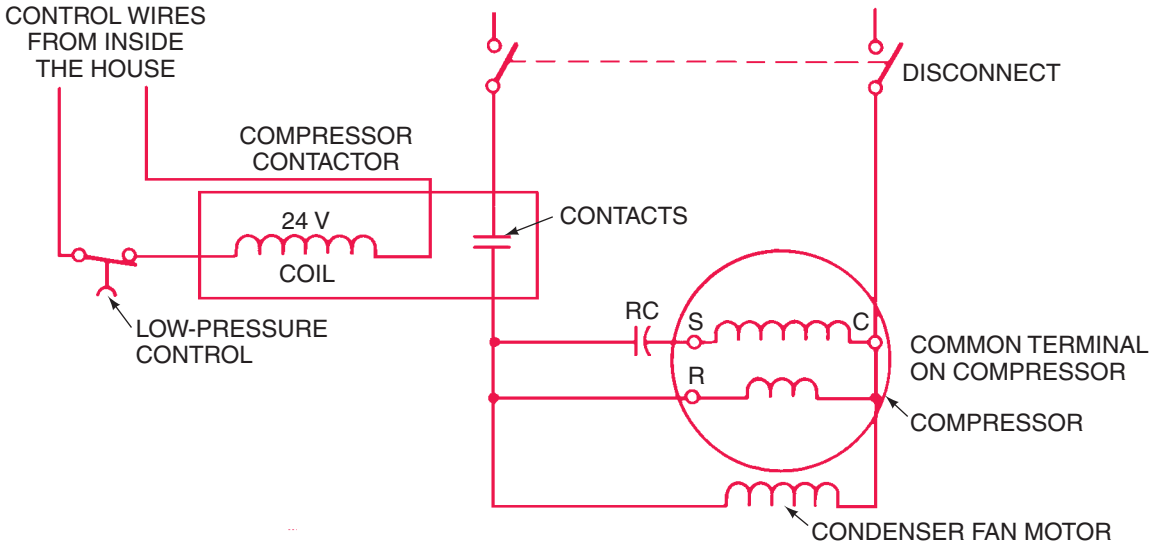
Figure 41.30 The wiring diagram of basic components in a control-and-compressor circuit.



When a compressor will not start, the problem can be either electrical or mechanical. The electrical portion of the problem is rather easy to prove. When the technician can prove the compressor is electrically sound and it will not start, the only other conclusion would be mechanical. The steps for checking a single-phase compressor electrically are as follows:

1. Check the compressor from winding to ground using either an ohmmeter or a megohmmeter. A megohmmeter will detect much smaller ground circuits and is used on larger equipment exclusively. If there is a circuit showing to ground, remove all wires from the compressor terminals and check just the terminals. If the ground is no longer there, the ground is somewhere in the circuit wiring, not the compressor. If a ground is still indicated, clean the compressor terminal block if there is a possibility that current can leak to ground due to dirt. If there is still a ground, condemn the compressor as grounded. **SAFETY PRECAUTION:** *If a compressor has a large amount of liquid refrigerant in the compressor housing, such as when the crankcase heater has been off for a long period, a circuit to ground may be detected. If the compressor crankcase heat has been off and the compressor housing is cool, it is advisable to let it heat for about 24 hours and check it again. The reason for this condition is probably that the refrigerant has floated up into the motor windings some system contamination that is normally dormant. After the 24-hour heating period, the system should operate correctly. Also, dirt around the motor terminals can cause a slight circuit. If there is a question, clean them with a degreasing solvent and try again.*•
2. Check the start winding for correct resistance from common to start.
3. Check the run winding for correct resistance from common to run. If the correct resistances are not readily available, make sure that the start winding and run winding have different resistances. The start winding should have much more resistance than the run winding. Either winding can have some shorted turns in the motor. **Figure 41.31** shows a start winding with *shorted*, sometimes called *shunted*, winding. **Figure 41.32** shows a start winding that has an open circuit.

Figure 41.31 A compressor with a shorted, or shunted, winding.

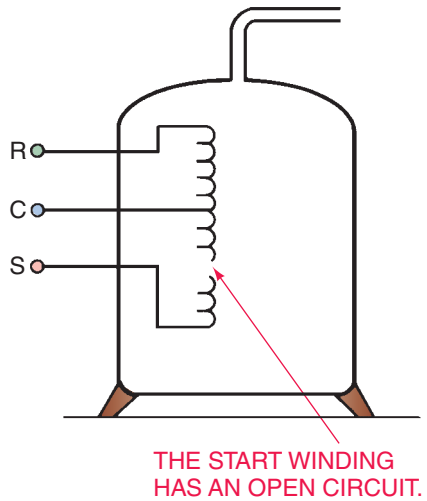
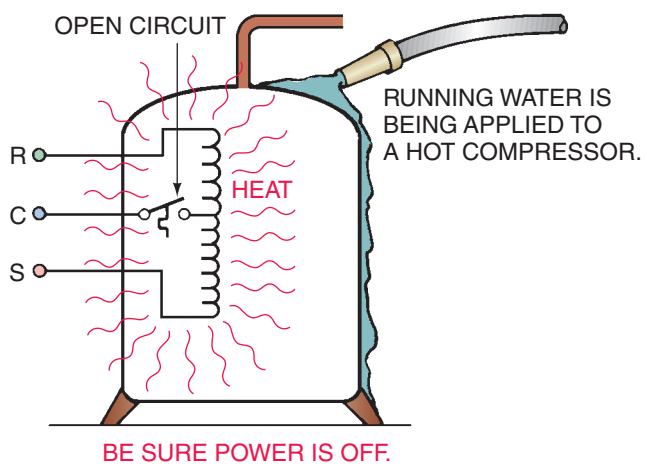
Figure 41.32 A compressor with an open start winding.



4. Check for continuity from the run to the common terminal. If this circuit is open, the winding thermostat may be open. If the compressor is hot to the touch, let it cool for several hours or cool it with water, **Figure 41.33**. **SAFETY PRECAUTION:** *Make sure all power is off and do not stand in water when electrically checking any circuit.*•
5. Check the voltage from common to run and from common to start using two different voltmeters while starting the motor. This voltage must be within ±10% of the motor's ratings. For example, many motors are rated at 208/230. The minimum voltage would be 187.2 V (208 × 0.90 = 187.2) and the maximum voltage would be 253 V (230 × 1.10 = 253). This voltage must be verified as close to the compressor terminals as possible, but do not use the terminals themselves. Follow the wiring back to the first junction, such as the load side of the compressor contactor. It is not unusual for a loose connection to create a low-line-voltage problem at the compressor. If there is any discoloration at the motor terminals, suspect a loose connection. **SAFETY PRECAUTION:** *Never start a compressor with the motor terminal cover box removed. If a motor terminal were to blow out while starting, there is the potential for a high-velocity blowtorch-type of fire. The electrical arc may ignite the escaping oil with the refrigerant, propelling it outward. The box and cover are built to enclose this type of malfunction.*•

Figure 41.33 Cooling a compressor with water.



The steps for checking a three-phase compressor electrically are as follows:

1. Check the compressor from all windings to ground using either an ohmmeter or a megohmmeter as described previously in step 1. Pay attention to the Safety Precautions.
2. Check each set of windings from winding to winding—T1 to T2, T1 to T3, and T2 to T3—on a three-lead motor. Some larger motors may be dual motors in the same housing; check both motors. There should be the same resistance across each motor winding on a three-phase motor. There should be no circuit from motor to motor in a dual motor application.

After completing these tests, and the motor passes them successfully, all that can be done in the field to prove that the motor is sound has been done. One more thing may be done for single-phase motors: a test cord that manually takes the place of the starting circuit components can be used to start the compressor. If the compressor will not start after being declared sound and with the use of a test cord, the motor can be condemned with confidence.

Mechanically checking the compressor comes next. When there is full voltage to the compressor terminals and it will not start, the compressor could be stuck. To test for this in single-phase compressors, use two voltmeters and check from common to run and common to start at the same time. For a three-phase compressor, use three voltmeters and check all three windings at the same time. With three-phase compressors, try reversing any two of the main leads to the contactor and start it again. If the motor has two contactors, it is a part winding-start compressor and it has two motors. Be sure to reverse the leads that feed both contactors. This will reverse the motor. If it will start backward, it may run long enough to allow for planning to change the compressor at a more convenient time, but it should not be relied on to run normally for an extended period. Internally, the compressor may be binding, and the bind will reoccur. Changing the compressor is the most permanent solution.

The most difficult problem to troubleshoot is checking the capacity of a compressor. The complaint will probably be that

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. the compressor runs all the time but the space temperature is not cool enough. This is a common complaint for both cooling and refrigeration systems. Many compressors will have two, three, or four cylinders with one or more of them not functioning. The smaller the compressor, the more difficult this is to prove. For any compressor that does not have the capacity to unload, or to run at reduced load or speed, follow these guidelines:

1. Try to get the system to operate as close to design conditions as possible. The amperage is the key to this procedure. If the amperage is considerably lower than the Rated Load Amperage (RLA) and the voltage is correct, the compressor is not pumping to capacity.
2. If there are gauges on the system, the suction pressure may be a little high with the discharge pressure a little low. This is a sign that the compressor is not doing maximum work. **Figure 41.34** shows an example of a residential system that is not operating at the proper gauge readings. Notice that the outdoor temperature is hot and the indoor unit is operating at the inside design temperature. This system will not remove humidity because the coil temperature is well above the dew point temperature of the indoor air. The indoor air may be cool, but it will feel warm because of the humidity and the compressor will run all the time. This could very well be first thing in the morning after the unit has run all night, because as the day goes by, the indoor air temperature will rise.
3. This is probably the only time that the suction pressure rises, the head pressure drops, and the amperage drops.
4. One possibility is to see if the head pressure will rise when the condenser airflow is partially blocked. Usually, the head pressure will not rise to the head pressure of a design day; if it does, the suction pressure will rise accordingly.

The other mechanical problem that can occur with a compressor is an internal leak, such as when a discharge valve reed becomes split or a head gasket leaks through. To determine what the problem is, install gauges and an ammeter. The unit may appear to be running correctly, but the compressor will be hot and will likely shut off from time to time from high temperature. Try to raise the head pressure to about 300 psig for R-22 and 475 psig for R-410A, and then shut the system off. Be prepared to listen closely to the compressor discharge line. A long screwdriver or stick with one end placed on the discharge line and the other end to your ear is a rudimentary "stethoscope" that works well for listening to internal sounds. **SAFETY PRECAUTION:** *Never use an ohmmeter to check a live circuit.*•

Figure 41.34 This system compressor is not functioning up to capacity. The head pressure is low, the suction pressure is high, and the amperage is low. The compressor is defective.

41.13 TROUBLESHOOTING THE CIRCUIT ELECTRICAL PROTECTORS—FUSES AND BREAKERS

One service call that must be treated cautiously is one involving a circuit protector, such as a fuse or breaker, opening the circuit. The compressor and fan motors have protection that will normally guard them from minor problems. The breaker or fuse is for large current surges in the circuit. When one is tripped, do not simply reset it. Perform a resistance check of the compressor section, including the fan motor. **SAFETY PRECAUTION:** *The compressor may be grounded (may have a circuit to the case of the compressor), and it could be dangerous to try to start it.* **Be sure to isolate the compressor circuit before condemning the compressor.** Take the motor leads off the compressor to check for a ground circuit in the compressor, **Figure 41.35**.

HVAC GOLDEN RULES

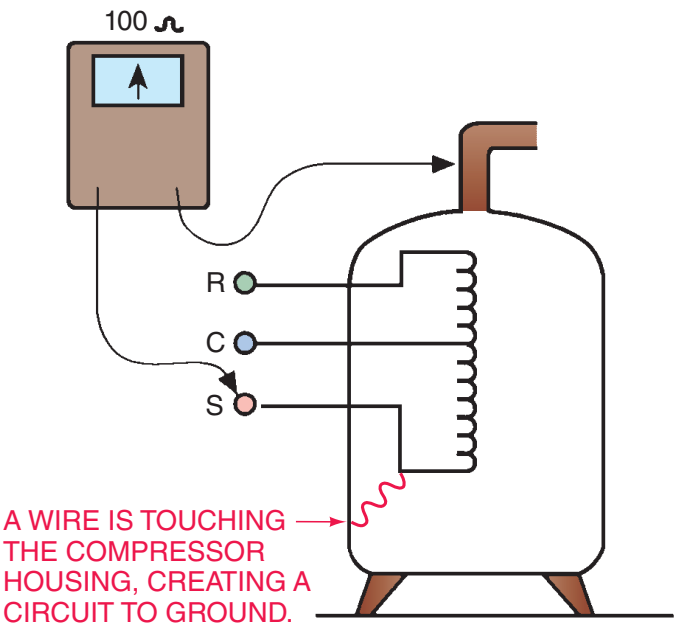
- Always carry the proper tools and avoid extra trips through the customer's house.
- Make and keep firm appointments. Call ahead if delayed. The customer's time is valuable, too.
- If possible, do not block the customer's driveway.

Added Value to the Customer

Here are some simple, inexpensive procedures that may be included in the basic service call.

- Touch-test the suction and liquid lines to determine possible over- or undercharge.
- Clean or change filters as needed.
- Lubricate all bearings as needed.
- Replace all panels with the correct fasteners.
- Inspect all contactors and wiring. This may lead to more paying service.
- Make sure that the condensate line is draining properly. Clean if needed. Algaecide tablets may be necessary.
- Check evaporator and condenser coils for blockage or dirt.

Figure 41.35 A compressor with winding shorted to the casing.



PREVENTIVE MAINTENANCE

Preventive maintenance for air-conditioning equipment involves the indoor airside, the outdoor airside (air-cooled and water-cooled), and electrical circuits.

The indoor airside maintenance is much the same for air-conditioning as for electric heat, where motor and filter maintenance is involved. The only difference is that the evaporator coil operates below the dew point temperature of the air and is wet. It will become a superfilter for any dust particles that may pass through the filter or leak in around loose panel compartment doors. Many air handlers have draw-through coil-fan combinations. The air passes through the coil before the fan. When the fan blades become dirty and loaded with dirt, it is a sure sign that the coil is dirty. The dirt has to pass through the coil first, and it is wet much of the time. When the fan is dirty, the coil must be cleaned.

The coil may be cleaned in place in the unit by two methods. One is by the use of a special detergent manufactured to work while the coil is wet. This detergent is sprayed on the coil and into the core of the coil with a hand-pump sprayer, similar to a garden sprayer. When the unit is started, the condensate will carry the dirt down the coil and down the

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

PREVENTIVE MAINTENANCE (*Continued*)

condensate drain line. This type of cleaner is for light-duty cleaning. Care must be taken that the condensate drain line does not become clogged with the dirt from the coil and pan.

The coil may also be cleaned by shutting the unit down and applying a more powerful detergent to the coil, forcing it into the coil core. After the detergent has had time to work, the coil is then sprayed with a water source, such as a water hose. Care must be taken not to force too much water into the coil, causing the drain pan to overflow. The water must not be applied faster than the drain can accept it.

Special pressure cleaners that have a nozzle pressure of 500 to 1000 psig may be used. These units have a low water flow, about 5 gal/min, and will not overflow an adequate drain system. The high nozzle pressure enables the water to clean the core of the coil.

It is always best to "backwash" a coil when cleaning with water. For backwashing, the water is forced through the coil in the opposite direction to the airflow. Most of the dirt will accumulate on the inlet of the coil and become progressively less as the air moves through the coil. If the coil is not backwashed, the accumulation of dirt may only be driven to the center of the coil. **SAFETY PRECAUTION:** *Never use hot water or a steam cleaner on refrigeration equipment if refrigerant is in the unit because the pressure will rise high enough to burst the unit at the weakest point. This may be the compressor shell. A refrigerant system must be open to the atmosphere before hot water or steam is used for cleaning.*•

In some cases, the coil cannot be cleaned in the unit. If the unit has service valves, the refrigerant may be pumped into the condenser-receiver and the coil removed from the unit. The coil will not contain any refrigerant and may be cleaned with approved detergent and hot water or with a steam cleaner. Approved cleaners may be purchased at any air-conditioning supply house. **SAFETY PRECAUTION:** *Follow the directions. Make sure no water can enter the coil through the piping connections.*•

The outdoor unit may be either air-cooled or water-cooled. Air-cooled units have fan motors that must be lubricated. Some motors require lubrication only after several years of operation. At that time, a recommended amount of approved oil is added to the oil cup. Some motors require more frequent lubrication.

The fan blades should be checked to make sure that they are secure on the shaft. At the same time, the rain shield, if there is one, on top of the fan motor should be checked. On upflow units, the shield should not allow water to enter the motor where the motor is out in the open.

Coils may become dirty from the dust that is being pulled through. It is hard to determine just by looking at a coil how much dirt is in the core. The coil should be cleaned at the first sign of dirt buildup or high operating head pressure.

Condenser coils may be easier to clean because they are on the outside. **SAFETY PRECAUTION:** *Make sure that all power is turned off, locked, and tagged so that someone cannot accidentally turn it on. The fan motor must be covered and care should be taken that water does not enter the controls. They may not all be in the control cabinet. Apply an approved detergent on the coil using a hand-pump sprayer. Soak the coil to the middle. Let the detergent soak for 15 to 30 min, then backwash the coil using a garden hose or spray cleaner.*•

Water-cooled equipment must be maintained like air-cooled equipment. Two things are done as part of the maintenance program to minimize the mineral concentrations in the water. One is to make sure the cooling tower has an adequate water bleed system. This is a measured amount of water that goes down the drain and is added back to the system with the supply water makeup line. Owners may suggest that the bleed system be shut off because all they see is water going down the drain. They may not realize that the purpose of this is to dilute the minerals in the water.

The other maintenance procedure is to use the correct water treatment. A water treatment specialist should supervise the setup of the treatment procedures. This will ensure the best-quality water in the system.

Electrical preventive maintenance consists of examining any contactors and relays for frayed wire and pitted contacts. When these are found, they should be taken care of before leaving the job. There can be no certainty about how long they will last. Single-phase compressors will just stop running if a wire burns in two or a contact burns away. A three-phase compressor will try to run on two phases, which is very hard on the motor. Wires should be examined to make sure they are not rubbing on the frame and wearing the insulation off the wire. Wires resting on copper lines may rub a hole in the line, resulting in a refrigerant leak.

41.14 DIAGNOSTIC CHART FOR AIR-CONDITIONING (COOLING) SYSTEMS

Many homes and businesses have air-conditioning (cooling). These systems operate in the spring, summer, and fall for the purpose of maintaining comfort for the occupants. The systems are often connected to the heating system. Air-conditioning may also be a part of a heat pump system. The air-conditioning system controls will be discussed here. Always listen to the owner to help to identify the potential problem.

Problem	Possible Cause	Possible Repair
No cooling, outdoor unit not running, indoor fan running	Open outdoor disconnect switch	Close disconnect switch.
	Open fuse or breaker	Replace fuse, reset breaker, and determine problem.
	Faulty wiring	Repair or replace faulty wiring or connections.
No cooling; indoor fan and outdoor unit will not run	Low-voltage control problem	
	A. Thermostat	Repair loose connections or replace thermostat and/or subbase.
	B. Interconnecting wiring or connections	Repair or replace wiring or connections.
	C. Transformer	Replace if defective.
		SAFETY PRECAUTION: *Look out for too much curren draw due to a ground circuit or shorted coil.*
No cooling; indoor and outdoor fan running, but compressor not running	Tripped compressor internal overload	
	A. Low line voltage	Correct low voltage, call power company, repair loose connections.
	B. High head pressure	
	1. Dirty outdoor (condenser)	Clean condenser.
	2. Condenser fan not running all the time	Check condenser fan motor and capacitor.
	3. Condenser air recirculating	Correct recirculation problem.
	4. Overcharge of refrigerant	Correct charge.
	C. Low charge, motor not being properly cooled	Correct charge; if due to leak, repair leak.
Indoor coil freezing	Restricted airflow	Change filters.
		Open all supply register dampers.
		Clear return air blockage.
		Clean fan blades.
		Speed fan up to higher speed.
	Low charge	Adjust unit charge—repair leak if refrigerant has been lost.
	Metering device	Change or clean metering device.
	Restricted filter drier	Change filter drier.
	Operating unit during low ambient conditions without proper head pressure control	Add proper low-ambient head pressure control.

41.15 SERVICE TECHNICIAN CALLS

Troubleshooting can take many forms and cover many situations. The following actual troubleshooting situations help show what the service technician does to solve actual problems.

SERVICE CALL 1

A residential customer reports that the central air conditioner at a residence is not cooling enough and runs continuously. *The problem is a low R-410A refrigerant charge.*

When the technician arrives the unit is running. The temperature indicator on the room thermostat shows the thermostat is set at 72°F, and the thermometer on the thermostat indicates that the space temperature is 80°F. The air feels very humid. The technician notices that the indoor fan motor is running. The velocity of the air coming out of the registers seems adequate, so the filters are not stopped up.

The technician goes to the condensing unit and hears the fan running. The air coming out of the fan is not warm. This indicates that the compressor is not running. Removing the door to the compressor compartment, the technician notices that the compressor is hot to the touch. This is an indication that the compressor has been trying to run. Gauges installed on the service ports both read the same because the system has been off. The readings are 235 psig, which corresponds to 80°F. The residence is 80°F inside, and the ambient is 90°F, so it can be assumed that the unit has some liquid refrigerant in the system because the pressure corresponds so closely to the chart. If the system pressure were 170 psig, it would be obvious that little liquid refrigerant is left in the system. A large leak would be suspected.

The technician decides that the unit must have a low charge and that the compressor is off because of the internal overload protector. The technician pulls the electrical disconnect and takes a resistance reading across the compressor terminals with the motor leads removed. The meter shows an

open circuit from common to run and common to start and a measurable resistance between run and start. This indicates that the motor-winding thermostat must be open, an indication verified by the hot compressor.

The technician covers all electrical components and terminals with plastic and locks out the electrical disconnect. Connecting a water hose, the technician runs a small amount of water over the top of the compressor shell to cool it. A cylinder of refrigerant is connected to the gauge manifold so that when it is time to start the compressor, the technician will be ready to add refrigerant and keep the compressor running. The gauge lines are purged of any air that may be in them. While the compressor is cooling, the technician changes the air filters and lubricates the condenser and the indoor fan motors.

After about 30 min, the compressor seems cool. The water hose is removed, and the water around the unit is allowed a few minutes to run off. The technician is careful not to stand in the water. When the disconnect switch is closed, the compressor starts. The suction pressure drops to 75 psig. Because the refrigerant is R-410A, the normal suction pressure for the system is 118 psig. Refrigerant is added to the system to bring the charge up to normal. The space temperature is 80°F, so the suction pressure will be higher than normal until the space temperature adjusts. To determine the correct charge, the technician must have a reference point. The following reference points are used in this situation because no factory chart is available.

1. The outside temperature is 90°F; the normal operating head pressure should correspond to a temperature of 90°F + 30°F = 120°F, or 417 psig. It should not exceed this when the space temperature is down to a normal 75°F. This is a standard-efficiency unit. The technician restricts the airflow to the condenser and causes the head pressure to rise to 440 psig as refrigerant is added.
2. The suction pressure should correspond to a temperature of about 35°F cooler than the space temperature of 80°F, or 45°F, which corresponds to a pressure of 128 psig for R-410A.
3. The system has a capillary tube metering device, so some conclusions can be drawn from the temperature of the refrigerant coming back to the compressor. A thermometer lead is attached to the suction line at the condensing unit. As refrigerant is added in the liquid state, the technician notices that the refrigerant returning from the evaporator is getting cooler. The evaporator is about 30 ft from the condensing unit, and some heat will be absorbed into the suction line returning to the condensing unit. The technician uses a guideline of 15°F of superheat with a suction line of this length. This assumes that the refrigerant leaving the evaporator has about 10°F of superheat and that another 5°F of superheat is absorbed along the line. When these conditions are reached, the charge is very close to correct and no more refrigerant is added.

A leak check is performed, and a flare nut is found to be leaking. It is tightened, and the leak is stopped. The technician loads the truck and leaves. A call later in the day shows that the system is working correctly.

SERVICE CALL 2

A residential customer calls the air-conditioning service company to report that the air-conditioning unit has been cooling correctly until afternoon, when it quit cooling. The residential unit has been in operation for several years. *The problem is a complete loss of charge.*

Upon arriving at the residence, the service technician, wanting to make a good first impression, rings the doorbell while maintaining a comfortable distance from the door. Once the customer answers the door, the technician politely introduces himself, handing out his business card while explaining the reason for the visit and waiting until the customer invites him into the house before entering. Also before entering he puts on shoe covers to protect the flooring. The technician carefully listens to the customer's description of the problem before examining the air conditioner. He finds the thermostat to be set at 75°F and the space temperature to be 80°F. The air coming out of the registers feels the same as the return-air temperature. There is plenty of air velocity at the registers, so the filters appear to be clean.

At the back of the house, the technician finds that the fan and compressor in the condensing unit are not running. The breaker at the electrical box is in the ON position, so power must be available. A voltage check shows that the voltage is 235 V. The wiring diagram indicates that there should be 24 V between the C and Y terminals to energize the contactor. The voltage actually reads 25 V, slightly above normal, but so is the line voltage of 235 V. The conclusion is that the thermostat is calling for cooling, but the contactor is not energized. The only safety control in the contactor coil circuit is the low-pressure control, so the unit must be out of refrigerant.

Gauges fastened to the gauge ports read 0 psig. The technician connects a cylinder of R-22 and starts adding a trace amount of refrigerant for the purpose of leak checking. When the pressure is up to about 2 psig, he stops the refrigerant. When nitrogen is added to push the pressure up to 50 psig, gas can be heard leaking from the vicinity of the compressor suction line. There is a hole in the suction line where the cabinet had been rubbing against it. This accounts for the fact that the unit worked well up to a point and quit working almost immediately.

The trace refrigerant (R-22) and nitrogen are allowed to escape to the atmosphere from the system, and the hole is patched with silver solder. A liquid-line drier is installed in the liquid line, and a triple evacuation is performed to remove any contaminants that may have been pulled into the system. The system is charged and started. The technician follows the manufacturer's charging chart to ensure the correct charge.

Once the work area is cleaned, the technician clearly explains to the customer what work was performed and why. He then politely explains some options of system operation and the advantages and disadvantages of each option. The bill he gives to the customer includes a detailed work description with costs. Shaking the customer's hand, the technician lets the customer know that the business is valued.

SERVICE CALL 3

A commercial customer calls to report that the air-conditioning unit at a small office building is not cooling. The unit was operating and cooling yesterday afternoon when the office closed for the day. *The problem is that someone turned the thermostat down to 55°F late yesterday afternoon, and the condensate on the evaporator froze solid overnight trying to pull the space temperature down to 55°F.*

The technician notices that the thermostat is set at 55°F when he arrives at the site. An inquiry reveals that one of the employees was too warm in an office at the end of the building and turned down the thermostat to cool that office. The technician notices no air is coming out of the registers. The air handler is located in a closet at the front of the building. Examination shows that the fan is running and the suction line is frozen solid at the air handler.

The technician stops the compressor and leaves the evaporator fan operating by turning the heat-cool selector switch to OFF and the fan switch to ON. It is going to take a long time to thaw the evaporator, probably an hour. The technician leaves the following directions with the office manager:

1. Let the fan run until air comes out of the registers, which will verify that airflow has started through the ice.
2. When air is felt at the registers, wait 30 min to ensure that all ice is melted and turn the thermostat back to COOL to start the compressor.

The technician then looks in the ceiling to check the air damper on the duct run serving the back office of the employee who was not cool enough and had turned down the thermostat. The damper is nearly closed; it probably was brushed against by a telephone technician who had been working in the ceiling. The damper is reopened. A call later in the day indicates that the system is working again.

SERVICE CALL 4

A residential customer reports that the air-conditioning unit is not cooling correctly. *The problem is a dirty con-denser.* The unit is in a residence and next to the side yard. When the homeowner mows the grass, the lawnmower throws grass on the condenser. This is the first hot day of summer, and the unit had been cooling the house until the weather became hot.

The technician notices that the thermostat is set for 75°F but the space temperature is 80°F. Plenty of slightly cool air is coming out of the registers. The technician goes to the side of the house where the unit is located. The suction line feels cool, but the liquid line is very hot. An examination of the condenser coil shows that the coil is clogged with grass and is dirty.

SAFETY PRECAUTION: *The technician shuts off the unit with the breaker at the unit and locks it out, then takes enough panels off to be able to spray coil cleaner on the coil.* A high-detergent coil cleaner is applied to the coil and allowed to stand for about 15 min to soak into the coil dirt. While this is occurring, he oils the motors and changes the filters. **SAFETY PRECAUTION:** *To keep the condenser fan motor from getting wet when the coil cleaner is washed off, it is covered with a plastic bag.*

A water hose with a nozzle to concentrate the water stream is used to wash the coil in the direction opposite to the airflow. One washing is not enough, so the coil cleaner is applied to the coil again and allowed to set for another 15 min. The coil is washed again and is now clean.

The unit is assembled and started. The suction line is cool, and the liquid line is warm to the touch. The technician decides not to put gauges on the system and leaves. A call back later in the day to the homeowner indicates that the system is operating correctly.

SERVICE CALL 5

A homeowner reports that the air-conditioning unit is not cooling. This is a residential high-efficiency unit. *The problem is that the TXV is defective.*

The service technician finds the house warm upon arrival. The thermostat is set at 74°F, and the house temperature is 82°F. The indoor fan is running, and plenty of air is coming out of the registers.

Before leaving the house to observe the condensing unit, the technician informs the homeowner why he is leaving and going outside. At the condensing unit the technician finds that the fan and compressor are running, but they quickly stop. The suction line is not cool. After gauges are attached to the gauge ports, the low-side pressure reads 25 psig, and the head pressure reads 170 psig; this corresponds closely to the ambient air temperature. The unit is off because of the low-pressure control. When the pressure rises, the compressor restarts but stops in about 15 sec. The liquid-line sight glass is full of refrigerant. The technician concludes that a restriction exists on the low side of the system. The TXV is a good place to start when there is an almost complete blockage. 4R *The system does not have service valves, so the charge has to be removed and recovered in an approved cylinder.* 4R

Before entering the house, the technician makes sure his shoes are clean and he puts the covers back on to protect flooring. He solders a new TXV into the system, which takes an hour to complete. After the valve is changed, the system is leak checked and evacuated to a deep vacuum. A charge is measured into the system, and the system is started. It is evident from the beginning that the valve change has repaired the unit.

After cleaning the work site, the technician explains to the homeowner how the problem was corrected. He gives

billing information while letting the homeowner know that the business is valued. While always making eye contact and remembering the customer's name, the technician shakes the customer's hand with a clean hand.

SERVICE CALL 6

An office manager calls to report that the air-conditioning unit in a small office building is not cooling. The unit was cooling correctly yesterday afternoon when the office closed for the day. *The problem is that at night an electrical storm tripped a breaker on the air handler.* The power supply is at the air handler.

The technician first goes to the space thermostat. It is set at 73°F, and the temperature is 78°F. There is no air coming out of the registers. The fan switch is turned to ON, and the fan still does not start. The technician checks the low-voltage power supply, which is in the attic at the air handler, and finds the tripped breaker. **SAFETY PRECAUTION:** *Before resetting it, the technician decides to check the unit electrically.*•

A resistance check of the fan circuit and the low-voltage control transformer proves there is a measurable resistance. The circuit seems to be safe. The circuit breaker is reset and stays in. The thermostat is set at COOL, and the system starts. A call later indicates that the system is operating properly.

SERVICE CALL 7

A residential customer calls. The homeowner found the breaker at the condensing unit tripped and reset it several times, but it did not stay set. *The problem is that the compressor motor winding is grounded to the compressor shell and tripping the breaker.* **SAFETY PRECAUTION:** *The homeowner should be warned to reset a breaker no more than once.*•

The technician goes straight to the condensing unit with electrical test equipment. The breaker is in the tripped position and is moved to the OFF position. **SAFETY PRECAUTION:** *The voltage is checked at the load side of the breaker to ensure that there is no voltage. The breaker has been reset several times and is not to be trusted.*• When the technician determines that the power is definitely off, he connects the ohmmeter to the load side of the breaker. The ohmmeter reads infinity, meaning no circuit. The compressor contactor is not energized, so the fan and compressor are not included in the reading. The technician pushes in the armature of the compressor contactor to make the contacts close. The ohmmeter now reads 0, or no resistance, indicating that a short exists. It cannot be determined whether the fan or the compressor is the problem, so the compressor wires are disconnected from the bottom of the contactor. The short does not exist when the compressor is disconnected. This verifies that the short is in the compressor circuit, possibly the wiring. The meter is moved to the compressor terminal box and the wiring is disconnected. The ohmmeter is attached to the motor terminals at the compressor. The short is still there, so the compressor motor is condemned.

The technician must return the next day to change the compressor. Before he leaves, he disconnects the control wiring and insulates the disconnected compressor wiring so that power can be restored. This must be done to keep crankcase heat on the unit until the following day. If it is not done, most of the refrigerant charge will be in the compressor crankcase and too much oil will move with the refrigerant when it is recovered. The technician performs one more task before leaving the job. The Schrader valve fitting at the compressor is slightly depressed to determine the smell of the refrigerant. The refrigerant has a strong acid odor. A suction-line filter drier with high acid removal capacity needs to be installed along with the normal liquid-line drier.

4R *The technician returns on the following day, recovers the refrigerant from the system, and then changes the compressor, adding the suction- and liquid-line driers.* 4R The unit is leak checked, evacuated, and the charge measured into the system with a set of accurate scales. The system is started, and the technician asks the customer to leave the air conditioner running, even though the weather is mild, to keep refrigerant circulating through the driers to clean it in case any acid is left in the system.

The technician returns on the fourth day and measures the pressure drop across the suction-line drier to make sure that it is not restricted with acid from the burned-out compressor. It is well within the manufacturer's specification.

SERVICE CALL 8

A residential customer calls to say that he can hear the indoor fan motor running for a short time; then it stops. This is happening repeatedly. *The problem is that the indoor fan motor is cycling on and off on its internal thermal overload protector because the fan capacitor is defective.* The fan will start and run slowly then stop.

The technician knows from the work order to go straight to the indoor fan section. It is in the crawl space under the house, so he carries electrical instruments on the first trip. The fan has been off long enough to cause the suction pressure to go so low that the evaporator coil is frozen. The breaker is turned off during the check. The technician suspects the fan capacitor or the bearings, so he also carries along a fan capacitor. After bleeding the charge from the fan capacitor, it is checked with the ohmmeter to see whether it will charge and discharge. **SAFETY PRECAUTION:** *Ensure that no electrical charge is in the capacitor be-fore checking it with an ohmmeter. A 20,000-Ω resistor should be used between the two terminals to bleed off any charge.*•

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The capacitor will not charge and discharge. The capacitor is then double-checked with a digital capacitor analyzer. The digital meter also indicates an open capacitor.

The technician oils the fan motor and starts it from under the house with the breaker. The fan motor is drawing the correct amperage. The coil is still frozen, and the technician must set the space thermostat to operate only the fan until the homeowner feels air coming out of the registers. Then the fan only should be operated for one-half hour (to melt the rest of the ice from the coil) before the compressor is started.

The service technician then clearly explains to the customer in everyday language what went wrong with the system and the work that was accomplished and politely asks the customer if there are any questions. Billing information is given to the customer, the customer is again thanked for the business, and the technician leaves the work site.

Solutions for the following service calls are not provided here. Please discuss the solutions with your instructor.

SERVICE CALL 9

A commercial customer reports that an air-conditioning unit in a small office building is not cooling on the first warm day.

The technician first goes to the thermostat and finds that it is set at 75°F, and the space temperature is 82°F. The air feels very humid. No air is coming from the registers. The air handler is in the attic. An examination of the condensing unit shows that the suction line has ice all the way back to the compressor. The compressor is still running.

What is the likely problem and the recommended solution?

SERVICE CALL 10

A residential customer reports the unit in the residence was worked on in the early spring under the service contract. The earlier work order shows that refrigerant was added by a technician new to the company.

The technician finds that the thermostat is set at 73°F, and the house is 77°F. The unit is running, and cold air is coming out of the registers. Everything seems normal until the condensing unit is examined. The suction line is cold and sweating, but the liquid line is only warm.

Gauges are fastened to the gauge ports; the suction pressure is 85 psig, far from the correct pressure of 74 psig (77°F − 35°F = 42°F, which corresponds to about 74 psig). The head pressure is supposed to be 243 psig to correspond to a condensing temperature of 115°F (85°F + 30°F = 115°F, or 243 psig). The head pressure is 350 psig. The unit shuts off after about 10 min running time.

What is the likely problem and the recommended solution?

SERVICE CALL 11

A residential customer calls to report that the air-conditioning unit is not cooling enough to reduce the space temperature to the thermostat setting. It is running continuously on this first hot day.

The technician finds the thermostat set at 73°F, and the house temperature is 78°F. Air is coming out of the registers, so the filters must be clean. The air is cool but not as cold as it should be. The air temperature should be about 55°F, and it is 63°F.

At the condensing unit the technician finds that the suction line is cool but not cold. The liquid line seems extra cool. It is 90°F outside, and the condensing unit should be condensing at about 120°F. If the unit had 15°F of subcooling, the liquid line should be warmer than hand temperature, yet it is not.

Gauges are fastened to the service ports to check the suction pressure. The suction pressure is 95 psig, and the discharge pressure is 225 psig. The airflow is restricted to the condenser, and the head pressure gradually climbs to 250 psig; the suction pressure goes up to 110 psig. The compressor should have a current draw of 27 A, but it only draws 15 A.

What is the likely problem and the recommended solution?

SERVICE CALL 12

A commercial customer calls to indicate that the air-conditioning unit in a small office building was running but suddenly shut off.

The technician introduces himself to the customer and carefully listens to what he has to say. Before being invited inside, the technician puts protective covers over his shoes. The technician then goes to the space thermostat and finds it set at 74°F; the space temperature is 77°F. The fan is not running. The fan switch is moved to ON, but the fan motor does not start. It is decided that the control voltage power supply should be checked first. The power supply is in the roof condensing unit on this particular installation. The technician explains to the customer the reason for leaving the building and proceeds outside.

SAFETY PRECAUTION: *The technician places a ladder against the building away from the power line entrance.*• Electrical test instruments are taken to the roof along with tools to remove the panels. The breakers are checked and seem to be in the correct ON position. The panel is removed where the low-voltage terminal block is mounted. A voltmeter check shows there is line voltage but no control voltage.

What is the likely problem and the recommended solution?

SAFETY PRECAUTION: *All troubleshooting by students or inexperienced people should be performed under the supervision of an experienced technician. If you do not know whether a situation is safe, consider it unsafe.*•

SUMMARY

- The superheat for an operating evaporator coil is used to prove coil performance.
- Standard air-conditioning conditions for rating equipment are 80°F return air with a humidity of 50% when the outside temperature is 95°F.
- The typical customer operates the equipment at 75°F return air with a humidity of 50%. This is the condition on which the normal pressures and temperatures in a unit are based.
- A high-efficiency evaporator normally has a boiling temperature of 45°F.
- Gauges fastened to the high side of a system are used to check the head pressure. The head pressure is a result of the refrigerant condensing temperature.
- The condensing refrigerant temperature has a relationship to the medium to which it is giving up heat.
- A standard-efficiency unit normally condenses the refrigerant at no more than 30°F higher than the air to which the heat is rejected.
- A high-efficiency condensing unit normally condenses the refrigerant at a temperature as low as 20°F warmer than the air used as a condensing medium.
- *Approach temperature,* or *temperature split,* are terms used to describe the temperature difference between two different heat exchange mediums, for example, the return-air temperature and coil boiling temperature of a refrigerant evaporator.
- *Temperature difference* is a term used to describe the difference between the inlet and outlet temperature of a heat exchanger, for example, the inlet air and the outlet air of an evaporator.
- An electronic thermometer may be used to check wet-bulb (using a wet wick on one bulb) and dry-bulb temperatures.
- The condenser has three functions: to take the superheat out of the discharge gas, to condense the hot gas to a liquid, and to subcool the refrigerant.
- A typical condenser may subcool the refrigerant 10°F to 20°F lower than the condensing temperature.
- Two types of metering devices are normally used on air-conditioning equipment: the fixed bore (orifice or capillary tube) and the TXV.
- The fixed-bore metering device regulates refrigerant flow by the pressure difference between the inlet and outlet of the device, which do not vary in size.
- The TXV modulates or throttles the refrigerant to maintain a constant superheat.
- To correctly charge an air-conditioning unit, the technician must follow the manufacturer's recommendations.
- The TXV system normally has a sight glass in the liquid line to aid in charging. A subcooling temperature check may be used when no sight glass is available.
- **SAFETY PRECAUTION:** *Before checking a unit electrically, the proper voltage and the current draw of the unit should be determined.*•
- The main electrical power panel may be divided into many circuits. The air-conditioning system normally uses two separate circuits for a split system and one circuit for a package system.
- When a hot compressor is started, assume that the system is low in refrigerant. A cylinder of refrigerant should be connected before starting so that refrigerant may be added before the compressor shuts off again.

REVIEW QUESTIONS

1. Before installing a gauge on the high-pressure side of a system, you should do which of the following?
   A. Turn on the system.
   B. Turn off the system.
   C. Adjust the system to a neutral position.
   D. Have a cylinder approved by the DOT nearby.
2. Capacitors should be shorted with a(n) _____ before checking with an ohmmeter.
3. The high- and low-side pressures on an operating air-conditioning system can be converted to the _____ and _____ temperatures by using a temperature/pressure relationship chart.
4. Why do most air-conditioning systems not need a defrost system?
5. A typical standard-efficiency evaporator under standard conditions will operate at a temperature of
   A. 30°F.
   B. 40°F.
   C. 50°F.
   D. 60°F.
6. The typical temperature difference between the entering air and the boiling refrigerant on a standard air-conditioning evaporator is _____°F.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

7. When the ambient outside air temperature is 95°F and the unit is a high-efficiency unit, the lowest condensing refrigerant temperature when the unit is operating properly is
   A. 110°F.
   B. 115°F.
   C. 120°F.
   D. 125°F.
8. When the outside ambient air temperature is 90°F, the temperature of the condensing refrigerant in a standard-efficiency unit should be approximately
   A. 120°F.
   B. 130°F.
   C. 140°F.
   D. 150°F.
9. If a condensing pressure is 260 psig for R-22, the condensing temperature will be
   A. 110°F.
   B. 120°F.
   C. 130°F.
   D. 140°F.
10. How is high efficiency accomplished in an air-conditioning condensing unit?
11. True or False: When troubleshooting a small system, the first step is to attach the high- and low-pressure gauges.
12. The suction gas may have a high superheat if the unit has a(n) _____ charge.
13. If the suction pressure is low and the suction line is warm, the system has a _____ evaporator.
    A. full
    B. starved
14. What electrical test instrument is used to measure continuity in a compressor winding?
15. What electrical test instrument is used to measure the current draw of a compressor?
16. Most condensers will subcool the refrigerant to between _____°F below the condensing temperature of the refrigerant.
    A. 0 and 5
    B. 5 and 10
    C. 10 and 20
    D. 20 and 30
17. What are two types of fixed-bore metering devices?
18. If no crankcase heat is at the compressor, what may happen to the refrigerant charge?
19. What is the purpose of the internal overload protector in the compressor motor?
20. If a condenser circuit breaker is tripped, you should
    A. reset it.
    B. check the suction pressure.
    C. check the high-side pressure.
    D. perform a resistance check of the compressor section.

Unit 42 Heat Gains and Heat Losses in Structures

Unit 43 Air Source Heat Pumps

Unit 44 Geothermal Heat Pumps

UNIT 42

HEAT GAINS AND HEAT LOSSES IN STRUCTURES

OBJECTIVES

After studying this unit, you should be able to

- explain the concepts of heat gain and heat loss.
- explain the importance of determining the heat gain and heat loss of a structure.
- determine the factors that go into heat gain and heat loss calculations.
- use appropriate charts and tables to determine the design heating and cooling temperatures for a particular city.
- explain how cooling and heating temperature differentials are determined using design indoor and outdoor temperatures.
- explain what is meant by a U-value and an R-value.
- explain how to use charts and tables to determine the U-value for particular building construction elements.
- explain the difference between net wall area and gross wall area.
- explain how the heat load on a structural panel is affected by the orientation of the panel.
- calculate the heat gain and heat loss of a simple structure.

42.1 INTRODUCTION TO HEAT GAIN AND HEAT LOSS

With many things in life, bigger is better. We want bigger houses, bigger boats, bigger paychecks, and bigger families. But, as we get bigger and bigger, the problems associated with these things get bigger as well. Air-conditioning and heating equipment is no exception. When it comes to sizing air-conditioning and heating equipment, however, bigger is definitely not better. When we refer to "bigger," we are referring to the capacity of the system to move Btus either into or out of a structure. The use of oversized equipment has many negative effects that more than outweigh the perceived benefits of larger equipment. Larger equipment, in general,

- costs more to manufacture, purchase, install, and maintain,
- costs more to operate because of larger motors and other electrical loads,
- requires larger air distribution systems which cost more than smaller ones, and
- will cool or heat the space quicker, resulting in more frequent system starts and stops.

Oversized air-conditioning equipment will cool the space faster. This results in more system off-time, decreasing the dehumidification effect that air-conditioning systems have on the occupied space. Decreased dehumidification leads to higher relative humidity in the occupied space. This leads to an increase in the possibility of mold growth in the space. Mold growth in the space puts the contractor at increased risk of litigation as a result of mold-related illness.

Undersizing equipment is not desirable either. The obvious result of an undersized heating or cooling system is that the equipment will not be able to maintain the space at the desired temperature at certain times of the season. If, during the summer months, the temperatures are much lower than average, an undersized air-conditioning system will be able to cool the space down to acceptable levels. If, however, the temperatures are higher than average, the system will not be able to handle the heat load on the structure. A similar situation arises with undersized heating equipment.

So, in order to make certain that the heating and cooling equipment that is selected for use in a structure is the right size, we need to know how much heat the structure loses in the cooler heating months and how much heat the structure gains in the warmer cooling months. In order to do this, a series of calculations must be made. These calculations are called heat gain and heat loss calculations. These calculations determine the amount of heat lost and gained by means of the envelope or shell of the structure, **Figure 42.1**. In simple terms, the envelope separates the inside of the structure from the outside. In the summer months heat leaks into the house, while in the winter, heat leaks out of the house.

Heat gain and heat loss calculations are important parts of the system design process. When these calculations are performed accurately, the equipment capacities selected will properly match the structure, helping to ensure that

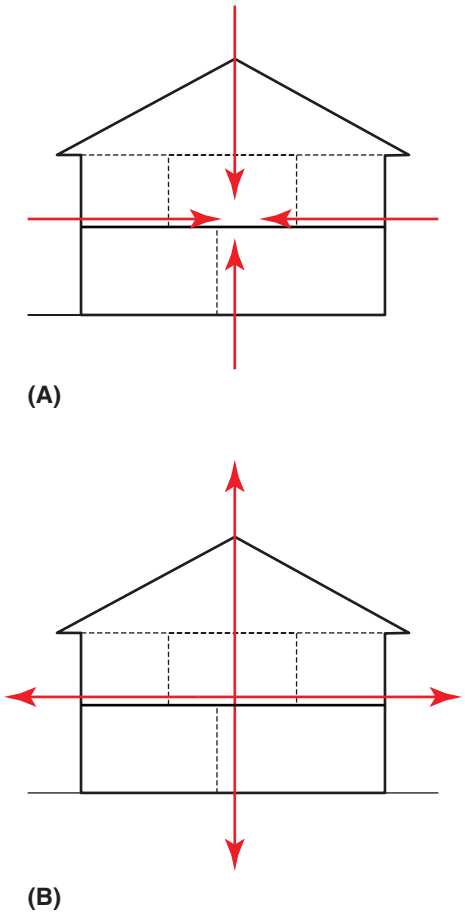
Figure 42.1 (A) In the warmer summer months, heat leaks into the structure. (B) In the colder winter months, heat leaks out of the structure.



the desired levels in the structure will be maintained over a large range of operating conditions. As was mentioned in Unit 35, "Comfort and Psychrometrics," comfort is the delicate balance between air temperature, relative humidity, air cleanliness, and air movement. Properly selected and installed equipment is, therefore, the basis for providing comfort. Quite often, comfort-related issues can be traced back to the system, so it's important to start out on the right foot with the right equipment. *Governmental agencies have stressed the importance and the environmental benefits of properly sized heating and cooling equipment. In order to qualify for many government rebates for new heating and cooling equipment, proof of an accepted heat gain and/or heat loss calculation must be provided.* Refer to the next paragraph for more about "acceptable" methods for estimating the heat gain and heat loss of a structure. It is very important to note that the material in this unit is not intended to replace industry-accepted methods for performing these calculations, but it will provide the reader with the concepts and methods involved in making them.

42.2 METHODS TO DETERMINE THE HEAT GAIN AND HEAT LOSS OF A STRUCTURE

There are many methods that are commonly used for estimating the heat gain and heat loss of a structure. Most of these methods rely on rules of thumb that provide very quick results and, as a result, do not provide very accurate estimations of the needs of the particular structure. When performing a heat gain or heat loss calculation, a few things must be taken into account:

- How accurate do the results have to be?
- How critical does the temperature control need to be?
- How critical does the humidity control need to be?
- Is an equipment rebate being applied for?

The most basic heat gain and heat loss calculations are based solely on the area or volume of the space being conditioned. For example, an air-conditioning system might be sized at so many Btus per square foot or so many Btus per cubic foot, **Figure 42.2**. These down-and-dirty, cookie-cutter methods do not take into account the geographic location of the structure; the construction materials used; the slope of the roof; the number of windows, doors, and other construction elements; or the orientation (north, south, east, or west) of the structure.

Some equipment manufacturers provide single-page forms that can be used to provide a general idea of the equipment size needed. These forms are typically much easier to complete than are other industry-accepted methods. If rebates are being applied for, it is important to check with the agency for a list of calculation methods that are acceptable.

The most popular method for determining the heat gain and heat loss of a residential structure is to use Manual J, **Figure 42.3**. Manual J is prepared by the Air Conditioning Contractors of America, ACCA, and is among the most comprehensive methods of determining the heating and cooling needs of residential structures. Manual J is available in both

abridged and unabridged versions. The abridged version can be used for most residential applications without sacrificing accuracy.

Whatever method is ultimately used to determine the heat gain and heat loss values for the project, it should be approved nationally. It might be necessary for a contractor or system designer to justify or defend the equipment selection process in court. If it is suspected that the equipment is responsible for structural damage, mold-related issues, or health-related problems, having a properly completed, industry-accepted heat gain or heat loss report will prove invaluable.

42.3 INDOOR AND OUTDOOR DESIGN CONDITIONS FOR HEATING AND COOLING

One important factor in determining the heat gain and heat loss of a structure is knowing the temperature difference between the inside and the outside of the structure. As this temperature differential, TD, increases, the rate of heat transfer from one side of the structure to the other will increase. Similarly, as this temperature differential decreases, the rate of heat transfer from one side of the structure to the other will decrease.

Consider the internal wall of a house that separates the hallway from a bedroom. This wall or panel has 70°F air on both sides. The heat transfer through the wall will be zero, since there is no temperature difference across the panel, **Figure 42.4**. Now consider an exterior wall of a house in the summer. The indoor house temperature is 75°F and the outside air temperature is 90°F. There will obviously be heat flowing through the wall since there is a 15°F TD across the panel, **Figure 42.5**. Now consider the same wall in the middle of the winter. The indoor house temperature is 70°F and the outside air temperature is 0°F. Now, the rate of heat transfer through the wall will be much higher, because of the 70°F TD. In addition, the heat will be moving in the opposite direction, **Figure 42.6**.

Figure 42.4 No heat transfer takes place through a wall or panel that has no temperature differential across it.

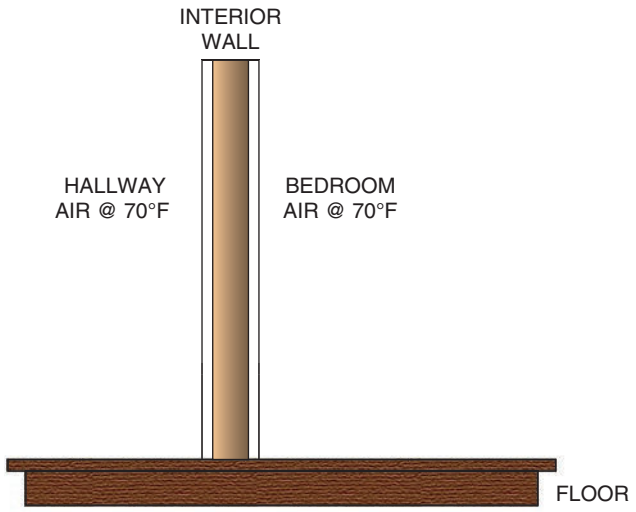

Figure 42.5 This wall has a temperature difference of 15 degrees across it, so heat will enter the structure since the outside air temperature is higher than the indoor temperature.

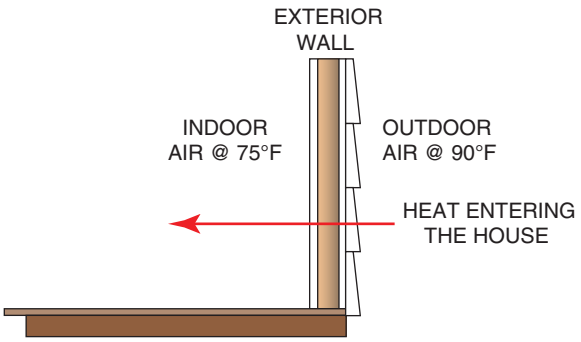

Figure 42.6 This wall has a temperature difference of 70 degrees across it, so heat will leak from the structure since the indoor air temperature is higher than the outside temperature.

Since the temperature on both sides of an exterior wall or panel is needed to help determine how much heat is entering or leaving the structure, we need to know something about the expected indoor temperatures as well as the expected outdoor temperatures in different geographic regions at different times of the year. Typically, the design indoor temperatures used for heat gain and heat loss calculations are as follows:

- Indoor design temperature for the heating season: 70°F
- Indoor design temperature for the cooling season: 75°F

Determining the design outdoor temperature requires the use of a table similar to that shown in **Figure 36.13** in Unit 36, "Refrigeration Applied to Air-Conditioning." Although tables that are prepared by different organizations will present data differently, the information, for the most part, is the same. For example, when determining the design outdoor temperature for cooling, ACCA Manual J provides one column, the 1% column, while the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) table provides three temperature columns: the 1% column, the 2.5% column, and the 5% column. Since most system designers use the ASHRAE 2.5% column for sizing cooling equipment, the ASHRAE 2.5% information is the same data that are included in the ACCA Manual J 1% column. To clarify this idea, a simplified comparison for Nogales, Arizona, and Modesto, California, is shown in **Figure 42.7**. Notice that the ACCA 99%–1% values correspond to the ASHRAE 97.5%–2.5% values.

To determine the temperature differentials for heating and cooling equipment in Nogales, Arizona, we would use the data from the table and the indoor design temperatures to get:

$$\text{Cooling Design TD} = \text{Outdoor Design Temperature} - \text{Indoor Design Temperature}$$
$$\text{Cooling Design TD} = 96°\text{F} - 75°\text{F}$$
$$\text{Cooling Design TD} = 21°\text{F}$$
$$\text{Heating Design TD} = \text{Indoor Design Temperature} - \text{Outdoor Design Temperature}$$
$$\text{Heating Design TD} = 70°\text{F} - 32°\text{F}$$
$$\text{Heating Design TD} = 38°\text{F}$$

For systems that will be installed in Modesto, California, we would use the data from the table and the indoor design temperatures to get:

$$\text{Cooling Design TD} = \text{Outdoor Design Temperature} - \text{Indoor Design Temperature}$$
$$\text{Cooling Design TD} = 98°\text{F} - 75°\text{F}$$
$$\text{Cooling Design TD} = 23°\text{F}$$
$$\text{Heating Design TD} = \text{Indoor Design Temperature} - \text{Outdoor Design Temperature}$$
$$\text{Heating Design TD} = 70°\text{F} - 30°\text{F}$$
$$\text{Heating Design TD} = 40°\text{F}$$

For a system that is being installed in Central Islip (Long Island), New York, with design cooling and heating temperatures of 85°F and 15°F, respectively, the cooling design TD would be 10°F (85°F − 75°F), while the heating design TD would be 55°F (70°F − 15°F). In a colder climate such as Big Rapids, Michigan, which has design cooling and heating temperatures of 87°F and 4°F, respectively, the cooling design TD would be 12°F (87°F − 75°F), while the heating design TD would be 66°F (70°F − 4°F).

42.4 U-VALUES AND R-VALUES

In addition to knowing the design indoor and outdoor temperatures for the structure, information about the construction materials used is also needed. The construction materials will have a major effect on the rate of heat transfer through the structural envelope. One of the most commonly used characteristics of building construction materials is the R-value. The R-value is typically used to rate the thermal resistance of insulation materials. The higher the R-value, the harder it is for heat to pass through the material. The R-values for some common building materials are shown in **Figure 42.8.** If the wall of a structure is made up of a number of different materials, the total R-value will be the sum of all of the individual R-values that make up the wall.

Consider a wall that is constructed from 4" brick, has 5/8" drywall on the inside surface, and has 3/4" plywood sheathing and insulating board-backed aluminum siding

Figure 42.7 For the most part, ACCA 99% and 1% values correspond to the ASHRAE 97.5% and 2.5% values.

LOCATION	ELEVATION	LATITUDE	ASHRAE HEATING 97.5% DRY-BULB	ACCA HEATING 99% DRY-BULB	ASHRAE COOLING 2.5% DRY-BULB	ACCA COOLING 1% DRY-BULB	DESIGN GRAINS @ 50% RELATIVE HUMIDITY

Figure 42.8 The R-values for some commonly used construction materials.

MATERIAL	R-VALUE	MATERIAL	R-VALUE
4″ Common Brick	0.80	Fiberglass Blown Insulation (attic)	2.2-4.3 per inch
4″ Brick Face	0.44	Fiberglass Blown Insulation (wall)	3.7-4.3 per inch
4″ Concrete Block	0.80	Cellulose Blown Insulation (attic)	3.13 per inch
8″ Concrete Block	1.11	Cellulose Blown Insulation (wall)	3.7 per inch
12″ Concrete Block	1.28	3/4″ Plywood Flooring	0.93
Lumber (2 x 4)	4.38	5/8″ Particleboard (Underlayment)	0.82
Lumber (2 x 6)	6.88	3/4″ Hardwood flooring	0.68
1/2″ Plywood Sheathing	0.63	Linoleum Tiles	0.05
5/8″ Plywood Sheathing	0.77	Carpet with fibrous pad	2.08
3/4″ Plywood Sheathing	0.94	Carpet with rubber pad	1.23
1/2″ Hardboard Siding	0.34	Wood Door (hollow core)	2.17
5/8″ Plywood Siding	0.77	Wood Door (1.75″ solid)	3.03
3/4″ Plywood Siding	0.93	Wood Door (2.25″ solid)	3.70
Hollow-backed aluminum siding	0.61	Single pane windows	0.91
Insulating board-backed aluminum siding	1.82	Single pane windows w/storm	2.00
Insulating board-backed aluminum siding (foil-backed)	2.96	Double pane windows with 0.25″ air space	1.69
1/2″ Drywall	0.45	Double pane windows with 0.50″ air space	2.04
5/8″ Drywall	0.56	Triple pane windows with 0.25″ air space	2.56
Fiberglass Batt Insulation	3.14 – 4.3 per inch	Asphalt Shingles	0.44
Rock Wool Batt Insulation	3.14 – 4.0 per inch	Wood Shingles	0.97

Source: ASHRAE manuals and ACCA Manual J charts

(foil-backed) on the outside, **Figure 42.9**. We can calculate the R-value for the wall by adding up the R-values of the materials:

4" Brick:	R-value = 0.80
5/8" Drywall:	R-value = 0.56
3/4" Plywood sheathing:	R-value = 0.94
Hollow-backed aluminum siding:	R-value = 2.96
	Total R-value = 5.26

Another characteristic of building construction materials is the U-value. The U-value describes the thermal conductivity of a material. The higher the U-value, the easier it is for heat to pass through the material. When designing a house, for example, it would be a good idea to use construction materials with high R-values and low U-values. The R-value and the U-value are inverses of each other. If a material has an R-value of 30, then the corresponding U-value will be 0.033, which is 1/30. In the example provided above, the U-value of the wall would be 0.19, which is 1/5.26.

The units of the U-value are Btu/h/°F/ft^2, or Btu per hour per degree Fahrenheit per square foot. This means that if the U-value of a material is 0.19, it will let 0.19 Btu of heat energy pass through each square foot of the material if the TD across the material is 1°F. The next section will provide some more numerical examples. **NOTE:** *The published R-value for insulation is very rarely indicative of the material's actual ability to restrict heat transfer. As the material is compressed, the R-value of the material decreases. R-19 batt-type cavity insulation, for example, will have an R-value of 19 at a thickness of 6.5 inches. Since the space in a 2 × 6 wall cavity is only 5.5 inches,*

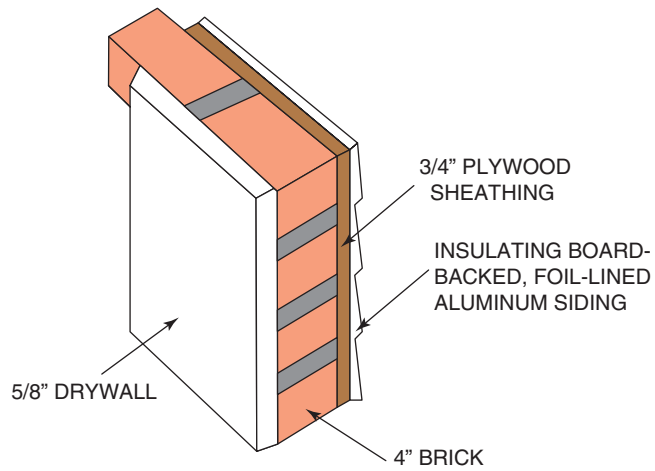
Figure 42.9 Illustration of a sample wall composition.



the insulation will be compressed somewhat in order to fit in the wall cavity and the R-value will drop to roughly 16.

42.5 INTRODUCTION TO HEAT GAIN AND HEAT LOSS CALCULATIONS

Up to this point, we have discussed the basic concepts that go into a heat gain or heat loss calculation. We will now take a look at some examples to provide some more insight into the calculation process.

Example 1 Consider the wall from **Figure 42.9**. If the wall is 8 ft high and 20 ft long, how much heat will pass through the wall if the TD is 20 degrees?

Solution: In general, the rate of heat transfer through a wall will be determined by

$$Q = \text{U-value} \times TD \times \text{Area}$$

where

Q is the quantity of heat, in Btu/h
U-value is the U-value of the wall
TD is the temperature differential across the wall
Area is the area of the wall

By plugging the values into the formula, we will get:

$$Q = \text{U-value} \times TD \times \text{Area}$$
$$Q = 0.19 \times 20^\circ F \times (8 \times 20)\ ft^2$$
$$Q = 0.19 \times 20^\circ F \times 160\ ft^2$$
$$Q = 608\ Btu/h$$

Example 2 Consider a single-pane window with a storm. If the window is 4 ft high and 6 ft long, how much heat will pass through the window if the TD is 30 degrees?

Solution: The U-value of the window can be found by first looking up the R-value of the window in **Figure 42.8**. Since the R-value is 2.00, the U-value is 0.5.

By plugging the values into the formula, we will get:

$$Q = \text{U-value} \times TD \times \text{Area}$$
$$Q = 0.5 \times 30^\circ F \times (4 \times 6)\ ft^2$$
$$Q = 0.5 \times 30^\circ F \times 24\ ft^2$$
$$Q = 360\ Btu/h$$

42.6 ELEMENTS OF STRUCTURAL HEAT LOSS (HEATING MODE)

When calculating the heat loss of a structure, it is necessary to take into account the entire envelope and all the contact the envelope has with the outside. Heat losses from the conditioned space can occur in a number of ways, including:

- Through exposed (exterior) walls
- Through windows and doors
- Through roofs
- Through ceilings to unconditioned attics or ceiling cavities
- Through partition panels
- Through below-grade (underground) walls
- Through slab and basement floors
- Through floors located above unconditioned spaces
- Duct losses to attics, ceiling cavities, and other unconditioned spaces
- Through cracks, openings, and deficiencies in structure

The total heat loss for a structure is simply the sum of the heat losses experienced by all of the construction elements that make up a particular structure.

HEAT LOSS THROUGH EXPOSED WALLS

The walls of a structure make up a large portion of the structural envelope. Walls account for a large percentage of the total heat loss of a structure, so it is very important to have accurate information regarding the construction materials used to fabricate them. Frame houses commonly have either 2×4 or 2×6 construction with insulation in between the wall studs. When calculating heat loss, it is important to know not only what lumber the house was framed with but also the R-value of the insulation. The size of the lumber can be determined a number of different ways. including:

- Blueprint information
- Measuring the thickness of the wall
- Inspection of the attic or basement
- Measuring through an electrical outlet or switch opening

Probably the easiest way to determine what size lumber was used to frame a house is to inspect the blueprint, if available. If the blueprint is not handy, an open window and a tape measure will help. The thickness of the wall will be the width of the window minus any moldings and other construction elements, such as drywall, paneling, shingles, and sheathing.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

It might be possible to visually inspect the lumber from the attic or basement, depending on the construction of the house. Another possible method for determining the size of the lumber used for framing is to access the wall cavity through an electrical switch or outlet box. Be sure to disconnect the power to the circuit before removing the switch or receptacle cover. Gently insert a blunt, nonmetallic object such as a paint stirrer or unsharpened pencil in the gap between the electric box and the drywall until it reaches the back end of the wall cavity.

The R-value of the insulation used can be determined by visual inspection or by determining its value based on the size of the studs that were used for construction. For example, if the house was constructed from 2 × 4 lumber and is insulated with fiberglass batt insulation, the R-value of the insulation be estimated to be between 10.15 and 13.3. This is because a 2 × 4 is 3.5 in. wide and fiberglass batt-type insulation has an R-value that ranges from 2.9 to 3.8 per inch. From this information, it is very likely that the insulation in the wall has an R-value of R-13, since R-13 is among the most common insulation values. Similarly, a wall framed with 2 × 6 lumber will likely have R-19 insulation if fiberglass batting has been used.

The insulation and studs are not the only components that make up a wall. In addition to these items, sheathing, siding, vapor barriers, and drywall are also used to create the final product. To make it easier to determine the values needed for calculations, tables are available that allow the user to simply look up the wall type and construction and obtain the needed values, **Figure 42.10**. So, if a house is framed with 2 × 6 wood studs and has board insulation with an R-value of R-6 and insulation with an R-value of R-19, the U-value for the wall will be 0.049.

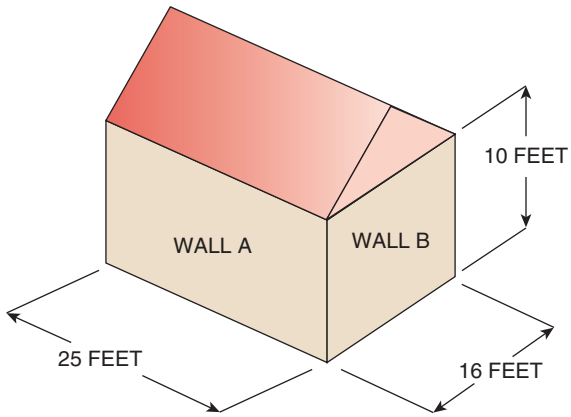
GROSS WALL AREA. *Gross wall area* is a term that is used to describe the area of a wall before any doors or windows are cut into it. The gross wall area of the wall in Example 1 in Section 42.4 is 160 ft², which is simply the height of the wall multiplied by the width of the wall. Consider the house in **Figure 42.11**, which has no windows or doors. The gross wall area of Wall A is 250 ft², while the gross wall area of Wall B is 160 ft² (ignoring the triangular portion of the wall in the attic).

Figure 42.10 The U-values for some exterior walls.

WALL CONSTRUCTION	STUD SIZE (WOOD)	BOARD INSULATION	INSUALATION R-VALUE	U-VALUE
Frame	2 x 4	R-2	R-11	0.086
Frame	2 x 4	R-2	R-13	0.081
Frame	2 x 4	R-4	R-11	0.073
Frame	2 x 4	R-4	R-13	0.069
Frame	2 x 4	R-6	R-11	0.064
Frame	2 x 4	R-6	R-13	0.060
Frame	2 x 6	R-2	R-15	0.077
Frame	2 x 6	R-2	R-19	0.063
Frame	2 x 6	R-4	R-15	0.066
Frame	2 x 6	R-4	R-19	0.055
Frame	2 x 6	R-6	R-15	0.058
Frame	2 x 6	R-6	R-19	0.049

Source: ASHRAE manuals and ACCA Manual J charts

Figure 42.11 Gross wall area is determined by multiplying the length and the width of the wall. The gross wall area of Wall A is 250 ft² and the gross wall area of Wall B is 160 ft².



NET WALL AREA. *Net wall area* is a term that is used to describe the area of a wall after the doors and windows are cut into it. The net wall area can be expressed mathematically as:

Net Wall Area = Gross Wall Area − Door Area − Window Area − Area of Other Components

Let's take a look at the wall in **Figure 42.12**. This wall has a gross wall area of 300 ft², which is simply the height of the wall multiplied by the width of the wall. To find the net wall area, we would subtract the area of the window and door. Using the formula for net wall area, we get:

Net Wall Area = Gross Wall Area − Door Area − Window Area
Net Wall Area = 300 ft² − Door Area − Window Area
Net Wall Area = 300 ft² − (3' × 7') − (6' − 3')
Net Wall Area = 300 ft² − 21 ft² − 18 ft²
Net Wall Area = 300 ft² − 39 ft²
Net Wall Area = 261 ft²

Figure 42.12 The net wall area is the gross wall area minus the area of all windows and doors in the wall. The net wall area for this wall is 261 ft².

HEAT LOSS THROUGH WINDOWS AND DOORS

The method used to determine the heat loss through windows and doors is basically the same as that used to determine the heat loss through the wall discussed earlier. For the wall in **Figure 42.12**, the construction materials are as follows:

Wall:	2 × 6 studs, R-19 cavity insulation, R-4 board insulation
Window:	Double pane with 0.50" of air space
Door:	2.25" solid wood
TD across panel:	40°F

To determine the heat loss via the construction materials, the U-values are needed. These values are obtained as follows:

Wall U-value:	0.055 (from **Figure 42.10**)
Window U-value:	0.49 (from **Figure 42.8** and using U = 1/R, 1/2.04 = 0.49)
Door U-value:	0.27 (from **Figure 42.8** and using U = 1/R, 1/3.70 = 0.27)

The heat transfer rate through the window is found as follows:

$$Q = \text{U-value} \times TD \times \text{Area}$$
$$Q = 0.49 \times 40°F \times (3 \times 6)\ ft^2$$
$$Q = 0.49 \times 40°F \times 18\ ft^2$$
$$Q = 352.8\ Btu/h$$

Similarly, the heat transfer rate through the door is found as follows:

$$Q = \text{U-value} \times TD \times \text{Area}$$
$$Q = 0.27 \times 40°F \times (3 \times 7)\ ft^2$$
$$Q = 0.27 \times 40°F \times 21\ ft^2$$
$$Q = 226.8\ Btu/h$$

We can then determine the heat loss for the entire wall by using the following:

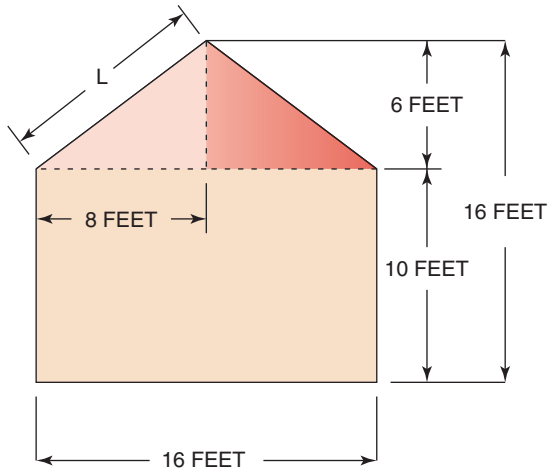
$$Q_{\text{Entire Wall}} = Q_{\text{Net Wall}} + Q_{\text{Window}} + Q_{\text{Door}}$$
$$Q_{\text{Entire Wall}} = [0.055 \times 261\ ft^2 \times 40°F] + Q_{\text{Window}} + Q_{\text{Door}}$$
$$Q_{\text{Entire Wall}} = 574.2\ Btu/h + 352.8\ Btu/h + 226.8\ Btu/h$$
$$Q_{\text{Entire Wall}} = 1153.8\ Btu/h$$

HEAT LOSS THROUGH ROOFS

A great deal of heat is lost through the roof. The calculation to determine the heat loss through the roof is similar to the method used earlier, but calculating the area of the roof involves a little geometry. If the roof in **Figure 42.11** has its peak at a height of 16 ft from the ground, we can calculate the length, L, of the sloped portions of the roof, **Figure 42.13**, by using Pythagorean Theorem as follows:

Height of triangle:	6 ft (16-ft peak height − 10-ft wall height)
Base of triangle:	8 ft (one half of the width of the house)

Figure 42.13 Geometry showing how to calculate the "L" dimension of this roof.



So, using the Pythagorean Theorem, we get:

$$L^2 = \text{Height}^2 + \text{Base}^2$$

or

$$L = \sqrt{\text{Height}^2 + \text{Base}^2}$$
$$L = \sqrt{6^2 + 8^2}$$
$$L = \sqrt{36 + 64}$$
$$L = \sqrt{100}$$
$$L = 10\ ft$$

NOTE: *It could also be noted that the length "L" is the hypotenuse of a 3-4-5 triangle, where one side is 6 (3 × 2) and the second is 8 (4 × 2). The hypotenuse, L, is therefore 10 (5 × 2).* • Since the house is 25 ft long, each half of the roof will be 10 ft × 25 ft, or 250 ft². So, the total area of the roof will be 500 ft². If the roof, for example has a U-value of 0.25 and the TD across the roof is 60°F, the heat loss attributed to the roof is

$$Q_{\text{Roof}} = \text{U-value} \times TD \times \text{Area}$$
$$Q_{\text{Roof}} = 0.25 \times 60°F \times 500\ ft^2$$
$$Q_{\text{Roof}} = 7500\ Btu/h$$

NOTE: *This example assumes that the roof separates the outside from the occupied space. If there is a flat ceiling located under the roof, the heat loss is calculated from the occupied space to the attic.* •

HEAT LOSS THROUGH CEILINGS TO UNCONDITIONED ATTICS OR CEILING CAVITIES

Since the basics are known, the best way to cover this is by example. Consider a house that has a footprint of 400 ft² and a ceiling is separating the occupied space from the unconditioned attic. The ceiling is insulated with R-30 insulation and the TD between the space and the attic is 60°F, **Figure 42.14**. The U-value of the ceiling will be 0.033, since

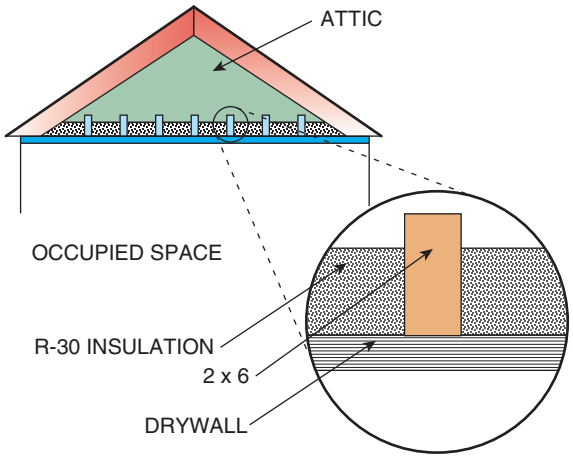
Figure 42.14 This attic is separated from the occupied space by drywall and R-30 insulation.



the U-value = 1/R. The heat loss from the structure via the ceiling can be found by:

$$Q_{Ceiling} = \text{U-value} \times \text{TD} \times \text{Area}$$
$$Q_{Ceiling} = 0.033 \times 60°\text{F} \times 400\ \text{ft}^2$$
$$Q_{Ceiling} = 800\ \text{Btu/h}$$

HEAT LOSS THROUGH PARTITION WALLS

Partition walls are walls that separate a conditioned interior space from an unconditioned interior space. The heat that is lost from the structure is determined using the same formula that has been utilized for most of this chapter, but the TD that is used is not the difference between the indoor and outdoor temperatures. Instead, the TD is the difference between the design indoor air temperature and the temperature of the air in the unconditioned space. If the outside temperature is 0°F, the indoor temperature is 70°F, and the temperature of an unheated garage is 40°F, the TD across the partition wall that separates the garage from the conditioned space is 30°F, **Figure 42.15**.

Figure 42.15 Partition walls separate a conditioned interior space from an unconditioned interior space.

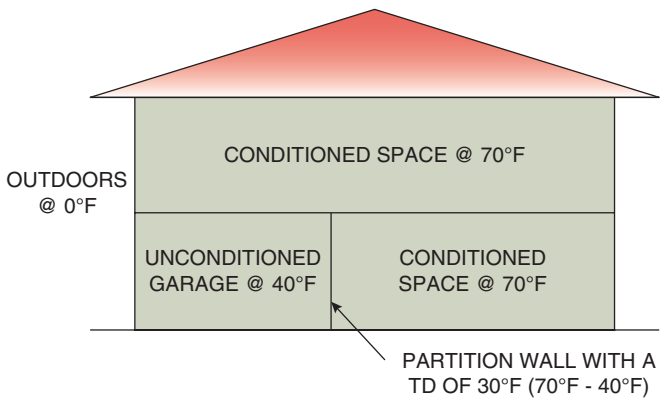


Figure 42.16 Some walls are partially above grade and partially below grade.

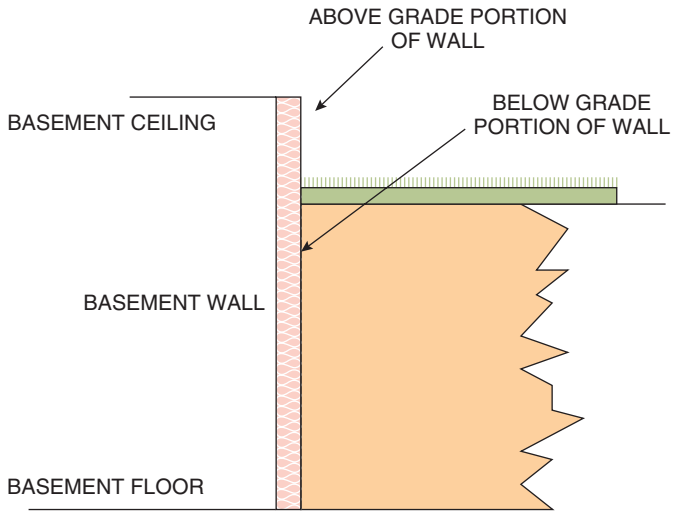

HEAT LOSS THROUGH BELOW-GRADE WALLS

The term *below grade* is used to describe walls or portions of walls that are below ground level. Some walls are partially above grade and partially below grade, **Figure 42.16**. When such is the case, the heat loss through the wall must be calculated as the sum of the heat loss from the above-grade portion of the wall and the heat loss from the below-grade portion of the wall. The U-values for the above-grade and below-grade portions of the wall vary as well.

The two important factors that affect the U-value for the below-grade portion of the wall are the materials used to construct the wall and how far below grade the floor is. The rate of heat loss through a below-grade wall decreases as the floor gets deeper into the ground. Let us take a look at a sample chart that might be used for basement walls that are made up of 8 in. of brick or stone and are framed with wood studs, **Figure 42.17**.

Let us consider a house that has a 40' × 60' footprint and a basement with a full 8′ ceiling. The basement floor is 6′ below grade and the design TD for the structure is 70°F. The basement walls are constructed of 8 in. of brick with 2 × 6 framing and R-19 insulation, **Figure 42.18**.

The heat loss through the basement walls is divided between the above-grade and below-grade portions of the wall. The above-grade portion of the walls will have a U-value of 0.069 and the below-grade portion of the walls will have a U-value of 0.043, from **Figure 42.17**. The area of the above-grade walls can be found by:

$$\text{Above-Grade Wall Area} = \text{Height of Above-Grade Wall} \times \text{Perimeter of Above-Grade Wall}$$
$$\text{Above-Grade Wall Area} = 2' \times (40' + 60' + 40' + 60')$$
$$\text{Above-Grade Wall Area} = 2' \times 200'$$
$$\text{Above-Grade Wall Area} = 400\ \text{ft}^2$$

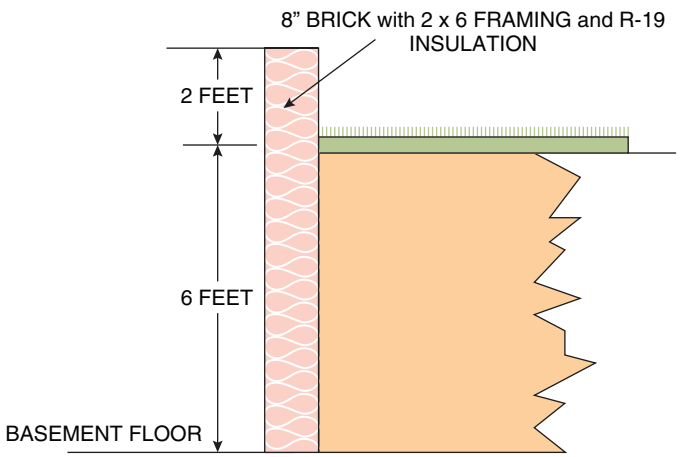
Source: ASHRAE manuals and ACCA Manual J charts

Figure 42.18 This 8-ft wall has a 2-ft portion above grade and a 6-ft portion below grade.



The heat loss through the above-grade portion of the wall is found by:

$$Q_{\text{Above-Grade Walls}} = \text{U-value} \times \text{TD} \times \text{Area}$$
$$Q_{\text{Above-Grade Walls}} = 0.069 \times 70°\text{F} \times 400\ \text{ft}^2$$
$$Q_{\text{Above-Grade Walls}} = 1932\ \text{Btu/h}$$

The heat loss through the below-grade portion of the wall is found by:

$$Q_{\text{Below-Grade Walls}} = \text{U-value} \times \text{TD} \times \text{Area}$$
$$Q_{\text{Below-Grade Walls}} = 0.043 \times 70°\text{F} \times (6 \times 200)\ \text{ft}^2$$
$$Q_{\text{Below-Grade Walls}} = 0.043 \times 70°\text{F} \times 1200\ \text{ft}^2$$
$$Q_{\text{Below-Grade Walls}} = 3612\ \text{Btu/h}$$

The total heat loss for the basement walls is the sum of the heat losses for the below-grade and above-grade walls as follows:

$$Q_{\text{Basement Walls}} = Q_{\text{Above-Grade Walls}} + Q_{\text{Below-Grade Walls}}$$
$$Q_{\text{Basement Walls}} = 1932\ \text{Btu/h} + 3612\ \text{Btu/h}$$
$$Q_{\text{Basement Walls}} = 5544\ \text{Btu/h}$$

HEAT LOSS THROUGH FLOORS LOCATED ABOVE UNCONDITIONED SPACES

Heat loss calculations performed on houses that have unconditioned basements or crawl spaces need to take into account the heat that is lost between the conditioned and unconditioned areas. Just as we addressed the concept of heat losses through partition walls a little earlier in this unit, the floors that separate conditioned from unconditioned areas act in much the same way as partition walls. The tables that are used to calculate the heat loss through a floor located over an unconditioned crawl space or basement are similar to the one shown in **Figure 42.19**.

Consider a basement that has a 40' × 60' footprint. The house has a design indoor temperature of 70°F and a design outside temperature of 10°F. The floor is insulated with R-19 blanket insulation. The calculated TD is 60°F (70°F − 10°F). Since the unconditioned basement is not as cold as the outside temperature, the TD that will be used for the calculation

Figure 42.19 Some U-values and TD values for floors that are located above unconditioned crawl spaces or basements.

FLOOR INSULATION	FLOOR U-VALUE	FLOOR TEMPERATURE DIFFERENCE (FOR SPECIFIC HEATING TEMPERATURE DIFERENTIAL, TD)								
		30°F	35°F	40°F	45°F	50°F	55°F	60°F	65°F	70°F

will be found in **Figure 42.19**. For the floor in our example, the TD that will be used is 29.1°F, which is the value that is found at the point where the R-19 floor insulation row intersects with the 60°F TD column. It can also be found from **Figure 42.19** that the U-value for the floor is 0.049. The floor loss calculation is as follows:

$$Q_{\text{Floor Over Unconditioned Basement}} = \text{U-value} \times \text{TD} \times \text{Area}$$
$$Q_{\text{Floor Over Unconditioned Basement}} = 0.049 \times 29.1°\text{F} \times 2400\ \text{ft}^2$$
$$Q_{\text{Floor Over Unconditioned Basement}} = 3422.16\ \text{Btu/h}$$

HEAT LOSS THROUGH SLAB FLOORS

Quite often, houses are built on slabs of concrete that are at ground level. These are referred to as slab-on-grade floors. A great deal of heat is lost from the edges of the slab and the heat loss is calculated using the running feet of exposed slab edge, not the area of the floor. The running feet of exposed edge is the perimeter of the slab. Insulation for the slab can be vertical or horizontal, or can be vertical insulation that turns under the slab, **Figure 42.20**. This type of construction element utilizes an F-value instead of a U-value. F-values are expressed in Btuh per running foot per degree Fahrenheit (Btuh/ft/°F) of the perimeter of a slab floor, as opposed to U-values, which are expressed in Btuh per square foot per degree Fahrenheit (Btuh/ft²/°F). An F-value table for various types of slab insulation would look similar to the table in **Figure 42.21**.

Consider a slab-on-grade floor that has a footprint of 40' × 70'. This slab is located in light, dry soil and has vertical, R-15 insulation. The TD that will be used is 60°F. The heat loss through this slab can be found by:

$$Q_{\text{Slab}} = \text{F-value} \times \text{TD} \times \text{Running Feet of Exposed Edge}$$
$$Q_{\text{Slab}} = 0.178 \times \text{TD} \times \text{Running Feet of Exposed Edge}$$
$$Q_{\text{Slab}} = 0.178 \times 60°\text{F} \times (40' + 70' + 40' + 70')$$
$$Q_{\text{Slab}} = 0.178 \times 60°\text{F} \times 220'$$
$$Q_{\text{Slab}} = 2{,}349.6\ \text{Btu/h}$$

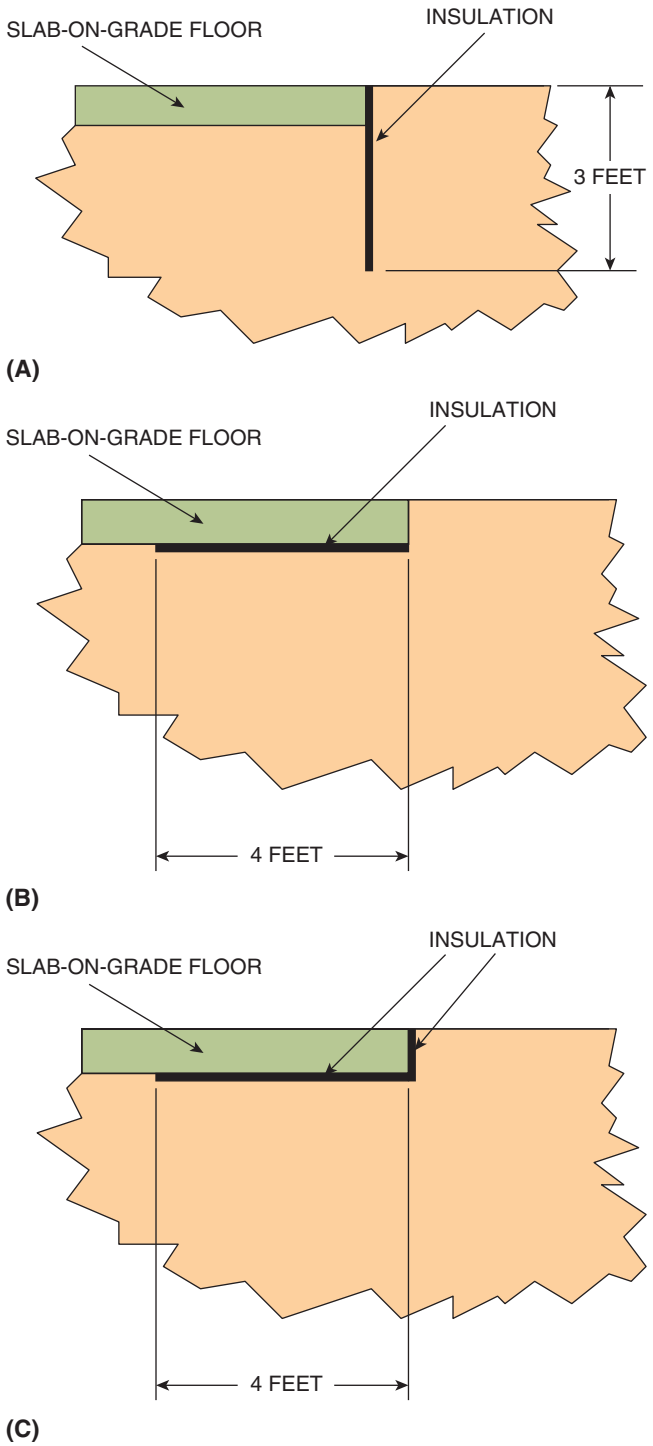
HEAT LOSS THROUGH CRACKS, OPENINGS, AND DEFICIENCIES IN STRUCTURE

No structure is completely airtight, so losses due to infiltration must be accounted for. The sensible heat formula, from Unit 35, "Comfort and Psychrometrics," is used to calculate these losses:

$$Q_{\text{Infiltration}} = 1.08 \times \text{cfm} \times \text{TD}$$

In this formula, 1.08 is a constant and the TD is the design temperature differential that has been used throughout this unit. The cfm value is an estimate of how many cubic feet of air are entering the structure each minute. This can be estimated by determining how many air changes occur each hour, abbreviated as ACH, and the internal volume of the house. The number of air changes per hour is determined from a table similar to that shown in **Figure 42.22**.

Figure 42.20 (A) Vertical insulation along the perimeter of a slab. (B) Horizontal insulation along the perimeter of a slab. (C) Vertical insulation along the perimeter of a slab that has a turn under.



To calculate the cfm, we can use the following formula:

$$\text{cfm (infiltration)} = (\text{ACH} \times \text{HOUSE VOLUME}) \div 60\ \text{min/h}$$

AIR CHANGES PER HOUR (FOR HEATING)				
	FLOOR AREA OF CONDITIONED SPACE			
CONSTRUCTION	900 – 1500	1500 – 2000	2000 – 3000	3000 and up
TIGHT	0.30	0.25	0.20	0.20
AVERAGE	0.75	0.60	0.50	0.45
LEAKY	1.70	1.45	1.15	1.00

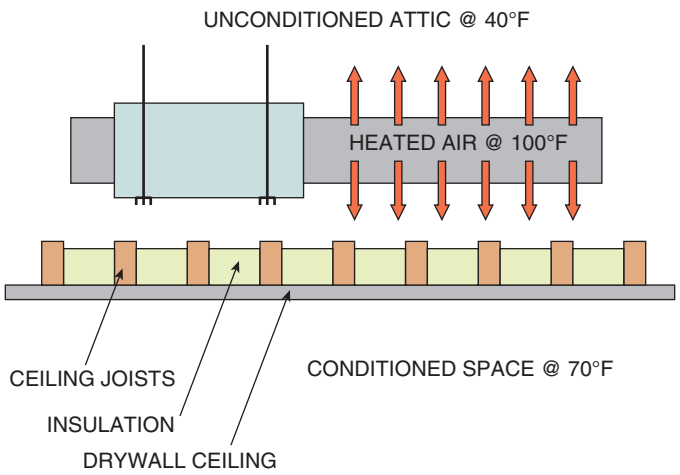
Figure 42.23 Heated air passing through ducts that are located in unconditioned spaces gives up heat to the unconditioned space.



Consider a house with the following characteristics:

- Average construction
- 2500 ft^2
- Single-story house with 8-ft ceilings
- Design TD is 60°F

From this information, we can determine that the ACH is 0.50 (from **Figure 42.22**), and that the volume of the house is 20,000 ft^3 (2500 ft^2 × 8 ft). We can then calculate the cfm of the infiltration by:

$$\text{cfm (infiltration)} = (\text{ACH} \times \text{HOUSE VOLUME}) \div 60 \text{ min/h}$$
$$\text{cfm (infiltration)} = (0.50 \times 20{,}000) \div 60$$
$$\text{cfm (infiltration)} = 167 \text{ cfm}$$

We can then determine the heat loss due to infiltration by:

$$Q_{\text{Infiltration}} = 1.08 \times \text{cfm} \times \text{TD}$$
$$Q_{\text{Infiltration}} = 1.08 \times 167 \times 60°\text{F}$$
$$Q_{\text{Infiltration}} = 10{,}821.6 \text{ Btu/h}$$

DUCT LOSSES TO ATTICS, CEILING CAVITIES, AND OTHER UNCONDITIONED SPACES

When heated air passes through ducts that are located in unconditioned spaces, heat is lost to the unconditioned space, **Figure 42.23**. The rate at which heat is lost depends on a number of factors, including the temperature of the air in the duct, the temperature of the air in the unconditioned space, and the amount of insulation on the duct. The duct losses are calculated as a percentage of the envelope load, but the percentage changes based on the conditions and location of the system. In general, duct losses are determined by the following:

$$Q_{\text{Duct Losses}} = \text{Envelope Load} \times \text{Loss Factor} \times \text{Duct Insulation Correction}$$

The envelope load is simply the sum of the individual heat losses of the structure. The heat loss factor is determined by a table similar to the one shown in **Figure 42.24**. The duct insulation correction value is determined by the duct wall

Figure 42.24 Tables used to determine heat loss factors for duct loss calculations.

HEAT LOSS FACTOR

insulation. For example, the following correction values might be found for a particular duct system type:

If the wall insulation is R-2, the duct insulation correction value is 1.48.
If the wall insulation is R-4, the duct insulation correction value is 1.15.
If the wall insulation is R-6, the duct insulation correction value is 1.00.
If the wall insulation is R-8, the duct insulation correction value is 0.93.

Consider a 2000 ft² house that has a total envelope loss of 15,000 Btu/h. The design outdoor air temperature is 0°F and the duct wall insulation is rated at R-4. The design supply air temperature to the occupied space is 110°F. The duct losses can be calculated as:

$$Q_{\text{Duct Losses}} = \text{Envelope Load} \times \text{Loss Factor} \times \text{Duct Insulation Correction}$$

$$Q_{\text{Duct Losses}} = 15{,}000 \text{ Btu/h} \times 0.25 \times 1.15$$

$$Q_{\text{Duct Losses}} = 4312.5 \text{ Btu/h}$$

42.7 ELEMENTS OF STRUCTURAL HEAT GAIN (COOLING MODE)

When calculating the heat gain of a structure, it is necessary to take into account the entire envelope and all the contact the envelope has with the outside. In addition, the occupants of the structure as well as any appliances, lighting, plants, fish tanks, and other heat/moisture-generating elements must be factored into the calculations. Since the sun creates a varying heat load on the structure as it moves across the sky based on the direction the house is facing, the orientation of the house is also a major consideration. Heat gains in the conditioned space can occur in a number of ways that include:

- Through exposed (exterior) walls
- Through doors
- Through roofs, walls, floors, and ceilings
- Through windows
- From people, appliances, lighting, and other elements
- Through cracks, openings, and deficiencies in structure
- Through duct runs through attics, ceiling cavities, and other unconditioned spaces

In summary, the heat gain on a structure is the sum of the conduction loads, the internal loads, the solar loads, and the infiltration loads. It is important to note that there is no heat gain through below-grade walls, slabs, and basement floors, so these construction elements do not need to be accounted for.

There are different methods of calculating the heat gain on a structure based on the type of house and the number of wall exposures it has. What is presented in the following sections is a general guideline to the methods and calculations used to determine the heat gain of a structure and is not intended to be a comprehensive, step-by-step procedure for obtaining an accurate heat gain calculation.

HEAT GAIN THROUGH EXPOSED (EXTERIOR) WALLS

Just as with the heat loss calculations, the heat gain through exterior walls is determined by the following formula:

$$Q = \text{U-value} \times TD \times \text{Area}$$

Since we are now dealing with a heat gain, we will add a subscript to the TD to clarify that this is the TD used to calculate the heat gain for cooling purposes:

$$Q = \text{U-value} \times TD_{\text{Cool}} \times \text{Area}$$

The TD_{Cool} is *not* necessarily the design TD that was found by determining the difference between the design outside temperature and the design indoor temperature of 75°F (Section 42.3). To determine the TD_{Cool} that will be used, a two-part chart is often needed, **Figure 42.25**.

Consider a 10' × 50' wall that has the following characteristics:

Wall:	2 × 6 studs, R-19 cavity insulation, R-5 board insulation
TD across panel:	Design TD of 20°F

From this information, we can determine that this particular wall has a U-value of 0.052 and is in Group H. We can then look up the TD_{Cool} to be used by finding the intersection point of the Group H wall and the 20°F TD to get a TD_{Cool} of 17.7.

The heat gain attributed to this wall is then found as follows:

$$Q_{\text{Wall}} = \text{U-value} \times TD_{\text{Cool}} \times \text{Area}$$

$$Q_{\text{Wall}} = 0.052 \times 17.7°\text{F} \times (10 \times 50) \text{ ft}^2$$

$$Q_{\text{Wall}} = 0.052 \times 17.7°\text{F} \times 500 \text{ ft}^2$$

$$Q_{\text{Wall}} = 460.2 \text{ Btu/h}$$

HEAT GAIN THROUGH DOORS

The same idea is applied to doors. Although there are no group numbers associated with doors, the TD_{Cool} concept is used here. The table that is used to find door-related information is similar to **Figure 42.26**.

Let's take a look a 3' × 7' solid-core wood door without a storm that is exposed to a design cooling TD of 20°F. This door has a U-value of 0.39 and a TD_{Cool} of 31°F. We can find the heat gain through this door as follows:

$$Q_{\text{Door}} = \text{U-value} \times TD_{\text{Cool}} \times \text{Area}$$

$$Q_{\text{Door}} = 0.39 \times 31°\text{F} \times (3 \times 7) \text{ ft}^2$$

$$Q_{\text{Door}} = 0.39 \times 31°\text{F} \times 21 \text{ ft}^2$$

$$Q_{\text{Door}} = 253.89 \text{ Btu/h}$$

HEAT GAIN THROUGH ROOFS, WALLS, FLOORS, AND CEILINGS

The same method that was used to calculate the heat gain through a door is applied to roof, walls, floors, and ceilings. There are no group numbers associated with these construction elements, but the TD_{Cool} concept is used here as well. The table that is used to find ceiling information is similar to **Figure 42.27**, which shows some information for insulated ceilings under an attic. Probably one of the most important things to keep in mind when performing a heat gain calculation on a

Figure 42.27 Table to obtain the U-values and temperature differentials that are used to calculate the heat gains through ceilings.

		DESIGN COOLING TD				
CEILING INSULATION	U-VALUE	10°F	15°F	20°F	25°F	30°F
R-7	0.112	35.0	40.0	45.0	50.0	50.0
R-11	0.081	35.0	40.0	45.0	50.0	50.0
R-15	0.061	35.0	40.0	45.0	50.0	50.0
R-19	0.049	35.0	40.0	45.0	50.0	50.0
R-21	0.044	35.0	40.0	45.0	50.0	50.0
R-30	0.032	35.0	40.0	45.0	50.0	50.0

structure is to use the proper charts and tables. Many charts and tables look similar to each other but have significant differences that can dramatically alter the results. It is also important to consider the fact that roofs and ceilings may not have the same area as the footprint of the structure if they are not parallel to the floor. As in the earlier heat loss example of a sloped roof, some geometry is needed to determine the actual area of the panel.

Let's take a look a 25' × 40' ceiling that is located under an attic. The ceiling has R-19 insulation and a design cooling TD of 15°F. This ceiling has a U-value of 0.049 and a TD_{Cool} of 40°F. We can find the heat gain through this ceiling as follows:

$$Q_{Ceiling} = \text{U-value} \times TD_{Cool} \times \text{Area}$$
$$Q_{Ceiling} = 0.049 \times 40°F \times (25' \times 40')\ ft^2$$
$$Q_{Ceiling} = 0.049 \times 40°F \times 1000\ ft^2$$
$$Q_{Ceiling} = 1960\ Btu/h$$

HEAT GAIN THROUGH WINDOWS

One of the major sources for heat gain on a structure is the windows. Not only is there heat transfer through the glass, there is also the possibility for a major solar load, depending on the direction the window faces. The amount of shading, from structural overhangs, on the window affects the solar load, as does the type and position of the internal shades, curtains, and blinds. In this text, we will be assuming that there is no structural shade on the windows and that all internal blinds, curtains, and shades are opened halfway. Since most new systems are designed long before people occupy the house, it is difficult to determine what type of window coverings will ultimately be used.

As was mentioned in the ceiling and roof section, many of the charts and tables that are used to determine the heat gain through windows look similar to each other but have significant differences that can dramatically alter the results. It is also important to make certain that the correct orientation (north, south, east, west, northwest, northeast, southeast, or southwest) for each window is used.

The tables used to calculate the heat gain of a window have a slightly different configuration, as they provide a multiplier that gives the heat gain per square foot for the window. All that is needed once the multiplier is determined is the area of the window. A table for window heat gain might look something like the table in **Figure 42.28**. This table provides information for single- and double-pane windows that have the drapes/curtains half open.

Consider a single-pane, 4' × 6' window that is exposed to a design cooling TD of 15°F. This window faces north. The shades on the window are half open. The heat gain through this window is determined by the following:

$$Q_{Window} = MULTIPLIER_{Window} \times \text{Area}$$
$$Q_{Window} = 22\ Btu/h/ft^2 \times \text{Area}$$
$$Q_{Window} = 22\ Btu/h/ft^2 \times 24\ ft^2$$
$$Q_{Window} = 528\ Btu/h\ (\text{north-facing window})$$

If we repeat the same calculation for the exact same window that is facing east, we will get a very different result:

$$Q_{Window} = MULTIPLIER_{Window} \times \text{Area}$$
$$Q_{Window} = 63\ Btu/h/ft^2 \times \text{Area}$$
$$Q_{Window} = 63\ Btu/h/ft^2 \times 24\ ft^2$$
$$Q_{Window} = 1512\ Btu/h\ (\text{east-facing window})$$

Figure 42.28 Table to obtain the multiplier (based on design cooling TD) that is used to determine the heat gain through a window.

		DESIGN COOLING TD				
WINDOW TYPE/COVERING	ORIENTATION	10°F	15°F	20°F	25°F	30°F
Single pane with drapes half open	North	17	22	27	32	37
Single pane with drapes half open	NE or NW	40	45	50	55	60
Single pane with drapes half open	East or West	58	63	68	73	78
Single pane with drapes half open	SE or SW	50	54	59	64	69
Single pane with drapes half open	South	28	32	37	42	47
Double pane with drapes half open	North	12	14	17	20	23
Double pane with drapes half open	NE or NW	32	34	37	40	43
Double pane with drapes half open	East or West	47	50	53	55	58
Double pane with drapes half open	SE or SW	40	43	45	48	51
Double pane with drapes half open	South	21	24	26	29	32

HEAT GAIN FROM PEOPLE, APPLIANCES, LIGHTING, AND OTHER ELEMENTS

The occupants of a house add to the heat gain of the structure. Since the human body acts as a radiator and gives off heat to the space, it contributes to the sensible heat load. In addition, the body produces a latent load since moisture evaporates from the surface of the body. The number of occupants in a particular house is estimated as the number of bedrooms plus one. So, a three-bedroom house would count four people when determining the heat gain. The estimated heat gain for each full-time occupant of the house is about 430 Btu/h, which breaks down to 230 Btu/h of sensible heat and 200 Btu/h of latent heat. So, a two-bedroom house would have three occupants and a heat gain component of 1290 Btu/h attributed to the occupants.

As far as appliance loads go, those performing a heat gain calculation resort to using default values based on the appliances present in the house. Typically, the following guidelines are used:

- 1200 Btu/h: House with a refrigerator and a vented cooking surface
- 2400 Btu/h: House with a refrigerator, vented cooking surface, dishwasher, clothes washer, vented clothes dryer, and miscellaneous electronic devices
- 3600 Btu/h: House with two refrigerators, vented cooking surface, dishwasher, clothes washer, vented clothes dryer, and miscellaneous electronic devices

HEAT GAIN THROUGH CRACKS, OPENINGS, AND DEFICIENCIES IN STRUCTURE

The infiltration loads are found in a manner similar to the method used when calculating the heat loss in a structure. The heat gain due to infiltration has both a sensible portion and a latent portion. The formulas for each are shown here:

$$Q_{\text{Infiltration Sensible}} = 1.08 \times \text{cfm} \times \text{TD}$$
$$Q_{\text{Infiltration Latent}} = 0.68 \times \text{cfm} \times \text{DG}$$

where

cfm is the amount of infiltration in cubic feet per minute
TD is the design cooling temperature differential
DG is the grains of moisture figure at design conditions and design relative humidity (refer to **Figure 42.7**)

Consider a house with the following characteristics:

- Single-story, average construction
- 10-ft ceilings
- 40' × 60' footprint (2400 ft²)

Figure 42.29 Table used to determine the number of air changes per hour for heat gain calculations.

AIR CHANGES PER HOUR (FOR COOLING)				
	FLOOR AREA OF CONDITIONED SPACE			
CONSTRUCTION	900 – 1500	1500 – 2000	2000 – 2500	Over 2500
TIGHT	0.15	0.10	0.10	0.10
AVERAGE	0.35	0.30	0.25	0.20
LEAKY	0.90	0.75	0.60	0.50

Source: ASHRAE manuals and ACCA Manual J charts

- Design cooling TD: 20°F
- Design grains of moisture @ 50% relative humidity: 30 grains

The cfm is found by the following:

$$\text{cfm (infiltration)} = (\text{ACH} \times \text{HOUSE VOLUME}) \div 60 \text{ min/h}$$

where the ACH, air changes per hour, for cooling is found from a table similar to that shown in **Figure 42.29**. In this case, the ACH will be 0.25.

Plugging the values into the cfm formula we get:

$$\text{cfm (infiltration)} = (\text{ACH} \times \text{HOUSE VOLUME}) \div 60 \text{ min/h}$$
$$\text{cfm (infiltration)} = (0.25 \times 24{,}000) \div 60$$
$$\text{cfm (infiltration)} = 100 \text{ cfm}$$

We can then determine the sensible heat gain due to infiltration by:

$$Q_{\text{Infiltration Sensible}} = 1.08 \times \text{cfm} \times \text{TD}$$
$$Q_{\text{Infiltration Sensible}} = 1.08 \times 100 \times 20°\text{F}$$
$$Q_{\text{Infiltration Sensible}} = 2160 \text{ Btu/h}$$

We can then determine the latent heat gain due to infiltration by:

$$Q_{\text{Infiltration Latent}} = 0.68 \times \text{cfm} \times \text{DG}$$
$$Q_{\text{Infiltration Latent}} = 0.68 \times 100 \times 30 \text{ grains}$$
$$Q_{\text{Infiltration Latent}} = 2040 \text{ Btu/h}$$

HEAT GAIN THROUGH DUCT RUNS THROUGH ATTICS, CEILING CAVITIES, AND OTHER UNCONDITIONED SPACES

The portion of the load on the system that is attributed to the duct system is expressed as a fraction of the load on the structure. The duct load, just as with the infiltration load, has both sensible and latent components. The sensible heat portion of the duct load is found by using the following:

$$Q_{\text{Sensible Duct Load}} = \text{Envelope Load} \times \text{Duct Load Factor} \times \text{Duct Insulation Correction}$$

The envelope load is the sum of all of the sensible heat gains in the structure. The duct load factor is the sensible heat factor and is found in a table or chart similar to the one shown

Figure 42.30 Table used to calculate sensible and latent heat gains attributed to duct systems.

HEAT GAIN FACTORS									
SENSIBLE HEAT GAIN FACTOR					LATENT HEAT GAIN (Btuh)				
DESIGN OUTSIDE AIR TEMP	FLOOR AREA OF CONDITIONED SPACE				DESIGN GRAINS OF MOISTURE	FLOOR AREA OF CONDITIONED SPACE			
	1000	1500	2000	2500		1000	1500	2000	2500
85°F	0.23	0.28	0.34	0.35	+/– 10	316	521	725	929
90°F	0.25	0.28	0.36	0.42	+/– 20	495	817	1,136	1,456
95°F	0.27	0.33	0.40	0.42	+/– 30	682	1,126	1,566	2,007
100°F	0.28	0.36	0.43	0.48	+/– 40	878	1,449	2,015	2,582

Source: ASHRAE manuals and ACCA Manual J charts

in **Figure 42.30**. The duct insulation correction factor is often provided in table form and often contains the following data:

- If the duct wall insulation is R-2, the duct insulation correction value is 1.71.
- If the duct wall insulation is R-4, the duct insulation correction value is 1.15.
- If the duct wall insulation is R-6, the duct insulation correction value is 1.00.
- If the duct wall insulation is R-8, the duct insulation correction value is 0.91.

Consider a 2500-ft^2 house that has a total envelope heat gain of 24,000 Btu/h. The design outdoor air temperature is 90°F and the duct wall insulation is rated at R-4. The design grains for the structure is 20 grains. The sensible duct heat gain can be calculated as:

$$Q_{\text{Sensible Duct Load}} = \text{Envelope Load} \times \text{Duct Load Factor} \times \text{Duct Insulation Correction}$$
$$Q_{\text{Sensible Duct Load}} = 24{,}000 \text{ Btu/h} \times 0.42 \times 1.15$$
$$Q_{\text{Sensible Duct Load}} = 11{,}592 \text{ Btu/h}$$

The latent duct heat gain can be determined directly from the right-hand portion of the table in **Figure 42.30**. For our 2500-ft^2 house that has a design grains value of 20, it can be seen that the latent duct load is 1456 Btu/h.

SUMMARY

- In order to ensure proper system operation, heating and cooling equipment must be sized properly.
- Oversized equipment costs more to manufacture, purchase, install, operate, and maintain.
- Undersized equipment will not be able to meet the comfort requirements of the space during peak loads.
- Accurate heat gain and heat loss calculations determine how much heat is lost by the structure in the winter and gained by the structure in the summer.
- Properly sized systems help ensure that the delicate balance among temperature, humidity, air movement, and air cleanliness is maintained.
- Heat gain and heat loss methods should be nationally recognized and accepted.
- Cookie-cutter methods of determining heat gain and heat loss should be avoided.
- The rate of heat transfer is affected by the construction materials used and the temperature difference across the material.
- The R-value is used to identify the thermal resistance of insulation materials.
- The U-value is used to identify the thermal conductivity of construction materials.
- The envelope of a structure is the shell of the structure and separates the inside from the outside.
- Structures can gain and lose heat through windows, walls, doors, ceilings, floors, roofs, and by infiltration.
- Duct systems are also important factors in determining the heat gain and heat loss of a structure.
- A heat gain or heat loss calculation is simply the sum of the individual heat gains and losses of all of the corresponding construction elements.
- Windows can be subject to substantial solar heat gains, so the orientation of windows must be taken into account.
- Occupants, lighting, and appliances all provide heat gains and must be accounted for when calculating the heat gain of a structure.

REVIEW QUESTIONS

1. An oversized air-conditioning system will
   A. cost more to install and operate.
   B. be more efficient than an undersized air-conditioning system.
   C. be better able to maintain the desired humidity in the conditioned space.
   D. require a smaller air distribution system than an undersized air-conditioning system.
2. Methods used to calculate the heat gain and heat loss of a structure should
   A. provide the same results for all houses with the same size footprint.
   B. provide only a very rough estimate of the needs of the structure.
   C. be nationally recognized and accepted.
   D. All of the above are correct.
3. An exterior wall
   A. separates a conditioned interior space from an unconditioned interior space.
   B. separates an interior conditioned space from the outside.
   C. separates one interior conditioned space from another conditioned interior space.
   D. separates an interior unconditioned space from the outside.
4. A partition wall
   A. separates a conditioned interior space from an unconditioned interior space.
   B. separates an interior conditioned space from the outside.
   C. separates one interior conditioned space from another conditioned interior space.
   D. separates an interior unconditioned space from the outside.
5. As the temperature differential across a panel increases,
   A. the rate of heat transfer through the panel will increase.
   B. the rate of heat transfer through the panel will decrease.
   C. the rate of heat transfer through the panel will remain unchanged since the temperature difference does not affect the rate of heat transfer.
6. The typical indoor design temperature used for heat gain calculations is
   A. 65°F.
   B. 70°F.
   C. 75°F.
   D. 80°F.
7. The typical indoor design temperature used for heat loss calculations is
   A. 65°F.
   B. 70°F.
   C. 75°F.
   D. 80°F.
8. If a heating system was being designed for use in Modesto, California, what temperature difference would be used for calculations?
   A. 30°F
   B. 40°F
   C. 50°F
   D. 60°F
9. If an air-conditioning system was being designed for use in Nogales, Arizona, what temperature difference would be used for calculations?
   A. 21°F
   B. 68°F
   C. 75°F
   D. 96°F
10. If the R-value of a construction material is 2.0, what is its U-value?
    A. 0.25
    B. 0.50
    C. 1.0
    D. 2.0
11. If a wall is made up of four different materials, all layered one on top of the other, how will the total R-value of the wall be determined?
    A. By the one material with the highest R-value
    B. By the one material with the lowest R-value
    C. By averaging the R-values of the materials
    D. By adding the R-values of the materials together
12. All of the following are taken into account on a heat loss calculation except
    A. exterior walls.
    B. interior walls.
    C. basement floors.
    D. top-floor ceilings.
13. All of the following are taken into account on a heat gain calculation except
    A. exterior walls.
    B. partition walls.
    C. basement floors.
    D. top-floor ceilings.

14. How much heat is lost through a 3' × 5' single-pane window with a storm that is exposed to a 60°F temperature differential?
    A. 450 Btu/h
    B. 900 Btu/h
    C. 1350 Btu/h
    D. 1800 Btu/h
15. Which of the following is(are) true regarding a 10' × 30' wall that has a 21-ft^2 door and a 20-ft^2 window cut into it?
    A. The gross wall area is 300 ft^2.
    B. The net wall area is 259 ft^2.
    C. Both A and B are correct.
    D. Neither A nor B is correct.
16. Which of the following is(are) true regarding the solar gain on windows?
    A. The solar gain due to north-facing windows is greater than the solar gain due to south-facing windows.
    B. The solar gain due to east-facing windows is greater than the solar gain due to west-facing windows.
    C. The solar gain due to west-facing windows is greater than the solar gain due to east-facing windows.
    D. The solar gain due to south-facing windows is greater than the solar gain due to north-facing windows.

UNIT 43

AIR SOURCE HEAT PUMPS

OBJECTIVES

After studying this unit, you should be able to

- describe a heat pump.
- list the components of a heat pump.
- describe a four-way reversing valve.
- list the various heat sources for heat pumps.
- compare the concepts of electric heating and heat pump heating.
- state how heat pump efficiency is rated.
- determine by the line temperatures whether a heat pump is in the cooling or the heating mode.
- define coefficient of performance.
- explain auxiliary heat.
- describe the control sequence on an air-to-air heat pump.
- describe techniques being used to improve the efficiency of heat pump systems.
- discuss recommended preventive maintenance procedures for heat pump systems.

SAFETY CHECKLIST

- ☑ When installing insulated ductwork or otherwise working around fiberglass, wear gloves, goggles, and clothing that will cover your skin. If fiberglass particles are in the air, wear a mask that covers your nose and mouth. To avoid skin irritation, do not wear short-sleeve shirts or short pants when working with fiberglass insulation.
- ☑ Be sure to protect your hands when working with metal duct, panels, and fasteners.
- ☑ Exercise all precautions when installing units on rooftops or in other hazardous locations.
- ☑ Observe all safety precautions when troubleshooting the electrical components of a heat pump. When units are located in crawl spaces and you are in contact with the ground, be careful not to establish a path for current to flow through your body to ground.
- ☑ Troubleshoot with the electrical power on only when it is absolutely necessary. At all other times, ensure that the power is off. When the power is off, lock and tag the disconnect panel. There should be only one key. Keep it with you so that another person will not be able to turn the power on while you are working on the equipment.
- ☑ Exercise caution if conditions are wet when you are troubleshooting an outside unit.
- ☑ When installing gauges or transferring refrigerant, wear gloves, goggles, and clothing to protect your skin, because refrigerant can freeze your skin and eye tissue.
- ☑ The hot gas line can cause serious burns and should be avoided.
- ☑ If water is used to melt the ice from the coil of the outdoor unit, turn the power off and protect all electrical components. If troubleshooting later with the power on, do not stand in this water.
- ☑ Use common sense and caution at all times while installing, maintaining, or troubleshooting any piece of equipment. As a technician you are constantly exposed to *potential danger*. Refrigerant, electrical shock hazard, rotating equipment, hot metal, sharp metal, and lifting heavy objects are among the most common hazards you will face.

43.1 REVERSE-CYCLE REFRIGERATION

Heat pumps, like cooling-only air-conditioning systems, are refrigeration machines. Refrigeration involves the removal of heat from a place where it is not wanted and depositing it in a place where it makes little or no difference. The heat can, under certain conditions, be deposited as heat reclaim in a place where it is wanted. The main difference between a heat pump and a cooling-only air-conditioning system is that the air conditioner can pump heat only one way, but the heat pump is a refrigeration system that can pump heat two ways. Since the heat pump has the ability to pump heat into as well as out of a structure, this very special type of system can provide both heating and cooling.

All compression-cycle refrigeration systems are heat pumps in that they pump heat-laden vapor. The evaporator of a heat pump absorbs heat into the refrigeration system, and the condenser rejects the heat. The compressor pumps the heat-laden vapor. The metering device controls the refrigerant flow. These four components—the evaporator, the condenser, the compressor, and the metering device—are the basic building blocks for the vapor-compression refrigeration system.

The **four-way reversing valve** in a heat pump system is used to switch the unit between the heating and cooling modes of operation. By changing the mode of operation of the system, the functions of the indoor and outdoor coils change as well. In the cooling mode, the indoor coil acts as the evaporator and the outdoor coil functions as the condenser. In the heating mode, the indoor coil functions as the condenser and the outdoor coil operates as the evaporator.

Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

43.2 HEAT SOURCES FOR WINTER

The cooling system in a typical residence absorbs heat into the refrigeration system through the evaporator and rejects this heat to the outside of the house through the condenser. The house might be 75°F inside while the outside temperature might be 95°F or higher. The air conditioner, a high-temperature refrigeration system, pumps heat from a low temperature inside the house to a higher temperature outside the house; that is, it pumps heat up the temperature scale. A low-temperature refrigeration system, such as a freezer in a supermarket, takes the heat out of ice cream at 0°F to cool it to −10°F so that it will be frozen hard. The heat removed from the freezer can be felt at the condenser as hot air. This example shows that there is usable heat in a substance, even at 0°F, **Figure 43.1**. There is heat in any substance until it is cooled down to −460°F, which is absolute zero.

If heat can be removed from 0°F ice cream, heat can also be removed from 0°F outside air. The typical heat pump does just that. It removes heat from the outside air in the winter and deposits it in the conditioned space to heat the house, **Figure 43.2**. (Actually, about 85% of the usable heat is still in the air at 0°F.) Since air is both the heat source and the heat sink, we refer to this type of heat pump as an *air-to-air* heat pump. In summer, the heat pump acts like a conventional air conditioner, removing heat from the house and depositing it outside. From the outside, an air-to-air heat pump looks like a central cooling air conditioner, **Figure 43.3**. The phrase "air-to-air" indicates the source of heat while the system is operating in the heating mode and the medium that is ultimately being treated. The first "air" represents the heat source, and the second "air" represents the medium being heated. For example, an "air-to-water" heat pump uses "air" to heat "water." Water-source heat pumps use water as the heat source in the heating mode and can be "water-to-water" or "water-to-air." The water-to-air heat pump, therefore, uses water as the heat source to heat air. The water source can be, for example, lakes or wells. Water-source heat pumps are discussed in Unit 44, "Geothermal Heat Pumps."

Figure 43.1 This low-temperature refrigerated box is removing heat from ice cream at 0°F. Part of the heat coming out of the back of the box is coming from the ice cream.

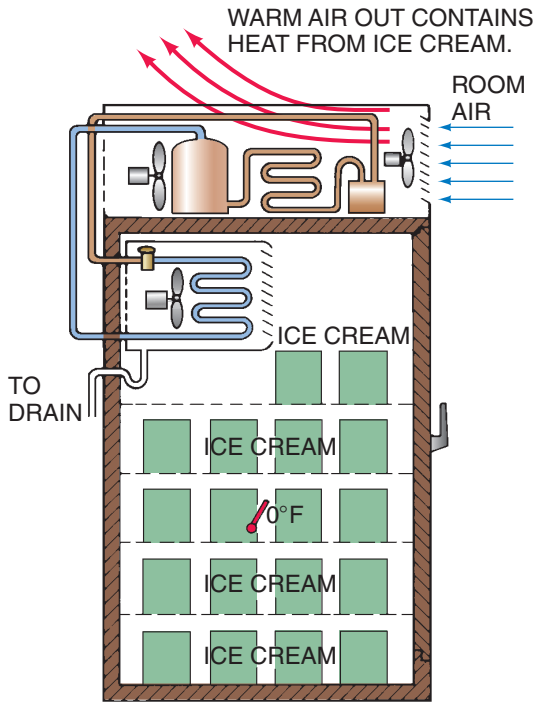

Figure 43.2 An air-to-air heat pump removing heat from 0°F air and depositing it in a structure for winter heat.

43.3 THE FOUR-WAY REVERSING VALVE

The refrigeration principles that a heat pump uses are the same as those covered earlier in the text, when traditional air-conditioning and refrigeration systems were discussed. However, a new component is added to allow the heat pump system to move heat in either direction. The air-to-air heat pump shown in **Figure 43.4** is operating in the cooling mode and is moving heat from inside the conditioned space to the outside.

When operating in the heating mode, heat energy is transferred from the outside to the inside, **Figure 43.5**. This change of direction is accomplished with a special component called a *four-way reversing valve*, **Figure 43.6**. This valve can best be described in the following way. The system refrigerant, which contains the heat absorbed into the refrigeration system, is pumped through the system by the compressor. The discharge gas from the compressor contains the heat that the system absorbs, as well as heat that is generated during the compression process. The four-way valve diverts the heat-laden discharge gas in the proper direction to either heat or cool the conditioned space. In the heating mode, the discharge gas is directed from the compressor to the indoor coil. In the cooling mode, the discharge gas is directed from the compressor to the outdoor coil. The reversing valve's position is controlled by the space temperature thermostat, which determines the system's mode of operation.

The four-way reversing valve is a four-port valve that has a slide mechanism in it, **Figure 43.7**. The position of the slide is determined by a solenoid that is energized in one mode of operation and not the other. The position of the slide also determines the mode of system operation. Most heat pump systems are designed to operate in the heating mode when the solenoid is not energized, **Figure 43.7(A)**. This is referred to as *failing in the heating mode*. For the remainder of this text it will be assumed that the heat pump system will operate this way. This may not always be the situation, so be sure to check each individual system being worked on. **Figure 43.7(B)** shows the position of the slide when the solenoid is energized and the system is operating in the cooling mode.

Typical reversing valves have one port isolated on one side and the remaining three ports on the other. The isolated port is where the hot gas from the compressor enters the valve. **Figure 43.7** shows the piping connections on the valve.

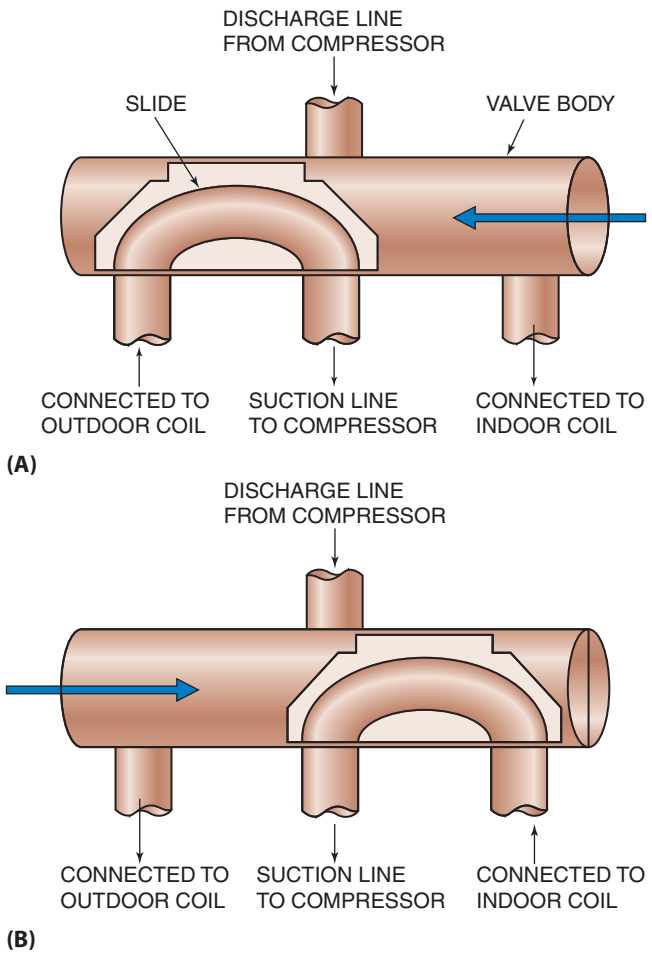
Figure 43.7 Internal slide in the four-way reversing valve. The solenoid determines the position of the slide. Most systems operate in the heating mode when the solenoid is de-energized. (A) Position of the slide when the solenoid is de-energized. (B) Position of the slide when the solenoid is energized.



Depending on the position of the slide, the hot gas will be directed to either the outdoor coil or the indoor coil. In either case, the coil that accepts the hot gas from the compressor is functioning as the condenser coil. Note that in **Figure 43.7(A)** the hot gas enters the valve at the top and is directed to the right-hand port, which is connected to the indoor coil. Since the indoor coil is receiving the hot gas from the compressor, the indoor coil is the condenser and the system is operating in the heating mode. Compare this with **Figure 43.7(B)**, where the hot gas from the compressor is being directed to the outdoor coil. Under these conditions, the system is operating in the cooling mode.

Smaller heat pump systems utilize smaller, direct-acting, four-way reversing valves. "Direct acting" implies that the solenoid itself provides the force needed to change the position of the slide in the valve. On larger systems, additional help is needed to move the slide. Valves in these systems, referred to

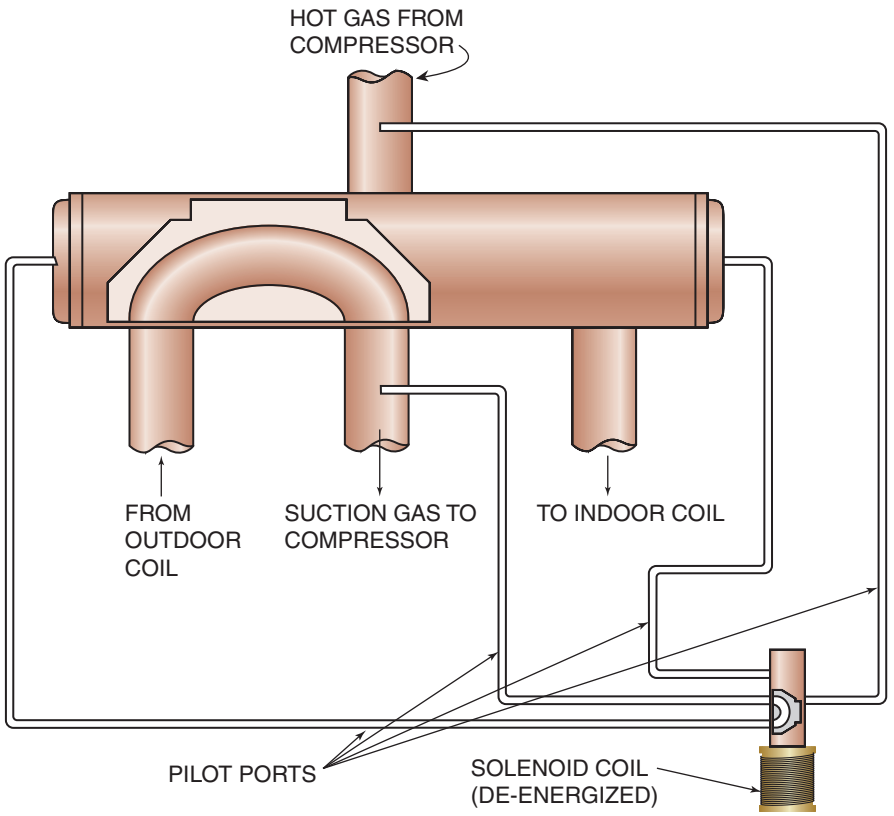
Figure 43.8 A pilot-operated four-way reversing valve. Notice the pilot valve in the bottom right-hand corner of the figure.



as pilot-operated reversing valves, **Figure 43.8**, use the high-side pressure in the heat pump system to help push the slide. The pilot-operated four-way reversing valve is actually two valves built into one housing. The control wires control a small solenoid valve that has very small piping that runs along the outside of the valve, as can be seen in the bottom right-hand corner of **Figure 43.8**. This valve is called a *pilot-operated* valve because a small valve controls the flow in a large valve.

The valve movement is controlled by pressure differences within the large portion of the valve. This pressure difference pushes the slide mechanism back and forth inside the body of the valve. When the solenoid is de-energized, high pressure from the compressor discharge pushes through the tubes on the pilot valve as shown in **Figure 43.9**. This exerts a pressure on the right side of the slide, pushing it to the left. The refrigerant on the left side of the slide is pushed back through the pilot valve and into the compressor's suction line. In this position, the hot gas from the compressor is directed to the indoor coil, putting the system into the heating mode. When the solenoid valve is energized, the high pressure is directed to the other end of the valve body and the slide mechanism moves to the right, putting the system in the cooling mode, **Figure 43.10**. This is why, when starting up a heat pump, you sometimes hear the swishing of refrigerant as the valve changes position while the pressure difference builds up in the system.

In case of failure, the four-way reversing valve is somewhat difficult to change due to the three connections located on one side. These are the largest piping connections in the system and are often very close to each other. A tubing cutter cannot be used, as the pipes are too close together. A hacksaw should never be used to cut the valve out of the system because doing so will create filings that can travel through the system, potentially causing problems with the compressor, metering device, and the movement of the slide mechanism inside the four-way reversing valve. In addition, unbrazing the valve is a difficult process as three ports would need to be heated at the same time. Tool and equipment manufacturers make torch tips with multiple flame heads that are intended to make the replacing of a four-way reversing valve much easier, **Figure 43.11**.

Also remember that there is a sliding piston inside the valve body. It slides on a neoprene, teflon, or nylon pad that has a low melting temperature. The valve body must be kept as cool as possible when installing the new valve. The valve body can be kept cool enough by a heat sink paste or by a wet rag wrapped around the valve body while it is being brazed in, **Figure 43.12**. If the wet rag option is used, make certain that no water is allowed to enter the piping, as this will pose problems later on. Avoid pointing the torch directly at the valve to avoid overheating and possibly causing damage to the reversing valve.

When removing a defective four-way reversing valve, it is often better to cut the piping back far enough with a tubing cutter and just braze additional pipe stubs into the system, **Figure 43.13**. You can get a clean installation this way and

the brazing of the stubs to the valve can be done in a vise, where you can control the heat much better. If the old valve is removed by using one of the specialty torch tips and without cutting the refrigerant lines back, the old stubs must be cleaned prior to the installation of the new valve. All of the old filler material must be removed or the pipe stubs will not fit into the new valve, **Figure 43.14**. This filler material is hard to remove; it must be filed off in a manner that will prevent the filings from entering the piping. It is often is difficult to clean up these stubs correctly. More information on checking the four-way reversing valve will be provided later in this unit.

43.4 THE AIR-TO-AIR HEAT PUMP

The air-to-air heat pump resembles the central air-conditioning system. Both have indoor and outdoor system components. When discussing typical air-conditioning systems, the heat exchangers are often called the evaporator (indoor unit) and the condenser (outdoor unit), but this terminology does not work for a heat pump system. The coil that serves the inside of the house in a heat pump system is called the *indoor coil*. The coil that is located outside the house is called the *outdoor coil*. The reason for the change in terminology is that the indoor coil of the heat pump is the condenser in the heating mode and the evaporator in the cooling mode. The outdoor coil functions as the condenser in the cooling mode and the evaporator in the heating mode. The mode is determined by the direction in which the refrigerant flows. See **Figure 43.15** for an example of the direction of the gas flow.

43.5 REFRIGERANT LINE IDENTIFICATION

Like cooling equipment, heat pumps are manufactured as split systems and package systems. On cooling-only, split-type systems, the field-installed refrigerant lines are typically the liquid line and the suction line. In a split-type air-to-air heat pump, the interconnecting refrigerant lines that are connected between the indoor unit and the outdoor unit are identified differently. The larger line of the two is called a *gas line* because it always carries gas. In previous units it was called a cold gas line or a suction line. In a heat pump it is always a gas line because it is the suction line when the heat pump is operating in the cooling mode and the discharge line when the system is operating in the heating mode, **Figure 43.16.**

Figure 43.13 The valve and stubs are held in a vise while the additional stubs are brazed in. Remember, the valve body must be kept cool during this process. The valve and stubs can be installed in the unit by cutting the stubs to fit.

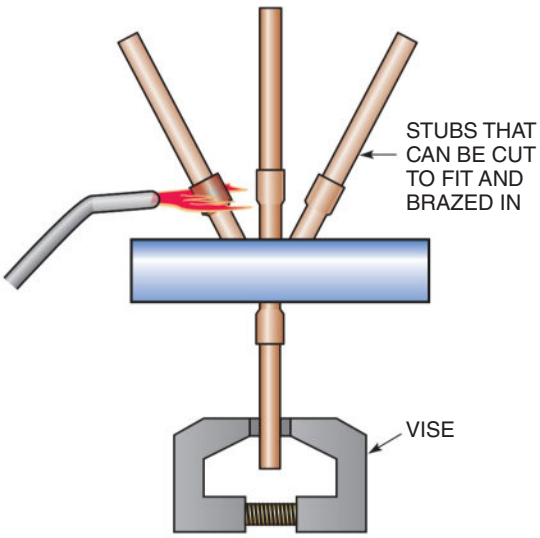

Figure 43.14 This stub has been pulled from a connection on a valve and has residue of silver brazing stuck to it. This braze material is very hard to clean off, which must be done before the stub is inserted into a new fitting.

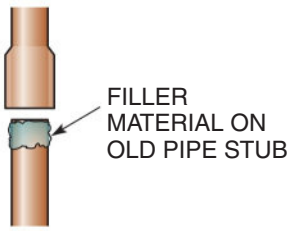

The smaller line carries liquid refrigerant in both the heating and cooling modes and is, therefore, called the liquid line, just as with cooling-only air-conditioning systems. The liquid flows toward the inside unit in summer and toward the outside unit in winter, **Figure 43.17**. The line is the same size as for cooling; the liquid direction is just reversed.

Figure 43.15 The heat pump refrigeration cycle shows the direction of the refrigerant gas flow.

43.6 METERING DEVICES

Because the direction of the liquid flow is reversed as the heat pump system changes over from one mode to the other, some of the refrigeration components in heat pumps are slightly different from those in cooling-only air-conditioning systems. The metering devices are different because there must be a metering device at the indoor unit as well as at the outdoor unit. For example, when the unit is in the cooling mode, the metering device is at the indoor coil. When the system changes over to heating, a metering device must then meter refrigerant to the outdoor coil. The methods used to switch from one metering device to the other will be discussed later in this unit.

43.7 THERMOSTATIC EXPANSION VALVES

The *thermostatic expansion valve* (TXV) is the metering device that is commonly found on heat pump systems. Because many TXVs allow refrigerant to flow in only one direction, a check valve needs to be piped in parallel with the valve to allow the refrigerant to bypass the valve when needed. For example, in the cooling mode, the valve needs to meter the flow of liquid refrigerant into the indoor coil. When the system reverses to the heating mode, the indoor coil becomes the condenser, and the liquid needs to be able to move freely toward the outdoor unit. The liquid flows through the check valve in the heating mode and is metered through the indoor TXV in the cooling cycle, **Figure 43.18**.

Figure 43.18 (A) In the heating mode, hot gas from the compressor flows through the indoor coil and through the open check valve to bypass the indoor metering device. (B) In the cooling mode, high-pressure liquid refrigerant is directed through the metering device because the check valve will be in the closed position.

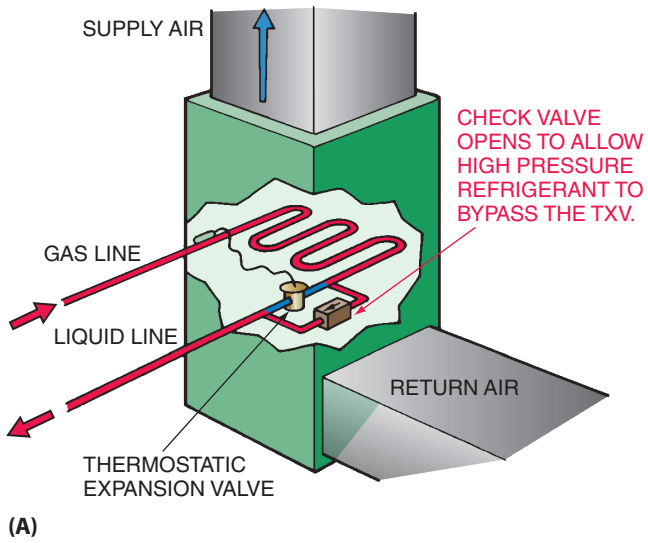

Figure 43.19 This illustration shows that care must be taken in the choice of a TXV. If an ordinary TXV sensing bulb were to be mounted on this gas line, it would get hot enough to rupture the valve diaphragm.

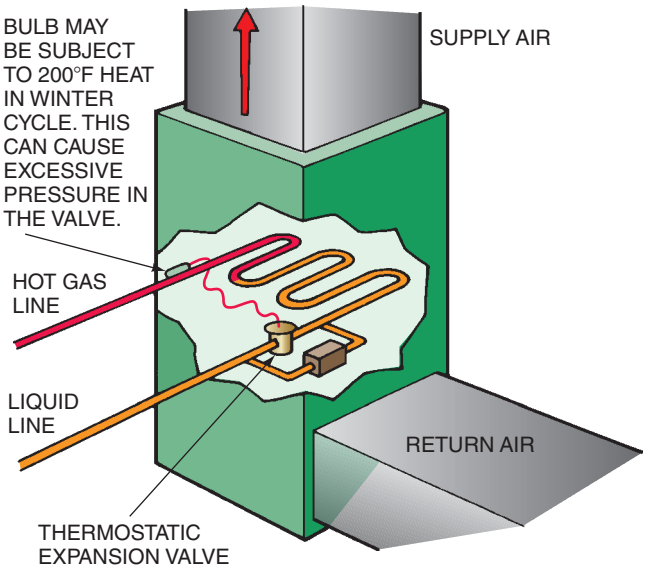

NOTE: *The TXV used in a heat pump must be carefully chosen. The sensing bulb for the valve is on the gas line, which may become too hot for a typical TXV bulb.* It is not unusual for the hot gas line to reach temperatures of 200°F. If the sensing bulb for a typical TXV is exposed to these temperatures, it is subject to rupture, **Figure 43.19**. A vapor-charged TXV, one with a limited charge in the bulb, is therefore usually used in a heat pump application. Remember from Unit 24, "Expansion Devices," that a limited-charge bulb does not continue to build pressure with added heat. It builds only a certain amount of pressure; then additional heat causes no appreciable increase in pressure.

The use of thermostatic expansion valves, along with filter driers and check valves, adds to the complexity of the refrigerant piping of a heat pump system. These additional components, piping, and pipe connections increase the possibility of system malfunction and refrigerant leaks. For these reasons, manufacturers offer *bidirectional thermostatic expansion valves*, which have a check valve built into the body of the TXV. The valve looks and operates in a manner similar to that of other TXVs, with the exception of the internal check valve. In operation, when refrigerant flow is desired through the expansion valve, the internal check valve will be in the closed position and the refrigerant will be directed through the needle and seat of the expansion valve. When refrigerant flows through the valve in the opposite direction, the check valve opens and the refrigerant is able to bypass the needle and seat in the valve. Be sure to check the part number of the TXV you are working with to determine whether or not it has an internal check valve.

43.8 THE CAPILLARY TUBE

The capillary tube metering device is not typically used on new-generation heat pump systems, but will often be encountered on older pieces of equipment. The capillary tube allows refrigerant flow in either direction, but this characteristic is not often used because capillary tubes of different sizes are required for the cooling and heating modes. Because of this, two capillary tubes are typically used. When used in this manner, check valves are used to reverse flow, allowing refrigerant

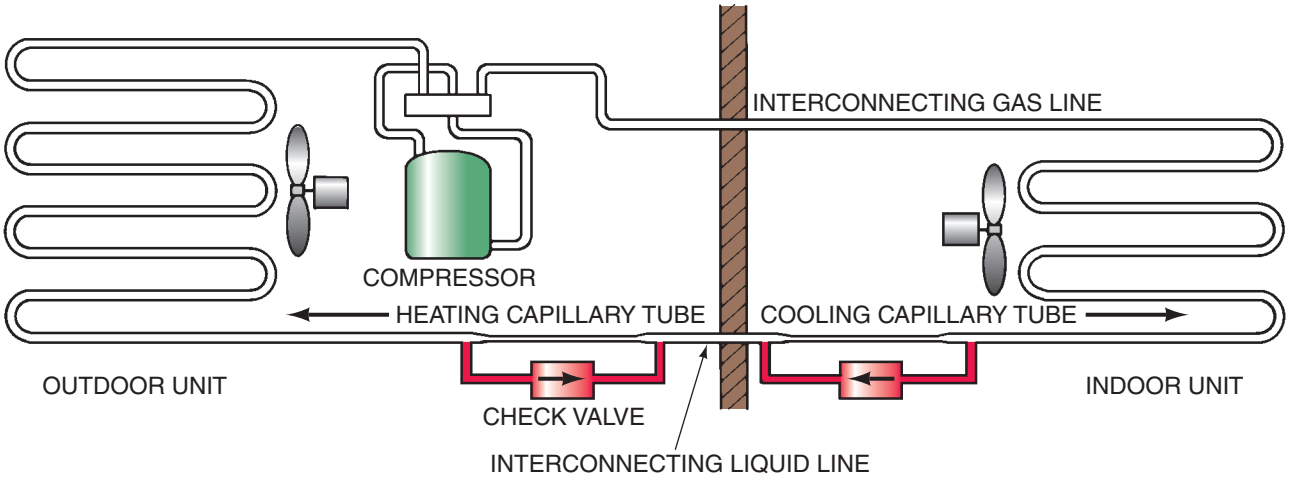
Figure 43.20 Capillary tube metering devices used on a heat pump. Notice that there are two check valves and two different capillary tubes.



to bypass the capillary tube that is not being used. In the heating mode of operation, the capillary tube at the indoor coil is bypassed. In the cooling mode, the capillary tube at the outdoor coil is bypassed, **Figure 43.20.**

43.9 COMBINATIONS OF METERING DEVICES

Sometimes two types of metering device are used in a single system. One popular combination is a capillary tube as the indoor metering device for summer operation, with a check valve piped parallel to allow flow in the other direction for winter operation. The outside unit may have a TXV with a check valve. This system is efficient because it uses the capillary tube only in the cooling mode. It is an efficient metering device for summer because the load conditions are nearly constant. The TXV used on the outdoor coil is efficient for the heating mode because winter conditions are not constant. The TXV will reach maximum efficiency sooner than the capillary tube in the same application because the TXV has the capability to open wide when needed. The capillary tube, being a fixed-bore-type metering device, cannot open or close. This allows the evaporator to become full of refrigerant earlier in the running cycle. This dual system uses each device at its best, **Figure 43.21.**

Figure 43.21 This unit uses a capillary tube for the indoor cycle and a TXV for the outdoor unit. The sensing element for this TXV is mounted on the compressor permanent suction line.

43.10 ELECTRONIC EXPANSION VALVES

The electronic expansion valve, discussed earlier in the text, is commonly found on newer heat pump systems, especially on ductless split-type heat pump systems. If the heat pump is a close-coupled unit with the indoor coil close to the outdoor unit, such as a package system (discussed in Unit 24, "Expansion Devices"), a single electronic expansion valve can be used. The valve will modulate refrigerant flow in either direction and maintain the correct superheat at the compressor's common suction line in the heating and cooling modes. The sensing element may be located on the common suction line just before the compressor to maintain refrigerant flow.

43.11 ORIFICE METERING DEVICES

Another common metering device used by some manufacturers is a combination flow device and check valve. This device, referred to as a piston, allows full flow in one direction and restricted flow in the other direction, **Figure 43.22.** Two of these devices are necessary with a split system—one at the indoor coil and one at the outdoor coil. The metering device at the indoor coil has a larger bore than the one at the outdoor coil because the two coils have different flow characteristics. The summer cycle uses more refrigerant in normal operation. When this metering device is present, a biflow filter drier is normally used in the liquid line when field repairs are done.

43.12 LIQUID-LINE ACCESSORIES

Liquid-line filter driers must be used in conjunction with all of the metering devices just described. Liquid-line filter driers help prevent particulate matter that may be in the refrigerant piping circuit from clogging or blocking the metering device. When standard liquid-line filter driers are installed in a system with check valves to control the flow through the metering devices, each drier is installed in series with one check valve and one expansion device. The flow direction is the same as with the metering device. If the same filter drier were installed in the common liquid line, it would filter in one direction and the particles would wash out in the other direction, **Figure 43.23.**

In the heating mode, the high-pressure refrigerant leaves the indoor coil and bypasses the cooling capillary tube by flowing through the indoor check valve and filter drier, **Figure 43.24.** Once at the outdoor unit, the refrigerant is directed through the outdoor metering device, as the outdoor check valve is in the closed position. In the cooling mode, the outdoor heating capillary tube is bypassed and the refrigerant is directed through the cooling metering device located at the indoor coil, **Figure 43.25.** Special *biflow* filter driers are manufactured to allow flow in either direction. They are actually two driers in one shell with check valves inside the drier shell to cause the liquid to flow in the proper direction at the proper time, **Figure 43.26.**

Figure 43.22 (A) This piston works like the ones illustrated in (B) and (C). (B) When the piston is positioned to the left, it only allows flow through the orifice, creating a metering device. (C) When the flow is reversed during the next season, the piston slides to the right and full flow is allowed. A heat pump may have two of these: one at the indoor unit for cooling and one at the outdoor coil for heating. These are very small devices and may be in a flare fitting.

43.13 APPLICATION OF THE AIR-TO-AIR HEAT PUMP

Traditionally, air-to-air heat pump systems were installed primarily in milder climates—in the "heat pump belt"—basically those parts of the United States where winter temperatures can be as low as 10°F. The reason for this geographical restriction was that the air-to-air heat pump absorbs heat from the outside air in the heating mode. As the outside air temperature drops, it was more difficult for the heat pump to absorb heat from it. For example, the evaporator must be cooler than the outside air for heat to be transferred into the evaporator. Normally, in cold weather, the heat pump evaporator will be about 20°F to 25°F cooler than the air from which it is absorbing heat. We will use a 25°F temperature difference (TD) in this text as the example, **Figure 43.27**. On a 10°F day, the heat pump evaporator will be boiling (evaporating) the liquid refrigerant at 25°F lower than the 10°F air. This means that the boiling refrigerant temperature will be −15°F. As the evaporator temperature goes down, the compressor loses capacity. Older compressors were single-speed, fixed-volume pumps and had more capacity on a 30°F day than on a 10°F day. The heat pump loses capacity as the outdoor ambient temperature drops and the heating capacity needs of the structure increase. On a 10°F day, the structure needs more heating capacity than on a 30°F day, but the traditional heat pump's capacity is lower. New generation heat pumps utilize inverter-controlled compressors and have the ability to change the speed of the compressor motor to closely match the needs of the conditioned space under a wide range of ambient conditions. For example, as the outside ambient temperature drops while the system is operating in the heating mode, an inverter-controlled compressor will speed up to lower the evaporator temperature. By lowering the temperature of the evaporator, more heat can be absorbed from the ambient air. Even with this technology, there are times when heat pump systems need help in order to meet the heating needs of the occupied space.

43.14 AUXILIARY HEAT

In an air-to-air heat pump system, the vapor-compression portion of the system may not, under certain conditions, be able to meet the heating needs of the structure. For this reason, some heat pump systems are equipped with second-stage heat. In many instances, this second-stage heat source is called *auxiliary heat*. The heat pump itself is the primary source of heat; the auxiliary heat source may be electric, oil, or gas. Electric auxiliary heat is the most popular because it is easy to incorporate electric heating elements into a heat pump system. Second-stage electric heat is covered in Section 43.25.

The occupied space will have different heating requirements as the outside temperature changes. The heating

requirements for the structure are inversely related to the outside ambient temperature. For example, a house might require 30,000 Btu/h of heat during the day when the outside temperature is 30°F. As the outside temperature drops, the structure requires more heat. It might need 60,000 Btu/h of heat in the middle of the night when the temperature has dropped to 0°F. The heat pump could have a capacity of 30,000 Btu/h at 30°F and 20,000 Btu/h at 0°F. The difference of 40,000 Btu/h must be made up with auxiliary heat.

43.15 BALANCE POINT

The term **balance point** is used to describe the outside ambient temperature at which a heat pump can pump in exactly as much heat as the structure is leaking out. In more technical terms, the balance point is the lowest outside ambient temperature at which the heat pump system can satisfy the heating needs of the structure without requiring the assistance of second-stage supplementary or auxiliary heat. At this point, the heat pump will completely heat the structure by running continuously. At any temperature above the balance point, the heat pump will cycle off and on. Below this point the heat pump will run continuously but will not be able to maintain the desired temperature. Although the auxiliary heat portion of a heat pump system will be operational at some temperature above the balance point, it is impossible for a heat pump system to satisfy the heating requirements of a structure without auxiliary heat if the temperature falls below the balance point.

43.16 COEFFICIENT OF PERFORMANCE

If the heat pump will not heat the structure all winter, why is it so popular? This can be answered in one word—*efficiency*. To understand the efficiency of an air-to-air heat pump, you need an understanding of electric heat. A customer receives 1 W of usable heat for each watt of energy purchased from the power company while using electric resistance heat. This is called 100% efficient, or a **coefficient of performance (COP)** of 1:1. The output is the same as the input. With a heat pump, the efficiency may be improved as much as 3.5:1 for an air-to-air system with typical equipment. When the 1 W of electrical energy is used in the compression cycle to absorb heat from the outside air and pump this heat into the structure, the unit could furnish 3.5 W of usable heat. Thus its COP is 3.5:1, or it can be thought of as 350% efficient. See **Figure 43.28** for a manufacturer's rating table for an air-to-air heat pump.

Figure 43.28 Rating tables of air-to-air heat pumps.

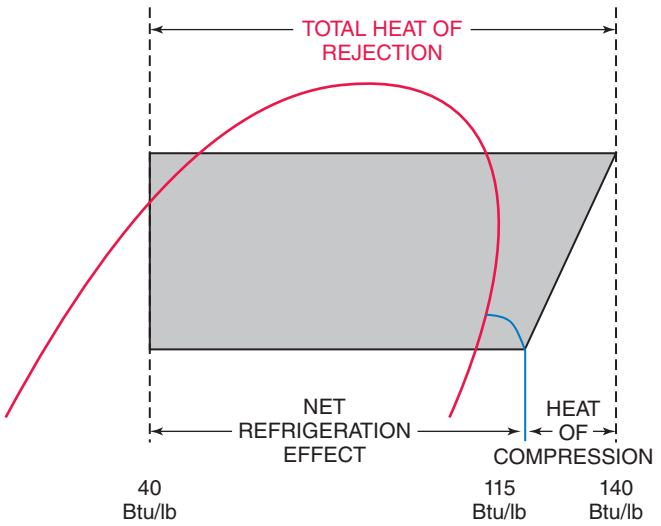
Figure 43.29 Pressure enthalpy chart showing the relationship between the total heat of rejection (THOR), net refrigeration effect (NRE), and the heat of compression (HOC).



To provide some insight into why the COP of a heat pump system is so high, it is necessary to take a look at the pressure enthalpy chart shown in **Figure 43.29**. For a system that provides cooling, the COP is defined as

COP = Net Refrigeration Effect ÷ Heat of Compression

From the values shown in **Figure 43.29**, the net refrigeration effect (NRE) is 75 Btu/lb (115 Btu/lb − 40 Btu/lb) and the heat of compression is 25 Btu/lb (140 Btu/lb − 115 Btu/lb). From this we can determine the COP to be 3 (75 Btu/lb ÷ 25 Btu/lb). For a system that is providing cooling, the NRE is what the occupant of the structure is benefiting from, since the refrigeration effect is what is taking place in the evaporator, or cooling, coil.

On a heat pump system that is operating in the heating mode, it is not the NRE that is providing the heat. Instead, the total heat of rejection (THOR) is what is conditioning the space. A portion of the THOR is the heat that is generated during the compression process. So, the compressor itself is contributing in two ways: It is providing the pressure difference to facilitate refrigerant flow through the system, and it is also generating heat that is directly transferred to the medium being heated. The COP for a heat pump system operating in the heating mode is given by the following formula:

COP = Total Heat of Rejection ÷ Heat of Compression

For the system shown in **Figure 43.29**, the COP is calculated as

COP = Total Heat of Rejection ÷ Heat of Compression
COP = 100 Btu/lb ÷ 25 Btu/lb
COP = 4

Notice that the COP of the heat pump system operating in the heating mode is higher than the COP of the same heat pump system operating in the cooling mode. This example is greatly simplified and intended to illustrate the contribution of the compressor heat to the efficiency of the heat pump system.

A high COP occurs only during higher outdoor winter temperatures. As the temperature falls, the COP also falls. A typical air-to-air heat pump will have a COP of 1.5:1 at 0°F, so it is still economical to operate the compression system at these temperatures along with the auxiliary heating system. Some manufacturers include controls to shut off the compressor at low temperatures, such as 0°F to 10°F. When the temperature rises, the compressor comes back on. Some manufacturers do not allow the compressor shut off at all. Long running times will not hurt a compressor or wear it out to any extent. They would rather have the compressor run all the time than have it restart with a cold crankcase when the temperature rises.

The *water-to-air* heat pump might not need auxiliary heat because the heat source (the water) can be relatively constant temperature all winter. The heat loss (the heat requirement) and the heat gain (the cooling requirement) of the structure might be almost equal. Consequently, these heat pumps have COP ratings as high as 4:1. Just remember that the higher COP ratings of water-to-air heat pumps are due not to the components of the refrigeration equipment but to the temperature of the heat source. Earth and lakes have a more constant temperature than air. Such pumps are very efficient for winter heating because of the COP and for summer cooling because they operate at water-cooled air-conditioning temperatures and head pressures.

43.17 THE SPLIT-TYPE, AIR-TO-AIR HEAT PUMP

Like cooling-only air-conditioning equipment, air-to-air heat pumps come in two styles: split systems and package (self-contained) systems. The split-system air-to-air heat pump resembles the split-system cooling air-conditioning system. The components look exactly alike from the outside.

43.18 THE INDOOR UNIT

The indoor unit of an air-to-air split system may be an electric furnace with a heat pump indoor coil where the summer air-conditioning evaporator would be placed, **Figure 43.30**. The outdoor unit may resemble a cooling condensing unit. The indoor unit, which contains the blower and coil, is the part of the system that circulates the air in the structure. The airflow pattern may be upflow, downflow, or horizontal to serve different applications. Some manufacturers have designed their units so that one unit may be adapted to all of these flow patterns by correctly placing the pan for catching and containing the summer condensate, **Figure 43.31**.

Coil placement in the airstream is important in the indoor unit. The electric auxiliary heat and the primary heat (the

Photo by Bill Johnson

heat pump) may need to operate at the same time in weather below the balance point of the house. **The refrigerant coil must be located in the airstream before the auxiliary heating coil.** Otherwise, heat from the auxiliary unit will pass through the refrigerant coil when both are operating in winter. If the

Figure 43.31 This heat pump indoor unit can be positioned either in the vertical (upflow, downflow) or horizontal position by placing the condensate pan under the coil in the respective position.

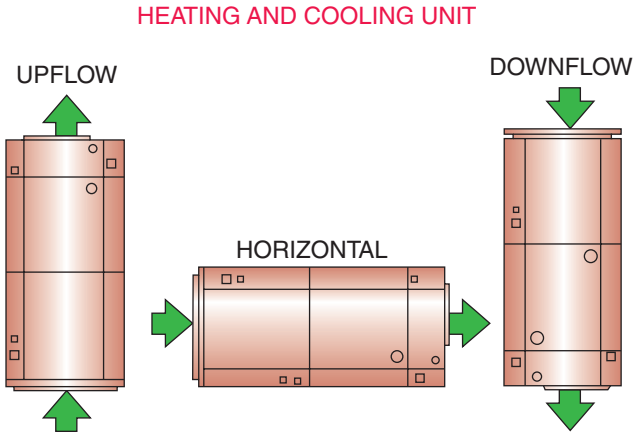

Figure 43.32 This illustration shows a heat pump coil installed after electric heating elements (oil and gas are the same).

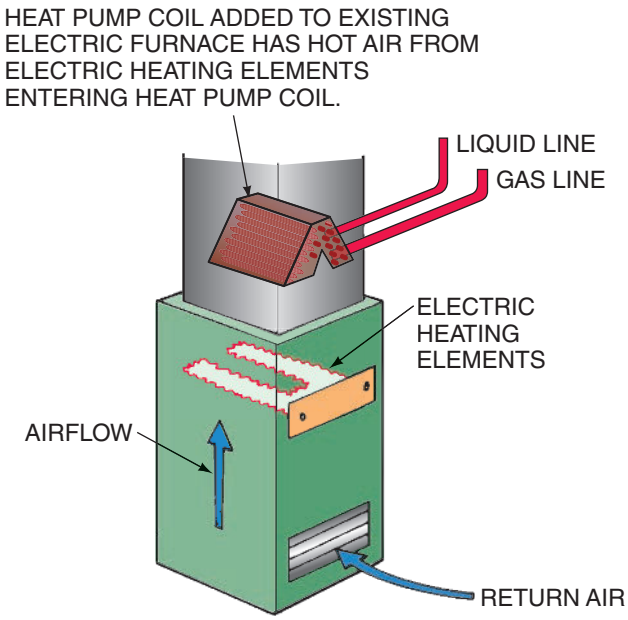

auxiliary heat is operating and is located before the heat pump coil, the head pressure will be too high and could rupture the coil or burn the compressor motor. Remember, the coil is operating as a *condenser* in the heating mode. It rejects heat from the refrigeration system, so any heat added to it will cause the head pressure to rise, **Figure 43.32.**

The indoor unit may be a gas or oil furnace. If this is the case, the indoor coil must be located in the outlet airstream of the furnace. When the auxiliary heat is gas or oil, the heat pump does not run while the auxiliary heat is operating. If the coil is not located after the furnace heat exchanger, it would sweat in summer, when it would be operating as an evaporator, and the outlet air temperature could be lower than the dew point temperature of the air surrounding the heat exchanger. For this reason, most local codes will not allow a gas or oil heat exchanger to be located in a cold airstream. Special control arrangements must be made when the auxiliary heat is gas or oil so that the heat pump will not operate while the gas or oil heat is operating. When a heat pump is added to an electric furnace, the indoor coil must be located after the heat strips. The same rules apply as for gas or oil. See **Figure 43.33** for an example of this installation.

43.19 TEMPERATURE OF THE CONDITIONED AIR

The heat pump indoor unit is installed in much the same way as a split-system cooling unit, but the air distribution system must be designed more precisely due to the temperature of the air leaving the air handler during the heating mode. Unlike

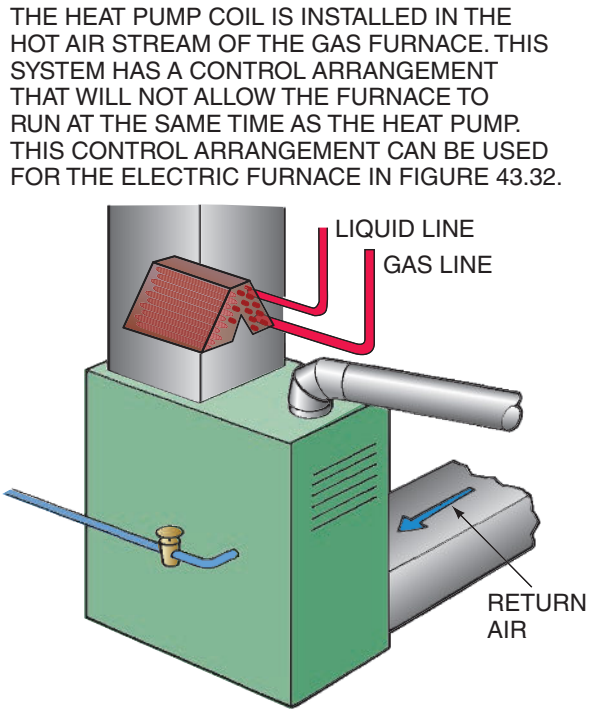
Figure 43.33 A gas furnace with a heat pump indoor coil instead of an air-conditioner evaporator.



the temperatures produced by gas and oil-fired systems that are normally used with electric cooling, the temperature of the air supplied by heat pumps is not as hot. The leaving-air temperatures are in the 100°F range when just the heat pump (first-stage heating) is operating. If the airflow is restricted, the air temperature will go up slightly, but the system's COP will drop. A reduced COP indicates a reduction in system efficiency.

When 100°F air is distributed to a conditioned space, it must be distributed carefully or drafts will occur. Normally, the air is introduced to the structure along the outside walls. The supply registers are either in the ceiling or the floor, depending on the structure. It is common in two-story houses for the first-story registers to be in the floor with the air handler in the crawl space below the house. The upstairs unit is commonly located in the attic with the supply registers located in the ceiling near the outside walls. The outside walls are where heat leaks out of a house in the winter and leaks into the house in the summer. If these walls are slightly heated in the winter by the airstream, less heat is taken out of the air in the conditioned space and the room stays warmer, **Figure 43.34**. Air at a temperature of 100°F mixed with room air does not feel like 130°F air mixed with room air from a gas or oil furnace. It may feel like a draft.

When air at 100°F enters the room from the supply register, it mixes with the air that is around the register, which may be at a temperature of 75°F. This would result in a mixed air temperature of about 80°F. If this mixed air blows on a person with a skin temperature of about 85°F, it will seem like the room is cool, not warm. Proper air distribution can help

Figure 43.34 This heat pump installation shows a good method of distributing the warm air in the heating mode.

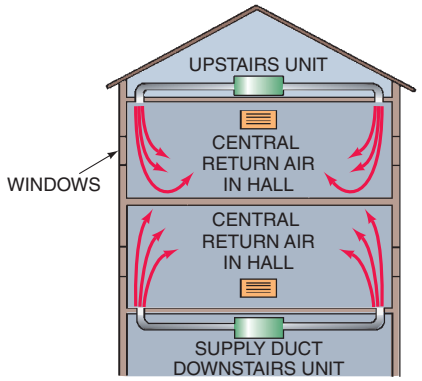


Figure 43.35 This air distribution system with the air being distributed from the inside using high sidewall registers shows the heat pump's 100°F air mixing with the room air of 75°F.

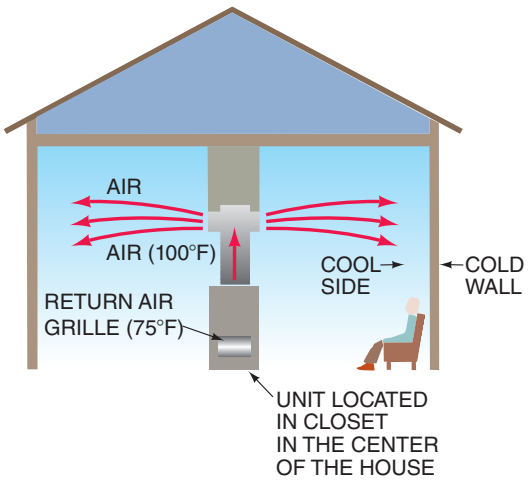

reduce the number of "draft" complaints. When 100°F air is distributed from the inside walls, such as high sidewall registers, the system may not heat satisfactorily. The air will mix with the room air and might feel drafty. The outside walls will also be cooler than if the air were directed on them, and a **cold wall** effect could be noticed in cold weather, **Figure 43.35**.

43.20 THE OUTDOOR UNIT

Manufacturers provide recommended installation procedures for their particular units that show the installer how to locate the unit for the best efficiency and water drainage. The installation of a heat pump system's outdoor unit is much like that of a traditional central air-conditioning system from an airflow standpoint. The unit must have a good air circulation around it, and the discharge air must not be allowed to recirculate. A more serious consideration is the direction of the prevailing wind in the winter, which could lower heat pump performance.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

If the unit is located in a prevailing north wind or a prevailing wind from a lake, system performance may be negatively affected. A prevailing north wind might cause the evaporator (outdoor coil in the heating mode) to operate at a lower-than-normal temperature. A wind blowing inland off a lake will be very humid and might cause excessive outdoor coil freezing when the system operates in the heating mode.

The outdoor unit must *not* be located where roof water will pour into it. The coil will be operating at a temperature that is often below freezing, so moisture that is not in the air itself should be kept away from the unit's coil. If it is not, excess freezing will occur. The outdoor unit is an evaporator in winter and will attract moisture from the outside air. If the coil is operating below freezing, the moisture will freeze on the coil. If the coil is above freezing, the moisture will run off the coil as it does in an air-conditioning evaporator. This moisture must have a place to go. If the unit is in a yard, the moisture will soak into the ground. **SAFETY PRECAUTION:** *If the unit is on a porch or walk, the moisture could freeze and create slippery conditions,* **Figure 43.36.**•

The outdoor unit is designed with drain holes or pans in the bottom of the unit to allow free movement of the water away from the coil. If they are inadequate, the coil will become a solid block of ice in cold weather. Ice accumulation on the outdoor coil acts as an insulator and will negatively affect the transfer of heat between the outside air and the refrigerant in the coil. As a result, the COP will be reduced. Generally, manufacturers recommend that the outdoor unit be placed on risers that keep the unit above the typical snow level for the region. When ice buildup is excessive, the defrost procedures for the unit may not be adequate. When this happens, a little more ice builds up each run cycle, until the normal defrost cycle will not remove the ice and other measures must be taken to get the unit back in normal operation. Defrosting methods are discussed in Section 43.23, "The Defrost Cycle."

SAFETY PRECAUTION: *Installing a heat pump involves observing the same safety precautions as when installing a "cooling only" air-conditioning system. The ductwork must be insulated, which requires working with fiberglass. Be careful when working with metal duct and fasteners and especially when installing units on rooftops and other hazardous locations.*•

43.21 PACKAGE AIR-TO-AIR HEAT PUMPS

Package air-to-air heat pumps are much like package air conditioners. They look alike and are installed in the same way. Therefore, give the same considerations to the prevailing wind and water conditions. Package heat pumps have all of the components in one housing and are easy to service, **Figure 43.37.** They have a separate compartment in which the supplementary electric strip heaters are mounted. Most package heat pump systems can accept different electric heat sizes from 5000 W (5 kW) to 25,000 W (25 kW).

The metering devices used for package air-to-air heat pumps are much like those for split systems. Some manufacturers use a common metering device for the indoor and outdoor coils because the two are so close together. When one metering device is used, it must be able to adjust for the varying refrigerant flow requirements in the heating and cooling modes of operation.

Package air-to-air heat pumps require that ductwork be run right up to the unit. Depending on the location of the unit, these duct runs can be either very short, or very long, **Figure 43.38.** In some cases, the duct will need to extend all the way to an outside wall of the structure for a crawl space installation. Supply and return ducts must be insulated to prevent heat exchange between the duct and the ambient air.

Package air-to-air heat pumps have the same advantage from a service standpoint as package cooling air conditioners or package gas-burning equipment. All of the controls

Figure 43.36 This heat pump was placed in the wrong location. The water that forms on the outside coil will run onto the walkway next to the coil and freeze.

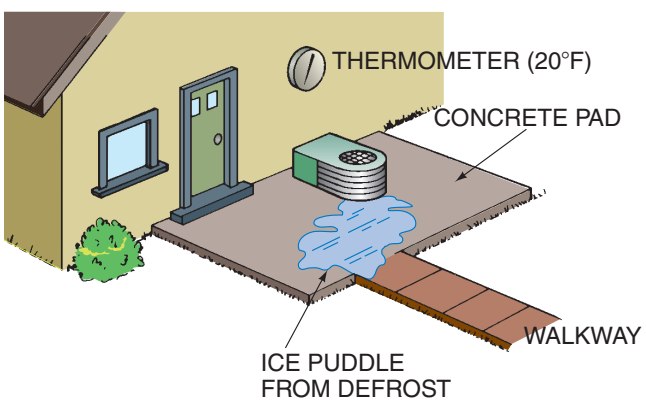

Figure 43.37 A package heat pump. All components are contained in one housing.

and components may be serviced from the outside. They also have the advantage of being factory assembled and charged. They are leak checked and may even be operated before leaving the factory. This reduces the likelihood of having a noisy blower motor or other defect.

43.22 CONTROLS FOR THE AIR-TO-AIR HEAT PUMP

The air-to-air heat pump is different from any other combination of heating and cooling equipment. The following items must be controlled at the same time for the heat pump to be efficient: space temperature, defrost cycle, indoor blower, the compressor, the outdoor fan, auxiliary heat, and emergency heat. Each manufacturer has its own method of controlling the heating and cooling sequence.

The space temperature for an air-to-air heat pump is not controlled in the same way as that for a typical heating and cooling system. There are actually two complete heating systems and one cooling system. The two heating systems are the reverse-cycle refrigeration cycle of the heat pump and the auxiliary heat from the supplemental heating system—electric, oil, or gas. The auxiliary heating system may be operated as a system by itself if the heat pump fails. When the auxiliary heat becomes the primary heating system because of heat pump failure, it is called *emergency heat* and is normally operated only long enough to get the heat pump repaired. The reason is that the COP of the auxiliary heating system is lower than the COP of the heat pump.

The space thermostat is the key to controlling the system. It is normally a two-stage heating and two-stage cooling thermostat that is used exclusively for heat pump applications. The number of stages of heating or cooling may vary. **Figure 43.39** shows a typical heat pump thermostat. These thermostats are

Figure 43.39 (A) A heat pump thermostat. (B) Notice the EMERGENCY HEAT option on the thermostat.

Photo by Eugene Silberstein

(A)

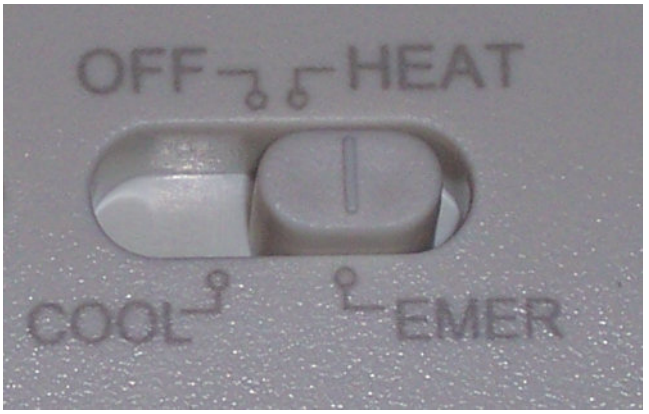

Photo by Eugene Silberstein

(B)

easily identified because they have an EMERGENCY HEAT position on the selector switch, **Figure 43.39(B)**. The wiring diagram in **Figure 43.40** represents the control wiring of a typical heat pump system.

The following sections describe the sequence of cooling and heating control of an automatic changeover thermostat—one that automatically changes from cooling to heating and back. **NOTE:** *This control sequence is only one of many. Each manufacturer has its own. The temperature-sensing element is a bimetal that controls mercury bulb contacts. Although not used in new thermostats, mercury bulbs will be encountered on older installations. The auxiliary heat is electric. The thermostat blower switch is in AUTO.*•

COOLING CYCLE CONTROL

When the first-stage bulb of the thermostat closes its contacts (on a rise in space temperature), the four-way reversing valve solenoid coil is energized, **Figure 43.41**. When the

Figure 43.40 A heat pump thermostat with two-stage heating and two-stage cooling.

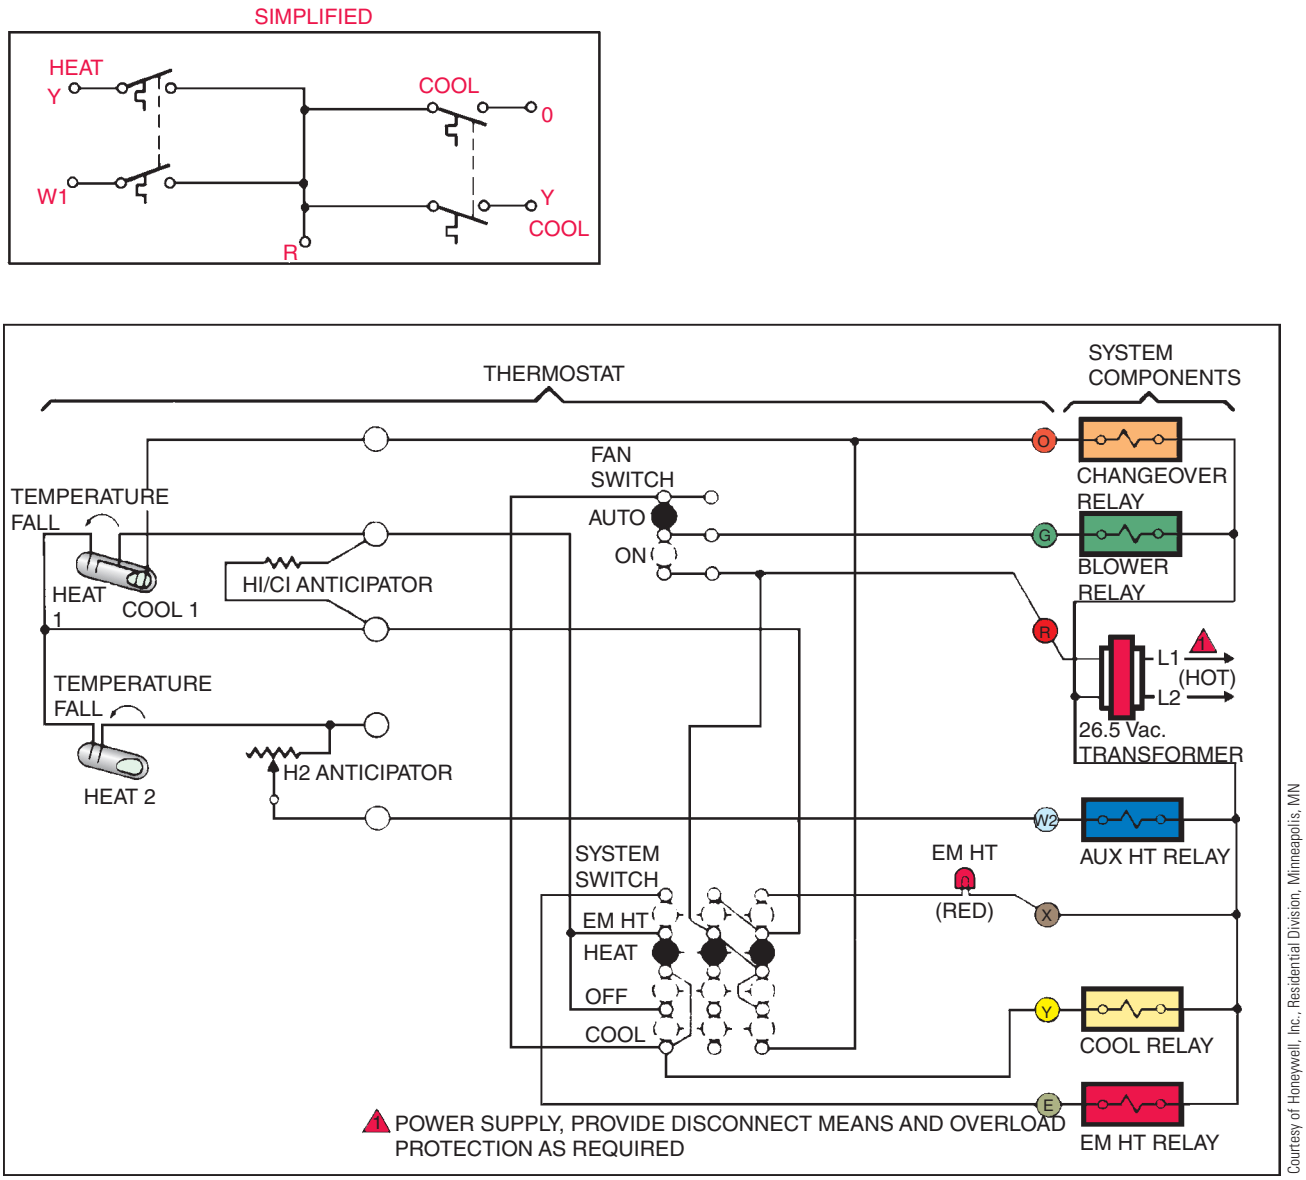

Figure 43.41 The first stage of the cooling cycle in which the four-way valve magnetic holding coil is energized.

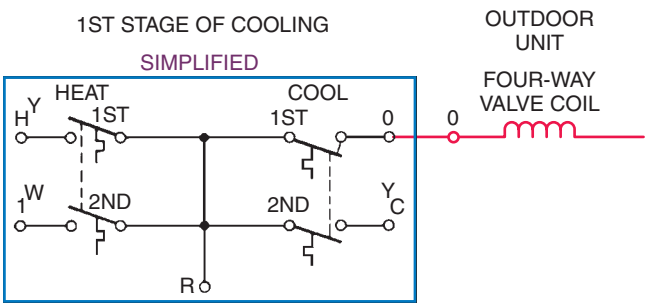

space temperature rises about 1°F, the second-stage cooling contacts of the thermostat close. The second-stage contacts energize the compressor contactor coil and the indoor blower relay coil to start the compressor, outdoor fan, and the indoor blower, **Figure 43.42**. When the compressor starts the second stage of operation, it diverts the hot gas from the compressor to the outdoor coil, and the system is in the cooling cycle.

When the space temperature begins to fall and is satisfied (because the compressor is running and removing heat), the first full contacts to open are the second-stage contacts. The compressor (and outdoor fan) and the indoor blower stop. The first-stage contacts remain closed, and the four-way valve remains energized. The system pressure will now

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Figure 43.42 This diagram shows what happens with a rise in temperature. The first stage of the thermostat is already closed; then the second stage closes and starts the compressor. The compressor was the last on and will be the first off.

equalize through the metering device for ease of compressor starting, but the four-way valve will not change position.

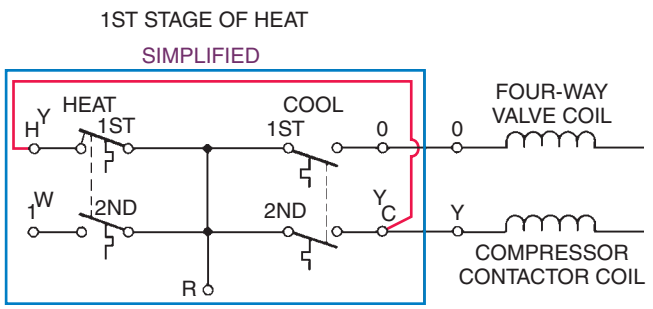
When the space temperature rises again, the compressor (and outdoor fan) and indoor blower will start again. If the outdoor temperature is getting cooler (e.g., in autumn), the space temperature will continue to fall, and the first-stage contacts will open. This deenergizes the four-way reversing valve solenoid coil, and the unit can change over to heat when it starts up. The four-way valve is a pilot-operated valve. It will not change over until the compressor starts and a pressure differential is built up.

SPACE HEATING CONTROL

When the space temperature continues to fall due to outdoor conditions, the first-stage heating contacts close. This starts the compressor (and outdoor fan) and the indoor blower. The four-way valve is not energized, so the hot discharge gas from the compressor is directed to the indoor coil. The unit is now in the heating mode, **Figure 43.43**. When the space temperature warms, the first-stage heating contacts open, and the compressor (and outdoor fan) and indoor blower stop.

If the outdoor temperature is cold, below the balance point of the structure, the space temperature will continue to fall because the heat pump alone will not be able to provide enough heat to the structure. The second-stage heating contacts will close and start the auxiliary electric heat to help the compressor. The second-stage heat was the last component to be energized, so it will be the first component off. This is the key to how a heat pump can get the best efficiency from the refrigerated cycle. It will operate continuously because it was the first on, and the second-stage auxiliary heat will stop and start to assist the compressor, **Figure 43.44**. There are as many methods of controlling the foregoing cooling and heating sequence as there are manufacturers. One common variation for controlling the heating system is to use outdoor thermostats to control the auxiliary heat, **Figure 43.45**. This keeps all of the auxiliary heat from coming on with the second stage of heating. It will come on based on outdoor temperature by the use of outdoor thermostats. These thermostats only allow the auxiliary heat on when needed, using the structure balance point as a guideline.

Figure 43.43 The space temperature drops to below the cooling set points for the first stage of heating; the compressor starts. This time, the four-way valve magnetic coil is de-energized, and the unit will be in the heating mode.



There are actually several balance points for any structure when a sophisticated heat pump system is installed. The first one mentioned previously was for the heat pump alone. Several stages of electric strip heat may be applied using balance points. It is vital that the strip heat not be operated any more than necessary. Later in this unit, we will explain why.

Consider a heat pump system that has 30 kW of total electric strip heat available in 10 kW increments that will be energized as needed. If the outdoor temperature drops down to a temperature that is just below the balance point of the system, a portion of the electric strip heaters will be energized. If after a period of time, the heat pump, along with some of the electric strip heaters, are not able to heat the space and the temperature in the structure continues to drop, additional electric strip heaters will be energized. If the space temperature still continues to drop, possibly from a drop in outside ambient temperature, still more additional electric strip heaters will be energized. The control of the supplementary electric strip heaters is accomplished by the thermostat as well as the outdoor temperature sensors or thermostats. The outdoor temperature sensors are typically low-voltage devices and are used to help anticipate the heating needs of the space, and to conserve energy. The goal is only to energize enough electric strip heaters as necessary to help the heat pump reach and maintain the desired space temperature.

One more aspect of this type of system should be discussed. Heat pump systems have an emergency heat mode that allows the owner to start all of the strip heat in the event of a heat pump failure. This mode of operation uses a relay that shuts off the heat pump and thermostatically controls all of the electric strip heaters. When in the emergency heat mode, an indicator light on the thermostat will illuminate to let the owner know that the system is operating in that mode. The control circuit wiring for the emergency heat mode is shown in **Figure 43.46**.

When strip heat is energized and operates along with the heat pump it is referred to as auxiliary, or supplementary, heat. When strip heat is used instead of the heat pump, in case of heat pump failure, it is called emergency heat. Many manufacturers use a signal light to alert the owner that the auxiliary heat is energized. This may be in the form of a blue light at the thermostat. If the blue light is on in mild weather, the owner might assume that the heat pump itself is not working properly because the strip auxiliary heat is helping it more than usual. This should prompt a call for service. When the system is switched to emergency heat, a red light is often switched on as well as the blue light. This should remind the owner to get the system serviced soon.

The technician should be familiar with four wiring sequences. The next four figures show how they work. These illustrations are from a generic HEAT-COOL thermostat that may be used with several manufacturers' equipment. Following the arrows, notice there is a change of direction in the way the power feeds some of these devices from one mode to the other, **Figure 43.47**, while the unit is in the cooling mode. Notice what devices are energized.

The four-way reversing valve is energized by the thermostat selector switch when it is placed in the cooling mode. The other devices that must be energized are the compressor, the outdoor fan, and the indoor blower. These components must operate in a coordinated fashion; they can be checked from the thermostat subbase by removing the thermostat. The terminals shown with letter designations are on the thermostat subbase. These may be jumped one at a time to see if the component will start. For example, if the technician jumps from R, which is the hot terminal, to G, the indoor blower will start up if the relay and the wiring are good. The technician can also shut off all power and use an ohmmeter between each terminal to the R terminal to establish that the circuit is good.

Figure 43.48 shows the first stage of heat. The four-way reversing valve is not energized, so the system will start up in the heating mode with the compressor and outdoor fan starting from the cool relay. The indoor blower is running. **Figure 43.49** shows the system operating in the heat mode with the first stage of electric heat operating from the second stage of the thermostat. Notice that the blue light on the thermostat is energized to show the homeowner that the strip heat is operating. The outdoor temperature should be below the heat pump's balance point if second-stage heat is being called for. If the system remains in second-stage heat even in mild weather, either the homeowner is turning the thermostat up to make it call or the heat pump system itself is not functioning correctly.

Figure 43.48 A generic HEAT-COOL heat pump thermostat in the first-stage heat mode with only the heat pump operating.

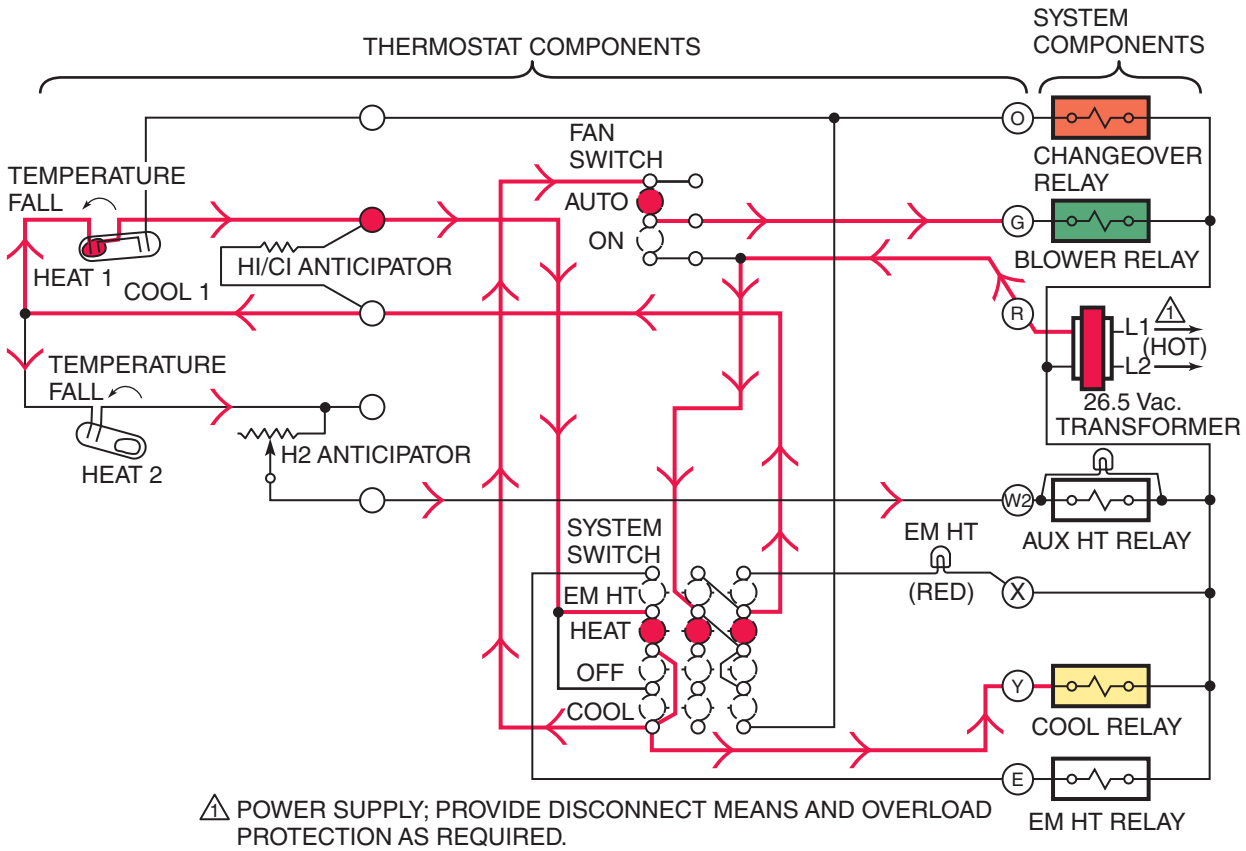

Figure 43.50 shows the system operating in the emergency heat mode. Notice there is no circuit to start the indoor blower. It must be started from an electric heat sequencer or from a thermal fan control or switch (see Unit 30, "Electric Heat"). When the emergency heat relay is energized, it will provide a circuit to jump out all outdoor thermostats and make all electric heat controllable through the second stage of the indoor thermostat. Both the blue auxiliary heat light and the red emergency heat light will remind the owner that excess energy is being used.

HEAT ANTICIPATOR

Conventional heat pump thermostats have heat anticipators just as gas and oil heat systems do. They can be more complicated with heat pumps because there are often two anticipators. The thermostat in **Figure 43.40** has two anticipators. The one in the first stage is preset and not adjustable. The one in the second stage is adjustable and is coordinated with the auxiliary heat relay. A study of Unit 15, "Troubleshooting Basic Controls," would help to answer any heat anticipator questions. When electric heat is involved, there can be many control variables that require understanding the heat anticipator because often the auxiliary heat has several controls that must be taken into consideration while working with heat anticipation. Unit 30, "Electric Heat," contains a lengthy discussion on electric heat that could also apply to auxiliary heat for a heat pump system.

ELECTRONIC THERMOSTATS

Most new thermostats use thermistors as the heat-sensing element. Remember, the thermistor is a resistor-type device that changes resistance with a change in temperature. There are several reasons why the thermistor is used. For one, mercury (Hg), which was used exclusively in older thermostats, is a poisonous, toxic, environmental hazard. There is a very small amount of mercury in each bulb of these older thermostats. A two-stage heat, two-stage cooling thermostat will often have four of these bulbs. When mercury bulbs were used, the temperature-sensing device was a bimetal strip or coil. The mass of the bimetal used to sense temperature caused rather large temperature swings. Remember, the thermostat's sensing element is located in a nearly dead air space under the cover of the thermostat. The thermistor has a very low mass and will respond much faster to temperature changes. For more information about electronic thermostats, see Unit 16, "Advanced Automatic Controls—Direct Digital Controls (DDCs) and Pneumatics."

One big difference in a system that has electronic controls as opposed to older analog controls is the number of features that can be incorporated into the system. These features often include timing functions, sensing functions, occupied and unoccupied settings, and error codes, which are explained in detail in Unit 16, "Advanced Automatic Controls—Direct Digital Controls (DDCs) and Pneumatics." Otherwise, troubleshooting the electronic thermostat is very similar to troubleshooting an older, analog, mercury bulb thermostat. If the electronic thermostat or control displays error codes, you follow them. Otherwise, treat it like a switch and jump from terminal to terminal at the subbase to determine if the thermostat has a problem. With a typical thermostat terminal designation, the R terminal is the hot terminal, the Y terminal is the compressor, the W terminal is heat, and the G terminal is the indoor blower. When the thermostat is disconnected from the subbase, a simple jumper placed from R to G should run the indoor fan. **NOTE:** *There may be a time delay built in, so the fan may not start for several minutes.* See Units 15, "Troubleshooting Basic Controls," and 16, "Advanced Automatic Controls—Direct Digital Controls (DDCs) and Pneumatics," for information on troubleshooting thermostats and wiring circuits. **Figure 43.51** shows an electronic thermostat along with its features.

43.23 THE DEFROST CYCLE

While operating in the heating mode, the outdoor coil functions as the evaporator. When the outside ambient temperature is warm—above about 50°F—the evaporator saturation temperature will likely be above freezing and the coil will not freeze. When the outside ambient temperature drops, the evaporator saturation temperature can drop below 32°F, and the outdoor coil can begin to freeze. If the frost on the coil is allowed to accumulate, system performance will be reduced. The defrost cycle is used to defrost the ice from the outdoor coil during the heating mode.

Remember that the outdoor coil must be colder than the outside air in order for the refrigerant in the coil to absorb heat from the outside air, **Figure 43.27**. The need for defrost varies with the outdoor air conditions, which include temperature and relative humidity, and the running time of the heat pump. For example, if the outdoor temperature is 45°F, the heat pump will very likely be able to satisfy the heating needs of the structure and cycle off from time to time. The frost will melt from the coil during this off time. As the outside ambient temperature falls, increased system run time causes more frost to form on the outdoor coil. If the outside air contains a great deal of moisture, the amount of ice that accumulates on the coil will increase. During cold, rainy weather, when the air temperature is 35°F to 45°F, frost will form so fast that the outdoor coil will very likely become covered with ice between defrost cycles. The formation of ice on the surface of the outdoor coil requires the removal of heat (144 Btu/lb) from the water. This heat energy is absorbed into the heat pump system. Later on, when a defrost cycle is initiated, the heat from the system is used to melt the ice that has formed on the outdoor coil.

Manufacturers have made significant advances in the managing of the defrost cycle to increase the efficiency of their equipment. Many years ago, heat pump manufacturers were not too concerned about system efficiency, but stricter government guidelines require that systems achieve higher efficiencies. As a result, the public has become aware of the importance and benefits of having an efficient system. Two important efficiency indicators are the seasonal energy efficiency ratio (SEER) for cooling and the heating seasonal performance factor (HSPF) for heating.

The SEER rating of a piece of equipment is the total cooling output for the system for an estimated typical cooling season divided by the actual power input for the entire season in watt-hours. Starting with the energy efficiency ratio (EER) rating where the steady-state output was divided by the power required to obtain the output, the EER was expanded to a seasonal ratio because it did not take into consideration the effects of starting and stopping the system, the defrost cycle, or different weather conditions, such as mild spring and fall seasons. Remember, a system does not get up to maximum efficiency for about 15 min after start-up. When the system cycles off, the cold

cooling coil is still available to absorb more heat from the conditioned space. Many manufacturers include a time-delay start on the indoor blower to let the coil become cool before air is passed through it. They may also include a time delay incorporated into the control scheme to keep the indoor blower operating at the end of the cooling cycle. This allows the cooling coil to remove more heat from the airstream at the end of the cycle. All of this is available because of electronic control systems.

The HSPF rating describes the seasonal performance for a particular piece of equipment. In the United States, we have cold dry areas, moderate humid areas, and everything in between these extremes. The HSPF rating for each piece of equipment can be used to calculate the cost of operation in six different zones in the United States. These zones were established by the Department of Energy (DOE). This gives the potential owner or the calculating contractor a method for predicting the cost of operation for a piece of equipment and compare it to other equipment for both summer and winter operation. The defrost cycle figures into this cost analysis.

The SEER and the HSPF ratings are a result of federal energy policies and are used by the Air-Conditioning, Heating and Refrigeration Institute (AHRI) to rate equipment. AHRI is a national trade association, whose members include the majority of the equipment manufacturers in the industry. It maintains a test laboratory for verifying equipment standards and publishes the SEER and HSPF ratings for equipment. The higher the efficiency rating, either SEER or HSPF, the higher the Btu output for the same input.

HOW IS DEFROST ACCOMPLISHED?

For the heat pump system to operate in the defrost mode, a number of things must take place:

- The four-way reversing valve switches the system into the cooling mode. This involves energizing the reversing valve coil for systems that fail in the heating mode—or de-energizing the reversing valve coil for heat pump systems that fail in the cooling mode.
- The outdoor fan motor is de-energized. With the fan not operating, more heat will be concentrated in the coil, allowing the frost to melt much faster than if the fan were operating.
- The indoor blower will remain on. Since the indoor coil is functioning as the evaporator in the defrost mode, the coil can freeze if the indoor blower is not operating.
- Some auxiliary heat is energized during defrost. This will help temper the cooler air being introduced to the occupied space during defrost. During defrost, the temperature of the occupied space should not be increased. If the temperature of the space is increased, the thermostat's set point may be reached and the heating cycle will end. If this happens, the defrost cycle will end as well and the ice removal process will stop.

When the heat pump system is in defrost with the auxiliary heat energized, the system is cooling and heating at the same time and is not efficient—so the defrost time must be minimized. *Demand defrost* means defrosting only when needed. Combinations of time, temperature, and pressure drop across the outdoor coil are used to determine when defrost should be started and stopped.

The factors that vary the operating cost of a piece of equipment are the number of defrosts per season, length of defrost, and whether the manufacturer tempers the air to the conditioned space during defrost with auxiliary heat. Remember, the unit will be in the cooling mode and blowing cold air during defrost. If the manufacturer can get the equipment rated without the auxiliary heat, the rating will be better. The equipment will have a better HSPF, but the customer may not be satisfied with the cool air that blows into the space during defrost.

INITIATING THE DEFROST CYCLE

Manufacturers often design their defrost control strategies to initiate defrost shortly after the coil starts to accumulate frost in order to maximize system performance. Some manufacturers use time and temperature to start defrost. This is called *time and temperature initiated* and is performed with a timer and temperature-sensing device. The timer is often incorporated into a solid-state, printed circuit board, **Figure 43.52**. The temperature sensor, such as the one used to measure the temperature of the outdoor coil, is typically a thermistor, **Figure 43.53**. The timer closes a set of contacts for 10 to 20 seconds for a trial defrost every 30, 60, or 90 minutes. The time interval between defrost trials is field set and is determined in part by climatic conditions, mainly humidity. In high-humidity climates, more frequent defrost may be needed. In very dry climates, the 90-minute time interval may be used. The timer contacts are in series with the temperature sensor contacts so that both contacts must be made at the same time. This means that two conditions must be met before defrost can start, **Figure 43.54**. In

Photo by Eugene Silberstein

operation, when the time delay period has elapsed, the timer will attempt to bring the heat pump system into defrost. If the temperature sensor determines that there is ice on the coil, defrost will start.

Another common method of starting defrost uses an air pressure switch that measures the air pressure drop across the outdoor coil. When the unit begins to accumulate ice, a pressure drop occurs and the air switch contacts close. This switch can be wired in conjunction with the timer and the temperature sensor to ensure that an actual ice buildup is on the coil. The combination of time and temperature only ensures that time has passed and the coil is cold enough to actually accumulate ice. It does not actually sense an ice thickness. It can be more efficient to defrost when an actual buildup of ice exists, **Figure 43.55**.

TERMINATING THE DEFROST CYCLE

Terminating the defrost cycle at the correct time is just as important as starting defrost only when needed. This is done in several ways. *Time and temperature* was the terminology used to start defrost. *Time or temperature terminated* is the terminology used to terminate one type of defrost cycle. The difference is that two conditions must be satisfied to start defrost, and either one of two conditions can terminate defrost. After defrost has started, time or temperature can terminate it. For example, if the defrost temperature sensor warms up to the point that it is obvious ice is no longer on the coil and its contacts break, defrost will stop. This temperature termination is normally 50°F at the location of the temperature sensor. If the contacts do not open because it is too cold outside, the timer will terminate defrost within a predetermined time period. Normally, the maximum time the timer will allow for defrost is 10 min, **Figure 43.56.**

ELECTRONIC CONTROL OF DEFROST

Electronic circuit boards and their controls can help the manufacturer more closely control the defrost cycle. They have the ability to accurately control time and temperature with electronic timers and thermistors. Some systems may use the difference in the entering air temperature and the coil temperature to arrive at a temperature split where defrost is desired. For example, suppose the outdoor temperature is 35°F. The coil will operate at about 20°F to 25°F colder than the outdoor coil. Using a 20°F temperature split as an example, suppose the coil begins to develop ice on the surface. As ice forms on the coil, the pressure across the coil will drop, but the temperature will also drop inside the coil as ice develops. The manufacturer may decide that it is time for a defrost when the coil temperature has dropped to 8°F below the normal operating temperature for that condition, **Figure 43.57.** If the time portion of the defrost initiation has been satisfied, the unit will start to defrost and will be terminated by the coil temperature. All of this is accomplished with the electronic circuit board and two thermistors.

Manufacturers of heat pumps may use other combinations of conditions to operate the defrost cycle that include air pressure drop across the coil. They look for something economical, reliable, and effective for making the HSPF number higher for a better rating.

43.24 INDOOR FAN MOTOR CONTROL

Starting the indoor blower motor of a heat pump differs from starting it in other heating systems. In other heating systems, the indoor blower is started with a temperature-operated switch. With a heat pump, the blower must start at the beginning of the cycle, which is controlled by the thermostat. The indoor blower is started with the blower terminal, often labeled G. The compressor operates whenever the unit is calling for cooling or heating, so the G or fan terminal is energized whenever there is a call for cooling or heating.

43.25 SECOND-STAGE ELECTRIC HEAT

During periods of colder weather, the air-to-air heat pump will often require auxiliary heat. This is usually accomplished with an electric furnace with a heat pump coil for cooling and heating. Electric heat is often started with a sequencer that has a

time-start and time-stop feature for the electric heating element. This means that the electric heating elements are energized for a time period if the unit is shut off by the thermostat's on-off switch. When the thermostat is allowed to control the system normally, the heat pump will be the first component to come on and the last to shut off. The indoor blower will start with the compressor through the blower relay circuit. The electric strip heat will operate as the last component to come on and the first to shut off. When the owner decides to shut off the heat at the thermostat and the strip heat is energized, the heating elements will remain energized until the sequencers cycle them off. A temperature switch is often used to sense this heat and keep the blower running until the heaters cool. The electric furnaces used for heat pumps are like the ones described in Unit 30, "Electric Heat."

Electric strip heaters are used for three purposes in the heat pump system. They provide

- supplementary heat when the heating system is operating below the balance point of the system,
- emergency heat when the reverse-cycle heat pump system is not functioning, and
- air tempering when the system is operating in the defrost mode.

Depending on the function these electric strip heaters are intended to serve, the number of heaters to be energized will change. When acting to provide supplementary heat, the number of heaters energized is determined by the outside ambient temperature. When the temperature is colder outside, more heaters can be energized. When the outside temperature is warmer, fewer, if any, heaters need to be brought into operation.

When providing emergency heat, all of the available strip heaters are energized. This is because the main/primary heat source is not operating and the strip heaters are attempting to satisfy the heating requirements of the space by themselves. When used to temper the air during defrost, it is very important not to energize too many strip heaters. As mentioned earlier in this unit, the heaters used to temper the air during defrost should not raise the temperature of the occupied space. Consider a heat pump system that has just gone into defrost. The space temperature is 70°F and the thermostat is set to 71°F. If the heaters temper the air too much, it is possible that the temperature of the space may increase by 1°F. If the temperature sensed by the thermostat reaches 71°F, the call for heat will end, as will the defrost cycle. If the defrost ends, any unmelted ice will remain on the outdoor coil when the system returns to the heating mode. If this continues, ice will continue to accumulate on the outdoor coil and system efficiency will be affected. So, to prevent this from occurring, the amount of heat added to the air during defrost should not exceed 80% of the sensible cooling capacity of the system. Consider the following example.

A heat pump system has a sensible cooling capacity of 60,000 Btu/h. During defrost, the system switches over to the cooling mode, so the air introduced to the occupied space will be cooled. We want to temper this air with enough heat to offset 80% of the cooling capacity—which, in this case, is 48,000 Btu/h (60,000 Btu/h × 0.80). The conversion factor between Btu/h and watts is 3.413 Btu/h/W, or Btu/Wh, so we will need to energize no more than 14,064 W (48,000 Btu/h ÷ 3.413 Btu/Wh) of electric heat. If the heat pump system is equipped with six 3.5-kW electric strip heaters (3500 W each), up to four heaters can be energized during defrost. These four heaters will provide 14 kW of heat (3.5 kW × 4) to the air passing over the strip heaters. Since the 14 kW (14,000 watts) is less than the maximum calculated value, the

space will not be heated above its present temperature during defrost. This will allow the system to complete its defrost cycle as needed.

43.26 SERVICING THE AIR-TO-AIR HEAT PUMP

Servicing the air-to-air heat pump is much like servicing a refrigeration system. During the cooling season, the unit is operating as a high-temperature refrigeration system; and during the heating season, it is operating as a low-temperature system with planned defrost. The servicing of the system is divided into electrical and mechanical servicing.

Servicing the electrical system is much like servicing any electrical system that is used to operate and control refrigeration equipment. The components that the manufacturer furnishes are built to last for many years of normal service. One significant point about a heat pump is that it has much more running time than a cooling-only unit. A typical cooling unit in a residence in Atlanta, Georgia, will run about 120 days per year. A heat pump may run 250 days, more than twice the time. In winter the heat pump may run for days and not stop when the temperature is below the balance point of the structure.

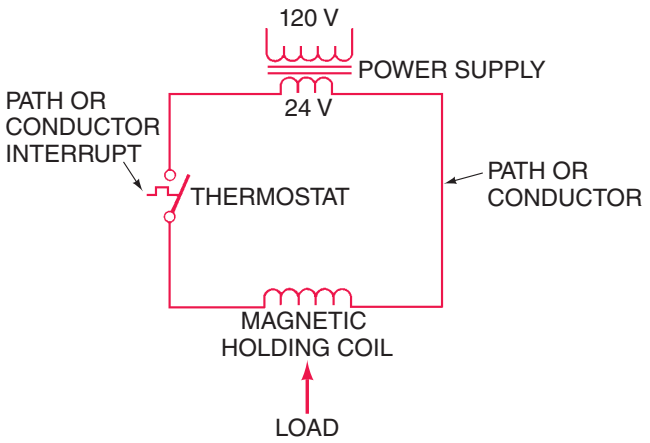
SAFETY PRECAUTION: *The same safety precautions must be observed when troubleshooting electrical components of a heat pump as were observed when servicing an air-conditioning system. When the units are located in crawl spaces and you are in contact with the ground, be careful not to establish a path for current to flow through your body to ground.*•

43.27 TROUBLESHOOTING THE ELECTRICAL SYSTEM

Troubleshooting the electrical system of an air-to-air heat pump is similar to troubleshooting a cooling air-conditioning system. Recall that there must be a power supply, a complete path for the electrical current to take, and a load before electricity will flow. The power supply provides the electrical energy to the unit, the complete path is the wiring, and the closed switches or electrical contacts and the loads are the electrical components that perform the work. Every circuit in the heat pump wiring can be reduced to these items. It is important that you think in terms of power, conductor, switch, and load, **Figure 43.58**.

It is usually easy to find electrical problems if some component will not function. For example, when a compressor contactor coil is open, it is evident that the problem is in the contactor. A voltage reading can be taken on each terminal of the contactor coil. If there is voltage and it will not energize the contacts, a resistance check of the coil will show whether there is a circuit through it. A correctly operating circuit has the correct resistance. No resistance or too little resistance will create too much current flow. Infinite resistance results in no current flow, as there is no path. It sometimes helps to be able to compare a suspected bad component (e.g., one with too little resistance) to a component of correct resistance, **Figure 43.59**.

Figure 43.58 This is the basic example of a power supply, a path or conductor, and a load for consuming power.



Electrical malfunctions that cause the technician real problems are the intermittent ones, such as a unit that does not always defrost so that ice builds up on the outdoor coil.

Figure 43.59 Magnetic holding coils used for the contactor. One of them has a measurable resistance of 0.5 Ω. The other one, the correct one, has a measurable resistance of 20 Ω. The one with the lower resistance is shorted. It will draw too much current and place a load on the control transformer. If the load is too great, it will overload the transformer.

The heat pump can be difficult to troubleshoot in winter because of the weather. **SAFETY PRECAUTION:** *If it is wet outside, the emergency heat feature of the heat pump should be used until the weather improves. It is hard enough to find electrical problems in cold weather; the moisture makes it dangerous.*•

TYPICAL ELECTRICAL PROBLEMS

1. Indoor blower motor and outdoor fan motor
   A. Open winding: motor will not start; may draw locked rotor amperage; may have infinite resistance across one winding, normal resistance across the other winding; motor will overheat.
   B. Shorted winding: motor may or may not start; motor will draw higher amperage.
   C. Shorted winding to ground: motor may or may not start; circuit breaker may trip or fuse may blow; motor may draw excessive current; there will be measurable resistance between the motor terminals and ground.
   D. Open run capacitor: motor will not start; motor will draw locked rotor amperage; motor will overheat.
   E. Open start capacitor: motor will likely not start; motor will draw high amperage; motor will overheat if unable to start.
   F. Shorted run capacitor: motor may or may not start; motor will draw higher amperage; motor will run slowly if it does start.
   G. Shorted start capacitor: motor will likely not start; if motor starts it will turn slowly and draw high amperage.

2. Compressor contactor, fan relays
   A. Coil winding open: device will not close NO contacts; will not open NC contacts.
   B. Shorted coil winding: low-voltage control circuit protection device may trip; control transformer may overload; device will not close NO contacts; will not open NC contacts.
   C. Pitted contacts: reduced voltage to the load being controlled; there will be a measurable voltage across closed contacts.

3. Defrost relay
   A. Coil winding open: contacts on the relay will not close or open automatically.
   B. Coil winding shorted: circuit overload.
   C. Pitted contacts: reduced voltage to the load being controlled; there will be a measurable voltage across closed contacts.

4. Compressor
   A. Open compressor motor winding: will not start; may draw locked-rotor amperage if only one winding is open.
   B. Shorted compressor motor winding: circuit breaker trips when compressor is energized.
   C. Shorted winding to ground: The breaker or fuse will open up. A short from winding to winding may allow the motor to start and run until the breaker trips or the overload opens.
   D. Open internal overload: no current draw; no compressor operation; compressor may be hot to the touch; there may be infinite resistance readings between common and run and common and start because the motor winding thermostat is open. There will be a measurable resistance between run and start because the meter is reading through the run and start windings.

5. Reversing valve solenoid
   A. Open coil: system will remain in the mode in which the system fails (usually heating); no defrost cycle.
   B. Shorted coil: fuse protection trips when system changes over.

6. Electric strip heaters
   A. Open heater: may or may not be noticeable, depending on how many heaters are affected; there may be a reduced air-tempering effect, a reduced heating capacity (second-stage and emergency heat modes), and/or no current draw through the heater circuit. Sometimes a heater will short to ground and stay energized operating in the 115-V mode. In the cooling cycle, it will heat the structure and cause the cooling to operate to cancel the heat being introduced to the structure. In the heating mode, it will cause excessive electrical costs.
   B. Open safety switch: no current flow through the heater.
   C. Open blower-proving device: no voltage supplied to the coil of the heater control relays or sequencer; no current flow through the heaters.

7. General wiring problems
   A. Loose electrical connections: burned connections; localized heat; intermittent system problems.
   B. Short circuit: tripping breakers or blowing fuses. **SAFETY PRECAUTION:** *breakers should not be reset repeatedly; damage can occur.*•

43.28 TROUBLESHOOTING MECHANICAL PROBLEMS

Mechanical problems can be hard to find in a heat pump, particularly in winter operation. Summer operation of a heat pump is similar to that of a conventional cooling unit. The pressures and temperatures are the same, and the weather is not as difficult to work in. Mechanical problems are solved with gauge manifolds, wet- and dry-bulb thermometers, and air-measuring instruments.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

SOME TYPICAL MECHANICAL PROBLEMS

1. Indoor unit
   A. Air filter dirty (winter); high head pressure; low COP.
   B. Dirty coil (winter); high head pressure; low COP.
   C. Air filter dirty (summer); low suction pressure.
   D. Dirty coil (summer); low suction pressure.
   E. Refrigerant restriction (summer); low suction.
   F. Refrigerant restriction (winter); high head pressure.
   G. Defective TXV on the indoor coil (summer); low suction pressure.
   H. Defective TXV on the outdoor coil (winter); low suction.
   I. Leaking check valve (summer); flooded indoor coil.
2. Outdoor unit
   A. Dirty coil (winter); low suction pressure.
   B. Dirty coil (summer); high head pressure.
   C. Four-way valve will not shift; stays in same mode.
   D. Four-way valve halfway; pressures will equalize while running and appear as a compressor that will not pump.
   E. Compressor efficiency down; capacity down, suction and discharge pressures too close together. Compressor will not pump pressure differential.
   F. Defective TXVs (winter); low suction pressure.
   G. Leaking check valve (winter); flooded coil.

The technician should be aware of three mechanical problems: (1) the four-way valve leaking through, (2) the compressor not pumping to capacity, and (3) charging the heat pump. These particular problems are different enough from commercial refrigeration that they need individual attention.

SAFETY PRECAUTION: *Be aware of the high-pressure refrigerant in the system while connecting gauge lines. High-pressure refrigerant can pierce your skin and blow particles in your eyes; use eye protection. Liquid refrigerant can freeze your skin; wear gloves. The hot gas line can cause serious burns and should be avoided.*•

43.29 TROUBLESHOOTING THE FOUR-WAY REVERSING VALVE

The four-way reversing valve can cause a technician a lot of confusion when troubleshooting. Several things can cause the four-way valve to malfunction:

1. The valve may be stuck in heating or cooling.
2. The coil may be defective.
3. The valve may have an internal leak.

The sign of a stuck reversing valve may be that it will not change from heating to cooling and back. When the valve is energized in the cooling mode and is trying to operate in the heating position, the first thing the technician should do is make sure the coil is energized. The technician may do this by using a voltmeter at the coil lead wires. Another procedure is to hold a screwdriver close to the coil to see if there is a magnetic field when the valve is supposed to be energized. If the valve is getting power and will not change over while the unit is running and there is a pressure difference from the high to the low side, the valve may be stuck. Remember, the valve will not change over unless there is a pressure difference between the high- and the low-pressure sides of the system because it is a pilot-operated valve. The technician may also feel the valve coil to see if it is hot. That is a sign that it is energized.

If the reversing valve is truly stuck, the technician may take a soft-face hammer or some other soft-surface instrument and tap the valve on one end and then the other to see if it will break loose. Something inside may be binding it. If it breaks loose, the technician should force the valve to change positions from heat to cool several times to see if it is free to operate. The valve should still be replaced, as the cause for the malfunction has not been addressed. The valve will stick again at some point in the future.

The solenoid coil on the reversing valve can have an open circuit, which will cause it to operate only in the de-energized mode. Since the coil is removable, it can be changed. It is always desirable to change the coil if that will repair the valve, rather than to change the complete valve.

A four-way reversing valve with an internal leak can easily be confused with a compressor that is not pumping to capacity. The suction pressure on a system with a leaking reversing valve will be higher than normal and the discharge pressure will be lower than normal. The capacity of the system will be reduced in both the heating and cooling modes. This is the same symptom as small amounts of hot gas leaking from the high-pressure side of the system to the low-pressure side. When a four-way reversing valve is suspected of leaking internally, a good-quality thermometer is used to check the temperature of the low-side line, the suction line from the evaporator (the indoor coil in summer or the outdoor coil in winter), and the permanent suction line between the four-way valve and the compressor. The temperature difference should not be more than about 3°F.

NOTE: *Take these special precautions when recording temperatures: (1) Take the temperatures at least 5 in. from the valve body (to keep valve body temperature from affecting the reading); and (2) insulate the temperature lead that is fastened tightly to the refrigerant line,* **Figure 43.60.**•

REPLACING THE FOUR-WAY REVERSING VALVE

If it is determined that the four-way reversing valve needs to be replaced, a few things should be kept in mind to ensure that the system will operate as intended after the repair is made. Make certain that

- the new valve is thoroughly inspected before installation. Check the valve for scratches, dents, and other imperfections on the bodies of the main and pilot valves. Dents can prevent the internal slide from moving within the valve. If possible, inspect the valve while still at the parts depot to prevent a second trip if the valve turns out to be damaged.
- the new valve is not dropped or mishandled.
- excessive heat is avoided when installing the valve.
- the new valve is piped so that the valve will fail in the same mode of operation as the original.
- the new valve is installed horizontally with the pilot tubes on top. This will prevent oil from entering the pilot ports and causing the valve to malfunction. Always follow the manufacturer's guidelines when replacing the valve.
- an exact part replacement is selected whenever possible. If the ports on the new valve are too small, excessive pressure drops will be present across the valve, compromising system performance. If the new valve is too large, the switchover time will be increased, resulting in sluggish system operation.

43.30 TROUBLESHOOTING THE COMPRESSOR

Checking a compressor in a heat pump for pumping to capacity is much like checking a refrigeration compressor except that there are normally no service valves to work with. Some manufacturers furnish a chart with the unit to show what the compressor characteristics should be under different operating conditions, **Figure 43.61**. If such a chart is available, use it.

The following is a reliable test, using field working conditions, that will tell whether the compressor is pumping at near capacity. The test will reveal any large inefficiencies.

1. Whether summer or winter, operate the unit in the cooling mode. In winter, the four-way valve may be switched by energizing it with a jumper or deenergizing it by disconnecting a wire to switch the unit to the summer mode. This will allow the auxiliary heat to heat the structure and keep it from getting too cold.
2. Block the condenser airflow until the head pressure is 440 psig (this simulates a 95°F day) and the suction pressure is about 118 psig. This assumes that the system is operating with R-410A as its refrigerant.
3. The compressor amperage should be at close to full load. The combination of discharge pressure, suction pressure, and amperage should reveal whether the compressor is working at near full load. If the suction pressure is high and the discharge pressure is low, the amperage will be low. This indicates that the compressor is not pumping to capacity. Sometimes a whistle can be heard when the compressor is shut off under these conditions. The suction line may also get warm immediately after shutting off the unit under these conditions. Such symptoms indicate that the compressor is leaking internally. **NOTE:** *If there is any doubt as to where the leak may be, perform a temperature check on the four-way valve.*

Figure 43.61 The performance chart for a 36,000-Btu/h R-410A heat pump system.

43.31 CHECKING THE CHARGE

Some heat pumps have a critical refrigerant charge. The tolerance could be as close as ±½ oz of refrigerant. **Therefore, do not install a standard gauge manifold each time you suspect a problem.** When a heat pump has a partial charge, it is obvious that the refrigerant leaked out of the system. Leak check the system and repair the leak before charging.

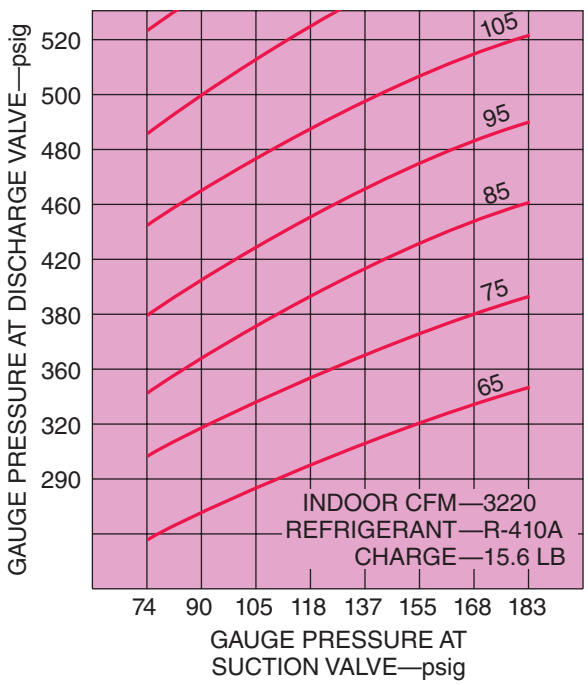
When a partial charge is found in a heat pump, some manufacturers recommend that the system be evacuated to a deep vacuum and recharged by measuring the charge into the system. Some manufacturers furnish a charging procedure to allow adding a partial charge. It is always best to follow the manufacturer's recommendation. **Figure 43.62** is a sample performance chart for a heat pump.

43.32 SPECIAL APPLICATIONS FOR HEAT PUMPS

The use of oil or gas furnaces for auxiliary heat with heat pumps is a special application, and several manufacturers have designed such systems because they provide several advantages. Usually, natural gas is less expensive to use as the auxiliary fuel than electricity. Fuel oil may be considered if such as system is already installed. Both systems have similar control arrangements. The heat pump's indoor coil can be used in conjunction with an oil or gas furnace, but the coil must be downstream of the oil or gas heat exchanger. In other words, the air must flow through the oil or gas heat exchanger first and then through the heat pump indoor coil. **SAFETY PRECAUTION:** *The gas or oil furnace must not operate at the same time that the heat pump is operating or high head pressures will result.*•

The control function can be accomplished with an outdoor thermostat set at the balance point of the structure to change the call for heating to the oil or gas furnace and to shut off the heat pump. This allows the heat pump to operate down to the balance point, when the oil or gas furnace will take over. When defrost occurs, the oil or gas furnace will come on during defrost because the same controls are used as for a standard heat pump and a call for auxiliary heat to warm the cool air during defrost is still part of the control sequence. **SAFETY PRECAUTION:** *A high-pressure control can prevent the compressor from overloading if a defrost does not terminate due to a defective defrost control.*•

Figure 43.62 An R-410A heat pump performance chart.



MAXIMUM HEAT PUMP RUNNING TIME

Other control modifications allow the heat pump to run below the balance point. Such arrangements have more relays and controls. The heat pump is designed to operate whenever it can. This is accomplished by using the second-stage contacts to start the oil or gas heat. This sequence stops the heat pump until the second-stage thermostat contacts satisfy. The heat pump then starts again. This sequence repeats itself each cycle. Before considering this control sequence, the system should be studied to see whether it is more economical to switch over from the heat pump to the auxiliary source or to restart the heat pump. The economic balance point of the structure may be determined by comparing the cost of fuels.

HEAT PUMP ADDED ON TO EXISTING ELECTRIC FURNACE

When a heat pump indoor coil is added to an existing electric furnace installation, the older furnace might not be set up to allow the heat pump coil to be located before the electric heating elements. If so, a wiring configuration similar to an oil or gas installation may be used, **Figure 43.63**.

Manufacturers have many different methods of building a heat pump with individual performance characteristics. There are many different piping configurations and special heat exchangers. This text is intended to explain the typical heat pump. If the technician encounters a different system from that described here, the manufacturer should be consulted.

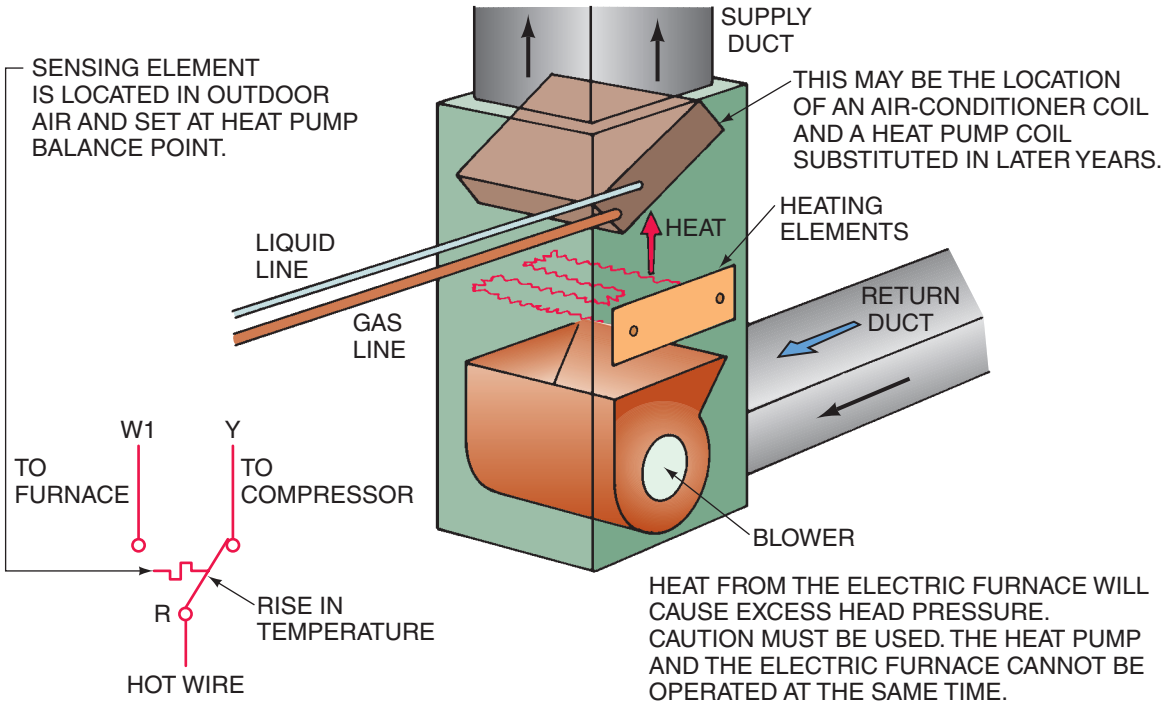
Figure 43.63 The electric furnace heat coils are below the heat pump coil and will cause a high head pressure if used incorrectly with a heat pump.



43.33 HEAT PUMPS USING SCROLL COMPRESSORS

Manufacturers are continually working to make heating and cooling equipment more efficient and less expensive to purchase. Some of the new techniques involve the use of improved compressors. Compressor pumping efficiency has been improved with the *scroll compressor,* **Figure 43.64**. This compressor is ideally suited for heat pump application because of its pumping characteristics. The scroll compressor does not lose as much capacity as the reciprocating compressor at the higher head pressures of summer or the lower suction pressures of winter operation. Because the compression takes place between two spiral-shaped forms, **Figure 43.65**, the scroll compressor does not have the top-of-the-stroke clearance volume loss that a reciprocating compressor has. The gas trapped in the clearance volume of a reciprocating compressor must reexpand before the cylinder starts to fill, which reduces efficiency (see Unit 23, "Compressors"). The scroll compressor is about 15% more efficient than the reciprocating compressor, and it has many of the same pumping characteristics as the rotary compressor. The scroll compressor does not require crankcase heat because it is not as sensitive to liquid as the reciprocating compressor. This results in a saving in power.

Scroll compressor pressures are about the same as those of reciprocating compressors, so the technician should not

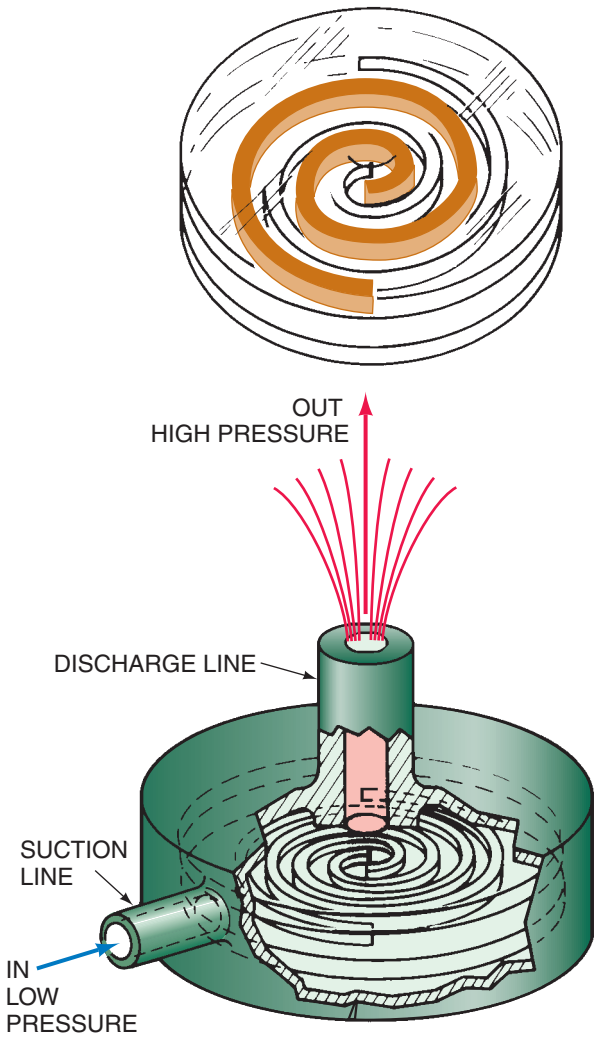
Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 43.65 The orbiting action between the scrolls in a scroll compressor provides compression.



see any difference in the gauge readings. Scroll compressors are cooled by the discharge gas, so the technician will notice that the compressor shell is much hotter than that of a compressor that is cooled by suction gas. The scroll compressor runs with less vibration and a lower noise level while simultaneously operating at several stages of compression. Each pocket of gas represents a stage of compression. **Figure 43.66** illustrates one pocket.

Figure 43.66 The compression of one pocket of refrigerant in a scroll compressor.

Courtesy Copeland Corporation

To prevent pressures from equalizing back through the compressor during the off cycle, the scroll compressor has a check valve at its discharge. When the compressor is shut off, the gas trapped between the check valve and the compressor scroll will back up through the scroll; the compressor will make a strange sound—resembling the rustling of a handful of marbles—at the moment it is shut off until these pressures equalize. The high-side pressure will then equalize through the metering device to the low side, just as in a reciprocating compressor system. The equalizing of pressure between the check valve and the scroll allows the compressor to start up without hard-start assistance because there is no pressure differential for the first starting revolutions. Thus there are fewer start components to purchase and fewer components to cause trouble.

The scroll compressor does not normally require a suction-line accumulator, which is usually included in reciprocating compressor systems, because it is not as sensitive to liquid floodback as the reciprocating compressor. The scroll compressor is more efficient, stronger, lighter, and requires fewer accessories for good performance. Unlike reciprocating compressors, scroll compressors tend to "wear in" with time, as opposed to wearing out.

43.34 HEAT PUMP SYSTEMS WITH VARIABLE-SPEED MOTORS

Another method of improving the efficiency of heat pump systems is the use of variable-speed motors for the compressor and both fan motors. This permits the selection of a different heat pump capacity. Previously, the selection of heat pump systems had been determined by their cooling capacity, but a typical structure in the heat pump belt requires about 2 to 2½ times as much heat as cooling. For example, a home in Atlanta, Georgia, may require 30,000 Btu/h for cooling and would typically require 60,000 to 75,000 Btu/h for heating. A heat pump that provides 30,000 Btu/h requires considerable auxiliary heat for winter conditions below the balance point of the structure. If the heat pump is selected to satisfy the winter capacity need, it would be oversized in the summer, which would result in poor performance and high humidity, along with low efficiency. The variable-speed heat pump narrows the gap because a system that comes closer to satisfying the heating requirement at full load can be chosen and it can run at part load and reduced power in warmer months. Less auxiliary heat is required, so year-round efficiency is achieved. Electronics and electronically controlled motors are what provide variable speeds. Each manufacturer has its own method of control and its own checkout procedures. Repair of a unit with variable-speed motors and electronic controls should not be attempted without the manufacturer's checklist.

HVAC GOLDEN RULES

When making a service call to a residence:

- Look professional and be professional. Wear clean clothes and shoes.
- Have a neat haircut, trim facial hair, and practice good oral hygiene by brushing teeth daily. Showering and daily use of underarm deodorant are strongly recommended.
- Wear coveralls for work under the house and remove them before entering the house.
- Ask the customer about the problem. The customer can often help you solve the problem and save you time.

Added Value to the Customer

Here are some simple, inexpensive procedures that may be included in the basic service call.

- Check line temperatures by touch for the correct temperature in summer or winter cycle.
- Clean or replace air filters as needed. This is very important for heat pumps.
- Make sure that all air registers are open—again very important for heat pumps.
- Replace all panels with the correct fasteners.
- Check indoor and outdoor coils for dirt or debris.
- Ask owners whether they have noticed any ice buildup in winter operation. This may lead to checking out the defrost cycle for the system.
- Check the gas line for proper insulation. Heat pumps may lose capacity due to loss of line insulation.

PREVENTIVE MAINTENANCE

The typical heat pump requires the same maintenance as an air-cooled air-conditioning system with electric heat. It is important that the air side of the system should always handle the maximum air for which it is designed. Some homeowners shut registers off in unused rooms, but this should never be done with a heat pump. The indoor system is the condenser in the winter cycle. Any reduction in airflow will cause high head pressure and a low COP, and so higher-than-normal power bills with less heating. For the same reason, filters should be maintained more carefully in heat pump systems. Reduced airflow cannot be allowed.

The outdoor unit should be examined for a dirty coil. The insulation on the outdoor gas line should extend all the way to the unit, or heat will be lost to the outdoor air. The gas-line temperature may be as high as 220°F and will transfer a lot of heat to the cold outside air. This is heat that is paid for but lost.

The contactor should be examined at least once a year for pitting and loose connections. This contactor functions about twice as many times each year as an air-conditioning system contactor. Frayed wires should be repaired or replaced. Wires or capillary tubes rubbing on the cabinet or refrigerant lines will soon cause problems and they should be adjusted or isolated.

The fan motor may require lubrication. Follow the manufacturer's directions.

The customer should be quizzed about the winter performance of a heat pump, including the amount of ice buildup on the outdoor unit. If excess ice seems to be a problem, defrost problems may be causing the unit to stay in defrost. Defrost may be simulated even in hot weather with most heat pumps by disconnecting the outdoor fan and running the unit in heating mode. With the outdoor fan motor disconnected, the unit will not overload because of high evaporator temperatures. Most manufacturers have a recommended procedure for checking defrost. If the system has the same timer as shown in **Figure 43.53**, the unit may be run until the coil and sensor are cold and covered with frost. This should be below the make point of 26°F. At this point, carefully jump terminal 3 to 4 on the timer with an insulated jumper. The unit should immediately go into defrost if the sensor circuit is made. Should it not go into defrost at this time, wait a few more minutes and try again. The sensor is large and may take a few minutes to make. If it will not go into defrost, leave the jumper on the 3 to 4 terminals and jump the sensor. If the unit immediately goes into defrost, the sensor is either defective or not in good contact with the liquid line.

After the unit goes into defrost normally, remove the jumper from 3 to 4 and allow the unit to terminate defrost. If the ambient temperature is above freezing and there is no ice accumulation, this should take about a minute. If it takes a full 10 min, the defrost control contacts may be permanently closed. They may be checked by allowing the control to rise to ambient temperature above 26°F and using an ohmmeter to see whether the contacts remain closed. They should be open when the sensor is above 50°F. One sign of permanently closed contacts is if the unit will go into defrost every time the timer calls for it to do so, whether the sensor is cold or not, and stay in defrost the full 10 min. This is hard on the compressor if the unit does not have a high-pressure control, because high pressure will occur at this time.

When performing maintenance on systems that have electronic circuit boards, the technician will need to work with the timing circuits. If the technician has to wait for each sequence to time out, the service will take too long. Most manufacturers have a method of advancing the timing circuits to a "quick time" that will speed up the service call and any checking procedures being performed.

The last thing the technician should do is make sure that all fasteners are in place and tight. It is common for the cabinet screws to become loose. These should be tightened to prevent the cabinet from rattling. If the screw holes are oversized due to service, use a screw one size larger. It is good practice to have a supply of rust-resistant, one-half oversize screws. Stainless screws cost more, but the heads do not rust off with time.

43.35 DIAGNOSTIC CHART FOR HEAT PUMPS IN THE HEATING MODE

The heat pump is the most complex of the heating and air-conditioning systems. They are found in many homes and businesses in the south and southwest parts of the United States, where the climate is best suited for heat pumps. These systems operate in both heating and cooling modes. The heating mode is discussed here.

Problem	Possible Cause	Possible Repair
Cooling Season	See summer air-conditioning (Unit 42)	
Heating Season		
No heat—outdoor unit will not run—indoor fan runs	Open outdoor disconnect	Close disconnect.
	Open fuse or breaker	Replace fuse, reset breaker, and determine problem.
	Faulty wiring	Repair or replace faulty wiring or connection.
No heat—indoor fan or outdoor unit will not run	Low-voltage control problem	Repair loose connections or replace thermostat and/or subbase.
	A. Thermostat B. Interconnecting—wiring or connections C. Transformer	Repair or replace wiring or connections. Replace if defective. **SAFETY PRECAUTION:** *Look out for too much current draw due to ground circuit or shorted coil.*
No heating; indoor and outdoor fans running, but compressor not running	Compressor overload tripped	Correct low voltage, call power company, or correct loose connections.
	A. Low line voltage B. High head pressure	Clean indoor coil. Check indoor fan motor and capacitor.
	1. Dirty indoor (condenser) coil 2. Indoor fan not running all the time 3. Overcharge of refrigerant 4. Restricted indoor airflow	Correct charge. Change filters. Open all supply registers. Clear return air blockage.
Outdoor coil (evaporator) freezes and ice will not melt	Defrost control sequence not operating	Follow manufacturer's directions and correct defrost sequence.
	Low charge; not enough refrigerant to perform adequate defrost	Correct charge and run unit through enough defrost cycles to clear ice off; then allow unit to run normally.
Unit will not change from cooling to heating or heating to cooling	Four-way reversing valve not changing over	Replace relay or circuit board.
	A. Defective defrost relay or circuit board B. Four-way reversing valve stuck C. Thermostat not changing to heat in subbase	Change four-way reversing valve. Repair or replace subbase.
Excessive power bill	Compressor not running; heating off or operating on auxiliary heat	Repair compressor circuit or replace compressor.
	Suction pressure too high and head pressure too low for conditions	Perform four-way reversing valve temperature check. If valve is defective, change valve. If valve is good, change compressor.

43.36 SERVICE TECHNICIAN CALLS

When reading through these service calls, keep in mind that three things are necessary for an electrical circuit to be complete and current to flow: a power supply (line voltage), a path (wire), and a load (a measurable resistance). The mechanical part of the system has four components that work together: The evaporator absorbs heat, the condenser rejects heat, the compressor pumps the heat-laden vapor, and the metering device meters the refrigerant. The 4-way valve is the component added to a typical air-conditioning system that makes the system a heat pump.

SERVICE CALL 1

A homeowner calls reporting that the air-conditioning system is heating, not cooling. This is the first time the unit has been operated in the cooling mode this season. *The problem is that the magnetic coil winding on the four-way valve is open and will not switch the valve over into the cooling mode.*

The service technician rings the doorbell and stands back until the customer comes to the door. He listens as the homeowner explains the problem, then turns the space thermostat to the cooling mode and starts the system. This is a split system with the air handler in a crawl space under the house. **SAFETY PRECAUTION:** *The technician goes to the outdoor unit and carefully touches the gas line (the large line); it is hot, meaning the unit is in the heating mode.*•

The technician removes the panel and checks the voltage at the four-way valve holding coil. A voltage of 24 V is present; the coil should be energized. The unit is shut off, and one side of the four-way valve coil is disconnected. A continuity check shows that the coil is open. The technician replaces the coil and starts the unit. It now operates correctly in the cooling mode. The technician then explains the problem and solution to the owner, presents the bill, and gets his copy signed.

SERVICE CALL 2

A store owner calls stating that the air-conditioning system in the small store will not start. The owner meets the technician upon arrival and explains the problem. The technician is glad that he is well groomed, because the owner gives him a close examination when they shake hands. This owner is very careful about the people working in the store because of the valuable merchandise. The store has a split-system heat pump with the outdoor coil on the roof. *The problem is that the 24-V holding coil for the four-way valve is burned and has overloaded the control transformer.* This has blown the fuse in the 24-V control circuit.

The technician begins by trying to start the unit at the space temperature thermostat. The unit will not start. When the FAN ON switch is turned to FAN ON, the fan will not start. He suspects a control voltage problem. The indoor unit is in a utility closet downstairs. **SAFETY PRECAUTION:** *The technician turns the power off and removes the door to the indoor unit.*• When the power is restored, there is no power at the low-voltage transformer secondary. The low-voltage fuse is checked and found to be blown. Before installing the new fuse, which is in a box in the utility room, the technician turns off the power and then replaces the fuse. He then removes one lead from the control transformer and fastens an ohmmeter to the two leads, leaving the transformer; the resistance is 0.5 Ω. This seems very low and will likely blow another fuse if power is restored. Some 24-V component must be burned and have a shorted coil. The meter should indicate a 20-Ω resistance. This will increase the current flow enough to blow the fuse. A look at the unit diagram will show which components are 24 V. One of them must be burned.

The technician decides to check the components in the indoor unit first and save a trip onto the roof, if possible. Each component is checked, one at a time, by removing one lead and applying the ohmmeter. There are three sequencers for the electric heat and one fan relay. There is no problem here. **SAFETY PRECAUTION:** *The technician goes to the roof and turns off the power.*• The compressor contactor is checked. It shows a resistance of 26 Ω. The four-way valve holding coil shows a resistance of 0.5 Ω. The technician installs a new coil, which shows a resistance of 20 Ω. The problem has been found.

The unit is put into operation with an ammeter attached to the lead leaving the control transformer to check for excessive current using an amperage multiplier made of thermostat wire wrapped 10 times around the ammeter lead. The current is 1 A, which is normal. When the owner is presented with the bill, she comments on the professional look and attitude of the technician. She says that she will continue to use the company.

SERVICE CALL 3

A customer reports that an ice bank has built up on the outdoor coil of the heat pump. The customer is advised to turn the thermostat to the emergency heat mode until a technician can get there. *The problem is that the defrost relay coil winding is open, and the unit will not go into defrost.*

The weather is below freezing, so there is still an ice bank on the outdoor coil when the technician arrives. The customer says the house is getting cold and requests that the technician do a fast job. **SAFETY PRECAUTION:** *With the unit off, the technician applies a jumper wire across terminals 3 and 4 on the defrost timer,* **Figure 43.67**.• The technician then starts the unit. This should force the unit into defrost if the timer contacts are not closing, but the unit does not go into defrost, so the jumper is left in place and the defrost temperature sensor is jumped. This satisfies the two conditions that must be met to start defrost, but nothing happens. **SAFETY PRECAUTION:** *The technician turns off the unit, turns off the power, locks and tags the panel, removes the jumpers, and checks the defrost relay.*•

The coil is open. The relay is changed for a new one, and the unit is started again. When the jumper is again applied to terminals 3 and 4, the unit goes into defrost. Remember that two conditions, time and temperature, must be satisfied before defrost can start. The temperature condition is satisfied because the coil is frozen. When the connection from terminals 3 to 4 is made, defrost is started. This would have occurred normally when the time clock advanced to a

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Figure 43.67 With the unit off, the technician applies a jumper wire from terminals 3 to 4 to cause a defrost to avoid having to wait for the timer. Because this is a high-voltage circuit, this exercise should not be performed unless the technician is very experienced.

Source: Carrier Corporation

trial defrost. By jumping from 3 to 4, the technician did not have to wait for the timer. The unit is allowed to go through defrost, but the coil is still iced.

The technician decides to shut off the unit and use artificial means to defrost the coil. **SAFETY PRECAUTION:** *The power is turned off, the panel is locked and tagged, and the electrical components are protected with plastic. A water hose is pulled over to the unit and city water is used to melt the ice. City water is about 45°F. Care is taken to not direct water onto the electrical components.* • Once the ice is melted, the unit is put back in operation. When presented with the bill, the customer thanks the technician for an efficient repair. A callback the next morning to the customer verifies that the unit is no longer icing.

SERVICE CALL 4

A homeowner reports that the heat pump unit is running continuously and not heating as well as it used to. *The problem is that the outdoor fan is not running because the defrost relay has a set of burned contacts—the ones that furnish power to the outdoor fan.* These contacts are used to stop the outdoor fan in the defrost cycle. They should also start the fan at the end of the cycle.

The technician arrives, talks to the customer, then goes to the outdoor unit and finds that the outdoor fan is not running during the normal running cycle. The gas line is warm, and the coil is iced up, so the unit is in the heating cycle. The fan is not running. The technician shuts the unit off and removes the panel to the fan control compartment. After fastening a voltmeter to the fan motor leads, the technician starts the unit. No voltage is going to the fan motor. The wiring diagram shows that the power supply to the fan goes through the defrost relay. **SAFETY PRECAUTION:** *The power is checked entering and leaving the defrost relay.* • Power is going in but not coming out. The defrost relay is changed, and the unit starts and runs as it should. The owner is happy to have the system operating again.

SERVICE CALL 5

A residential customer calls to report that the heat pump serving the residence is blowing cold air for short periods of time. This is a split-system heat pump with the indoor unit in the crawl space under the house. *The problem is that the contacts in the defrost relay that bring on the auxiliary heat during defrost are open and will not allow the heat to come on during defrost.*

The technician talks to the homeowner about the symptoms. Being familiar with the particular heat pump, the technician believes that the problem is in the defrost relay or the first-stage heat sequencer. The first thing to do is to see whether the sequencer is working correctly. The space temperature thermostat is turned up until the second-stage contacts are closed. The technician goes under the house with an ammeter and verifies that the auxiliary heat will operate with the space thermostat. Checking the defrost relay is the next step. This can be done by falsely energizing the relay, by waiting for a defrost cycle, or by simulating a defrost cycle. The technician decides to simulate a defrost cycle in the following manner. **SAFETY PRECAUTION:** *The power is turned off. To prevent the outdoor fan from running, one of the motor leads is removed.* • Then the unit is restarted. This causes the outdoor coil to form ice very quickly and make the defrost temperature thermostat contacts close. When the coil has ice on it for 5 min, the technician jumps the contacts on the defrost timer from 3 to 4, and the unit goes into defrost, **Figure 43.67**.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The technician goes under the house and checks the electric strip heat; it is not operating. The problem must be the defrost relay. By the time the technician gets back to the outdoor unit, the unit is out of the defrost cycle. He decides that the defrost cycle is functioning as it should, so he carefully energizes the defrost relay with a jumper wire. The 24-V power supply feeds terminal 4 and then should go out on terminal 6 to the auxiliary heat sequencer. These contacts are not closing. The technician changes the defrost relay and energizes the new relay. Going back under the house, the technician goes verifies that the strip heat is working. A callback later verifies that the unit is operating properly. The technician presents the bill to the owner, gets it signed, and leaves.

SERVICE CALL 6

A customer reports that a large amount of ice has built up on the outdoor unit of the heat pump. *The problem is that the changeover contacts in the defrost relay are open.* The system is not reversing in the defrost cycle. When this happens, the 10-min maximum time causes the unit to stay in heating without defrosting the outdoor coil, because the timer is still functioning.

After knocking on the door, the technician stands back to wait for the customer to open it. He asks the customer to describe the situation. She explains that after watching other heat pumps in the neighborhood, she knows hers is not defrosting correctly. The technician goes to the outdoor unit first because it is obvious there is a defrost problem. The coil looks like a large bank of ice.

The technician removes the control box panel and jumps the timer contacts from 3 to 4; the unit fan stops, but the cycle does not reverse as it should. (See the wiring diagram in **Figure 43.67**.) A voltage check at the four-way valve coil shows that no voltage is getting to the valve. The technician then jumps from the R terminal to the O terminal, and the four-way valve changes over to cooling, so he removes the jumper. The valve must not be getting voltage through the defrost relay. The defrost relay contacts are jumped from 1 to 3, and the valve reverses. He changes the defrost relay and simulates another defrost by jumping the 3 to 4 contacts. The defrost thermostat contacts are still closed, and the unit goes into defrost. The unit has so much ice accumulation that the technician uses water to defrost the coil and get it back to a normal running condition. A call the next day indicates that the unit is defrosting correctly.

SERVICE CALL 7

A shop owner calls to report that the heat pump in the small shop is running constantly. The unit is blowing cold air for short periods every now and then. The power bill was excessive last month, and it was not a cold month. This is a split system with 20-kW strip heat for quick recovery so that the customer can turn the thermostat back to 60°F on the weekend and have quick recovery on Monday morning. The outdoor unit is in the rear of the shop. *The problem is that the contact in the defrost relay that changes the unit to cooling in the defrost mode is stuck closed.* The unit is running in the cooling mode, and the strip heat is heating the structure. It must also make up for the cooling effect of the cooling mode.

The technician sets the thermostat to the first stage of heating. The air at the registers is cool, not warm. The unit should have warm air in the first stage of heat (85°F to 100°F), depending on the outside air temperature. The indoor coil is in a closet in the back of the shop. The gas line is not hot but cold. This indicates that the unit is in the cooling mode, but a voltage check should be performed. (See the wiring diagram in **Figure 43.68**.)

Figure 43.68 The contacts that change the unit to cooling for defrost are stuck closed.

The technician removes the control voltage panel cover and finds 24 V at the C to O terminals. This means the four-way valve coil is energized, and the unit should be in the cooling mode. Now the technician must decide whether the 24 V is coming from the space thermostat or the defrost relay. He removes the field wire from the space thermostat; the valve stays energized. The voltage must be coming from the defrost relay. The wire is replaced on the O terminal, and the wire on terminal 3 on the defrost relay is carefully removed. The unit changes to heating. The defrost relay is changed, and the unit operates correctly.

The technician explains in simple terms what happened, showing the shop owner the part. The owner thanks him for the explanation and goes on to say that most technicians do not take the time to inform customers what the problem was. A callback later finds the unit to be operating as expected.

SERVICE CALL 8

A store manager reports that the heat pump heating a small retail store has large amounts of ice built up on the outdoor unit. The unit is located outside in back of the store. *The problem is that the defrost thermostat contacts are not closing when the timer advances to the defrost cycle*. This is a combination control—the timer and the sensor are built into the same control.

The technician finds a large bank of ice on the coil of the outdoor unit. After removing the control panel cover, he discovers that this unit has a timer that can be advanced by hand. The timer and the defrost sensor are built into one control. It is obvious that the sensor is cold enough for the contacts to make, so he advances the dial of the timer all the way around. The unit does not go into defrost, so the contacts in the timer sensor must be faulty. The technician installs a new timer and advances it by hand until the contacts make. The unit goes into defrost normally. One defrost cycle does not melt enough ice from the coil to leave the heat pump on its own. The technician forces the unit through three more defrosts before the ice is melted to a normal level. If a water hose had been available, he could have used it to melt the ice to save time. The technician then explains the problem and solution to the store manager and presents the bill.

SERVICE CALL 9

While on a routine service call at an apartment house complex, the technician notices a unit go into defrost when there is no ice on the coil. The unit stays in defrost for a long time, probably the full 10 min allowable. This is a split-system heat pump and should have defrosted for only 2 or 3 min with a minimum of ice buildup. The compressor was loud, as if it were pumping against a high head pressure. *The problem is that the defrost thermostat contacts are shut*. The unit is going into defrost every 90 min and staying for the full 10 min. The timer is terminating the defrost cycle after 10 min. Toward the end of the cycle, the head pressure is very high. The technician goes to the manager and explains what the problem is and gets the go-ahead to perform the repair.

The technician shuts off the unit, removes the panel to the control box, removes one lead of the defrost thermostat, and takes a continuity check across the thermostat. The circuit should be open if the coil temperature is above 50°F but the contacts are closed. (This control should close at about 25°F and open at about 50°F. Allow plenty of time for this control to function because it is large and it takes a while for the unit's line to exchange heat from and to the control.) The technician changes the defrost thermostat and puts the unit back into operation. After the work is complete, the technician takes the defective part to the manager with an explanation and presents the bill.

SERVICE CALL 10

A residential customer reports no heat in the home. There is a smell of something hot or burning. **SAFETY PRECAUTION:** *The customer is told to turn off the unit at the indoor breaker to stop all power to the unit.* • *The problem is that the indoor fan motor has an open circuit and the electric strip heat is coming on from time to time and then shutting off because of excessive temperature*.

Upon arrival, the technician explains to the customer that there is not likely to be any fire problem because the unit is totally enclosed. The technician goes to the space thermostat and sets it to OFF. The electrical breakers are then energized. He turns the thermostat to FAN ON. The fan relay can be heard energizing, but the fan will not start. The indoor unit is under the house in the crawl space, so the technician takes tools and electrical test equipment to the unit. **SAFETY PRECAUTION:** *The breaker under the house is turned off and the door to the fan compartment is opened. The fan motor is checked and found to have an open winding.* • The motor is replaced with a new one, and the unit is started.

The technician uses an ammeter to check all three stages of electric heat for current draw. One stage draws no current. **SAFETY PRECAUTION:** *The breaker is again turned off and the electric heat is checked with an ohmmeter.* • The circuit in one unit is open. This happened because the fan was not running and the unit overheated. A new fuse link is installed, and the heat is started again. This time it is drawing current. The technician puts the unit panels back together and again goes to the owner and explains what was done and that the safety controls did what they were supposed to do.

SERVICE CALL 11

A homeowner reports that the residential heat pump smells hot and not much air is coming out of the registers. **SAFETY PRECAUTION:** *The customer is told to shut off the unit at the breaker for the indoor unit.* *The problem is that the indoor fan capacitor is defective, and the fan motor is not running up to speed.* The fan motor is cutting off periodically from an internal overload.

When he arrives and hears the owner's explanation, the technician sets the thermostat to OFF and turns on the breaker. The FAN ON switch at the thermostat is set to ON. The fan relay can be heard energizing, and the blower starts. There does not seem to be enough air coming out of the registers. The blower motor is not running smoothly. The technician goes to the attic crawl space where the indoor unit is located, taking tools and electrical test instruments. **SAFETY PRECAUTION:** *The breaker next to the indoor unit is shut off and the access panel to the control box is removed.* The breaker is then turned on. The blower does not turn up to speed. The breaker is turned off again. The fan capacitor is removed and a new one is installed. The breaker is energized again, and the blower comes up to speed. A current check of the blower motor shows the fan is operating correctly. **SAFETY PRECAUTION:** *The power is shut off, locked, and tagged, and the motor is oiled.* The technician then replaces all panels and turns on the power. After completing the work, the technician explains to the owner what repairs were made and presents the bill.

SERVICE CALL 12

A homeowner calls indicating that his unit is blowing cool air from time to time. One of the air registers is close to his television chair, and the cool air is a bother. *The problem is that the breaker serving the outdoor unit is tripped, apparently for no reason.* The control voltage is supplied at the indoor unit, so the electric auxiliary heat is still operable.

The technician talks to the customer about the system symptoms and then turns the space temperature thermostat to the first stage of heat; he notices that the outdoor unit does not start. When the thermostat is turned to a higher setting, the auxiliary heat comes on and heat comes out of the registers. With the thermostat in the first-stage setting, only the outdoor unit should be operating. The auxiliary heat should not be operating. In the second stage, the heat pump and the auxiliary heat should both be operating.

The technician goes to the outdoor unit and finds that the breaker is tripped. **SAFETY PRECAUTION:** *There is no way of knowing how long the breaker has been off, but it is not wise to start the unit because there has been no crankcase heat on the compressor. The breaker is switched to the off position and the panel is locked and tagged.* Using an ohmmeter, the technician checks the resistance across the contactor load-side circuit to make sure there is a measurable resistance. It is normal, about 2 Ω (there is a compressor motor, fan motor, and defrost timer motor to read resistance through). The contactor load-side terminals are checked to ground to see whether any of the power-consuming devices are grounded. The meter reads infinity, the highest resistance. Someone may have turned the space temperature thermostat off and back on before the system pressures were equalized so the compressor motor would not start. This means that the compressor tried to start in a locked-rotor condition and the breaker tripped before the motor overload protector turned off the compressor. A sudden, brief power outage then power coming back on will cause the same thing.

The technician does not reset the breaker before going to the indoor thermostat and setting it to the emergency heat mode. This prevents the compressor from starting with a cold crankcase. The technician then tells the homeowner to switch back to normal heat mode in 10 hours. This gives the crankcase heater time to warm the compressor. The homeowner is instructed to see whether the outdoor unit starts correctly or if the breaker trips. If the breaker trips, the thermostat should be set back to emergency heat, the breaker reset, and the technician called. If the technician must go back, the compressor could have a starting problem and may not start the next time. The technician explains to the customer that this procedure will save another service call and another expense. The customer does not call back, so the unit must be operating correctly.

SERVICE CALL 13

A customer says that the heat pump is running constantly in the heating mode in mild weather. It did not do this last year; it cut off and on in the same kind of weather. *The problem is that the check valve in the liquid line (parallel to the TXV) is stuck open and not forcing liquid refrigerant through the TXV.* This is overfeeding the evaporator and causing the suction pressure to be too high, hurting the efficiency of the heat pump. For example, if it is 40°F outside, the evaporator should be operating at about 15°F for the outside air to give up heat to the evaporator. If the evaporator is operating at 30°F because it is overfeeding, it will not exchange as much heat as it should. The capacity will be down.

The technician talks to the owner to get some details, then turns the room thermostat to the first stage of heating, and goes to the outdoor unit at the back of the house. The unit is running. The gas-line temperature is warm but not as hot as it should be. The compressor compartment door is removed so the compressor can be observed. It is sweating all over from liquid refrigerant returning to the compressor. This means that the TXV is not controlling the liquid refrigerant flow to the evaporator. After fastening a gauge manifold to the high and low sides of the system, the technician discovers that the suction pressure is higher than normal and the head pressure is slightly lower than normal. The head pressure is down slightly because some of the charge that would normally be

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. in the condenser is in the evaporator. After attaching the thermometer lead to the suction line just before the four-way valve, the superheat is found to be 0°F. The outdoor coil is flooded. Not enough refrigerant is flooding to the compressor to make a noise because the liquid is not reaching the cylinders. It is boiling away in the compressor crankcase.

The technician tries adjusting the TXV but it makes no difference. The TXV is open and not closing or else the check valve is open and bypassing the TXV. The technician gets a TXV and a check valve from the supply house. 4R *The unit charge is removed and recovered in an approved recovery cylinder.* 4R The old check valve is first removed and tested. The technician can blow nitrogen vapor through the valve in either direction, so the check valve is defective. He changes it, but leaves the TXV alone. The unit is pressured, leak checked, evacuated, and charged. When the unit is started in the heating mode, it operates correctly. The check valve was the problem. The superheat is checked to be sure that it is normal (8°F to 12°F) and the unit panels are assembled. The technician gives an explanation to the customer about the repair. The customer thanks the technician for being professional. A call later verifies that the unit is cycling as it should.

SERVICE CALL 14

A residential customer reports that the R-22 heat pump serving the home is not performing to capacity. The power bills are much higher than last year's, although the heating season has been much the same. The customer would like a performance check of the heat pump. *The problem is that the compressor has a damaged suction valve due to liquid floodback on start-up.* The owner had shut the disconnect off at the outdoor unit last summer and left it off all summer. When the unit was started in the fall, the compressor had enough liquid in the crankcase to damage one of the suction valves. If the crankcase heat had been allowed to operate for 8 to 10 hours before starting the unit, this would not have happened. Note that if one cylinder of a two-cylinder compressor is not pumping, the compressor will pump at half capacity.

The technician meets the customer and gets an explanation of the system operation. Based on the explanation, the technician installs gauges on the system and starts it. He uses the manufacturer's performance chart to compare pressures. The unit is running a high suction pressure and a low discharge pressure. The technician switches the unit to cooling and blocks the outdoor coil airflow to build up head pressure. The head pressure goes to 200 psig and the suction pressure to 100 psig. The compressor current is below normal. The compressor is not pumping to capacity; it is defective. A temperature check of the gas lines at the four-way reversing valve proves that the reversing valve is not leaking internally.

The technician gets a new compressor from a supply house. The old compressor is not under warranty, so there is no compressor exchange. 4R *The refrigerant is recovered and the compressor is changed.* 4R A new bi-flow liquid-line filter drier is installed. The system is pressured, leak checked, and evacuated before charging. The charge is measured into the system, the system is started, and it operates correctly. The technician explains, in simple terms, what happened: The disconnect must be turned on for at least 10 hours before starting the compressor after the power has been off for the summer. A call to the customer later in the day proves that the system is functioning correctly. The outdoor unit is satisfying the room thermostat and shutting the unit off from time to time because the weather is above the balance point of the house.

SERVICE CALL 15

A customer calls the heating and cooling service company to claim that the R-410A heat pump serving the residence must not be operating efficiently because the power bill has been abnormally high for the month of January compared with last year's bill. Both years have had about the same weather pattern. *The problem is that the four-way reversing valve is stuck in mid-position and will not change all the way to heat.*

The technician talks to the customer about the heat pump performance. She then turns the room thermostat to the first stage of heating and goes to the outdoor unit. The gas line leaving the unit is warm, not hot as it should be. Gauges installed on the system show that the head pressure is low and the suction pressure is high. The compressor amperage is low. All of these are signs of a compressor that is not pumping up to capacity. The outside temperature is 40°F and the coil does not have an ice buildup, so the unit should be working at a high capacity.

The technician suspects the compressor and so performs a compressor performance test. A jumper wire is installed between the R and O terminals to energize the four-way reversing valve coil and change the unit over to the cooling mode. The thermostat is left in the first-stage heat mode. If the house begins to cool off, the second stage of heat will come on and keep the house from getting too cool. A plastic bag is wrapped around the condenser coil to slow the air entering the coil. The head pressure begins to climb, but the suction pressure rises with it. The compressor will not build a sufficient differential between the high and low sides. Generally, the unit should be able to build 500 psig of head pressure with 118 to 140 psig suction, but this unit has a 200 psig suction and a 400 psig head pressure.

Before condemning the compressor, the technician decides to check the four-way valve operation. He fastens the two leads of an electronic thermometer on the cold gas line entering and leaving the four-way valve. A difference in temperature should not be more than 3°F between these two lines, but it is 15°F. 4R *The four-way reversing valve is leaking hot gas into the suction gas. The four-way reversing valve is changed after the refrigerant is recovered.* 4R The unit is started

after the pressure leak test, evacuation, and charging. It now performs to capacity with normal suction and head pressures. The technician explains the service procedures to the customer and presents the bill before leaving.

SAFETY PRECAUTION: *Use common sense and caution while troubleshooting any piece of equipment. As a technician, you are constantly exposed to potential danger. High-pressure refrigerant, electrical shock hazard, rotating equipment shafts, hot metal, sharp metal, and lifting heavy objects are among the most common hazards you will face. Experience and listening to experienced people will help to minimize the dangers.*•

SERVICE CALL 16

A local company has an apartment house complex with 100 package heat pumps under contract for routine service. While on a routine visit, the technician notices that a compressor is sweating all over in the heating cycle. *The problem is that one of the newer technicians serviced this unit during the last days of the cooling season and added refrigerant to the system.* The system is a capillary tube metering device system. The unit now has an overcharge.

The technician knows that a compressor should never sweat all over, so he installs a gauge manifold to check the pressures. A charging chart is furnished with this unit to use when adjusting the charge. When the gauge readings are compared with the chart readings, both the suction and the discharge pressures are too high. This symptom calls for reducing the charge. 4R *Refrigerant is allowed to flow into an approved empty cylinder until the pressures on the chart compare to the pressure in the machine.* 4R An observant technician has saved a compressor.

Solutions for the following service calls are not provided here. Please discuss the solutions with your instructor.

SERVICE CALL 17

A beauty shop owner calls to say that the unit serving the shop is blowing cool air from time to time.

This is a split system with the outdoor unit on the roof. When the technician turns the thermostat to the first stage of heat, cool air comes out of the air registers. The technician goes to the outdoor unit—the outdoor fan is running, but the compressor is not. **SAFETY PRECAUTION:** *The power is turned off. The panel is locked and tagged before the technician removes the cover to the compressor compartment.*• An ohm check shows that there is an open circuit between the R and C terminals and between the S and C terminals, but there is continuity between R and S. The compressor body temperature is warm, not hot.

What is the likely problem and the recommended solution?

SERVICE CALL 18

A residential customer calls to say the heat pump outdoor unit is off because of a tripped breaker. The customer reset it three times, but it would not stay reset.

The technician goes to the outdoor unit first and sees that the breaker is in the tripped position. He decides that before resetting it a motor test should be performed. **SAFETY PRECAUTION:** *A volt reading is taken at the compressor contactor line side; 50 V is present.*• This must be caused by the repeated resetting of the breaker—voltage is leaking through the breaker. When the main heating breaker is turned off, the 50 V disappears. **SAFETY PRECAUTION:** *If the technician had taken a continuity reading first, the meter would have been damaged.*• With the main breaker off, a resistance check on the load side of the compressor contactor shows a reading of 0 Ω to ground (the compressor suction line is a convenient ground).

What is the likely problem and the recommended solution?

SERVICE CALL 19

A call from an owner of a two-story house indicates that the unit serving the upstairs of the house is blowing cold air part of the time and not heating properly.

The technician turns the space temperature thermostat to the first stage of heating and notices that cool air is coming out of the air registers. The outdoor unit can be seen from a window and the fan is running. The technician goes to the outdoor unit and finds that the gas line leaving the unit is barely warm, not hot. The compressor is either not running, or it is running and not working. The compressor access panel is removed, and the compressor can be touched and seen. It is hot to the touch.

What is the likely problem and the recommended solution?

SERVICE CALL 20

A dress shop manager reports that the heat pump serving the shop will not cool properly. This is the first day of operation for the system this summer. The compressor was changed about two weeks ago after a bad motor burn. The system has not operated much during the two-week period because the weather has been mild.

The technician turns the thermostat to the cooling mode and starts the unit. The compressor is on the roof, and the indoor unit is in a closet. When the technician goes to the indoor unit and feels the gas line, it is hot. The unit is in the heating mode with the thermostat set in the cooling mode. The technician goes to the roof and removes the low-voltage control panel. In this unit, the four-way valve is energized in the cooling mode, so it should be energized at this

time. A voltmeter check shows that power is at the C to O terminals (a common terminal and the four-way valve coil terminal). The technician removes the wire from the O terminal and hears the pilot solenoid valve change (with a click). Every time the wire is touched to the terminal, the valve can be heard to position. This means that the pilot valve is moving.

What is the likely problem and the recommended solution?

SERVICE CALL 21

A retail store owner reports that the R-410A heat pump serving the store is blowing cold air from time to time and not heating as it normally does. It runs constantly. The unit has a TXV.

The technician turns the thermostat to the first stage of the heating mode. The air coming out of the air registers is cool; it feels like the return air. The outdoor unit is on the roof, and the indoor unit is in an attic crawl space. The thermostat is set with the first stage calling for heat; the outdoor unit should be on. The technician goes to the roof. The outdoor unit is running, but the gas line is cool. A gauge manifold is installed on the high and low sides of the system. The low side is operating in a vacuum, and the high-side pressure is 202 psig, which corresponds to the inside temperature of 70°F. This indicates that liquid refrigerant is in the condenser (the indoor coil). If the condenser pressure were 105 psig, well below the 202 psig corresponding to 70°F, it would indicate that the unit is low in refrigerant charge.

What is the likely problem and the recommended solution?

SUMMARY

- All compression-cycle refrigeration systems are similar to heat pumps; however, heat pumps have the capability of pumping heat either way.
- The four-way reversing valve enables the heat pump to reverse the refrigeration cycle and reject heat in either direction.
- *Water-to-air* is the term used to describe heat pumps that absorb heat from water and transfer it to air.
- Commercial buildings may use water to absorb heat from one part of a building and reject the same heat to another part of the same building.
- Air-to-air heat pumps are similar to summer air-conditioning equipment.
- There are two styles of equipment: split systems and package (self-contained) systems.
- New terms are used for heat pump components because of the reverse-cycle operation.
- The terms *indoor coil* and *outdoor coil* are also used with package heat pumps to avoid confusion.
- The refrigerant lines that connect the indoor coil with the outdoor coil are the gas line (hot gas in winter and cold gas in summer) and the liquid line.
- The liquid line is always the liquid line; the flow reverses from season to season.
- Several metering devices are used with heat pumps. The first to be used was the TXV, and there may be two in a system.
- Some manufacturers use the electronic expansion valve with close-coupled equipment because it will meter in both directions and maintain the correct superheat.
- When standard filter driers are used with a heat pump installation, they must be placed in the circuit with the check valve to ensure correct flow. The filter drier must be piped in series with a check valve, or when the flow reverses, it will backwash and the particles will be pushed back into the system.
- The air-to-air heat pump loses capacity as the outside temperature goes down.
- At the balance point, the heat pump alone will run constantly and just heat the structure.
- Auxiliary heat is the heat that a heat pump uses as a supplement.
- Auxiliary heat is normally electric resistance heat. Oil- and gas-fired furnaces may be used in some installations.
- When the auxiliary heat is used as the only heat source, such as when the heat pump fails, it is called emergency heat.
- Emergency heat is controlled by a switch in the room thermostat.
- The coefficient of performance (COP) is determined from dividing the heat pump's heating output by the input. A COP of 3:1 is common with traditional air-to-air heat pumps at the level of 47°F outdoor temperature. A COP of 1.5:1 is common at 0°F.
- The efficiency of a heat pump is a result of its being used to capture heat from the outdoors and to pump that heat indoors.
- A heat pump is installed in much the same manner as a cooling air conditioner.
- The terminal air must be distributed correctly because it is not as hot as the air from oil or gas installations. With only the heat pump operating, air from a heat pump is normally not over 100°F.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- **SAFETY PRECAUTION:** *There must be provision for water drainage at the outdoor unit in winter.*
- The indoor fan must run when the compressor is operating, and the compressor operates in both summer and winter modes.
- The four-way reversing valve determines whether the unit is in the heating or cooling mode.
- The technician can tell which mode the unit is in by the temperature of the gas line. It can get very hot.
- The space temperature thermostat controls the direction of the hot gas by controlling the position of the four-way valve.
- Because the heat pump evaporator operates below freezing in the winter, frost and ice will build up on the outdoor coil.
- When the system is in defrost, it is in the cooling mode with the outdoor fan off to aid in the buildup of heat.
- Defrost is normally instigated (started) by **time and temperature** and terminated by **time or temperature**.
- The refrigerant charge is usually critical with a heat pump.
- The use of scroll compressors increases the efficiency of heat pump systems.

REVIEW QUESTIONS

1. How does a heat pump resemble a refrigeration system?
2. Name the three common sources of heat for heat pumps.
3. What large line connects the indoor unit to the outdoor unit?
   A. A discharge line
   B. A liquid line
   C. An equalizer line
   D. A gas line
4. Why is the indoor unit not called an evaporator?
5. When is the outdoor unit called an evaporator?
   A. Heating season
   B. Cooling season
   C. Defrost periods
   D. Spring and fall seasons
6. The indoor coil is called a condenser during the _____ season.
7. Why is it important to have drainage for the outdoor unit?
8. Which metering device is most efficient in heat pumps?
   A. A thermostatic expansion valve
   B. An automatic expansion valve
   C. A capillary tube
   D. An orifice or restrictor
9. Where is the only permanent suction line on a heat pump?
10. What type of drier may be used in the liquid line of a heat pump?
11. Where must a suction-line drier be placed in a heat pump after a motor burnout?
12. What controls the heat pump to determine whether it is in the heating cycle or the cooling cycle?
13. Can a heat pump switch from heating to cooling and from cooling to heating automatically?
14. What must be done when frost and ice build up on the outdoor coil of a heat pump?
15. True or False: All heat pumps are practical anywhere in the United States. Explain your answer.
16. Why are scroll compressors more efficient than reciprocating compressors?
17. Describe why variable-speed compressor motors are more efficient than single-speed motors in heat pump systems.

UNIT 44

GEOTHERMAL HEAT PUMPS

OBJECTIVES

After studying this unit, you should be able to

- describe an open- and closed-loop geothermal heat pump system.
- explain how water quality affects an open-loop geothermal heat pump.
- describe different ground-loop configurations for closed-loop geothermal heat pump systems.
- explain the advantages and disadvantages of series- and parallel-flow configurations in geothermal heat pump systems.
- explain the different system fluids and heat exchanger materials.
- describe different geothermal well types and water sources for heat pumps.
- explain some of the most common service problems with geothermal heat pump systems.
- list and explain the governing formulas that calculate the amount of heat rejected or absorbed by the water side of a geothermal heat pump.
- describe a direct geothermal (Direct GeoExchange) heat pump system.

SAFETYCHECKLIST

- ☑ Always wear protective clothing and eye shields when working with geothermal heat pumps. They contain high-pressure refrigerants, which can freeze skin and cause serious injury.
- ☑ When working around geothermal heat pumps, antifreeze solution or water leaking from the system can cause an electrical hazard. When troubleshooting with the electrical power on, extra care must be taken to prevent electrical shocks.
- ☑ Closed-loop geothermal heat pumps also contain a solution in the ground loop that can be harmful if not handled properly. Both protective clothing and eye protection must be worn when in contact with this fluid. Also, some antifreeze solutions used in closed-loop systems can be flammable, so never expose them to extreme heat or an open flame.

44.1 REVERSE-CYCLE REFRIGERATION

Geothermal heat pumps are refrigeration machines. They are very similar to air source heat pumps in that they can remove heat from one place and transfer it to another. However, geothermal heat pumps use the earth, or water in the earth, for their heat source and heat sink. Energy is transferred daily to and from the earth by the sun's radiation, rain, and wind. Each year, more than 6000 times the amount of energy currently used by humans is striking the earth from the sun. In fact, less than 4% of the stored energy in the earth's crust comes from its hot molten center. Heat pumps use this energy stored in the earth's crust for heating. *In the summer months, because the temperature of the earth's crust is cooler than the air just above it, summer air-conditioning heat loads can be transferred to the earth.*

Geothermal heat pumps can pump heat in two directions. Because of this, they are normally used for space conditioning: heating and cooling. The same four basic components of heat pumps mentioned in Unit 43, "Air Source Heat Pumps"—the compressor, condenser, evaporator, and metering device—operate and control geothermal heat pumps. The *four-way valve* also controls the direction of heat flow in geothermal heat pumps. For a review of basic heat pump theory and operation, review Unit 43.

44.2 GEOTHERMAL HEAT PUMP CLASSIFICATIONS

Geothermal heat pumps are classified as either **open-loop** or **closed-loop** systems. Open-loop, or *water-source*, systems use water from the earth as the heat-transfer medium and then expel the water back to the earth in some manner. This process usually involves a well, lake, or pond. Open-loop systems need a large volume of clean water to operate properly. This same water supply also can be used for drinking and cooking.

Closed-loop, or **earth-coupled**, systems use a heat-transfer fluid, which is reused and circulated in plastic pipes buried within the earth or within a lake or pond. Closed-loop or earth-coupled systems are used where the water is rich in minerals, where local codes prohibit open-loop systems, or where not enough water exists to support an open-loop well water system. Both open-loop and closed-loop systems will be covered in detail in the following sections.

Whether the geothermal heat pump system is an open-loop, closed-loop, or earth-coupled system, water is still the source of heat when the system is operating in the heating mode. For this reason, these heat pumps are referred to as water-source heat pumps. Water-source heat pumps can be classified as

either water-to-air or water-to-water. Water-to-air heat pumps are used to heat air in the occupied space; water-to-water heat pumps are used to heat water, which would be appropriate for an application such as a radiant heating system.

44.3 OPEN-LOOP SYSTEMS

Open-loop, water-source heat pump systems involve the transfer of heat between a water source and the air or water being circulated to a conditioned space. Remember, open-loop systems use water from the earth as the heat-transfer medium and then expel the water back to the earth. During the heating mode, heat is being transferred from the water source to the conditioned space. During the cooling mode, the heat removed from the conditioned space is deposited into the water. **Figure 44.1** illustrates both a heating and a cooling application of an open-loop, water-to-air heat pump. Defrost systems are not needed in geothermal heat pump systems.

In the *heating mode*, water is supplied from a water source to a coiled, coaxial heat exchanger, **Figure 44.2**, by a circulating pump, **Figure 44.1(A)**. The heat exchange takes place between the water and the refrigerant. Refrigerant is carried in the outer section of the coaxial heat exchanger and the water flows in the inner tube, **Figure 44.2(A)**. Notice that the inner tube is ribbed to increase both the surface area and the heat-transfer rate between the fluids, **Figure 44.2(B)**. The refrigerant side of the heat exchanger is the refrigeration system's evaporator. Heat is absorbed from the water into the vaporizing refrigerant. The refrigerant vapor then travels through the reversing valve to the compressor, where it is compressed. The heat-laden hot gas from the compressor then travels to the condenser. The condenser is a refrigerant-to-air, finned-tube heat exchanger located in the ductwork. It is often referred to as the *air coil*. Heat is then rejected to the air as the refrigerant condenses. A fan delivers the heated air to the conditioned space. The condensed liquid then travels through the expansion valve and vaporizes in the evaporator, absorbing heat from the water source. The process is then repeated. High-resistance, electric strip heaters can be used for auxiliary and/or emergency heat when the heat pump needs assistance.

In the *cooling mode,* the water loop acts as the condensing medium for the refrigerant, **Figure 44.1(B)**. Discharge gas from the compressor travels through the reversing valve to the outer portion of the coaxial (tube-within-a-tube) heat exchanger of the water loop. The refrigerant side of the heat exchanger is the refrigerant system's condenser. A refrigerant-to-water heat exchange takes place. The water loop absorbs heat from the refrigerant and condenses it. Subcooled liquid refrigerant then travels to the expansion valve and on to the *air coil*, where it evaporates and absorbs heat from the air. The air is cooled and dehumidified. A fan delivers this air to the conditioned space. The heat-laden, superheated, refrigerant gas then travels from the air coil and through the reversing valve to the compressor, where the refrigerant is compressed. The process is then repeated.

For smaller residences, a single water-source heat pump is normally used, but larger houses may require more than one. For commercial applications, multiple heat pumps are combined into a system with a common water-piping loop. This loop provides a means for transferring the rejected heat from one heat pump in the cooling mode to another heat pump, which is in the heating mode. Commercial applications may also be connected to a well, a pond, a lake, or an earth-coupled closed-loop system. These systems may also contain a *boiler* and *cooling tower* to maintain desired loop temperatures, **Figure 44.3**.

44.4 WATER QUALITY

Water quality is the most important factor to consider when dealing with open-loop systems that rely on well water. Listed here are three of the most important questions involving water quality that technicians and designers have to look at before choosing an open-loop, well-water system for heating and cooling applications.

- Will the well deliver enough water in gallons per minute (gpm) to the heat pump?
- What is the temperature of the well water?
- Is the well water clean and low in minerals?

Enough water flow in gpm has to be available to properly feed the system and handle the required heating and cooling capacities. Remember, this well water is the heat-transfer

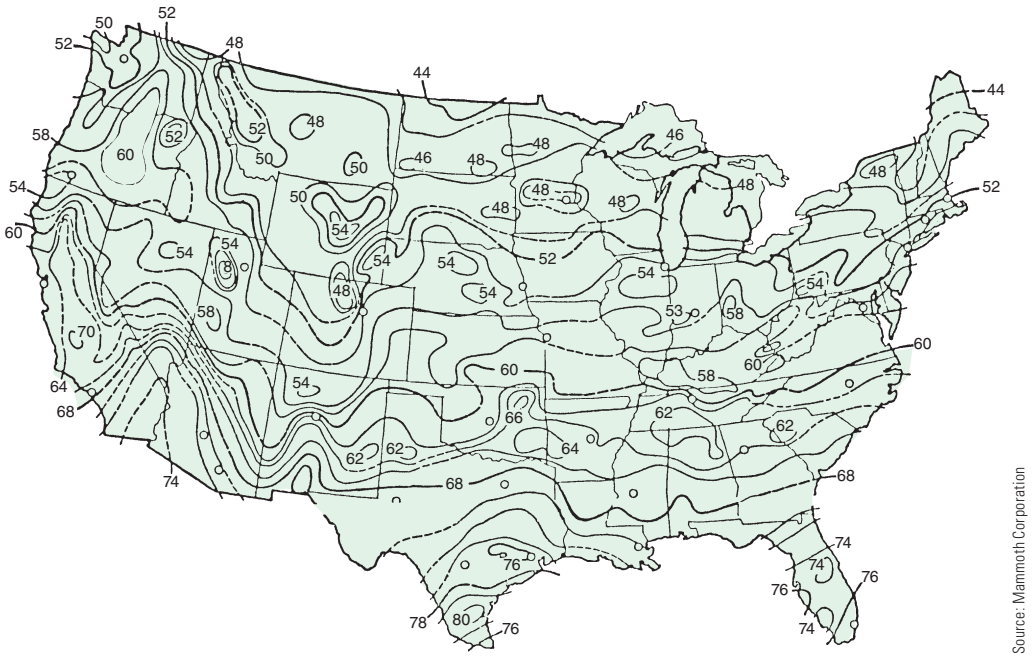
Figure 44.4 Temperature (°F) in wells ranging from 50 ft to 150 ft deep.



medium between the earth and the refrigerant in the heat pump. Consult with the heat pump manufacturer for specific information on water flow rates in gpm required for their heat pumps. The local well driller can determine whether enough water is in the well to properly operate the heat pump.

Well-water temperature is another important factor. It is one of the factors that determines the heat pump's capability to transfer heat energy because the temperature difference between the water and the refrigerant drives the potential for heat transfer. The larger the temperature difference, the greater the heat transfer. **Figure 44.4** illustrates water temperatures in wells ranging from 50 to 150 ft in depth within the United States.

Cleanliness of the well water is another major factor to consider when dealing with an open-loop, well-water system. The water cannot be contaminated with sand, dirt, clay, or any solid mineral particulate. All of these materials may cause a gradual wearing down of the coaxial heat exchanger in which the water flows with a significant velocity. Minerals eventually will foul the walls of the water side of the coaxial heat exchanger.

The heat exchangers of water-source heat pumps allow water to flow in one direction and refrigerant to flow in the other, called **counterflowing**. The water and refrigerant never come in physical contact with one another. The heat exchangers are the coiled, coaxial, tube-within-a-tube type. Water flows through the inner tube, and refrigerant flows in the outer jacket, which is made of steel. **Figure 44.5** shows the heat exchanger and a cross section. Notice that the inner tubes have extended surfaces, called *leads*, which increase the surface area for better heat transfer. The leads cause turbulence in both the water and refrigerant loops, which also increases the heat transfer between the water and the refrigerant. The temperature differential (delta-T) between the entering and leaving water in open-loop systems usually ranges between 7°F and 10°F. This means that if water is entering the heat exchanger at 55°F and leaving at 47°F during heating, the delta-T would be 8°F. This is an acceptable differential because it falls between the 7°F to 10°F range. However, always consult with the manufacturer of the heat pump about specific temperature differences; they may vary between manufacturers and geographical locations.

The inner tubes of most coaxial heat exchangers, which handle the water circuit, are made of copper. However, an alloy of copper, called *cupronickel*, is also available. Heat exchangers made of cupronickel have a higher resistance to corrosion from acid cleaning. They also have a higher resistance to abrasion than copper heat exchangers. Because of this, cupronickel heat exchangers will have a longer service life. However, they will foul just as fast as copper heat exchangers. **Figure 44.6** can be used as a guideline for determining whether a cupronickel heat exchanger should be used in an open-loop heat pump system.

44.5 CLOSED-LOOP SYSTEMS

In closed-loop heat pump systems, many yards of plastic pipe are buried in the earth. The pipe can be placed in either a horizontal or vertical configuration, depending on how

MAMMOTH WATER COIL SELECTION GUIDE

POTENTIAL PROBLEM	USE COPPER COIL	USE CUPRONICKEL COIL
SCALING- Calcium and magnesium salts (hardness)	Less than 350 ppm (25 grain/gallon)	More than 350 ppm (up to sea water)
Iron oxide	Low	High
CORROSION-* pH	7–9	5–7 and 8–10
Hydrogen sulfide	Less than 10 ppm	10–50 ppm
Carbon dioxide	Less than 50 ppm	50–75 ppm
Dissolved oxygen	Only with pressurized water tank	All systems
Chloride	Less than 300 ppm	300–600 ppm
Total dissolved solids	Less than 1000 ppm	1000–1500 ppm
BIOLOGICAL GROWTH- Iron bacteria	Low	High
SUSPENDED SOLIDS	Low	High

*Important—If the concentration of these corrosive exceeds the maximum tabulated in the cupronickel column, then the potential for serious corrosion problems exists. Water treatment may be required.

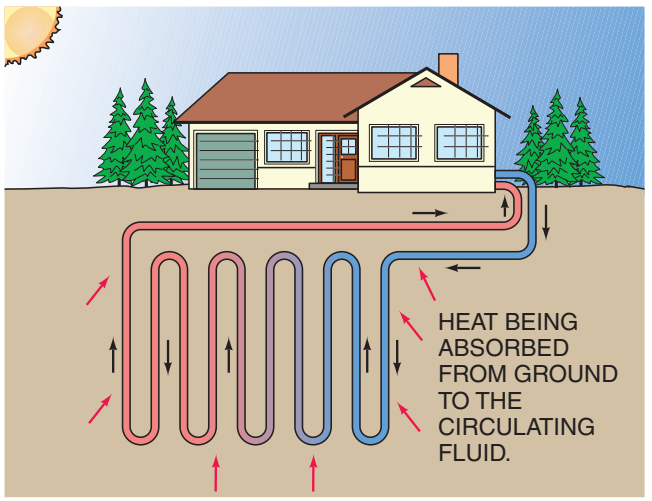
much land is available and the soil composition. The loops of piping are called either **ground loops** or **water loops**, **Figure 44.7** through **Figure 44.13**. A completely sealed and pressurized loop of water, or water and antifreeze solution, is circulated by a low-wattage centrifugal pump through the pipe buried in the ground. In the winter or heating mode, heat is transferred from the ground, through the plastic pipe, to the liquid in the ground loop. During the summer

Figure 44.7 A ground loop showing a series-vertical configuration in the heating mode.



or cooling mode, heat is rejected away from the circulating fluid, through the plastic pipe, and into the ground.

This fluid circulating in the plastic pipes or ground loop exchanges its energy with a **refrigerant loop**. The antifreeze-to-refrigerant heat exchange occurs within the heat pump's antifreeze-to-refrigerant heat exchanger, a coiled, coaxial, tube-within-a-tube exchanger contained within the cabinet of the heat pump, **Figure 44.14** and **Figure 44.15**. This heat exchanger is not subject to fouling because the closed-loop system uses the same treated water in its loop. *This is probably one of the main advantages a closed-loop system has over an open-loop system. Water-quality problems, which often foul the water side of open-loop heat exchangers, are almost nonexistent with closed-loop systems.*

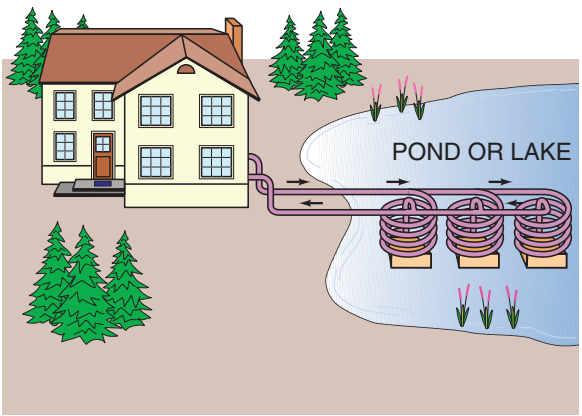
Figure 44.13 A pond or lake loop.



An **air loop** is used to distribute heated or cooled air to the building. This is accomplished through a finned-coil, air-to-refrigerant heat exchanger located in the ductwork. A *squirrel cage blower* is used to move the air through the air distribution system. **Figure 44.14** and **Figure 44.15** illustrate the ground, refrigerant, and air loops in the heating and cooling modes, respectively.

A fourth loop, or **domestic hot water loop**, is often used for heating domestic hot water from the hot discharge gas coming from the heat pump's refrigerant compressor. Because the discharge of the compressor is the hottest part of the refrigeration system, heat can be transferred easily from the hot refrigerant to the cool domestic water. However, a separate heat exchanger is again needed. This heat exchanger is also a coiled, coaxial, tube-within-a-tube. The domestic hot water is pressurized and circulated through the loop by a circulating pump. The refrigerant loop, which is in the outer shell of the heat exchanger, gives up heat to the cooler domestic water, which is in the inner tube of the same heat exchanger. The hot refrigerant and cool water counter-flow one another, meaning they flow in opposite directions through the heat exchanger. This helps desuperheat the refrigerant and at the same time heat the domestic water. More modern systems have heat exchangers that not only desuperheat the refrigerant but also condense it for increased heat transfer. These systems can often supply 100% of domestic hot water demands. **Figure 44.16** illustrates a domestic hot water heat-exchanger loop.

44.6 GROUND-LOOP CONFIGURATIONS AND FLOWS

Ground loops can be vertical, horizontal, slinky, or of a pond/lake type. Loops can also have series or parallel fluid flows, which will be covered later in this section. **Figure 44.7** through **Figure 44.13** illustrate these loop configurations. Loop configuration choices will depend on how much land is available. The choice also depends on the type of soil found on the land and the contour of the land. Both of these factors affect excavation and drilling costs because very hilly or rocky land can become expensive to excavate or drill.

Vertical systems are used when there is a shortage of land or space restrictions, **Figure 44.7** and **Figure 44.8**. If the soil is rocky, a rock bit is used on the rotary drill. If the land available is without hard rock, a *horizontal loop* should be considered, **Figure 44.9**, **Figure 44.10**, and **Figure 44.11**.

The **slinky loop** is a flattened, circular coil of plastic pipe resembling a Slinky®, **Figure 44.12(A)**. Due to their configuration, slinky loops can reduce the trench length from one-third to two-thirds as compared with other loop systems.

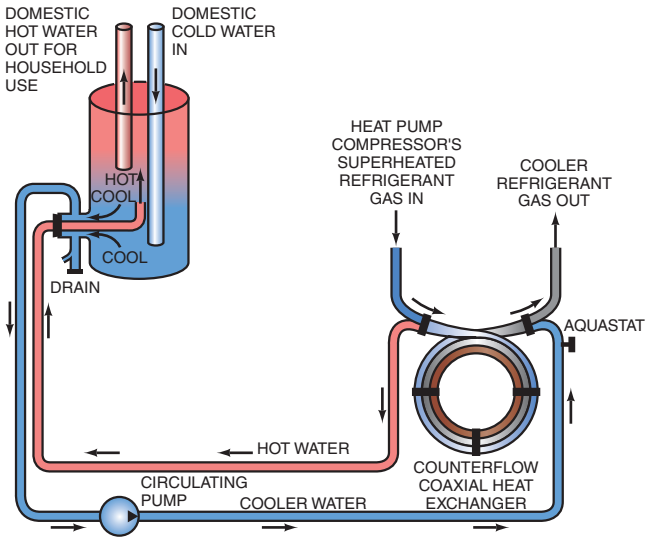
Figure 44.16 A domestic hot water loop showing a counterflow, coaxial heat exchanger. The water is heated by the refrigerant loop.



Loops can also be installed in lakes or ponds, **Figure 44.13**. A prefabricated slinky ground loop is shown rolled-up and waiting to be transported to the job site in **Figure 44.12(B)**. Slinky ground loops are very popular because their geometry allows good heat-transfer qualities between the earth and the ground loop while still maintaining a relatively small footprint. Four slinky ground loops in a freshly excavated trench are shown waiting to be rolled out against the floor of the trench in **Figure 44.12(C)**. Rolling out the loops against the floor of the excavated trench assures good thermal contact between the earth and the polyethylene piping making up each slinky loop, **Figures 44.12(D)**, **(E)**, and **(F)**.

In the residential, closed-loop, geothermal heat pump design illustrated, each loop is about 600 ft in length. The piping making up the slinky loops often averages from 600 to 700 ft; the lengths will vary depending on geographical location and soil conditions. Each slinky ground loop should ideally be about 12–15 ft apart horizontally. The depth that the ground loops are buried varies from 5–8 ft, depending on soil conditions. In the residential design shown, each slinky ground loop has the equivalent of 1 ton of capacity, giving the application illustrated a 4-ton capacity, **Figure 44.12(F)**. Also, in this residential design, the piping making up the ground loops is 0.75-in.-diameter polyethylene plastic pipe. The supply and return headers that connect the slinky loops in parallel and enter the house consist of 1.25-in.-diameter polyethylene plastic pipe, **Figure 44.12(G)**.

The heat bonding or fusing of the slinky loops to the supply and return headers that enter the house is shown in **Figures 44.12(H)**, **(I)**, and **(J)**. Plastic polyethylene tee fittings are heat-fused to the slinky loops. The supply and return headers are then heat-fused to the tee fittings. **Figure 44.12(H)** shows a technician applying special vise-grip pliers, which will custom-fit themselves around the plastic pipe to hold it in place. A deburring tool is then used to smooth the outside edges of the pipe, making it easier to slide the plastic pipe into the plastic tee fitting. The pipe and coupling tee are then heated to 500°F for approximately 15 sec with a **fusion iron**. After the heating of the plastic pipe and coupling tee is complete, the fusion iron is removed and the plastic pipe is pushed into the coupling tee, **Figure 44.12(I)**. The plastic pipe and coupling tee must be held together until they have cooled in order to properly complete the fusion process, **Figure 44.12(J)**. When the fusion process is performed properly, the two plastic pieces that have been fused will cool and harden together, creating a watertight seal for the ground loop.

Another decision that needs to be made is whether the ground heat exchanger or loop should be *series* or *parallel flow*. **Figure 44.17** illustrates both series and parallel flow paths in horizontal and vertical ground loops. In the **series flow**, only one path exists for the fluid to flow along. Air trapped in the plastic pipe is much easier to remove in a series loop, because the fluid's path is very well defined. The trapped air can be removed by power flushing, which involves connecting the heat pump and ground loop to a purging unit or pump stand that has a built-in, high-volume, high-velocity, and high-head circulating pump. The pump stand or purging unit also has a built-in air separator. The air then can be purged from the system, **Figure 44.18**. It is important that all the air be removed before the system is started, because air can erode and corrode any metal components in the water loop and can block fluid flow in the loop. Power flushing also removes any debris that may damage the bearings of the circulating pump. A system breakdown can result in either of these cases.

Listed here are advantages of a series-flow system:

- Ease of removing trapped air
- Simplified flow path
- Higher heat transfer per foot of pipe

Some disadvantages of a series-flow system are:

- Larger-diameter plastic pipe is needed, meaning more antifreeze solution
- Higher installation costs
- Higher pressure drops

Parallel-flow systems can use smaller-diameter pipe because of their lower pressure drops. Smaller-diameter pipe has a lower cost; however, if there are air problems in the water loop, it is very difficult to remove the air with high-velocity water flushing because of the path choices. Excess air can also block the water flow in parallel systems. To make sure that pressure drops are equal in each parallel path, pipe lengths must be fairly equal. If not, the parallel path with the least resistance, or shortest length, will be fed with the most fluid, and the path with the most resistance will be partially starved of fluid. Unequal flow paths will seriously affect heat

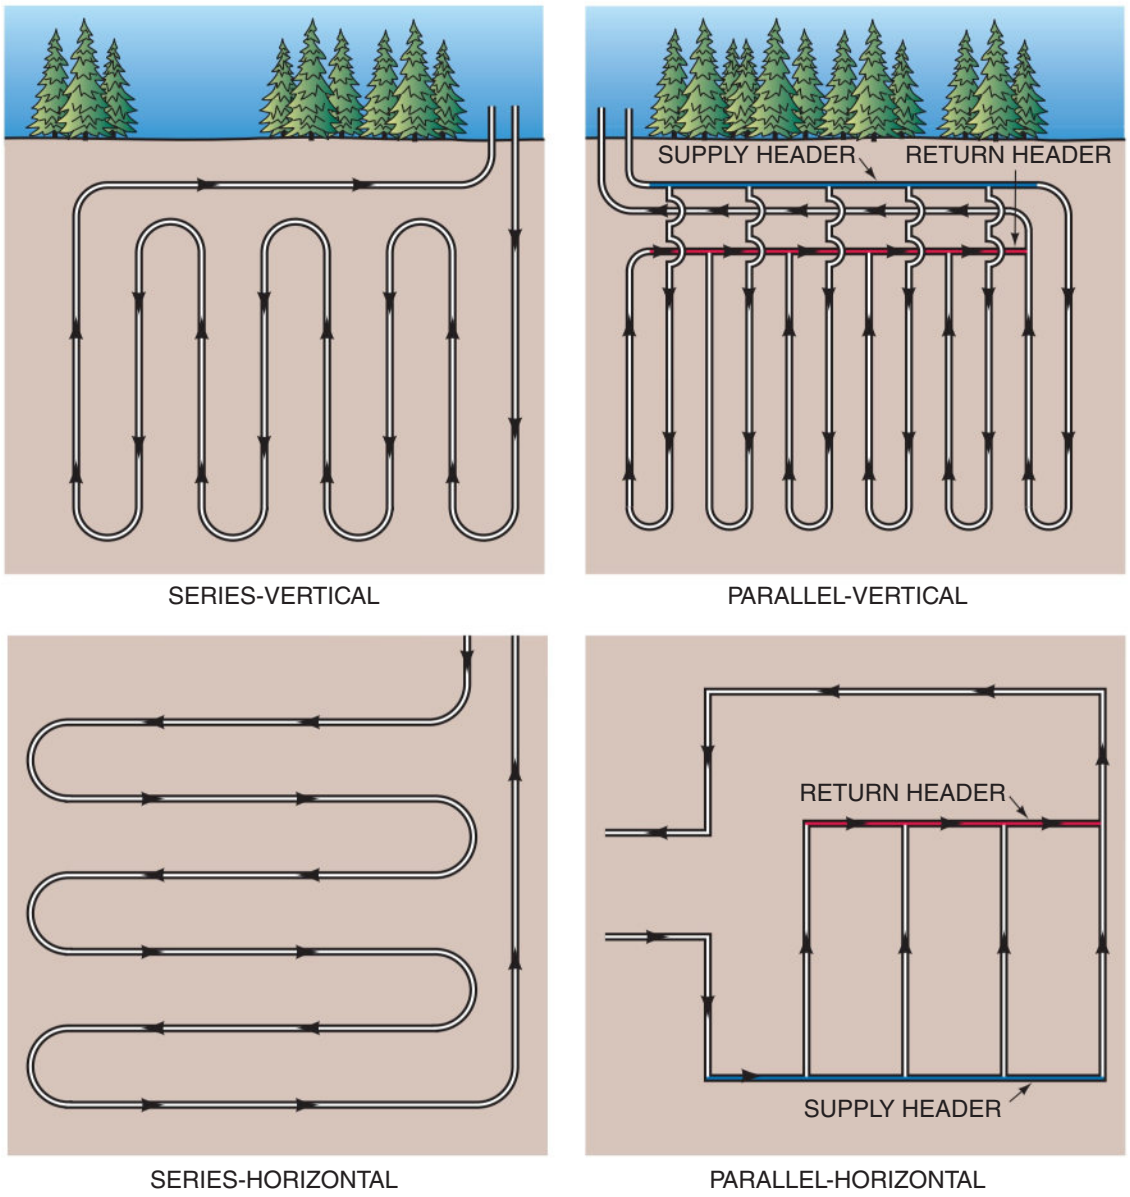
Figure 44.17 Different flow paths in ground loops.



pump capacity. As a result, large-diameter headers are used at the inlet and outlets of the water loops to ensure that each loop experiences the same pressure for equal fluid flow.

Listed here are advantages of a parallel-flow system:

- Smaller-diameter and lower-cost piping
- Lower installation and labor costs
- Less antifreeze required

Some disadvantages of parallel fluid flow in ground loops are:

- Difficulty of removing air in the ground loops because of parallel paths
- Balancing problems if piping is of unequal length or unequal resistance

44.7 SYSTEM MATERIALS AND HEAT EXCHANGE FLUIDS

The buried piping or underground heat exchanger is usually made of **polyethylene** or **polybutylene**. These two materials can be bonded or joined through a heating process, which will give the piping joints a very long life. The antifreeze solutions inside the buried piping are used to prevent freezing of the heat pump heat exchanger and for good heat transfer. A lot of heat pumps in southern states use only pure water as a heat exchange fluid for the ground loop, because there is

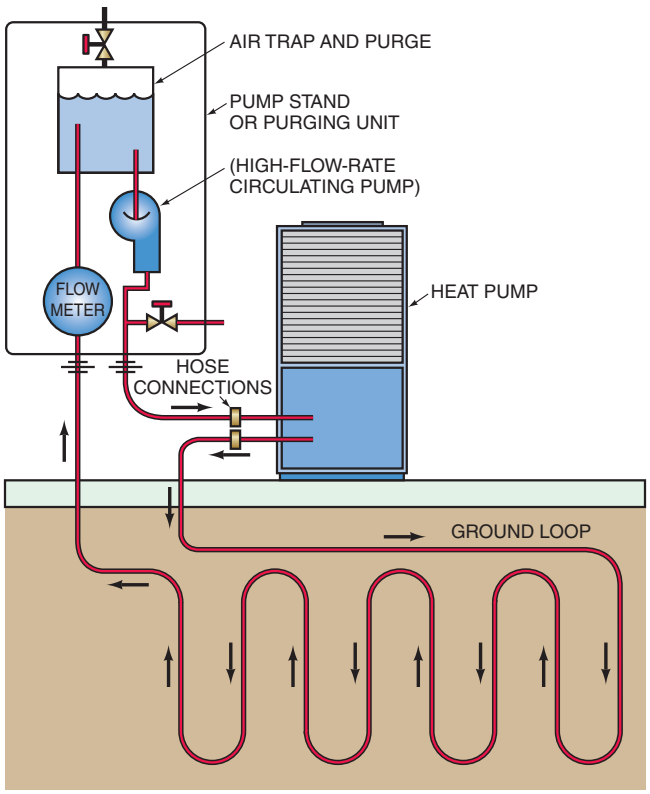
Figure 44.18 A schematic of a purging unit hooked up to a heat pump for power flushing air and debris from the ground loop.



no threat of the loop freezing in the winter. Three choices for antifreeze solutions are:

- **Salts**—Calcium chloride and sodium chloride
- **Glycols**—Ethylene glycol and propylene glycol
- **Alcohols**—Methyl, isopropyl, and ethyl

Any fluid used must

- last a long time without breaking down.
- transfer heat readily.
- have a low cost.
- be environmentally safe.
- be noncorrosive.
- be nontoxic.

Salts are safe, nontoxic, and transfer heat well. Salts also are economical, environmentally safe, and will not break down in time. Salts are, however, corrosive when in contact with some metals, especially when mixed with air. Because of this, designers must select the proper metals to use in systems. Installers and service technicians must also make sure that the systems remain air-free if salts are to be used successfully in ground loops.

Glycols are safe, most of the time are noncorrosive, transfer heat fairly well, and also are economical. Glycols do have a track record of turning to gel at really low temperatures, which decreases their heat transfer capabilities and burdens the circulating pump responsible for their flows. Glycols have a shorter life than salts.

Alcohols can burn and are combustible if they are mixed with air. This is their major disadvantage. Alcohols are somewhat toxic, are relatively noncorrosive, transfer heat fairly well, and are relatively inexpensive to purchase. If handled properly and not mixed with air, alcohols can be a safe alternative to salts and glycols.

All system components—the coaxial heat exchangers, circulating pumps and flanges, and of course all plastic piping—must be carefully chosen when used in contact with salts, glycols, or alcohols. Sometimes, certain alcohols and salts are mixed with softened water from a domestic well-water system. They make good low-viscosity, water-soluble antifreeze solutions, but they can also be strong solvents, so strong as to dissolve some metals in the system. When some alcohols, like methanol, are mixed with high-sodium-content water from a water supply containing a water softener, they can attack the iron bodies of the circulator pumps in the system. The iron bodies of the pumps actually become the sacrificial anode for the system because they are the least noble metals in the galvanic series. This problem can be corrected by replacing the antifreeze solution with a reputable premixed inhibited antifreeze made with deionized or distilled water. Many chemical companies market premixed geothermal loop fluids that have great antifreeze, anticorrosive, and heat-transfer properties. These premixed commercial solutions are also nontoxic. Common automotive windshield deicer or antifreeze should never be used in a geothermal loop because they often are toxic and do not have the proper inhibitors in their solutions. The flushing and fill process using geothermal loop fluids are not a homeowner's or business owner's do-it-yourself project. It should always be done by a reputable trained and licensed professional.

Historically, the refrigerant used in water-source heat pumps was R-22. However, the Clean Air Act phaseout of R-22 because of its chlorine content—and ozone-depleting potential—will soon replace R-22 with chlorine-free, environmentally friendly alternative refrigerants. R-410A is the leading alternative refrigerant for replacing R-22 in new heat pump and air-conditioning equipment. However, there are other, alternative refrigerants and refrigerant blends that are also substitutes for R-22 in new equipment and retrofitted systems. Always follow the refrigerant manufacturer's retrofit guidelines before using any alternative refrigerant to replace R-22. Refer to Unit 3, "Refrigeration and Refrigerants," and Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycle, Reclaiming, and Retrofitting," for more detailed information on alternative refrigerants and refrigerant blends.

Beginning in the year 2010, the importing and production of HCFC-22 (R-22) is banned, except for use in equipment manufactured before January 1, 2010. Beginning in the year 2015, the production and importing of any HCFC refrigerant is banned, except as refrigerant for equipment manufactured before January 1, 2020. There will be a 90%

cap on R-22 production from the baseline production year of 1989. In the year 2020, HCFC-22 will be totally banned, and beginning in the year 2030, there will be a total ban on all HCFC refrigerants. However, existing systems with HCFC refrigerants will still be in use and it will still be legal to use recovered and reclaimed HCFC refrigerants.

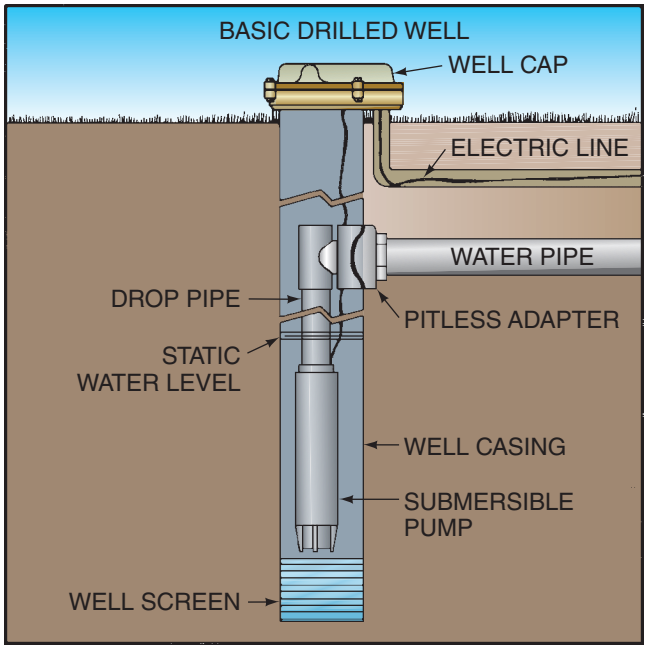
44.8 GEOTHERMAL WELLS AND WATER SOURCES FOR OPEN-LOOP SYSTEMS

Water sources for open-loop systems may be an existing well or a new well. A well pump delivers the water from the well to the heat pump. Some popular well categories are the following:

- Drilled well
- Return well
- Geothermal well
- Dry well

Figure 44.19 shows a **drilled well**. Notice that an electric water pump, complete with electrical lines, is encased underground within the well casing. This type of pump is often referred to as a submersible well-water pump. The water pump gets its water from an underground aquifer. Other water sources may be a pond, lake, or swimming pool. The water is then discharged into a lake, stream, or marsh. **Figure 44.20** illustrates an open-loop, geothermal heat pump system in which a water pump delivers water to the heat pump from a well and the water is then discharged to a pond.

Figure 44.19 A basic drilled well.



Source: Mammoth Corporation

Most wells for geothermal heat pump systems are **grouted**. Grouting is a procedure in which a cement-like material is injected between the well casing and the hole drilled for the well. When the grout hardens, it forms a seal and prevents any contamination from other water sources in the same local area. It also prevents rain or other miscellaneous surface water from seeping into the well and polluting it. Grouting also makes the entire well structure sturdier and can prevent rusting of the well casing.

Return wells are used to discharge the water back into the ground after it has gone through the heat pump's heat exchanger, **Figure 44.21**. Return wells should be at least 100 ft from the supply well to prevent early mixing of the supply and return water. Also, the return well must be at least as large as the supply well to handle the water flow. If early mixing of supply and return water occurs, the supply-water's temperature could be increased or decreased, depending on the season. This could seriously affect the capacity of the heat pump. In some cases, the return well may discharge its water into the supply well. This ensures that a good volume of water is available to the heat pump's heat exchanger. However, adequate supplies of water must be available to ensure that supply water temperatures are not seriously affected.

Notice in **Figure 44.21** that a slow-closing *solenoid valve* is installed in the return line. The slow closing of the solenoid valve prevents a pressure pulse, known as **water hammer**, from occurring each time the valve opens when the heat pump cycles on. Solenoid valves are almost always positioned in the return line to keep the coaxial heat exchanger in the heat pump at the same pressure as the **pressure tank** during the off cycle. Pressurization helps keep any dissolved minerals in the water so that they will not precipitate out and foul the heat exchanger. Minerals are more soluble in water as the pressure increases.

The return or drop pipe in the return well must end below the static water level in the well. Static water level is the level to which water will rise in a well as it naturally seeks its own level. The level of the return pipe keeps it free of air and helps to prevent the growth of algae and bacteria within the return line. Such a growth would restrict water flows and decrease capacities by coating the inside of the line.

Dedicated geothermal wells are closed-loop systems that draw water from the top of the water column, circulate it through the heat pump where it either absorbs or rejects heat energy, and then return the water at a different temperature to the bottom of the water column, **Figure 44.22**. The water discharged to the bottom of the well will be at its normal temperature before it is drawn to the top of the well. Dedicated geothermal wells are used where there is not enough water in the underground aquifer to use other standard well systems.

A **dry well** is used to discharge water in an open-loop system. Dry wells are nothing more than a large reservoir in the ground filled with gravel and sand, **Figure 44.23**. They are usually used in sandy soil conditions. The used water is filtered as it seeps through the gravel and sand, and it eventually makes its way back to the underground aquifer.

Figure 44.22 A dedicated geothermal well.

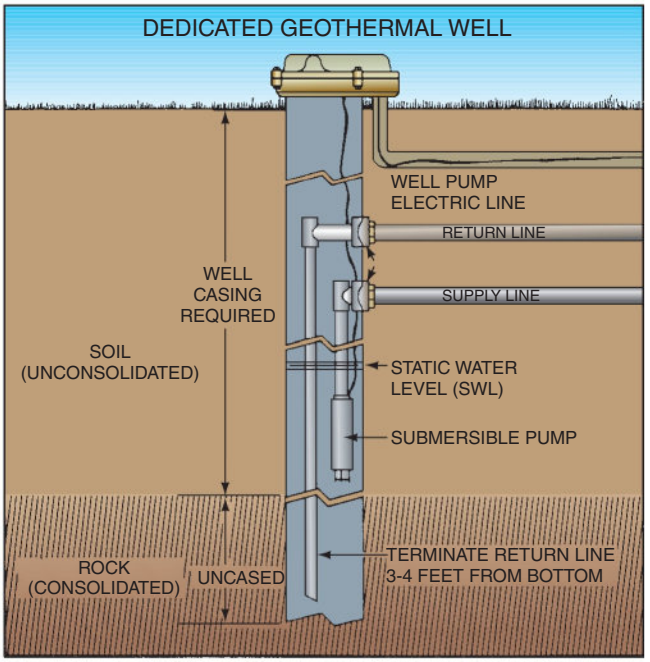

Figure 44.23 A dry well.

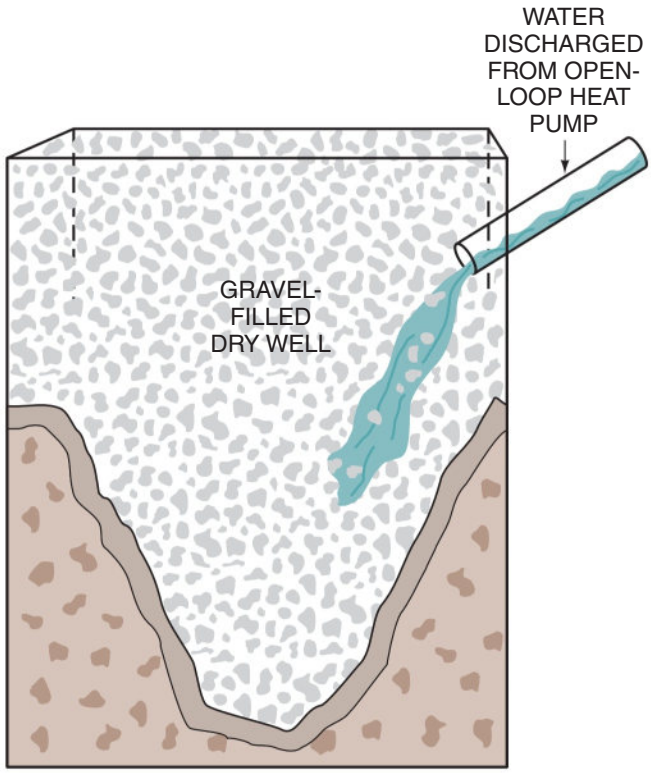
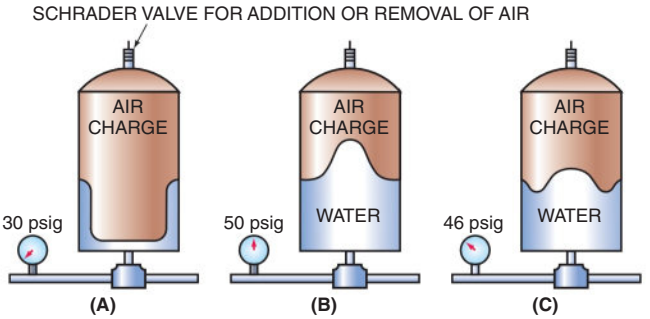


Most well systems in houses today use pressure tanks. They are also used extensively with open-loop geothermal heat pump systems. The pressure tank is nothing more than a small pressurized tank for water storage. The main purpose

Figure 44.24 The operation of a well system's pressure tank.



(A) FACTORY AIR CHARGE.

(B) WELL PUMP HAS PRESSURIZED AIR CHARGE AND WATER PRESSURE IS 50 psig. THE WELL PUMP WILL NOW SHUT OFF BECAUSE PRESSURE SWITCH HAS OPENED ON A RISE IN PRESSURE.

(C) WHEN WATER IS USED BY THE HEAT PUMP, THE PRESSURE IN THE AIR CHARGE PUSHES WATER INTO THE SYSTEM. THE PUMP STAYS OFF. THE WELL PUMP ONLY COMES ON WHEN PRESSURE SWITCH CLOSES ON A DROP IN PRESSURE.

of the tank is to prevent the well pump from short cycling. Even when the well pump is off, the pressure tank can supply water when the open-loop heat pump calls for heating or cooling. When they come from the factory, pressure tanks have a compressed air charge in them. Some tanks have a fitting that allows the addition or subtraction of air for customization. This air charge is inserted in the tank on top of the water and is separated from the water by a rubber bladder. The well pump fills the pressure tank with water. The water displaces the bladder, creating higher pressure within the air charge. This increases the pressure in the pressure tank. When an maximum operating pressure is reached, the well pump will automatically be shut off by a pressure switch. The well pump will remain off until the pressure in the tank reaches a minimum pressure. The pump is then cycled on, and the process is repeated. The pressure tank should be sized so that the well pump does not start any more often than one time every 10 min. **Figure 44.24** illustrates the operation of a pressure tank.

44.9 WATER-TO-WATER HEAT PUMPS

Up to this point in this unit, our discussion has primarily focused on the water-to-air heat pump system. Now we will examine another heat pump configuration that is gaining popularity at a surprisingly fast rate: the water-to-water heat pump, **Figure 44.25**. In the past, applications for water-to-water systems were rather limited, given the fact that the water temperatures attainable were rather low for many heating situations. In an R-22 heat pump system, water can be heated to a temperature as high as 130°F; in an R-410A system, the water temperature will not likely

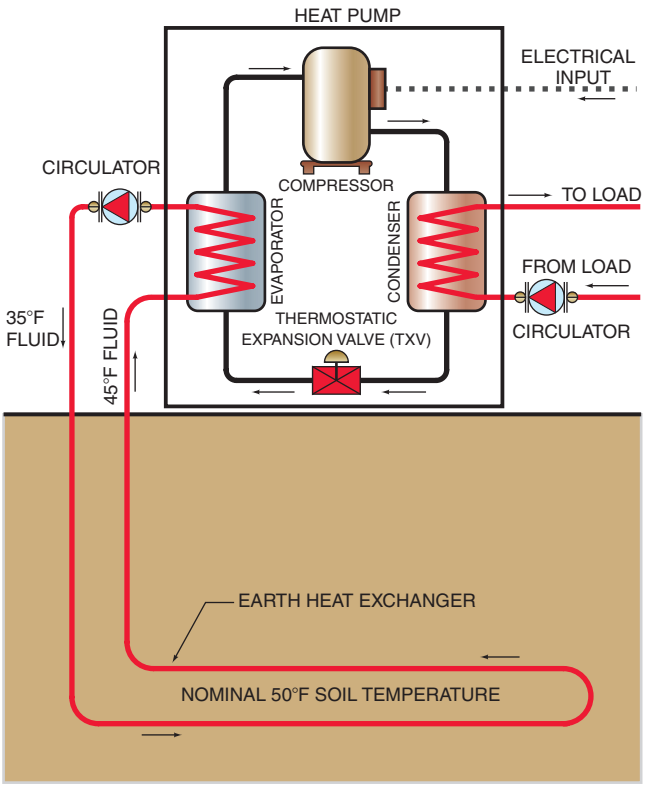
Figure 44.25 A water-to-water heat pump installed as part of a hydronic heating system.

Figure 44.26 Heat exchanger configuration on a water-to-water heat pump system.



be higher than 120°F. Given the increasing popularity of radiant heating systems that rely on lower-temperature water than do conventional baseboard heating systems, the water-to-water heat pump has become a viable option for providing hot water at a reasonable cost.

Water-to-water heat pumps utilize two coaxial heat exchangers, as compared to only one in the water-to-air system, **Figure 44.26**. Water-to-water systems can be configured as either open-loop or closed-loop systems. When operating in the heating mode, the coaxial heat exchanger that is linked to the ground loops is functioning as the evaporator, while the heat exchanger that is heating the water is operating as the condenser. In order to ensure continued satisfactory operation of the system, the water flow through the condenser must be unrestricted. A restricted water flow will cause the head pressure to rise, possibly causing the system to shut off on safety. This could pose a problem, especially since the heat pump system often controls more than one heating circuit. When only one or two zones are calling for heat, a high head-pressure situation may arise. For this reason, it is very common to see a buffer tank installed on the condenser water side of the water-to-water heat pump system, **Figure 44.27**.

The buffer tank is nothing more than a large tank that both receives water from the condenser and supplies water to the condenser. The heat pump will cycle on and off on the basis of the temperature of the water in the tank. The cut-in temperature is the temperature at which the heat pump will cycle on; the cut-out temperature is the temperature at which the heat pump will cycle off. As with other controls, the difference between the cut-in and cut-out temperatures is the

Figure 44.27 Buffer tank location on a water-to-water heat pump system.

differential. The smaller the differential, the shorter the heat pump run time will be—but the temperature of the water will vary very little. The larger the differential, the longer the heat pump run time will be. The longer run-time option is more efficient because more power is consumed when the system first starts up.

The size of the buffer tank can be determined by crunching some numbers. The factors that affect the size of the tank are as follows:

- The capacity of the heat pump, $Q_{\text{Heat Pump}}$
- The desired temperature differential (ΔT) of the tank water
- The heat load on the space, Q_{Space}
- The desired run time of the heat pump, T

The formula for the buffer tank volume is

$$\text{Volume}_{\text{Buffer Tank}} = \frac{T(Q_{\text{HeatPump}} - Q_{\text{Space}})}{\Delta T \times 500}$$

Let's assume that we have a heat pump with a 24,000-Btu capacity and that we want the temperature of the water in the buffer tank to range from 90°F to 105°F. There is also a 10,000-Btu load on the space and we want the heat pump to run for 10 min. From this information, we get the following:

$$\text{Volume}_{\text{Buffer Tank}} = \frac{T(Q_{\text{HeatPump}} - Q_{\text{Space}})}{\Delta T \times 500}$$

$$\text{Volume}_{\text{Buffer Tank}} = \frac{10 \times (24,000 - 10,000)}{(105°\text{F} - 95°\text{F}) \times 500}$$

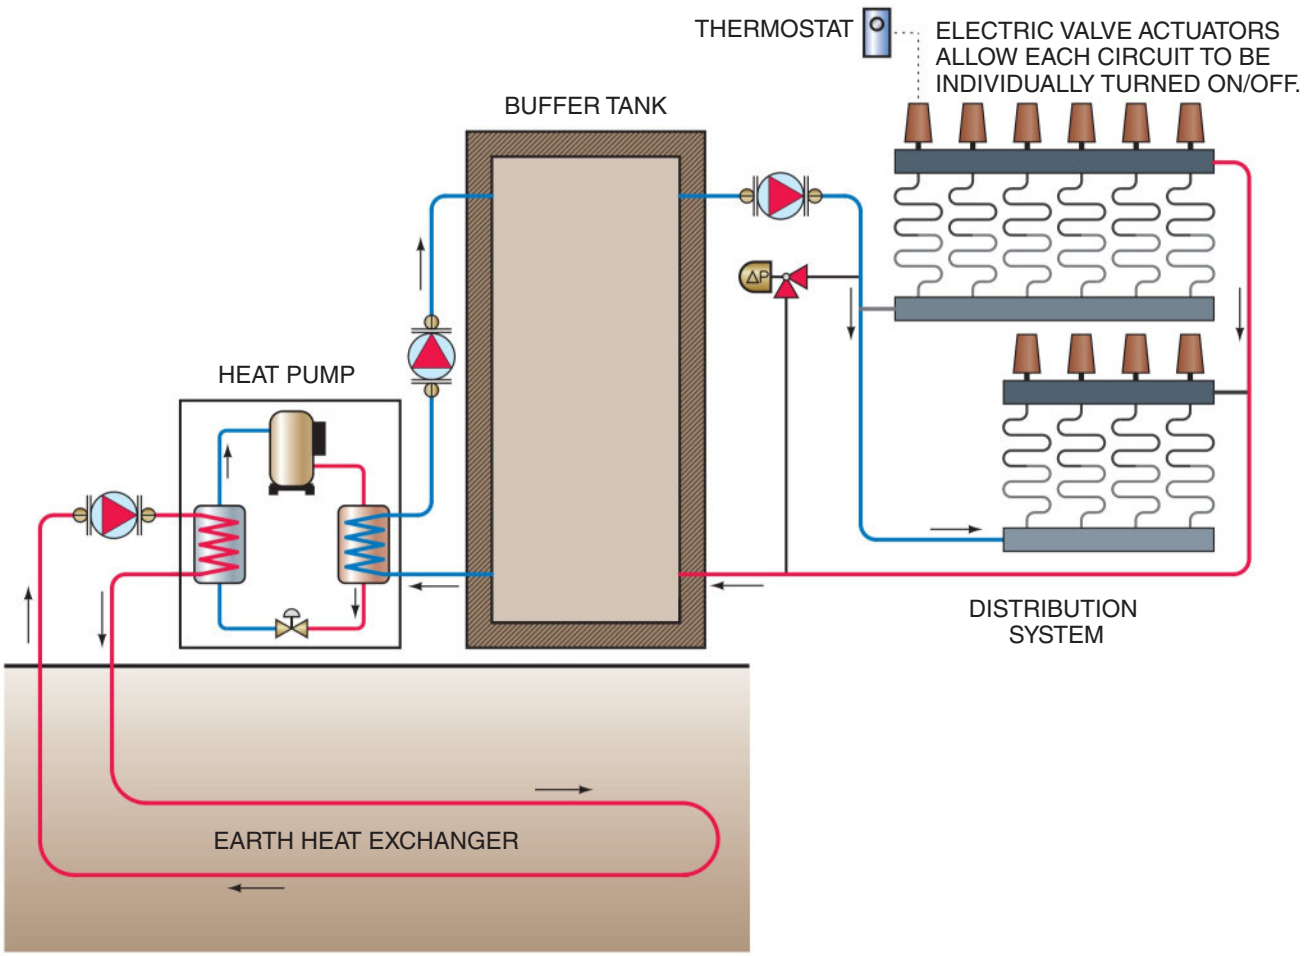
$$\text{Volume}_{\text{Buffer Tank}} = 140,000 \div 5,000$$

$$\text{Volume}_{\text{Buffer Tank}} = 28 \text{ Gallons}$$

By using a tank that is larger than calculated, the run time of the heat pump can be increased.

The buffer tank functions as the water-supply tank for the radiant heating system. One pump moves the water from the condenser to the tank and from the tank to the condenser. The second pump moves water from the buffer tank to the hot water heating circuits and from the heating circuits back to the tank, **Figure 44.28**. As long as the heating zones are calling for heat, the pump that carries

Figure 44.28 Piping connections between (1) the heat pump and the buffer tank and (2) the buffer tank and the heating circuits.



the heated water into the heating zones will operate. This does not mean, however, that the heat pump is operating, as the heat pump will cycle on and off to maintain the desired water temperature in the buffer tank. As more and more zones call for heat, the temperature of the water returning to the buffer tank will be lower, so the heat pump will cycle on for a longer period of time to maintain temperature.

44.10 TROUBLESHOOTING

Troubleshooting geothermal heat pumps is much like servicing the air-to-air heat pumps covered in Unit 43, "Air Source Heat Pumps". However, one of the minor differences is how access is gained to pressures and temperatures in the water or ground loop. **Figure 44.29(A)** shows pressure and temperature port locations and mountings on the water or ground loop. **Figure 44.29(B)** illustrates a pressure and temperature port adapter used in performance testing the heat pump. The temperature probe is used for measuring the temperature difference between the inlet and outlet of the water's coaxial heat exchanger. The pressure gauge is used for determining the flow rate through the heat exchanger by acquiring the pressure drop across the heat exchanger. A curve or chart of flow in gpm versus pressure drop has to be used in conjunction with the pressure measurements.

The refrigerant system is accessed just as in any other heat pump system, and troubleshooting is very similar to troubleshooting any other refrigeration or air-conditioning system. Even the electrical system is very similar to other refrigeration and air-conditioning systems. Because of this, this troubleshooting section will cover mainly the water loop or ground loop of geothermal heat pump systems. If a review of the refrigeration system (refrigerant loop) or airflow system (air loop) is needed, see Unit 36, "Refrigeration Applied to Air-Conditioning"; Unit 37, "Air Distribution and Balance"; Unit 41, "Troubleshooting"; and Unit 43, "Air Source Heat Pumps."

The *ground loop* in closed-loop systems, which is sometimes referred to as the water loop, consists of the antifreeze solution, which is contained in the plastic pipes buried within the earth or lake. An open-loop system uses water from a well that is discarded back to the earth in some way. In either case, a water-to-refrigerant heat exchange takes place in the coaxial heat exchanger within the geothermal heat pump. The *governing formula* that determines the amount of heat absorbed in the heating mode or the amount of heat rejected in the cooling mode is

Heat quantity in Btu/h = (gpm) × (Temp. Diff.) × (500)

gpm = Gallons per minute of antifreeze circulated

Temp. Diff. = Difference in temperature between water in and out of the heat exchanger.

500 = A number that accounts for the specific heat of the fluid circulated, the weight of 1 gal of water (8.33 lb), and a time factor to convert from gpm to Btu/h. 500 is used for pure water. However, this number can vary depending on the specific heat of the antifreeze solution; 485 is usually used for an antifreeze solution.

The two variables in the preceding list are the gpm of antifreeze solution and the temperature difference of the antifreeze solution in and out of the coaxial, water-to-refrigerant heat exchanger. If either of these two variables changes, the heating and/or cooling capacity of the heat pump will be affected. Flow rates of antifreeze in the ground loop can be measured by flowmeters installed in the pipes or by the pressure drop across the coaxial heat exchanger. If the pressure drop technique is used, a curve of pressure drop versus flow rate in gpm must be used.

For example, a low gpm flow rate of antifreeze can be caused by a bad circulating pump, air restriction in the piping, contamination or a kinked pipe in the closed loop, or a low water-supply pressure in the open-loop system. If the heat pump is in the *heating mode,* the refrigerant side of the coaxial heat exchanger is the evaporator and low suction pressure will be noticed in the refrigeration loop. This causes low evaporating temperatures. Because of the reduced flow rates in the water side of the coaxial heat exchanger, the water will stay in contact longer with a colder coil. This will increase the temperature difference within the water. The service technician will notice a lower suction pressure and a higher temperature difference between water in and water out of the heat exchanger.

If the heat pump is in the *cooling mode,* the refrigerant side of the coaxial heat exchanger is now the condenser and the ground loop or water loop is the condensing medium. A reduced flow of water will cause high head pressures in the refrigerant loop. An increase in the temperature difference of the water in and out of the heat exchanger will also occur. This is because the water stays in contact with a hotter coil for a longer time.

If minerals in the water of an open-loop system foul and restrict the coaxial heat exchanger's surface on the water side, poor heat transfer will take place between the water and the refrigerant because the scale will act as an insulator. This will cause a low temperature difference between water in and out of the heat exchanger in both the heating and cooling modes. This results in a high head pressure in the cooling mode and low suction pressure in the heating mode. Closed-loop systems hardly ever have this problem because the same treated water/antifreeze solution is circulated throughout the loop.

If for some reason the loop has been designed too short in a closed-loop system, low water or antifreeze solution temperatures coming into the heat pump will be experienced in the heating mode. This will cause low suction pressures in the refrigerant loop. In the cooling mode, high water or antifreeze solution temperatures coming into the heat pump will be experienced, which will cause high head pressures. These same symptoms will occur if the loop is in the wrong type of soil or if there is poor thermal contact between the soil and the water loop.

44.11 DIRECT GEOTHERMAL HEAT PUMP SYSTEMS

To review, the traditional, closed-loop geothermal heat pump system consists of an antifreeze or water solution circulated through plastic pipes buried in the ground. This solution, which is circulated by a small liquid centrifugal pump, acts as a heat-transfer fluid. The plastic pipes containing the heat-transfer fluid are often referred to as the *ground loop* or *water loop*, **Figure 44.7**.

In the heating mode, heat is transferred from the ground, through the plastic pipe, to the ground loop. The circulated heat-transfer fluid within the plastic pipes then exchanges its heat energy with a *refrigerant loop*. This heat exchange occurs within the heat pump's antifreeze-to-refrigerant heat exchanger contained within the cabinet of the heat pump. The antifreeze-to-refrigerant heat exchanger is usually a coiled, coaxial, tube-within-a-tube, **Figure 44.5**. **Figure 44.14** illustrates the entire traditional, closed-loop geothermal heat pump system. These systems are often referred to as a *two-step* or *indirect* heat exchange because the antifreeze or water solution is a secondary refrigerant. The heat added to the conditioned space is withdrawn from the circulating fluid in the ground loop by the refrigerant in the refrigerant loop. Various ground-loop configurations for traditional, closed-loop geothermal heat pump systems are illustrated in **Figure 44.7** through **Figure 44.13**.

DIRECT GEOTHERMAL SYSTEMS

Direct geothermal heat pump systems consist of small 3/8- to 7/16-in. copper pipes or polyethylene plastic-coated copper pipes buried in the ground with refrigerant flowing through them, **Figure 44.30**. The copper pipes act as the evaporator where the refrigerant experiences a phase change from liquid to vapor. This is often referred to as the *earth loop, phase-change loop,* or *refrigerant loop*. For clarification purposes, this loop will be referred to as the refrigerant loop for the rest of this unit. In the heating mode, heat is absorbed from the earth "directly" to the vaporizing refrigerant in the refrigerant loop. The refrigerant vapor then travels through the reversing valve to a refrigerant management system and then to the compressor, where it is compressed and superheated to a higher temperature. The superheated, heat-laden hot gas from the compressor then travels to the condenser. The condenser is a refrigerant-to-air, finned-tube heat exchanger located in the ductwork of the conditioned space or building, **Figure 44.31**. It is often referred to as the *air coil*. Heat is then rejected to the air as the refrigerant condenses at a higher temperature than the air. A blower delivers the heated air to the conditioned space. The condensed liquid then travels through the expansion valve and vaporizes in the evaporator or refrigerant earth loop buried in the ground. The process is then repeated. Heating and cooling schematics of a waterless, earth-coupled, closed-loop geothermal heat pump system are shown in **Figure 44.32**.

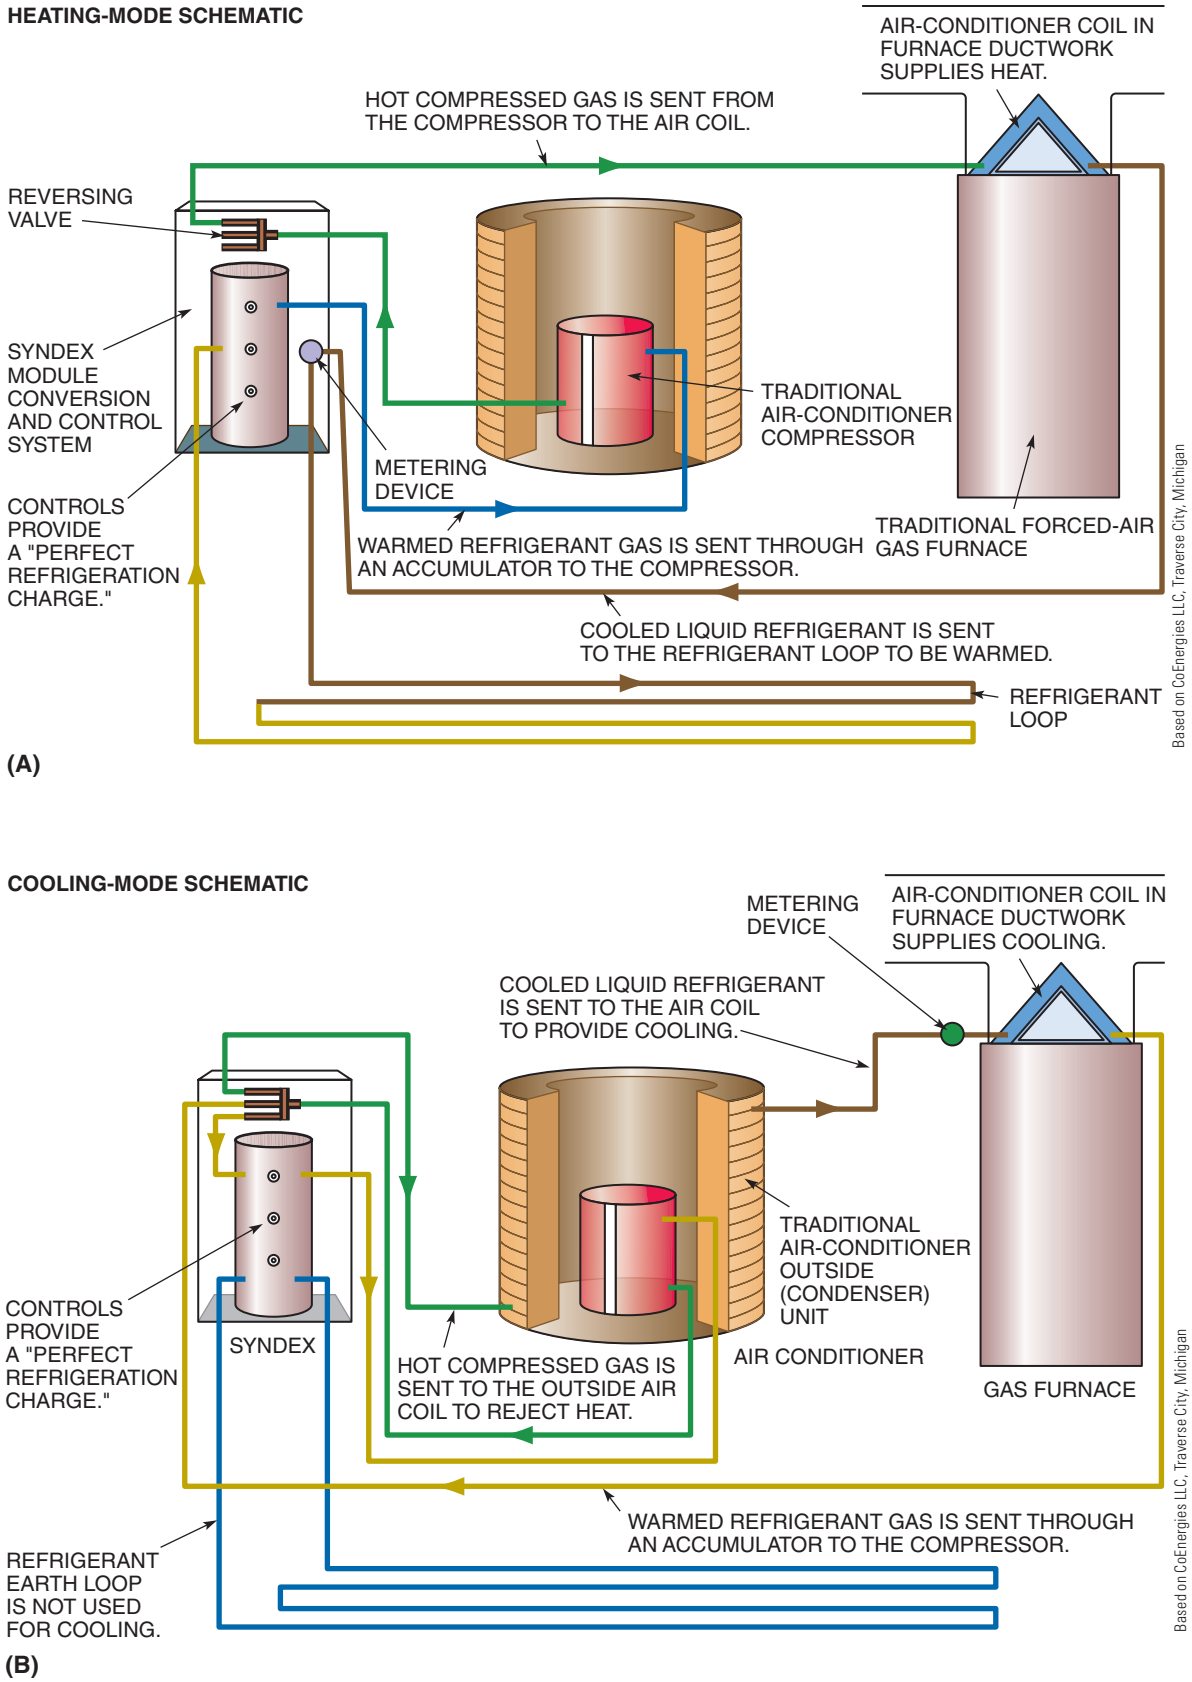
(B)

Figure 44.32 (A) A heating-mode schematic. (B) A cooling-mode schematic.



No water or antifreeze solution acts as a heat transfer fluid in these systems. The refrigerant earth loop or evaporator, which is buried in the earth, extracts heat directly from the earth. This is often referred to as a *direct* or *one-step* heat exchange. The American Society of Heating, Refrigeration, and Air-Conditioning Engineers (ASHRAE) and the Air-Conditioning, Heating and Refrigeration Institute (AHRI) refer to these types of heat pump systems as Direct GeoExchange systems. This system eliminates the coaxial heat exchanger, the liquid centrifugal pump, antifreeze or water heat-transfer fluids, and the need for system flushing common in traditional closed-loop, indirect geothermal heat pump systems. Because there is one less heat exchanger, the thermal efficiency of the heat pump is improved.

Also, by using one less heat exchanger, one less temperature difference does not have to be created and maintained within the geothermal heat transfer system. Now, there are only heat transfers from (1) the earth to the refrigerant loop and (2) the refrigerant loop to the air inside the house. In an indirect geothermal system, there is one extra heat transfer and thus one extra temperature difference to deal with. With indirect geothermal systems, the heat transfers occur from (1) the earth to the water loop in the ground, (2) the water loop to a refrigerant loop, and (3) the refrigerant loop to the air inside the house. The refrigerant-loop phase changes liquid refrigerant to vapor and takes advantage of the *latent heat of vaporization* of the refrigerant being used. The refrigerant loop also absorbs heat directly from the earth, which allows for higher efficiencies. In some system designs, the buried refrigerant loop is not utilized in the cooling mode, and the conventional air conditioner's outside condenser takes its place.

The direct geothermal heat pump system can be easily retrofitted to a common home furnace gas-heating and conventional air-conditioning system, **Figure 44.33**. Once retrofitted, the home's conventional air-conditioning outside condenser coil and fan is not used for the heating mode. However, the condenser coil will be used during cooling, as before the conversion, but will operate with a perfect or critical refrigerant charge because of a refrigerant management system, which will be mentioned shortly.

Home energy costs for heating and cooling can be reduced as much as 50% when the system is retrofitted to a direct geothermal system. This is especially true when fossil fuels are used exclusively. Because the system uses a precise refrigerant-management module that will eliminate the common problems of an improperly charged air-conditioning system, the cooling system's performance will be greatly improved. The improved heating and cooling efficiencies result in overall energy savings for almost every geographical region of North America.

The refrigerant-management module is installed between the outside air conditioner and the home's furnace. It manages the refrigerant circulated in the buried refrigerant loop, **Figure 44.33**. This buried refrigerant loop, combined with a conventional furnace, air-conditioning compressor, and inside air coil, provides geothermal heating in the winter months and cooling in the summer months. The system responds automatically to the thermostat inside the home. The home's conventional furnace can be used as second-stage or emergency heating, with the direct geothermal heat pump providing first-stage heat. The furnace will not operate at the same time as the heat pump system because once second-stage heat is turned on, the heat pump will be locked out until the thermostat is satisfied.

Figure 44.33 A retrofitted system showing the refrigerant management module.

INSTALLATION AND REFRIGERANT-LOOP PIPING

Installation costs for a retrofit are generally less than the installation of a comparable traditional, stand-alone, earth-coupled geothermal heating and cooling system. By using the one-step or direct heat exchange process between the phase-changing refrigerant and the earth, the homeowner's existing conventional air-conditioning compressor acts as the refrigerant pump and heat generator. All other heat energy to and from the system is directly transferred heat energy.

As mentioned earlier, the refrigerant loop buried in the ground consists of 3/8- to 7/16-in. copper pipe or copper pipe covered with polyethylene plastic. The polyethylene plastic pipe has two small vents or grooves that allow the pipe to act as a vented double-wall heat exchanger, **Figure 44.34**. Any refrigerant or oil leaks in the buried copper piping can vent to the grooves in the plastic coating, which will be vented to the surface. This surface venting allows for ease of leak detection and protects the ground from refrigerant and oil contamination, making it a more environmentally conscious system. Each copper pipe loop is approximately 70 to 100 ft long and is buried in trenches 3 to 4 ft deep. A trencher is used to dig the trench for the polyethylene plastic-coated copper pipe, **Figure 44.35**, and the piping is then

Figure 44.34 Two small vents, or grooves, allowing the pipe to act as a vented double-wall heat exchanger.

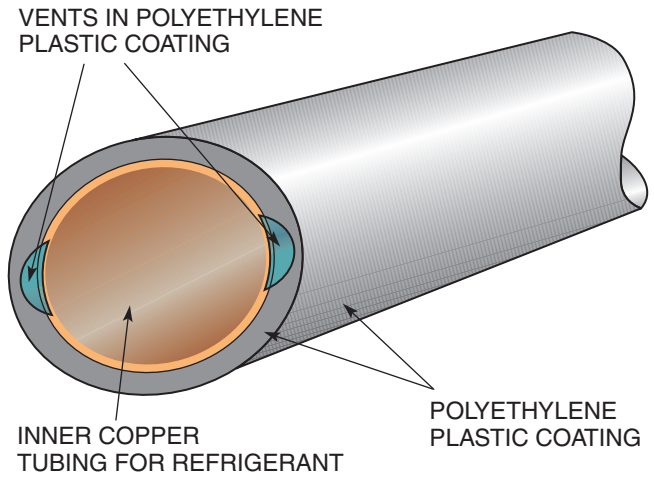

Figure 44.35 A trencher digging the trench for the refrigerant loop.

Source: CoEnergies LLC, Traverse City, Michigan

covered with sand for good thermal efficiency. The trenches are then backfilled and restored to their natural grade. These shallow trenches are generally quicker to install than traditional closed-loop, indirect, geothermal heat pump systems containing antifreeze or water in their ground loops. Each buried refrigerant loop is a one-piece circuit without any buried joints. The number of loops depends on the capacity of the system and the soil composition.

Each refrigerant-loop circuit's pipe supply and return ends are brazed to a copper header that is contained in an easily accessible header box, **Figure 44.36(A–D)**. In the unlikely event that a leak should occur, the header is easily accessible through the header box. The individual refrigerant loops in separate trenches all meet at the header box or header pit, where the circuits are soldered together. Remember, there are no joints or connections anywhere below the ground. The two supply and return lines are then

Figure 44.36 (A) A copper header to which the refrigerant loop supply and return ends are brazed. (B) A copper header being brazed to supply and return loops by a technician. (C) Copper headers showing supply and return ends of piping.

(D)

insulated and routed to the air conditioner, **Figure 44.37**. The refrigerant lines of the existing conventional air conditioner are tapped into and diverted to the header pit, where the refrigerant can be circulated through the waterless earth loop buried in the ground.

The earth loop, often referred to as the refrigerant loop, may be installed in three different configurations: (1) diagonal, (2) vertical, and (3) horizontal. All three configurations are shown in **Figure 44.38**. Diagonal drilling rigs are shown in **Figures 44.39** through **Figures 44.43**. A horizontal installation is shown in **Figure 44.44**.

The refrigerant (earth) loops are connected to a refrigerant distributor or manifold. The manifold's function is to divide the refrigerant flow equally to each loop and maintain balance within the refrigerant ground-loop system. There is a vapor and a liquid manifold for each refrigerant ground loop. The vapor manifold is the larger of the two manifolds because it transports evaporated refrigerant vapors back to the compressor. The liquid manifold has smaller tubing than the vapor manifold because of the liquid refrigerant's higher density. Most earth loops are grouted with a plasticized grout for good heat transfer with the earth and to protect any underground aquifers nearby. The grout puts a seal around the earth loops that are lowered into the small-bore holes. This grout seal prevents any surface water from running down into an aquifer by way of the bore holes that house the earth loops.

The main ports to each manifold are connected to the heat pump's compressor unit by means of a line set comprised of one vapor and one liquid tube. **Figures 44.45** through **Figures 44.47**

show some refrigerant- (earth) loop manifold systems. To ensure equal distribution of refrigerant, it is critical that the manifolds are installed vertically, as shown in **Figure 44.45** and **Figure 44.46**. **Figure 44.45** illustrates the interface of a line set, the liquid and vapor manifolds, and the individual refrigerant

(earth) loops for a typical direct geothermal system. The heat pump's refrigerant (earth) loop piping, air handler, and compressor unit are shown in **Figure 44.48**. The internals of the heat pump's compressor unit are shown in **Figure 44.49**.

There are many configurations possible for diagonal, vertical, and horizontal earth loops. The choice of the specific configuration depends on several factors involved in the design and application of these direct geothermal systems.

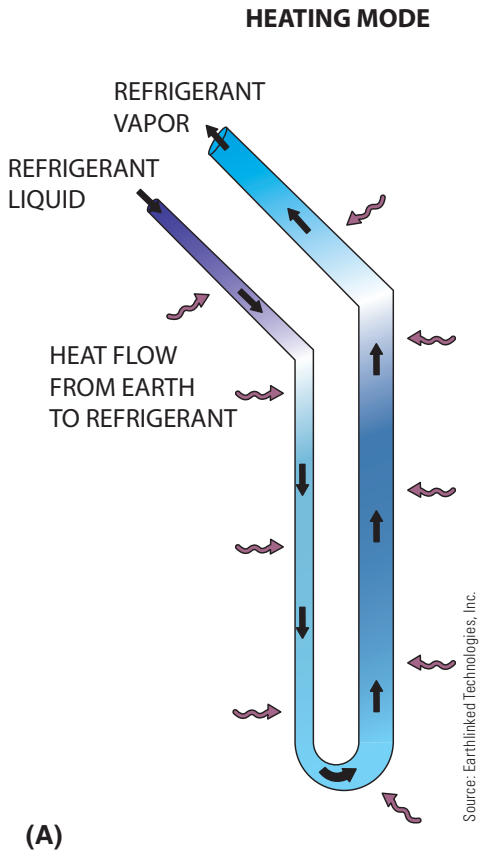
HEATING MODE

In the heating mode, liquid refrigerant from the heat pump's indoor coil (condenser) is expanded and enters the smaller-diameter tube of the refrigerant (earth) loop or evaporator. Heat is then transferred from the warmer earth into the refrigerant loop. While absorbing this heat, the refrigerant in the loop is boiled (evaporated) to a vapor as it progresses through the refrigerant (earth) loop, **Figure 44.50(A)**. The refrigerant vapor then exits the earth loop and is returned to the compressor unit. The refrigerant vapor is now compressed by the heat pump's compressor to a higher pressure and temperature. The compression process usually raises the refrigerant vapor temperature from about 40°F to about 160°F. The hot, superheated refrigerant vapor is now delivered to the indoor coil (condenser), where it gives off heat to the building's indoor air with the assistance of a blower, **Figure 44.50(B)**. As the refrigerant vapor gives off heat, it gradually condenses back to a 100% liquid state.

As mentioned earlier, the compression process raises the temperature of the refrigerant vapor to about 160°F. Because this hot, superheated vapor leaving the compressor is hotter than the home or buildings inside air temperature, heat transfers into the air as the air passes over the fan coil located in the air handler, **Figure 44.50(B)**. This warms your home or building.

Figure 44.50 (A) The earth loop showing heat being transferred from the earth into the phase-changing (evaporating) refrigerant.



COOLING MODE

In the cooling mode, superheated refrigerant vapor is pumped by the heat pump's compressor into the larger-diameter (vapor) earth loop tubing. In this mode, the refrigerant temperature entering the refrigerant (earth) loop is higher than that of the surrounding earth itself. Heat will now be transferred from the refrigerant in the earth loop to the earth, **Figure 44.51(A)**. As this superheated refrigerant loses heat to the surrounding earth, it becomes saturated and gradually starts turning to a liquid (condensing). More and more of the vapor is condensed as it travels through the earth loop until it reaches 100% liquid. The refrigerant now exits the earth loop as a liquid. This liquid is now reexpanded to a lower pressure and temperature in the indoor coil (evaporator). Heat is absorbed into the indoor coil from the house or building with the assistance of a blower, **Figure 44.51(B)**.

REFRIGERANT-MANAGEMENT SYSTEM

The refrigerant-management system consists of two components: (1) liquid flow control and (2) active charge control.

Figure 44.50 (B) System schematic in the heating mode.

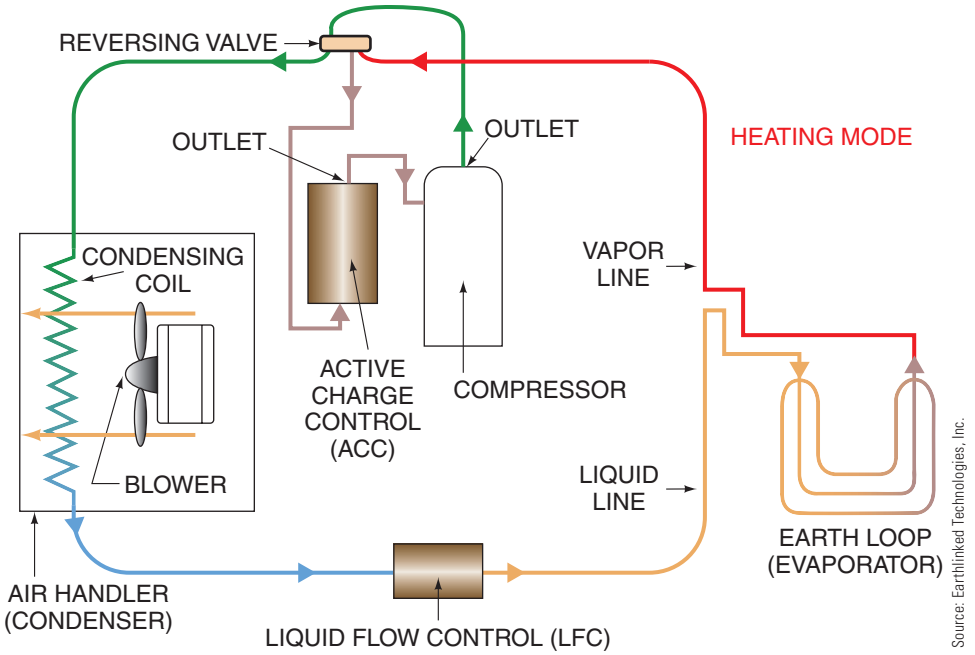

Figure 44.51 (A) The earth loop showing heat being transferred to the earth from the phase-changing (condensing) refrigerant.

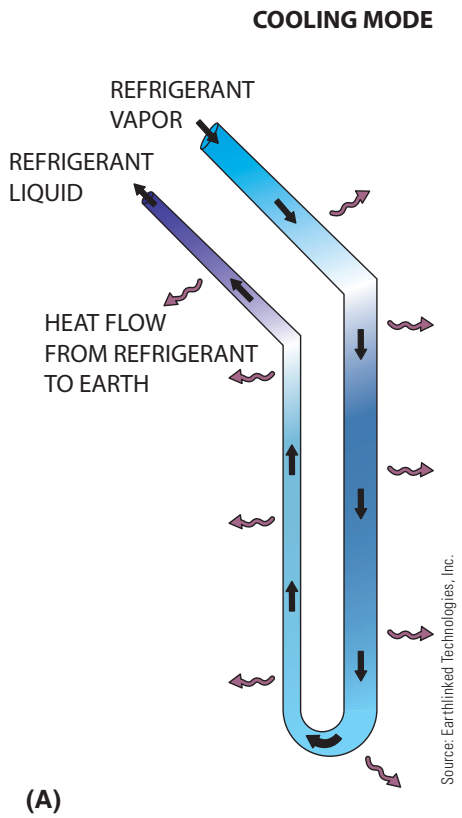

The refrigerant-management system components have three main objectives:

1. To improve the system efficiency, reliability, and serviceability
2. To continuously return lubricating oil back to the compressor without returning liquid refrigerant
3. To stabilize liquid and vapor refrigerant flow in long refrigerant (earth) loop runs, under all heat loading conditions

To operate at optimum efficiency, the three major components of all heat pumps (compressor, condenser, and evaporator) require the refrigerant to be in a particular physical state appropriate for each component.

The compressor needs liquid-free refrigerant vapor from the evaporator that contains little or no superheat at its inlet. The condenser needs the saturated refrigerant vapor to be completely condensed just before it reaches the condenser outlet. The condenser's bottom passes are not used for subcooling liquid; only desuperheat and condensing are to take place in the condenser. This prevents liquid refrigerant from "backing up" in the condenser's bottom and producing subcooled liquid, which would take away valuable internal volume for condensing. The condensed liquid seal at the condenser's outlet also ensures that no uncondensed vapor passes through the condenser. The evaporator needs liquid refrigerant at its inlet. As the liquid in the evaporator evaporates, the last drop of liquid refrigerant should complete the evaporation process just as it reaches the evaporator outlet. This is the optimum

(B)

"flooded" evaporator condition that produces maximum system efficiency without any evaporator superheat at the tailpipe of the evaporator. By eliminating superheat, the entire evaporator remains active to phase-changing (evaporating) refrigerant. Also, any liquid refrigerant that passes through the evaporator should not reach the compressor.

LIQUID FLOW CONTROL

Figure 44.52 shows the liquid flow control. This proprietary control replaces all other expansion devices, including thermostatic expansion valves (TXVs), electronic expansion valves (EXVs), automatic expansion valves (AXVs), fixed orifices, and capillary tubes. The control regulates the rate of liquid

Figure 44.52 Liquid flow control.

LIQUID FLOW CONTROL ADVANTAGES

- COORDINATES WITH THE CONDENSER TO SET THE PROPER RATE OF REFRIGERANT FLOW FOR THE ENTIRE SYSTEM
- PREVENTS VAPOR FROM "BLOWING THROUGH" FROM THE CONDENSER
- ENSURES ZERO SUBCOOLING SO THAT ALL OF THE CONDENSER IS ACTIVE
- REDUCES DISCHARGE PRESSURE
- REDUCES COMPRESSOR POWER REQUIREMENTS AS THE RESULT OF LOWERED DISCHARGE PRESSURE

refrigerant flowing from the condenser to the evaporator by directly responding to the amount of vapor bubbles arriving at the control from the condenser's outlet. It positively meters the liquid refrigerant flow to the evaporator and passes liquid at the rate it is produced in the condenser. By using the vapor bubbles from the condenser's outlet as a signal for how much liquid is being produced in the condenser, the control ensures that vapor is present throughout the whole condenser, thus eliminating liquid subcooling at the condenser's outlet. Because subcooled liquid is not allowed to back up in the last passes of the condenser, the condenser will have more internal volume for desuperheating and condensing to take place. *The end result is a larger condenser with lower condensing pressures, lower compression ratios, and higher system efficiencies.* The liquid flow control also prevents vapor from blowing through from the condenser to the evaporator due to the lack of a liquid seal (subcooled liquid) at the condenser's outlet.

Some advantages of the liquid flow control are that it:

- *coordinates with the condenser to set the proper rate of refrigerant flow for the entire system,*
- *prevents refrigerant vapor from blowing through the condenser to the evaporator,*
- *ensures zero liquid subcooling at the condenser's outlet,*
- *reduces the condensing, which gives the system a lower compression ratio, higher efficiencies, and a higher mass flow rate of refrigerant, and*
- *reduces the compressor's power requirements because of lower condensing pressures and lower compression ratios.*

ACTIVE CHARGE CONTROL

The active charge control (ACC) consists of a thermally insulated reservoir that replaces the standard accumulator, **Figure 44.53**. Its purpose is to constantly deliver refrigerant vapor and oil to the compressor under optimum conditions and quantities. The control provides a means of bringing vapor from the evaporator into contact with liquid refrigerant stored within its reservoir.

Inside this control, liquid from the reservoir flows through an orifice into an evaporator tube through which the incoming vapor passes. The liquid is entrained in the vapor stream and circulated back to the reservoir by way of a deflector plate located at the exit of the evaporator tube. If the incoming vapor is superheated, the contact with the liquid evaporates some of the stored liquid, thus reducing the superheat to near zero. Conversely, if the incoming vapor contains liquid refrigerant, the liquid is trapped in the reservoir. In either event, the refrigerant vapor leaving the active charge control has very little superheat and because of this, contains no liquid refrigerant. The vapor is almost a saturated vapor when it enters the compressor. The high vapor density entering the compressor results in higher mass flow rates of refrigerant through the compressor and system. Refrigerant coming from the evaporator and into the active charge control is continuously mixed with liquid refrigerant, which passes through an orifice from the liquid reservoir of the control.

The turbulence of the liquid/vapor mixture in the tube causes foaming and misting of the refrigerant/oil mixture.

Figure 44.53 Active charge control.

ACTIVE CHARGE CONTROL ADVANTAGES

- PREVENTS ANY LIQUID OR UNEVAPORATED REFRIGERANT FROM REACHING THE COMPRESSOR
- EVAPORATES OR TRAPS REFRIGERANT AS NECESSARY TO KEEP THE SYSTEM PROPERLY CHARGED AND THE EVAPORATOR "FLOODED" AND TO PREVENT BUILD-UP OF SUPERHEAT AT THE COMPRESSOR INLET
- INCREASES SUCTION PRESSURE BY ELIMINATING SUPERHEAT
- IMPROVES VOLUMETRIC EFFICIENCY OF THE COMPRESSOR
- CONTINUOUSLY ALLOWS THE PASSAGE OF COMPRESSOR OIL ENTRAINED IN THE REFRIGERANT
- PROVIDES A MEANS FOR QUICKLY AND EASILY DETERMINING WHETHER THE SYSTEM IS PROPERLY CHARGED
- ALLOWS THE COMPRESSOR TO RUN COOLER
- REDUCES COMPRESSOR POWER REQUIREMENT AS A RESULT OF INCREASED SUCTION PRESSURE

A circulator deflector plate above the inlet tube deflects the mixture radially outward, causing a vortex. This action also reduces the velocity of the mixture as it continues to move outward. The refrigerant vapor is drawn upward to the outlet at the upper portion of the tube. Oil mist entrained in the vapor mist also exits the tube at its top. Any liquid refrigerant droplets and any foam bubbles containing liquid refrigerant are too heavy to be entrained in the vapor stream and fall into the reservoir. Any liquid refrigerant arriving at the active charge control's inlet from the evaporator's outlet is deflected and trapped in the reservoir by the same action. Refrigerant must be evaporated to leave the active charge control, which ensures that no liquid refrigerant returns to the compressor.

The active charge control also acts as a reserve of refrigerant so that the refrigerant charge in the system is not critical. Its function will increase the system's active charge in circulation if the vapor reaching the ACC is superheated. The ACC will also reduce the active system charge if arriving vapor contains liquid refrigerant. Consequently, the system operates with an optimum refrigerant charge in active circulation under all heat-loading conditions, providing maximum system efficiency.

The ACC provides a means of quickly and easily determining when the system is properly charged without using gauges, wet- and dry-bulb readings, or charging charts. A service technician can determine if the system is properly charged simply by observing the liquid level through refrigerant-level indicators or sight glasses mounted on the side of the ACC, **Figure 44.49** and **Figure 44.53**.

44.12 SERVICE TECHNICIAN CALLS

The following service calls deal with both open- and closed-loop systems. They include some of the most common problems experienced with geothermal heat pump systems. Notice that a problem with one loop will usually affect the performance of the other loops in the heat pump.

SERVICE CALL 1

A rural homeowner reports that his heat pump seems to be running much too often and often shuts down on the low-temperature control. The low-temperature control consists of a thermistor located on the refrigerant line (evaporator) and connected to the control board. It is the third service call in one month to reset the low-temperature protection control. The homeowner also has noticed that his electric bills have risen steadily in the past two months. It is the heating season, and the heat pump is an open-loop system that gets its water from a drilled well located near the house. The heat pump's refrigerant loop contains R-22. *The problem is that the water side of the coaxial heat exchanger has been fouled with mineral deposits. This will not allow a good heat exchange between the water loop and the refrigerant loop.*

Arriving at the residence, the service technician makes sure his uniform is clean and his service van is not blocking the customer's driveway. After ringing the doorbell and maintaining a reasonable distance from the door, the technician introduces himself and his company when the homeowner answers. Once invited into the house, the technician slips on a pair of protective shoe covers to protect the customer's floors. After patiently listening to the customer and politely asking a few questions, the technician proceeds to the thermostat on the inside wall of the living room. He turns the space thermostat to a high setting in an attempt to keep the unit running while troubleshooting.

The technician installs gauges on the refrigerant loop and notices low suction pressure of about 48 psig. The normal suction pressure for that particular system should be about 55 psig for this geographical region with an entering-water temperature of 47°F. The technician then measures the temperature difference between the inlet and outlet of the water through the heat exchanger. There is a drop of only 4°F across the heat exchanger. The normal temperature drop for this geographical region is usually 7°F to 10°F.

The combination of the low suction pressure and a low temperature drop in the water indicates that a reduced heat transfer is taking place between the refrigerant loop and the open water loop. This could be caused by minerals in the water that have built up and fouled the heat exchanger on the water side, which would explain the high monthly electric bills. Because a good heat exchange could not take place between the water and the refrigerant, the heat pump's capacity was reduced. This forced the system to rely on electric strip heaters to meet the heating demands of the home.

The technician then tells the homeowner that the heat exchanger will have to be chemically cleaned and maybe replaced. He then clearly and concisely explains what work has to be done and why, explaining politely any options and the advantages and disadvantages of each. The customer decides to wait a few weeks for spring to break before having the system serviced. The technician then politely shakes the customer's hand and lets him know that he is a valued customer. The technician again thanks the customer and leaves the house.

SERVICE CALL 2

Homeowners are complaining that their heat pump keeps shutting down automatically. Power has to be manually switched off and then back on to reset the electrical lockout relay. The heat pump is a closed-loop system with two circulating pumps hooked in parallel in the water loop. It is the heating season, and the heat pump's refrigeration circuit runs on R-22. *The problem is that one of the two*

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

parallel pumps in the water loop is not operating, causing low flow rates.

The service technician turns the space thermostat to a high setting in an effort to keep the heat pump running. The pump runs for about 5 min and then shuts down on its lock-out relay. After turning the power off, the technician uses an ohmmeter and determines that the heat pump's low-pressure control (LPC) is opening, which causes the lock-out relay to hold the circuit open. The technician lets the heat pump stay off for about 20 min and analyzes the situation. He then quickly restores power to the heat pump. This resets the lock-out relay, and the heat pump runs again.

The technician then measures the temperature difference between the water in and out of the refrigerant-to-water heat exchanger. The temperature drop is 9°F instead of the normal 5°F for this closed-loop system. This indicates that the antifreeze solution in the ground loop is staying in contact with the heat exchanger longer because of the slower flow rate, causing an increased temperature drop in the solution. A lower suction pressure on the refrigerant loop is noticed after gauges are installed.

The service technician then examines the circulating pumps and determines that one of the two parallel pumps is not running. The antifreeze flowmeter indicates that there are only 7 gpm of fluid being circulated instead of the normal 14 gpm. This explains the increase in temperature difference of the antifreeze solution through the heat exchanger. The technician then applies a voltmeter to the motor terminals of the circulating pump that is not operating. The correct line voltage of 115 V is measured at the terminals, which means that the motor is defective. The technician then shuts down the heat pump and replaces the circulating pump's motor with a new one. The power is turned back on, and the system runs normally.

SERVICE CALL 3

A store owner is complaining of hardly any cooling and a reduced airflow coming from the registers in the building. The owner also has to manually reset the heat pump's electronic lock-out relay by turning the power off and then back on about eight times daily. It is the cooling season. *The problem is that the heat pump's air loop air filter is plugged with lint and dust. This prevents the correct air volume from entering the air coil.*

A service technician arrives, installs gauges on the unit, and notices that the suction pressure is 35 psig. This is a very low suction pressure for an R-22 system; the normal suction pressure should be about 60 to 65 psig for that geographical region. The technician also checks out the airflow problem and agrees with the store owner that something is restricting the airflow. A current reading of the air coil's fan motor is 3 A. The nameplate says the motor should be pulling around 9 A. This low amperage indicates that the fan is not moving enough air and the fan motor is only partially loaded. The technician then pulls out the air filter located in the return air just before the air coil and notices that it is almost completely filled with lint and dust. However, even with the air filter pulled, a restricted airflow problem and low suction pressure still exist and the fan motor continues to pull low current. The technician then decides to have a look at the air coil. He shuts off the power to the unit and removes the plenum to the heat pump. The air coil is completely covered with a blanket of ice and frost. The technician then melts the iced coil with a large blow drier while the power is turned off.

The technician then explains to the building owner that a dirty air filter has caused a restricted airflow to the air coil. This restriction in the airflow has caused a low suction pressure because of the reduced heat load from the building entering the air coil. The low suction pressure made the refrigerant flowing through the air coil's tubes colder, which finally froze the coil solid. The low suction pressure was tripping the LPC, and the unit was being locked out by its lock-out relay. This is why the store owner would have to reset the unit about eight times daily. The restricted airflow also unloaded the fan motor, causing it to draw low current. The technician then explains to the store owner the importance of keeping the air coil filters clean and also tells the building owner that it is not wise to reset the heat pump any more than once before calling a service technician. After putting the plenum back on the unit and installing a clean air filter, the technician starts the heat pump. The proper airflow has been established, and the suction pressure is normal at 65 psig. The fan motor is also drawing normal current.

SERVICE CALL 4

A homeowner is complaining about his heat pump running continuously in the heating mode. Another complaint is that his winter electric bills are unusually high. When the homeowner enters the basement where the heat pump is located, a crackling sound can be heard in the water loop as it enters the circulating pump. The ground loop is a parallel-vertical bore, **Figure 44.8**. *The problem is that a flange leak at the inlet of the circulating pump has let air enter the water or ground loop and has blocked one of its parallel paths. This actually shortens the loop and causes colder return-water temperatures—which decreases the heat pump capacity.*

A service technician arrives at the scene, politely introduces himself and his company, and asks if he can be escorted to where the crackling sound is coming from. He then carefully listens to the crackling sound within the water in the ground loop as it flows through the circulating pump. The technician also notices that the electric strip heaters are on. This is what has been causing the high electric bills.

The technician carefully questions the homeowner about the system configuration of the water loop. The homeowner says that the configuration is a parallel-vertical bore system. The service technician then measures the temperature

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

difference between the water in and the water out of the coaxial heat exchanger. The measured temperature difference is only 2°F. The temperature difference should be 4°F to 5°F for that geographical region. This indicates to the service technician that the water is coming back to the heat exchanger too cold. One loop of the parallel system is being blocked by air, thus shortening the entire loop. This severely decreases the capacity of the heat pump and explains why the electric strip heaters are coming on, causing high electric bills. This would also explain the low temperature difference across the heat exchanger and the crackling sounds at the circulating pump.

The technician determines that the ground loop needs to be power flushed to rid it of air. He then politely explains to the customer what work has to be done and why. The system's circulating pump is valved off, and a new flange is installed on the circulating pump to prevent any more air from entering the system. A portable pump cart or purging unit is brought in and hooked up to the ground loop and heat pump. The purging unit power flushes the loop and heat exchangers. The air that was trapped in the ground loop is purged from the top of the pump cart, **Figure 44.18**. The system is then hooked back up to the normal circulating pump and put back into operation.

After about 2 hours of run time, the technician measures the temperature difference across the coaxial heat exchanger. The temperature drop is a normal 5°F. No crackling sound can be heard in the water circuit. The house is up to temperature without the electric strip heaters operating. The technician is satisfied that the heat pump is operating normally. After answering the customer's questions, the technician hands the customer the billing information, work description, and costs for the services rendered. The technician shakes the customer's hand while thanking him for being a valued customer and then leaves the house.

SERVICE CALL 5

A homeowner is complaining about high electric bills in the winter. The residence has a geothermal heat pump that has a closed-loop, horizontal, two-layer ground loop, **Figure 44.10**. The system uses R-22 as a refrigerant. The owner of the house uses a setback (night/day) thermostat, which is kept at 72°F during the day and 65°F at night. *The problem is with the setback thermostat. At 8 AM the thermostat switches its set point from 65°F to 72°F. However, the microprocessor (smart board) on the heat pump is programmed to kick on the electric strip heat whenever more than a 2°F differential exists between the set point on the thermostat and the actual room temperature. In this case, there would be a 7°F temperature differential at 8 AM every morning.* A technician is called after the homeowner has received the third high electric bill.

A service technician arrives at the residence at 10 AM and immediately enters the basement where the heat pump is housed. He installs gauges on the high and low sides of the system and temperature probes on the inlet and outlet of the coaxial heat exchanger. While the heat pump is running, the temperature difference across the heat exchanger is determined to be 5°F. This is the recommended temperature difference for a closed-loop system in that geographical region. The suction pressure also reads normal at 45 psig for an entering-water temperature of 33°F.

The technician then checks the flow rate of the antifreeze solution at the flowmeter and determines it to be normal. Just as the technician tells the homeowner that everything looks good, the unit shuts down for a normal off cycle. The technician then asks the homeowner where the thermostat is so the unit can be cycled back on and more tests can be made.

The technician realizes the thermostat is a setback thermostat. The homeowner is questioned as to the setback function on the thermostat with this heat pump. The homeowner explains how it is set back from 72°F to 65°F in the evening. The technician then explains how the heat pump's electric strip heaters will kick on if a 2°F differential is reached between the set point of the thermostat and the room temperature. The technician also explains to the homeowner that this is happening at 8 AM every morning and running up his electric bill. He then tells the home-owner that it is best not to use the setback function with this style of heat pump. The homeowner agrees and thanks the technician for the advice. The technician reprograms the thermostat to a normal operation, makes sure the heat pump is operating correctly, and then leaves.

SERVICE CALL 6

A closed-loop geothermal heat pump system keeps shutting down in the heating mode. It is the heating season and the customer has called for service five times in the last month. *The problem is that this particular system is a closed-loop system and the equipment was installed with the control board set for open-loop temperature conditions. A dual-in-line pair (DIP) switch on the control board should have been changed from open-loop to closed-loop configuration. The system was cycling off on low-temperature control.* Installers commonly overlook this switch setting or often forget to change it to the proper loop configuration. The oversight will result in high heating bills and repeated service callbacks until the setting is discovered and corrected.

The service technician politely introduces himself to the customer. He recognizes that the customer is a bit upset because of this being the fifth service call in the month. The technician is very sympathetic and listens carefully, making sure not to criticize the customer even in a joking manner. The technician also maintains his professionalism and does not take anything the customer says personally. After politely listening to the customer and asking a few questions, the technician goes to the basement and opens up the front

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

cover of the heat pump. Having handled a problem like this before, the technician is experienced enough to check the setting on the control board. Sure enough, the technician recognizes the problem and makes a quick change.

Often, a magnifying glass has to be used to read the small print near the DIP switch on the control board. Other manufacturers may use a jumper wire, or a control wire change to a sensor, instead of a DIP switch as a method of changing the loop configuration at the control board.

The service technician then politely explains to the customer what was done and why the system acted in such a manner. The technician lets the customer know that he is a valued customer and explains that this service call and the previous service calls are covered by his service contract. Handshakes are then exchanged and the technician again thanks the customer while maintaining eye contact. The service technician then leaves the house but calls the customer back the next day to make sure the system has not cycled off.

SUMMARY

- Energy is transferred daily to and from the earth by solar radiation, rainfall, and wind.
- Geothermal heat pumps use the earth, or water in the earth, for their heat source and heat sink.
- Because the earth's underground temperature in the summer is cooler than the outside air, heat loads from summer air-conditioning can be rejected underground more efficiently.
- Geothermal heat pumps are very similar to air source heat pumps in that they both use reverse-cycle refrigeration.
- Geothermal heat pumps are classified as either open- or closed-loop systems.
- Water quality is one of the most important considerations in the design of an open-loop geothermal heat pump system.
- Open-loop systems usually use well water as their heat source and heat sink. The water is then returned to the earth in some way. Fouling of the heat exchanger can be a problem if water quality is poor.
- Water sources for open-loop systems may be an existing well or a new well. A well pump delivers the water from the well to the heat pump. There are many types of wells.
- Pressure tanks are used in conjunction with wells in open-loop systems.
- Closed-loop heat pump systems recirculate the same antifreeze fluid in a closed loop. This eliminates water-quality problems.
- Closed-loop or earth-coupled systems are used where there is insufficient water quality or quantity or where local codes prohibit open-loop systems.
- The ground loop for closed-loop systems can either be a vertical, horizontal, slinky, or pond/lake type. Loops can also have series or parallel fluid flows.
- The buried piping or underground heat exchanger is usually either polyethylene or polybutylene pipe. Both of these materials can be welded by a heat fusion process.
- The antifreeze solutions inside the buried piping are used to prevent freezing of the heat pump heat exchanger and for heat transfer purposes. Some southern climates do not need an antifreeze additive.
- The water-to-water heat pump is becoming popular for use in radiant heating systems.
- Water-to-water heat pump systems often use a buffer tank to store the heated water until it is needed by the heating circuits.
- Water-to-water heat pump systems often have three circulator pumps: one on the ground-water circuit, one between the heat pump and the buffer tank, and one between the buffer tank and the heating circuits.
- Waterless heat pump systems utilize buried refrigerant lines instead of buried water lines.
- Waterless heat pump systems transfer heat into and out of the refrigerant by using the ground as the heat source in the winter and as the heat sink in the summer.

REVIEW QUESTIONS

1. Geothermal heat pumps, or water-source heat pumps, are classified as either _____ loop or _____ loop systems.
2. An important factor (or factors) involving water quality with regard to open-loop heat pump systems is(are)
   A. water temperature.
   B. water cleanliness.
   C. water volume in gpm.
   D. all of the above.
3. Explain the *ground loop* or *water loop* of a closed-loop, geothermal heat pump system.
4. Explain the *refrigerant loop* of a closed-loop, geothermal heat pump system.
5. The _____ loop is used to distribute heated or cooled air to the building of a geothermal heat pump system.
6. True or False: Domestic hot water can be heated with a geothermal heat pump system.

7. Two materials used in the buried piping of the ground loop of a closed-loop, geothermal heat pump system are _____ and _____.
8. Antifreeze solutions that can be used in the ground loop of a closed-loop geothermal heat pump system can be
   A. alcohol.
   B. salts.
   C. glycols.
   D. all of the above.
9. What is the main difference between a copper and a cupronickel coaxial heat exchanger, and where is each used?
10. A(n) _____ well draws water from the top of the water column, circulates it through the heat pump, and then returns the water to the bottom of the water column.
11. Which of the following is a process in which a cement-like material is injected between the well casing and the hole drilled for the well?
    A. Grouting
    B. Cementing
    C. Sealing
    D. Separating
12. The function of the pressure tank in an open-loop, geothermal heat pump well system is to prevent the well pump from _____.
13. If 14 gpm of water is flowing through an open-loop heat pump with a temperature difference of 7°F, how much heat in Btu/h is being absorbed or rejected in the heat pump? Show all work and units.
14. Explain the operation/purpose of the buffer tank on a water-to-water heat pump system.
15. How will oversizing the buffer tank on a water-to-water heat pump system affect the run time of the system?
16. Explain why a waterless, earth-coupled, closed-loop geothermal heat pump system is more efficient than a conventional closed-loop geothermal heat pump system.
17. Explain how refrigerant and oil leakage are found in a waterless, earth-coupled, closed-loop geothermal heat pump system.
18. What kind of material is used in the waterless ground loop in a waterless, earth-coupled, closed-loop geothermal heat pump system?

DOMESTIC REFRIGERATORS AND FREEZERS

OBJECTIVES

After studying this unit, you should be able to

- define refrigeration.
- describe the refrigeration cycle of household refrigerators and freezers.
- describe the types, physical characteristics, and typical locations of the evaporator, compressor, condenser, and metering device.
- describe the typical operating conditions for domestic evaporators, condensers, and compressors.
- explain how the evaporator is defrosted.
- describe how to dispose of the condensate.
- discuss typical refrigerator and freezer design.
- describe the cabinets used on refrigerators and freezers.
- explain the purpose of mullion and panel heaters.
- describe the electrical controls used in household refrigerators and freezers.
- discuss ice-maker operation.
- describe various service techniques used by the refrigeration technician.
- describe condenser efficiency relative to ambient air passing over it.
- describe procedures for moving upright and chest-type freezers.

SAFETYCHECKLIST

- ✅ Technicians should wear appropriate back brace belts and use proper personal equipment when moving or lifting appliances.
- ✅ Never place your hands under a freezer that has been lifted. Use a stick or screwdriver to position a mat under the freezer feet.
- ✅ Never allow refrigerant pressures to exceed the manufacturer's recommendations.
- ✅ Always follow all electrical safety precautions.
- ✅ Never use a sharp object to remove ice from an evaporator.
- ✅ Remove refrigerator doors or latch mechanisms before disposing of a refrigerator.
- ✅ Tubing lines may contain oil that may flare up and burn when soldering. Always keep a fire extinguisher within reach when soldering.
- ✅ When accessing the refrigerant circuit on a domestic refrigerator or freezer, be sure to cut the line with a tubing cutter. Never use a torch to open the system, as pressures within the system can build to unsafe levels.
- ✅ Be sure to throw away any cardboard boxes, plastic wrapping, and other shipping/packing materials to reduce suffocation/choking potential.
- ✅ Be sure to unplug the appliance before servicing.
- ✅ Make certain the appliance is properly grounded.
- ✅ Check to make certain that all safety-related devices and controls are operational.

45.1 REFRIGERATION

The term refrigeration refers to the moving of heat from a place where it is not wanted to a place where it makes little or no difference. Domestic refrigerators and freezers are no exception to this definition. Heat enters domestic refrigerators and freezers through the walls of the box by conduction and convection, as well as when warm food is placed inside. When the food is warmer than the box temperature, the temperature in the box increases. Earlier discussions on heat transfer told us that heat travels naturally from a warm to a cold substance, **Figure 45.1**. In the case of the domestic refrigerator or freezer, the cold substance is the low-pressure, low-temperature refrigerant in the evaporator coil, while the warm substance is the product being cooled in the appliance. The refrigerator ultimately moves the heat from inside the box to the surrounding area, where it makes little or no difference, **Figure 45.2**. In order to accomplish this heat transfer, heat must be transferred from the box into the refrigeration system and then transferred from the refrigeration system to the surrounding air. The evaporator acts to absorb heat from the product being cooled as well as from the box itself into the refrigeration system, while the condenser acts to reject heat from the refrigeration system to the outside.

Domestic refrigerators and freezers are package units that are completely assembled and charged with refrigerant at the factory, so no refrigerant lines need to be run and no evacuation or field charging must be done. The air inside the box flows through or across the cold, refrigerated coil or evaporator, **Figure 45.3**, transferring both sensible and latent heat to the coil. The sensible heat transfer is responsible for lowering the air temperature in the box. The latent heat transfer results in the dehumidification of the air in the box. The product of the dehumidification process is known as condensation. Since the evaporator coil on a properly operating refrigerator or freezer operates at a temperature below 32°F, the condensate will freeze on the surface of the coil. After the air in the box has transferred heat to the coil, it circulates back to the box at a colder temperature so that it can absorb more heat and humidity.

Figure 45.1 Heat from surrounding air seeps through the walls of the refrigerator or freezer into the box itself. Heat is also added to the box when the door is opened and when warm product is placed inside.

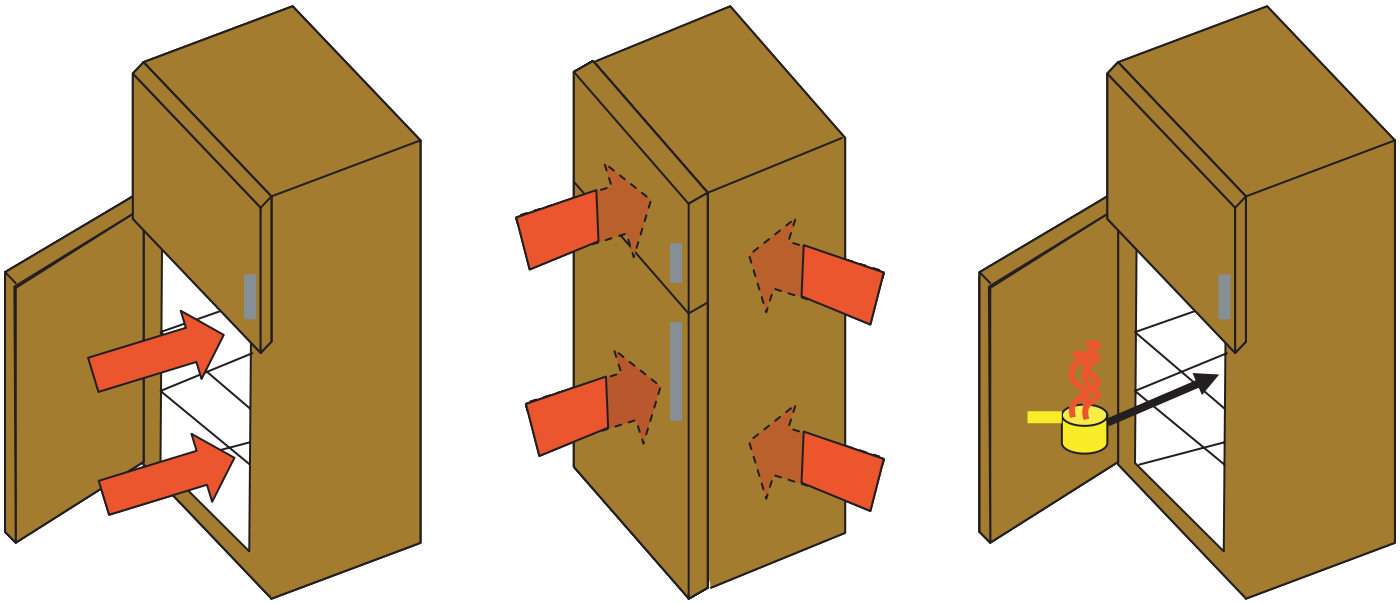

Figure 45.2 The evaporator coil absorbs heat from the box, while the condenser coil is the heat transfer surface that is responsible for rejecting heat to the surrounding air.

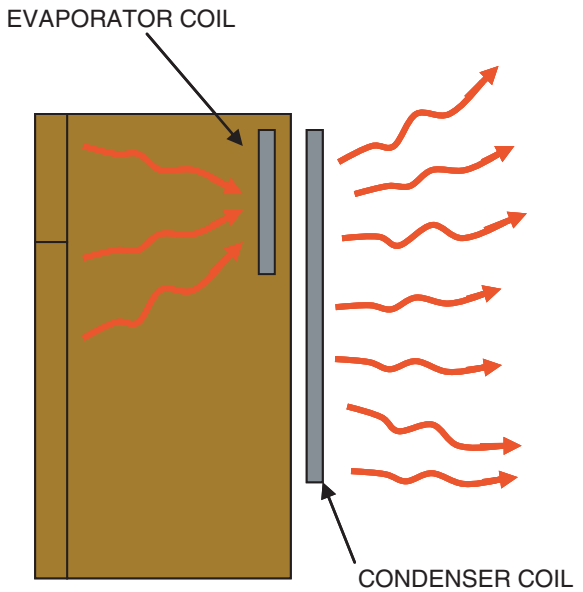

This process continues until the box temperature reaches the desired level.

The typical box temperature of the refrigerator portion of the appliance is about 35°F to 40°F when the room temperature is in the 70°F to 75°F range. However, if a refrigerator is subjected to extreme temperatures, such as when the appliance is located outside in the summer or winter, **Figure 45.4**, it will not perform the same. The typical temperature for the

Figure 45.3 Air gives up heat to the cold evaporator coil.

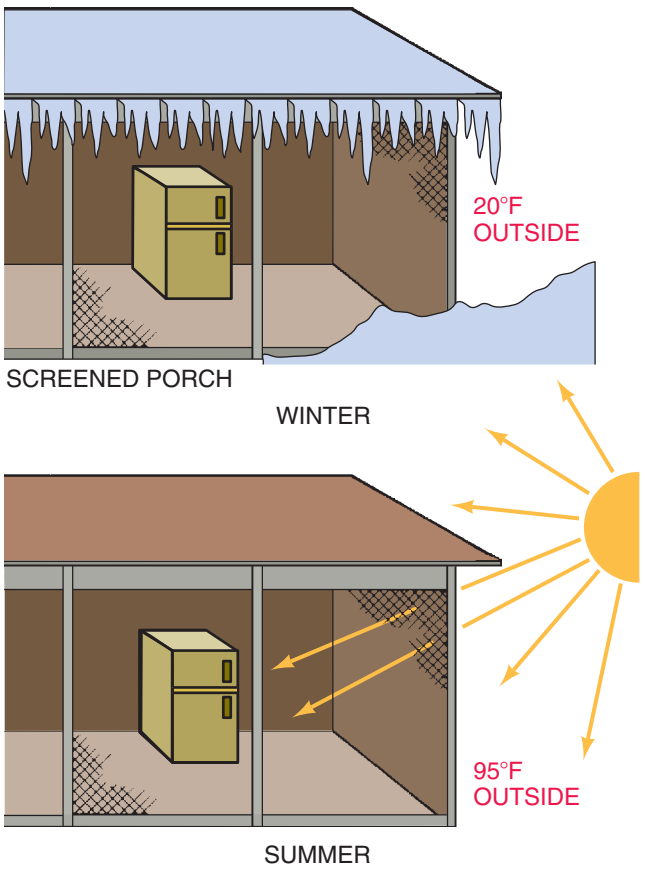
Figure 45.4 The ambient temperature for these refrigerators is not within their proper operating range.



freezer portion of the system is about 0°F, given normal conditions for the air surrounding the appliance. The typical box temperature for a stand-alone freezer is also about 0°F.

PRODUCT PACKAGING

It is important that products being stored in refrigerators or freezers be packaged properly to prevent dehydration and freezer burn. With regards to fresh foods, improperly wrapped products can dehydrate and dry out much faster than otherwise intended, shortening the shelf life of the products. Freezer burn, a result of product dehydration, causes the product to look dry and burned. Although it does not completely ruin the product, freezer burn does make it look unattractive and may change the flavor of the item.

Freezer burn occurs in the vicinity of a tear in a package where moisture leaves the food and transfers to the air. The moisture is in the solid state while in the food and is changed to the vapor state in the air, where it collects on the coil. This moisture is then carried off during defrost. This process of changing from a solid to a vapor is known as sublimation. Ice cubes, for example, become smaller as a result of sublimation if stored for long periods of time in the freezing compartment. Moisture changes from a solid to a vapor and collects on the evaporator as ice. It is melted during defrost and leaves in the condensate.

THE REFRIGERATED BOX

As we have mentioned earlier in this unit, heat passes through the walls of the box and ultimately winds up inside the box. As the amount of heat that enters the box increases, the refrigeration system will have to work harder and harder. It is therefore desirable to reduce the rate at which heat enters the storage portions of refrigerators and freezers. The next two sections will discuss some features that are incorporated to increase the efficiency of the appliances.

THE DOMESTIC REFRIGERATED BOX. As kitchens become more like showplaces than simply functional, food preparation areas, box design has become an important marketing and selling tool. Once ignored by interior designers, kitchens are fast becoming the single most important room in the house from the point of view of real estate merchandising. So manufacturers are now faced with the task of creating appliances that are both energy-efficient and stylish. Not only are domestic refrigeration systems available in a wide range of colors but many come with such features as ice and water dispensers, partial access from the outside, and even computer interfaces with Internet access and monitors built right in, **Figure 45.5**.

Early-generation refrigerators were designed with one outside door and a freezer compartment door on the inside, **Figure 45.6**. The doors had gaskets with air pockets inside them that compressed when the door was closed, **Figure 45.7**. Eventually, the ability of the gasket to effectively seal would be greatly reduced as the material aged. The door would then allow room air to enter the box, which increased the load on the evaporator and caused more frost accumulation, **Figure 45.8**. Older-style refrigerator doors had mechanical door latches that could be opened only from the outside. If a child were to get inside and close the door, they could get trapped and suffocation could result. **SAFETY PRECAUTION:** *Caution must be used when one of these refrigerators is taken out of service. The door must be made safe. This is most commonly done by removing the door from the appliance.* Be sure to check with local requirements regarding appliance disposal, as they vary from one geographic region to another. Most, if not all, guidelines require that, at a minimum, the appliance doors be removed before disposal.

The box must be airtight to prevent excess load and frost. If the door is shut and the air inside the box cools, the volume of the air will decrease and the door may be hard to open immediately after closing. *Modern refrigerators have magnetic strip gaskets all around the doors, which also have compression-type gaskets that maintain a good seal to help keep air out,* **Figure 45.9**. These magnetic gaskets are much easier to

replace than the old type of gasket. The typical box has two outside doors: side by side or over and under. In the side-by-side styles, the freezer is usually on the left. The appliance shown in **Figure 45.5** is configured in this manner. Notice that the ice dispenser is in the left-hand door. Condensate is allowed to travel from the inside of the box to a collecting pan that is located under the box, where it is evaporated. A trap arrangement in the drain line prevents air from traveling into the box through this opening, **Figure 45.10**.

The refrigerator may be designed to accommodate an ice maker in the frozen-food compartment. Water piping connections and a bracket to which the ice maker can be fastened are provided. A wiring harness may also be included so the ice maker can be easily powered. This arrangement does

not require any wiring by the technician, since the ice maker just needs to be plugged in.

Even though the main storage area in the refrigerator maintains a temperature of about 40°F, various compartments may be maintained at different temperatures, such as the fresh vegetable crisper and the butter warmer. The conditions in the crisper are maintained by enclosing it in a drawer to keep the temperature slightly cooler and slow the rate of food dehydration, **Figure 45.11**. The butter warmer may have a small heater in a closed compartment to keep the butter at a slightly higher temperature than the space temperature so it will spread more easily.

The interior surfaces of most refrigerators or freezers are made of plastic. This surface is easy to keep clean and will last for years if not abused. The plastic in the freezing compartment is at very cold temperatures and, as a result, is quite fragile. For this reason, care must be taken not to drop frozen food on the bottom rail because it may break.

A sweating problem around the doors due to the differences in temperature in the various refrigerator compartments may occur because the gasketing material may be below the dew point temperature of the room air. Special heaters, called mullion and panel heaters, are located around the doors to keep the temperature of the box facing above the dew point temperature of the room air, **Figure 45.12**. Some units have an energy-saver switch that allows the owner to shut off some of the heaters when not needed, such as in the winter when the humidity is normally low. An explanation of the wiring for these heaters is discussed in Section 45.9, "Wiring and Controls."

Refrigerated boxes, whether vertical two-temperature appliances or chest-types freezers, should be leveled according to the manufacturer's instructions. Usually, they should be tilted slightly to the rear for proper door closing. Leveling is important, especially if the unit has an ice maker. In this case, the water may overflow the ice maker when it is automatically filled. Most refrigerators have leveling devices for the feet or rollers, **Figure 45.13**.

As mentioned, refrigerators are manufactured in over-and-under and side-by-side door configurations. The boxes that are over-and-under seem to have more room because the compartments are typically wider than those in the side-by-side models. Compartments in the side-by-side models appear narrow and deep. This does not affect the function of the box but may make service more difficult.

Figure 45.12 Mullion and panel heaters.

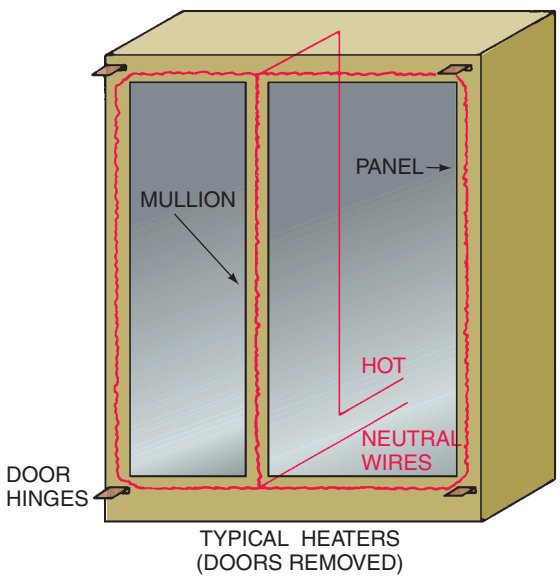

Figure 45.13 Leveling devices for feet or rollers.

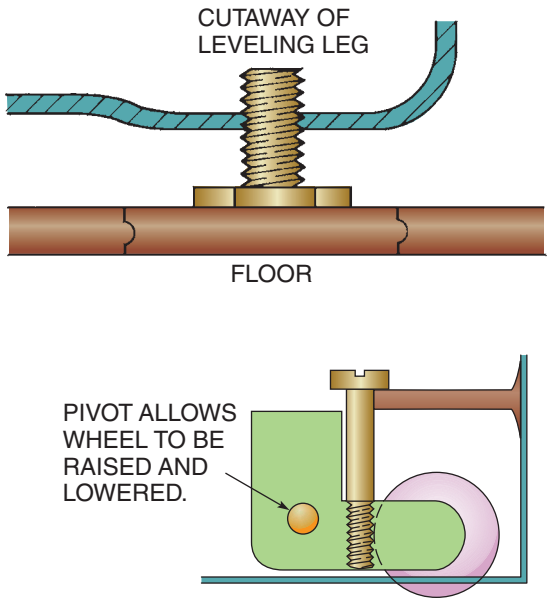

The stand-alone domestic freezer may be configured as either an upright type or a chest. The door of the upright freezer may open to the left or right, as convenient. The door of a chest freezer, known as the lid, lifts up, **Figure 45.14**. The upright box takes up much less space and is often used in the kitchen, where floor space is at a premium. It is probably not as efficient as a chest freezer, because every time the door is opened, air in the box falls out at the bottom of the opening, **Figure 45.15**. This does not change the food temperature much, just the temperature of the air, which must be recooled, thus causing increased compressor run time and wasted energy. Moisture also enters with the air and will

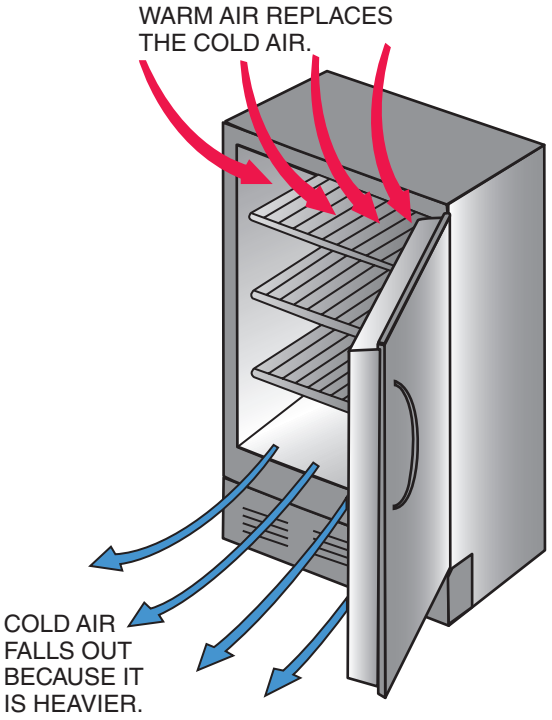
Figure 45.15 Cold air falls out of an upright freezer.



collect on the surface of the evaporator coil. The amount of time that the freezer door is open should be kept to a minimum. When a chest freezer is opened, the air stays in the box, since the cooler air in the box is heavier than the warmer surrounding air. Locating food in a chest freezer is not as easy as it is in an upright freezer because the upright freezer has multiple shelves, while the chest freezer may have lift-out baskets so food stored on the bottom may be reached.

A refrigerator may have some extra features for convenience, such as an outside ice dispenser or ice-water dispenser, **Figure 45.16.** The unit shown in **Figure 45.16** also has a digital display of the freezer and refrigerator compartment temperatures, along with a water filter alarm and a vacation mode. Appliances that have door-mounted accessories require wiring and water connections to the door, as well as a chute that connects the ice maker to the dispenser. These features add to the cost and make service more complex.

DOMESTIC FREEZER BOX INTERIOR

Many freezer interiors may have a plastic lining. The plastic is strong and easy to clean and maintain. However, it may be brittle at the low temperatures inside the box, so care should be taken not to strike it. Some boxes have metal liners and plastic trim. The metal may be either painted or coated with porcelain. The walls of the typical modern box are much like those of the refrigerator—a sandwich construction of metal or plastic on the inside, metal on the outside, and foam

Figure 45.16 A water and ice dispenser on the outside.

Photo by Eugene Silberstein

insulation, in between, **Figure 45.17.** Older boxes typically have fiberglass insulation within the walls.

INSIDE THE UPRIGHT BOX. A light is normally located in the freezer so that the food can be more easily seen. A door switch is used to turn the light on and off. The upright box has door storage for small packages, so the door must be strong enough to support the weight of these packages as well as the door itself. Also, it is not uncommon for a package of frozen meat to be dropped and break the bottom plastic rail of an upright freezer, **Figure 45.18.** All damage to the

Figure 45.17 Sandwich construction of a refrigerator wall.

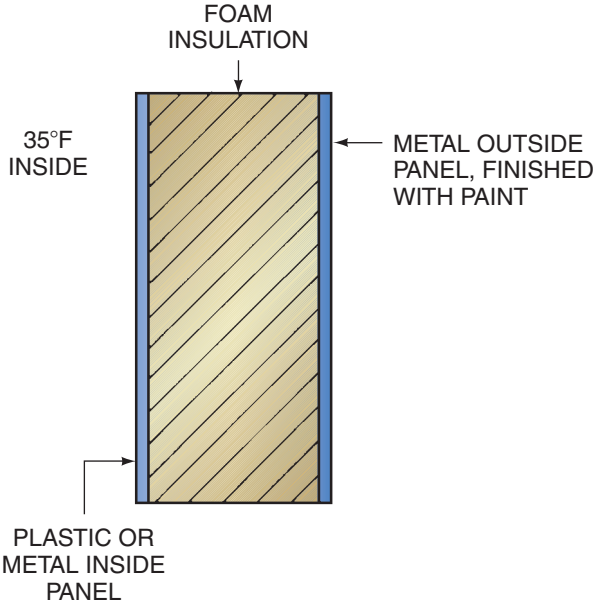


Figure 45.18 If frozen food is dropped, it may break the plastic rail in a freezer.

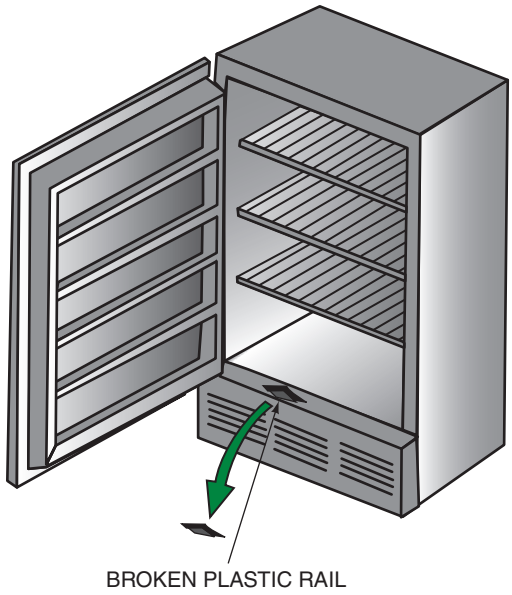

interior plastic surfaces of the box should be repaired. The plastic interior is typically repaired by refastening the broken piece with epoxy glue, **Figure 45.19**. Most adhesives cannot be applied while the surfaces being joined are cold, so the appliance should be turned off or put into defrost so the rail can warm up enough for the repair to be made.

The upright box has many of the same gasket and door alignment features as the refrigerator. The gaskets must remain tight fitting and the door must remain in alignment, or leaks will occur. Leaks will cause the compressor to run more than it was designed to and cause frost buildup. Many freezers have a manual defrost because defrosting is not needed as often as with refrigerators because the doors are not opened as frequently.

The freezer evaporator, which freezes the food inside, may be one of three types—forced-air, shelf, or a plate in the wall of the freezer, **Figure 45.20**. Plate evaporators may be tubes with wires connecting them or stamped to make a shelf, **Figure 45.21**. The fastest method of freezing food is to lay it directly on the plate or tube evaporator. However, the amount of available plate surface area is limited.

INSIDE THE FREEZER CHEST. The lid of a freezer chest is hinged at the back, and the liner may be metal or plastic. The gaskets located around the lid of the box must be in good condition, or moist air will leak in. This will cause frost buildup, normally right inside the lid where air is entering. The step at one end of the freezer compartment is where the compressor is located, **Figure 45.22**. If care is not taken when loading a chest-type freezer, food will be hard to find at the bottom. Larger parcels should be located on the bottom, and all parcels should be dated. Most freezers have baskets that may be removed and set aside while locating food that is at the bottom.

Figure 45.19 The piece may be glued back in place when the freezer is defrosted and cleaned.

45.2 CAPACITY OF DOMESTIC SYSTEMS

Ideally, domestic appliances are used to store and maintain perishable items at the desired temperature. Domestic freezers, for example, work more efficiently when frozen items rather than unfrozen items are placed inside them for storage purposes. The capacity of domestic freezers is not great enough to accomplish the freezing of large amounts of product at once. Manufacturers' guidelines differ as to how much product should be introduced to the refrigerator or freezer portions of the appliance at a time. For example, a manufacturer might suggest that in order to ensure proper system operation, the appliance owner should not add more than 3 pounds of fresh food per cubic foot of freezer space at one time.

Many home owners may purchase large amounts of freshly butchered meat and poultry and try to freeze the whole amount at one time in their home freezers. This causes problems. When food is frozen, ice crystals form in the product, **Figure 45.23.** When food is frozen slowly, the ice crystals that form are larger than those that form when food is frozen quickly at lower temperatures. These larger ice crystals are sharp and may puncture the cells of the product. When a steak, for example, is frozen slowly at a high temperature and then thawed out, there will be a noticeable puddle of water and blood around the steak, **Figure 45.24.** This puddle is a direct result of the cell punctures. In order to minimize the amount of cell damage to the product, it is a good idea to lower the

Figure 45.23 Food frozen slowly creates large ice crystals.

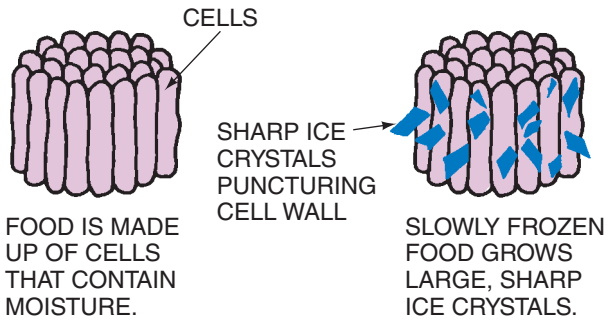

Figure 45.24 Large ice crystals may puncture the cell walls of the food.

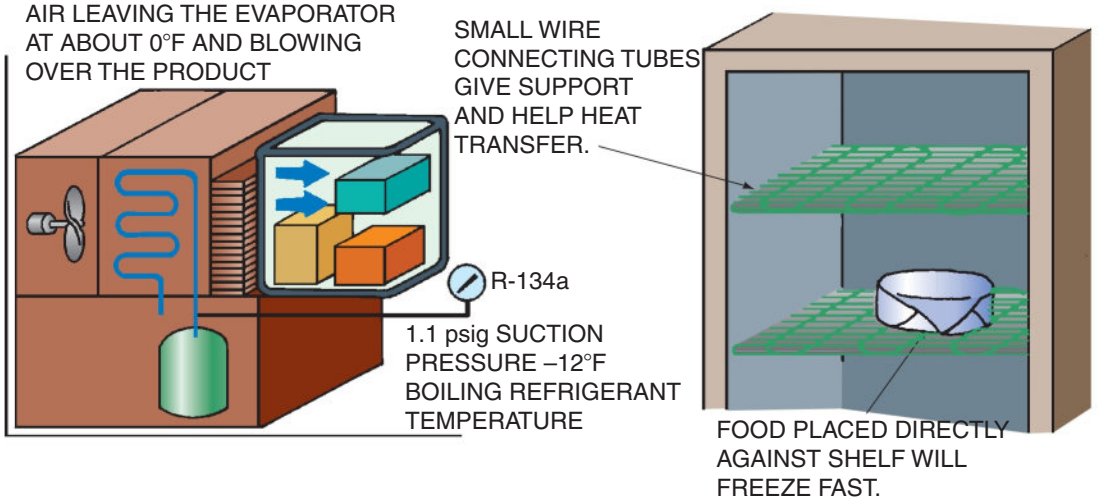
Figure 45.25 Two quick-freeze methods—using a special compartment or placing food directly on the evaporator.



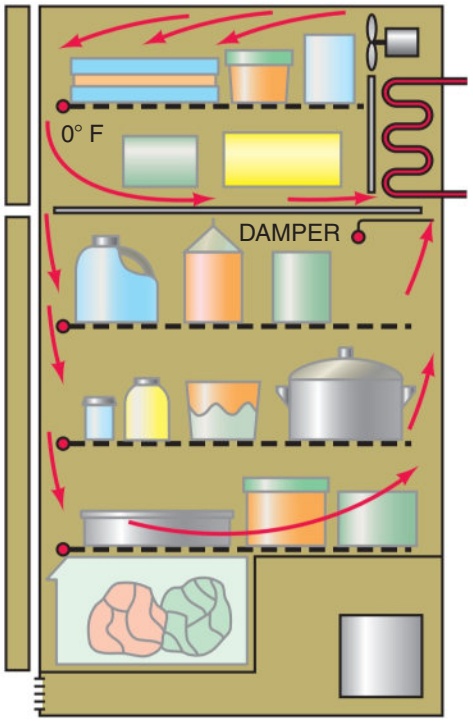
temperature of the product to as close to 32°F as possible by placing it in the coldest portion of the refrigerator for several hours, then move it to the freezer and locate it in the coldest place in the freezer, which may be a quick-freeze compartment or an evaporator plate, **Figure 45.25**. The quick-freeze compartment is typically used to make ice quickly when the appliance owner is, for example, throwing a party.

45.3 THE EVAPORATOR

The evaporator on a domestic refrigerator or freezer is the heat transfer surface that absorbs heat into the refrigeration system. To accomplish this, the surface on the evaporator coil must be cooler than the air in the refrigerated box. In a stand-alone domestic freezer, the evaporator will operate at a temperature that will maintain the entire box at the desired temperature. The household refrigerator must maintain two different compartments at two different temperatures with a single compressor. Therefore, the single compressor operates under conditions for the lowest box temperature. The freezer compartment is the cooler of the two spaces in the appliance and is typically maintained at a temperature close to 0°F. Since new domestic refrigerators and freezers operate with refrigerant R-134a, any box temperature below 0°F will cause the low side pressure of the system to be in a vacuum. This is not desirable since any pinhole leak on the low side of the system will pull air and moisture into the system.

The evaporator in the household refrigerator typically maintains refrigerator and freezer compartments at different temperatures by one of two methods. One method is by allowing part of the air from the frozen-food compartment to flow into the fresh-food compartment, **Figure 45.26**. It may also be accomplished with two evaporators that are in series, one for the frozen-food compartment and the other

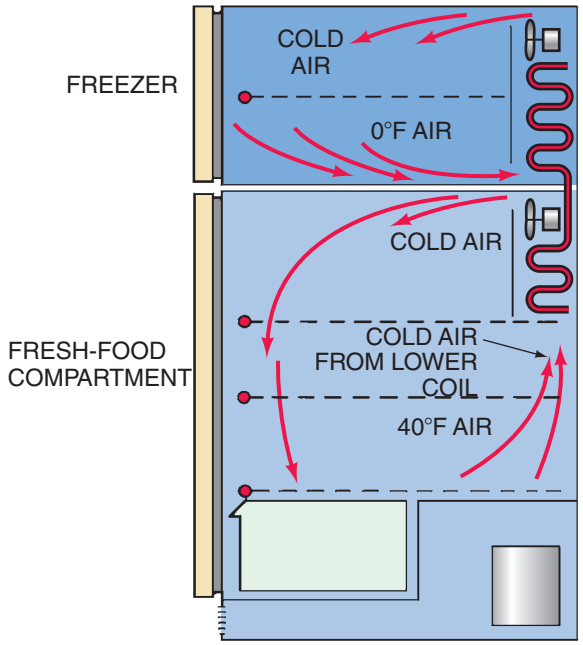
Figure 45.26 Air flows inside the refrigerated box from the low-temperature compartment to the medium-temperature compartment.



for the fresh-food medium-temperature compartment, **Figure 45.27**. When configured in this manner, both evaporators are of the mechanical draft type. In either case, frost will form on the evaporator and a defrost method must be used. This is described in more detail later.

The evaporators in household refrigerators can be of two types, natural draft or mechanical draft, **Figure 45.28**. Natural-draft evaporators rely on natural convection current to

Figure 45.27 A two-evaporator box.



circulate air through the refrigerated space, while mechanical-draft evaporators use fans to move air across and through the evaporator coil. The fan improves the efficiency of the evaporator and allows for a smaller evaporator. Space saving is desirable in a household refrigerator, so most use mechanical-draft coils. However, other units are manufactured with natural-draft coils for economy and simplicity.

Natural-draft evaporators are normally the flat-plate type with the refrigerant passages stamped into the plate, **Figure 45.29**. They are effective from a heat-transfer standpoint and require that natural air currents be able to flow freely over them. The food in the frozen-food compartment may be in direct contact with the flat-plate evaporator, as they are quite often used as shelves on which product is placed. Air from the bottom and sides may flow to the fresh-food compartment, **Figure 45.30**.

Figure 45.28 Natural-draft and mechanical-draft evaporators.

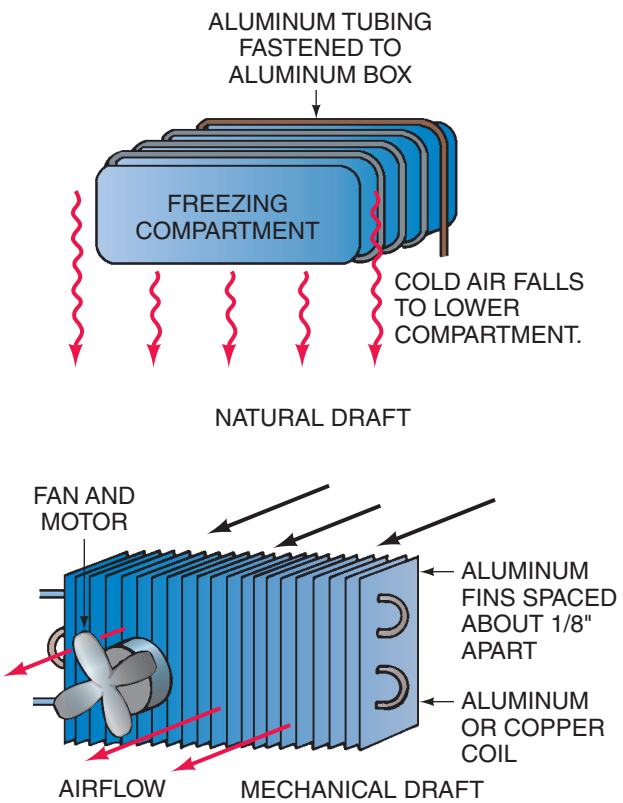


Figure 45.29 A stamped-plate evaporator.

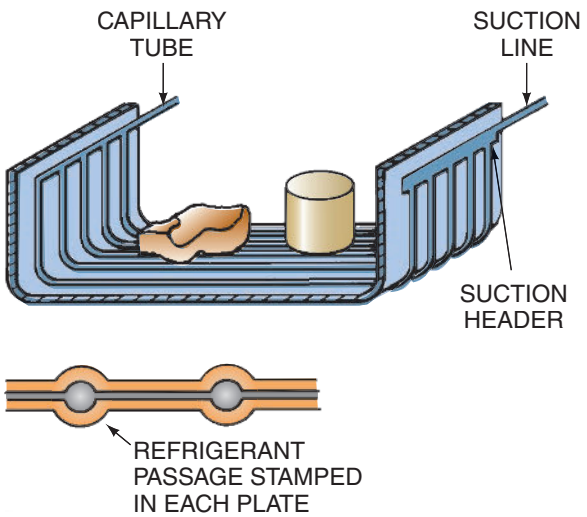

Figure 45.30 Air flows to the fresh-food compartment from the flat-plate evaporator.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Natural-draft evaporators are more visible than forced-draft evaporators and are subject to physical abuse. Although there are automatic methods for defrosting evaporator coils on domestic refrigerators and freezers, appliances manufactured with natural-draft evaporators almost always employ the manual defrost method. A manual defrost system requires that the unit be shut off and the door to the compartment normally left open to accomplish the defrost. Frost is melted by room temperature, **Figure 45.31.** In a few instances, owners have become impatient and have used sharp objects to remove the ice. This may puncture the evaporator. **SAFETY PRECAUTION:** *Sharp objects should never be used around the evaporator,* **Figure 45.32.**• Defrost may be more quickly accomplished with a small amount of external heat, such as a hair drier, heat gun, or a small fan that blows room air into the box until the ice is melted. These methods are not recommended as the electrically powered fan or heater is put in a wet location. A pan of warm water may be placed under the coil. The melted ice normally drips into a pan below the evaporator, **Figure 45.33.**

Forced-draft evaporators are used to reduce the space the evaporator normally takes up. The amount of air moving through the evaporator coil is measured in cubic feet per minute, or cfm, and is obtained by multiplying the velocity of the air passing through the evaporator coil, in feet per minute, by the cross-sectional area of the coil, in square feet.

Figure 45.31 Manual defrost.

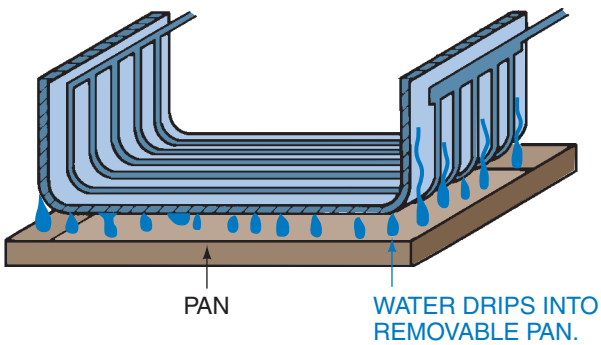

Figure 45.32 Sharp objects may puncture the evaporator. **SAFETY PRECAUTION:** *Do not use sharp objects to chip frost and ice.*•

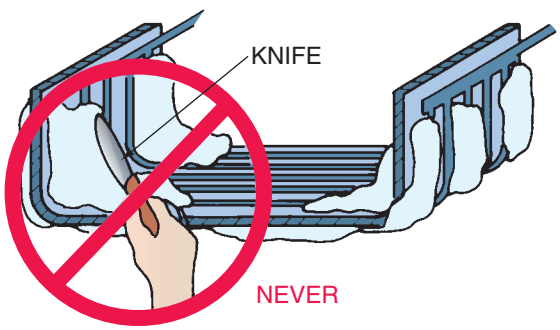

Figure 45.33 Melted ice (condensate) is caught in the pan.

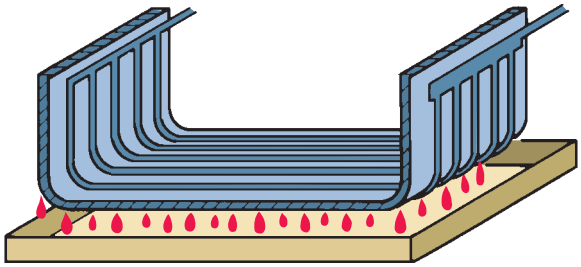

If the velocity of the air passing through the coil is increased by using a fan, the evaporator coil can be smaller and the same air volume can be maintained. The smaller the evaporator, the more internal space is available for food. The evaporator fan and coils are normally recessed in the cabinet and not exposed, **Figure 45.34.** Because the coils and fans are recessed, air ducts may provide the airflow direction; dampers may help control the volume of the air to the various compartments. Most evaporators have an accumulator installed in the suction line at the outlet of the coil. The accumulator allows the evaporator to operate as full as possible with liquid refrigerant and still protect the compressor by allowing liquid to collect and boil into a vapor before returning to the compressor.

EVAPORATOR COIL CONSTRUCTION

Evaporators may be made of aluminum tubing, regardless of whether they are of the forced-draft or natural-draft type. When the evaporator coil tubing is used for shelves, the

Figure 45.34 A forced-draft evaporator.

Figure 45.35 Shelf-type evaporators are normally steel tubing with wire to add support.

Photo by Bill Johnson

evaporator is commonly made of steel. This gives it strength to hold the food and provides a method of fastening the wire connectors to the tubes, **Figure 45.35**. One reason for using steel for the shelves is increased durability, since the products being cooled will be in contact with them and subject to user abuse. Another reason for using steel is the ease with which the support wires can be connected to the tubing.

Forced-draft evaporators are normally made of aluminum tubing with fins to increase the effective heat-transfer surface area of the coil. The fins are spaced fairly wide apart to allow for frost to build up and not block the airflow, **Figure 45.36**. The spacing of the evaporator fins on a domestic refrigerator or freezer is much wider than that found in an air-conditioning system. This is because frost does not form on the evaporator coil of a properly operating air-conditioning system, so the fins can be positioned closer together. Evaporators on domestic refrigerators and freezers do not typically require regular maintenance because air is recirculated within the refrigerated box and they do not have air filters, as is the case with an air-conditioning system.

Figure 45.36 Fin spacing on a low-temperature evaporator.

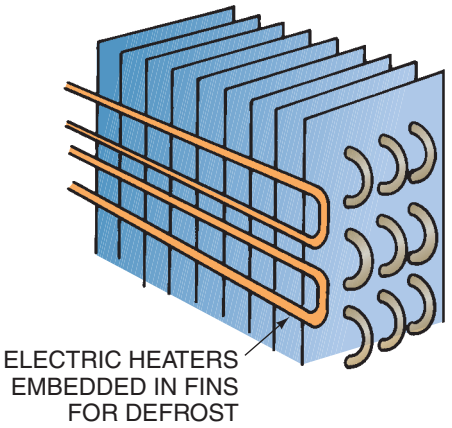
Figure 45.37 Electric defrost.



ELECTRIC DEFROST

EVAPORATOR DEFROST

Even though the temperatures in the refrigerated portions of a domestic refrigerator are above freezing, it is important to remember that the evaporator coil must be at a temperature that is lower than the desired space temperature in order to absorb heat from the box and the products contained within. In the case of the domestic refrigerator or freezer, the evaporator coil, under normal conditions, will always be a temperature that is lower than 32°F. Since this is the case, moisture that condenses on the evaporator coil surface will freeze. This frost must be removed. Two common methods for defrosting evaporator coils are manual and automatic.

Manual defrost is accomplished by turning off the unit, removing the food, and using room heat, a pan of hot water, or a small heater to melt the ice that has formed on the coil. A large amount of frost may accumulate on an evaporator by the time it is defrosted. The water that forms as a result of this type of defrost must be disposed of manually. Units that require manual defrost normally have coils that food has touched. The shelves should be cleaned and sanitized when the frost is removed. Automatic defrost is accomplished by external heat from electric heating elements that are positioned close to the evaporator coil surface, **Figure 45.37**.

No matter how the defrost is accomplished, the water from the coil must be dealt with. With automatic defrost, a pint of water may be melted from the evaporator with each defrost. This water is typically evaporated using the heat from the compressor discharge line or by heated air from the condenser. This is discussed in more detail in Section 45.5, "The Condenser."

45.4 THE COMPRESSOR

The compressor circulates the heat-laden refrigerant by removing it from the evaporator as a low-pressure, low-temperature superheated vapor and pumping it into the

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

condenser as a high-temperature, high-pressure superheated vapor. The compressors used in domestic refrigerators and freezers are very small compared to the ones used in air-conditioning and commercial refrigeration systems. They are all in the fractional horsepower size, ranging from about 1/10 horsepower to 1/3 horsepower, depending on the size of the box. In many of these systems, it is hard to tell which is the suction and which is the discharge line, as the sizes of these lines do not differ by much.

Compressors have a suction line, a discharge line, and one or two process tubes protruding from the shell. Older compressors often had oil cooler lines connected to them as well, making the identification of the particular tubes all the more difficult. Although newer compressors do not, for the most part, have oil cooler lines, a shell diagram is required to know which line to pipe to which connection when replacing a compressor with one that is not an exact replacement, **Figure 45.38**.

The compressors used in household refrigerators are all welded, hermetically sealed types, **Figure 45.39.** These compressors are reliable and made to last many years. A typical refrigerator may be used continuously for 20 or more years.

The compressor is located at the bottom of the refrigerator and accessed from the back. The refrigerator must be moved away from the wall for service. Most modern, large refrigerators have small wheels so the box can be moved out for cleaning and to provide easy access for service, **Figure 45.40**. These wheels are often retractable. Once the appliance has been placed in its desired position, the wheels are retracted into the appliance so that the unit itself rests on the floor and will not slide back and forth. This feature is common on refrigerators and freezers that have slide-out compartments, **Figure 45.41**. So, in order to slide the unit from the wall, the wheels must first be lowered to prevent potential damage to the floor. Compressors are typically mounted on internal springs and external flexible, rubber-like feet, **Figure 45.42**. The refrigerator is located in the living area and must have a low noise level. The lines connecting the compressor to the refrigerant piping may be of copper or steel. Correct solder must be used when repairing any piping connections.

As mentioned, domestic refrigerators and freezers utilize welded hermetic compressors. Servicing them requires a skilled technician. Many units do not even have service ports for attaching gauges to get compressor suction and discharge readings. When the manufacturer does furnish a service port, it may be in the form of a special port that requires special connectors, **Figure 45.43**. When the special connectors are not furnished, line tap valves, **Figure 45.44**, are often used.

These should be used only when necessary, and the manufacturer's instructions must be strictly followed, or the results will be unsatisfactory. Only soldered line tap valves may be left on the line. *It is a violation of the Clean Air Act of 1990 to leave nonsoldered line tap valves on a system. These valves do leak and leaving them on a system is, in effect, an example of intentional refrigerant venting. Individuals who violate the laws set forth by the EPA regarding safe and proper refrigerant handling are subject to heavy fines.*

45.5 THE CONDENSER

Domestic refrigerator condensers are all air-cooled. This permits the refrigerator to be moved to a new location or house as necessary. The condensers are either cooled by natural convection or by small induced-draft-air fans, **Figure 45.45**.

Natural convection (static) condensers were the first type used and are very simple in operation. There are no fans to move air across the surface of the coil. Natural convection currents are created as the air, as it absorbs heat from the refrigerant, becomes less dense and rises. This phenomenon is often referred to as the chimney effect, and these condensers, when located at the back of the appliance, are also referred to as chimney-type condensers. Care must be used when locating a refrigerator that has a natural convection condenser to ensure that air can flow freely over it. Poor air circulation through and across the condenser coil results in high operating pressures and reduced system capacity. Because of the reduced capacity, unit run time also increases. In severe cases, the unit may run all the time and still not keep the food compartment cool. The appliance shown in **Figure 45.46** is operating with a low-side pressure of 6.7 psig, which corresponds to an evaporator saturation temperature of about 1°F. This is much higher than desired, especially if the freezer compartment is to maintain a temperature of 0°F. This unit is also operating with a high-side pressure of 191 psig, which corresponds to a condenser saturation temperature of about 127°F. This is much higher than expected for a unit installed inside a conditioned space. This compressor is operating with high head pressure and may very well fail prematurely.

Care must be used when moving any appliance, but the external condenser type of refrigerator requires special care or the condenser coil may be damaged. If a two-wheeled hand truck is used, the belt should be placed under the condenser

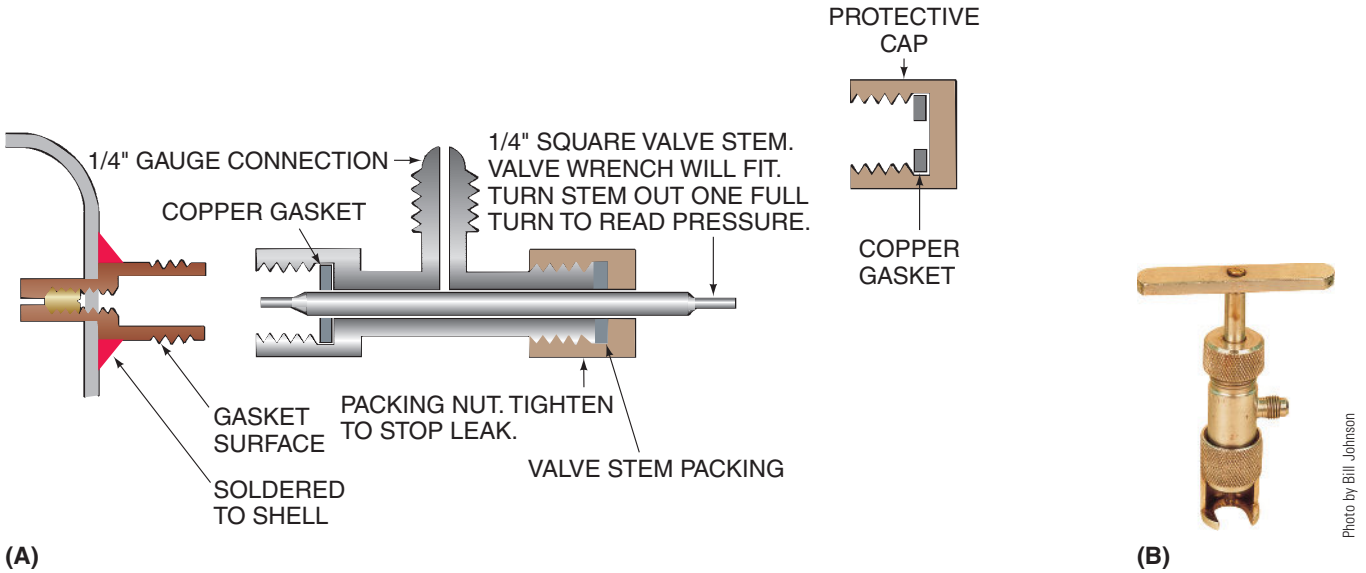

Figure 45.44 A tube-piercing valve.

and around the unit, **Figure 45.47**. Because of the potential for damage to the exposed condenser coil, steel is commonly used in the construction of this heat-transfer surface. Some natural convection condensers have been located in the outside wall of the refrigerator by fastening the condenser tubes to the inside of the outer sheet metal shell. This unit may work well in the open, where air can circulate over it, but may not work in a tight alcove. The exterior walls of this type of unit are normally very warm, and the condensers are often referred to as hot-wall condensers.

Induced-draft condensers have solved many of the problems just described. The induced-draft condenser is located under the refrigerator and typically at the back, **Figure 45.48.** Air is taken in on one side of the bottom front of the box, pulled across the condenser coil and then discharged out the other side of the front, **Figure 45.49.** Because both inlet and outlet are close to the floor and at the front, they are not easily obstructed. Induced-draft condensers require an established air pattern to pull the air over the finned tubes. The air pattern is often maintained by cardboard partitions and a cardboard backing at the bottom of the compressor compartment, **Figure 45.50**. **NOTE:** *All partitions must be in the correct position or high head pressures and long or continuous running times will occur.* Many service technicians and homeowners may have discarded the cardboard back cover thinking it was part of the appliance's packaging and not necessary. The refrigerator will not perform correctly without the back cover in place, and permanent damage can result.

Induced-draft condensers are typically used on units that have automatic defrost, and they may require more care. They are smaller and lint or large particles may become trapped in the fins, **Figure 45.51**. The air pulled through the condenser, in conjunction with the heat of the discharge line, may be used to evaporate any water from defrost, **Figure 45.52**. Although refrigerators are typically located in the kitchen, stand-alone freezers with induced-draft condensers are often located in remote areas of the home, such as laundry rooms. These rooms have more lint than other parts of the house and may be much warmer. These freezers must be more closely observed because of potential problems such as lint/dirt and higher-than-desirable operating temperatures and pressures. Lint will collect in the fins of the condenser and the defrost drain pan and can cause a problem.

USING THE CONDENSER FOR CONDENSATE DISPOSAL

All domestic refrigerators are low-temperature appliances and accumulate frost on the evaporator. When defrost occurs, something must be done with the water. The compressor and condenser sections of the refrigerator are used to evaporate this water.

Figure 45.50 Cardboard partitions. Be sure to replace all cardboard partitions on an induced-draft condenser.

The heat available at the compressor discharge line can be used to evaporate the water when direct contact is made. Many units are designed so that the discharge line is passed through the pan that collects the defrost water, **Figure 45.53**.

Figure 45.52 The discharge air in conjunction with heat in the discharge line may be used to evaporate condensate from defrost.

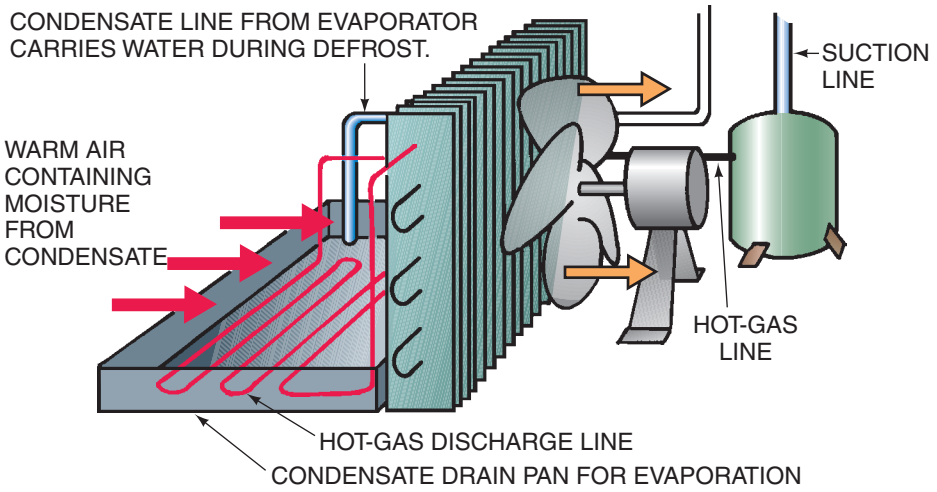

Figure 45.53 Compressor heat used to evaporate condensate.

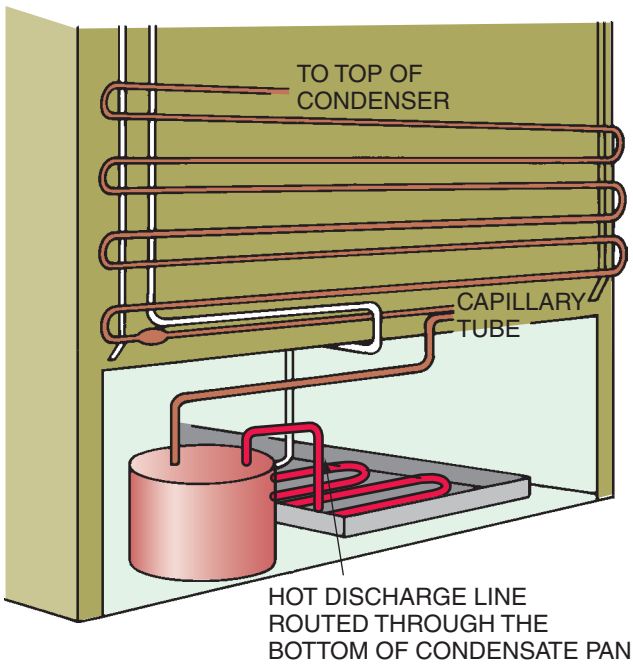
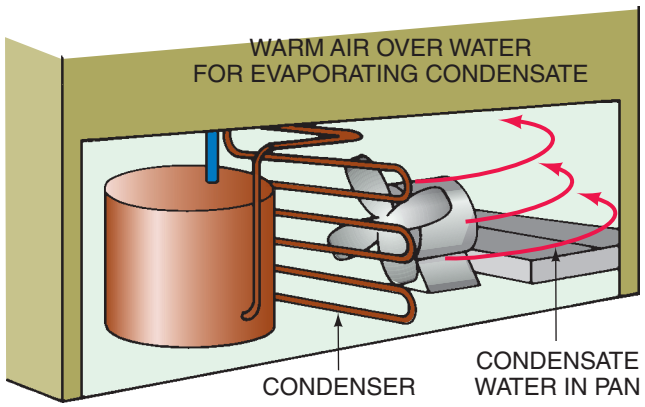


This method is used primarily on units with natural-draft condensers. When the unit has an induced-draft condenser, warm air from the condenser may be pulled over a collection pan of water for the purpose of evaporation, **Figure 45.54.** In either case, the unit has the compressor running time from one defrost cycle to the next to evaporate the water, depending on the manufacturer's design. Defrost may occur during the off cycle or as few as two or three times per 24 hours. The collection pan in the bottom of the unit is a place where lint and dirt may collect. This pan can and should be removed occasionally and cleaned.

Figure 45.54 Warm air from the condenser used to evaporate condensate.



45.6 METERING DEVICE

Domestic refrigerators and freezers use the capillary tube metering device. This is a fixed-bore device, and the amount of refrigerant flow through it is determined by the bore of the tube and its length, which are predetermined by the manufacturer. The capillary tube is usually fastened for heat exchange to the suction line, **Figure 45.55.** In some cases, the capillary tube may be run inside the suction line, **Figure 45.56.** This helps prevent liquid from returning to the compressor and improves the evaporator capacity by subcooling the liquid in the capillary tube, **Figure 45.57.** The capillary tube may be serviced if necessary and may in some cases be changed for another one, but this is difficult and usually not practical.

It was mentioned earlier that a domestic refrigerator performs correctly only when located in the living space. The capillary tube metering device is one reason for this. This device is sized to pass a certain amount of liquid refrigerant at typical living condition temperatures, which

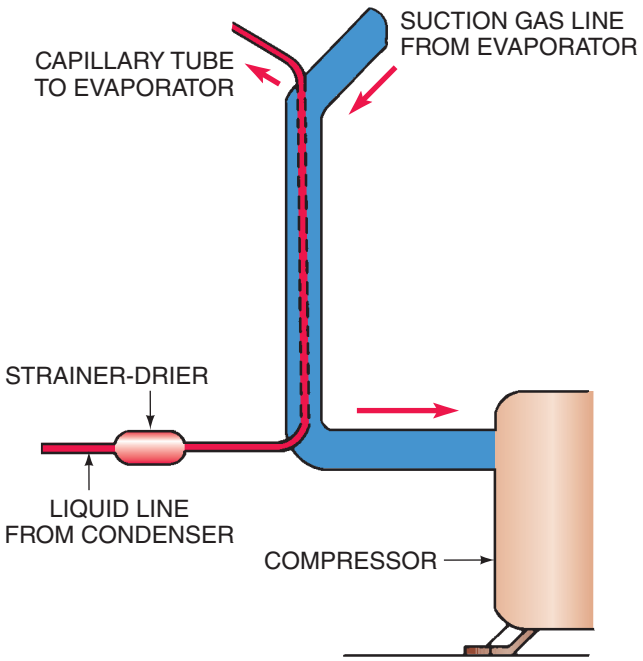

Figure 45.57 Heat exchange between the capillary tube and the suction line.

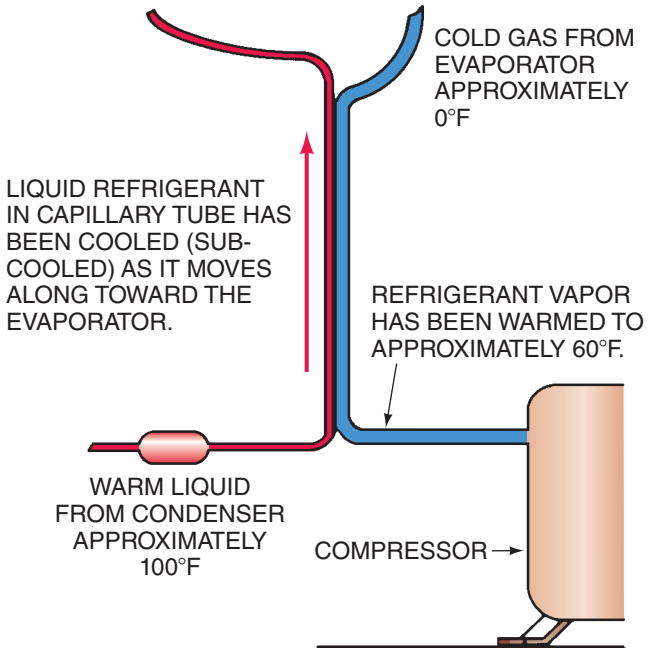

Figure 45.58 The capacity of a refrigerator is reduced by high ambient temperature.

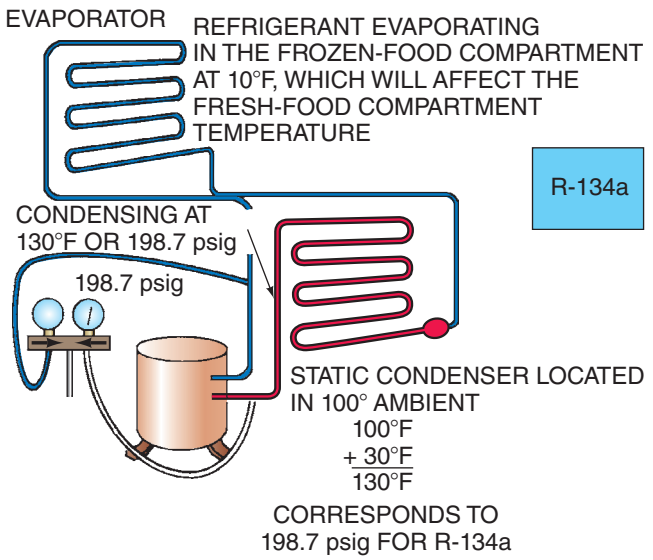

may be considered to be between 65°F and 95°F. If the room ambient temperature is greater, the head pressure will climb and push more refrigerant through the capillary tube, causing the suction pressure to rise. Capacity will suffer to some extent, **Figure 45.58**. Most residences will not exceed the extreme temperatures for long periods of time. For example, the temperature may rise to 100°F in the daytime if the house does not have air-conditioning, but it will cool down at night. The refrigerator may work all day and not cool down to the correct setting but may cycle off at night.

Domestic refrigerators and freezers are not intended to be placed outdoors or in buildings where the temperatures go below 65°F and rise higher than 95°F—unless the manufacturer's literature states that they can be operated at other temperatures. Poor performance and shorter life span may be expected if the manufacturer's directions are not followed.

45.7 TYPICAL OPERATING CONDITIONS

The common refrigerant used for newly manufactured domestic refrigerators and freezers is R-134a. However, the technician must first read the unit's nameplate to determine the type of refrigerant used and then consult a temperature/pressure chart to determine the correct pressures and temperatures for that particular system. Some old refrigerators and freezers still in service contain other refrigerants, such as R-12.

Ideally, a home freezer operates with a box temperature cold enough to freeze ice cream hard, that is, a temperature of about 0°F. The evaporator must operate at a temperature that will lower the air temperature to a point below 0°F. When the air temperature is 0°F, the evaporator coil temperature may be as low as −12°F. This saturation temperature corresponds to a pressure of 1.1 psig for R-134a. With a forced-draft evaporator, the coil temperature may be a little higher because air is forced over the evaporator. **Figure 45.59** provides saturation temperature and pressure information for an R-134a appliance with a static, or natural-draft, condenser. **Figure 45.60** provides typical operating pressures and temperatures for R-134a appliances operating with both forced-draft and natural-draft evaporators. These are the temperatures and pressures expected at the end of the cycle, which is about the time the compressor is going to stop. Temperatures and pressures during a pulldown will, of course, be higher, depending on the box temperature. It can be seen from the figures that evaporator saturation temperatures lower than −12°F should be avoided for R-134a to prevent the low side pressure from pulling into a vacuum.

Figure 45.59 Typical operating pressures and temperatures for an R-134a appliance with a static condenser.

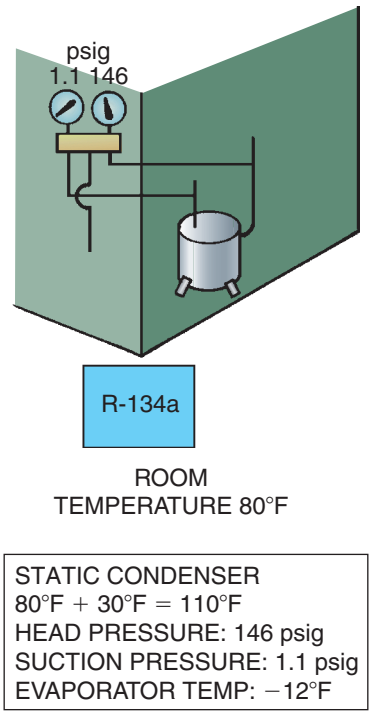

Figure 45.60 Some typical evaporator conditions for forced- and natural-draft evaporators.

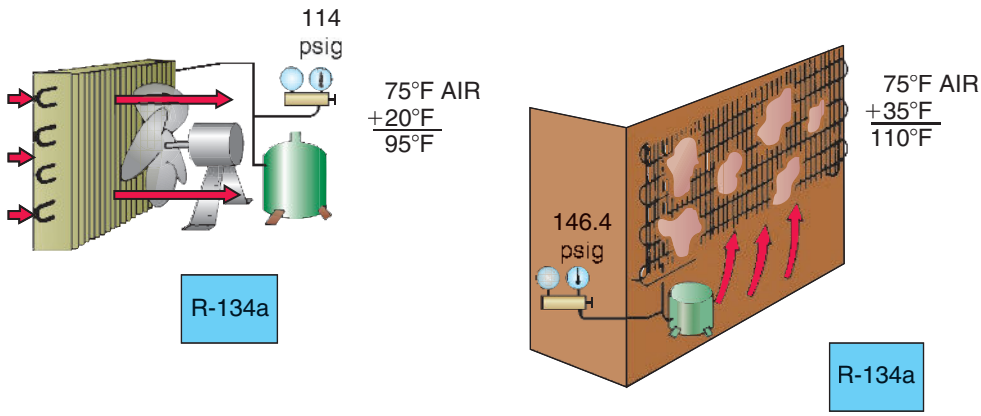
Figure 45.61 The refrigerant typically condenses at 20°F to 35°F higher than the ambient temperature.



BEST CASE: CLEAN INDUCED-DRAFT CONDENSER.

WORST CASE: NATURAL-DRAFT CONDENSER THAT IS PARTIALLY DIRTY.

Operating pressures and temperatures for the condenser are determined using gauge readings. The freezer, like the refrigerator, may have no gauge ports. Gauges should not be installed on the appliance except as a last resort. The typical refrigerator or freezer is designed to be located within the living space, so 65°F to 95°F air will be passing over the condenser. Static, natural draft, condensers should be able to condense the refrigerant at a temperature ranging from 30°F to 35°F higher than the ambient air temperature. For example, if the room temperature is 75°F, then the condenser saturation temperature should be between 105°F (75°F + 30°F) and 110°F (75°F + 35°F). Fan-assisted condensers should be able to condense the refrigerant at a temperature that is about 20°F higher than the ambient air temperature. So, if the room temperature is 75°F, then the condenser saturation temperature should be about 95°F (75°F + 20°F). The closer the condensing temperature is to the temperature of the air passing over it, the more efficient the condenser. A condenser that condenses at 25°F higher than the ambient temperature is more efficient than a condenser that condenses at 35°F higher than the ambient, **Figure 45.61**. Some typical head pressures for R-134a are shown in **Figure 45.62**.

The compressor is the heart of the system, and the technician should be able to readily recognize any compressor problems. On a freezer that is operating normally the compressor is hot to the touch. All compressors are air- or refrigerant-cooled. Compressors that are air-cooled should have fins. Refrigerant-cooled compressors may be cooled with the suction gas. The compressor should not be noisy; it is mounted on rubber feet to keep it quiet. But if the freezer is not level, it may vibrate or bind, so leveling a freezer is important. If a compressor is sitting level and steady and still vibrates, check to see whether the lines are secure and are not touching any part of the appliance. If vibration and noise persist, liquid refrigerant may be returning to the compressor. If it is, the compressor will sweat on the side, **Figure 45.63**.

Figure 45.62 Some typical R-134a head pressures.

	FORCED-AIR CONDENSER	NATURAL-DRAFT CONDENSER
COOL ROOM	65° F + 20° F 85° F CONDENSING TEMPERATURE 95.3 psig R-134a	65° F + 30° F 95° F CONDENSING TEMPERATURE 114 psig R-134a
NORMAL ROOM	75° F + 20° F 95° F CONDENSING TEMPERATURE 114 psig R-134a	65° F + 30° F 95° F CONDENSING TEMPERATURE 135 psig R-134a
HOT ROOM	95° F + 20° F 115° F CONDENSING TEMPERATURE 158.5 psig R-134a	95° F + 30° F 125° F CONDENSING TEMPERATURE 184.6 psig R-134a
HOT ROOM DIRTY CONDENSER	95° F + 35° F 130° F CONDENSING TEMPERATURE 198.7 psig R-134a	95° F + 40° F 135° F CONDENSING TEMPERATURE 213.5 psig R-134a

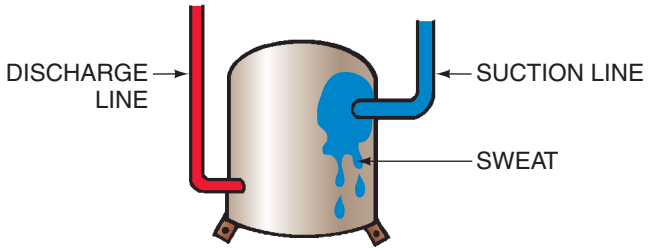
Figure 45.63 If liquid refrigerant is returning to the compressor, it will be sweating on the side.



If there is a question concerning the capacity of the compressor, such as when the unit is not cold enough, first suspect an additional load on the appliance. For example, an interior light that remains on will add additional heat to the system and may cause the compressor to keep running even though the space temperature may be cold enough. A leaky gasket will also cause an extra load, or the owner may be using the box too often and opening the door too much. All conditions should be analyzed before the compressor is condemned.

45.8 ICE-MAKER OPERATION

The ice maker in a domestic refrigerator used to freeze water into ice cubes is in the low-temperature compartment of the box. Generally, a tray filled with water from the home water supply is placed in the freezing compartment. Most newer refrigerators that are equipped with ice makers and water dispensers have water filters built into the appliance to filter the water that is used for consumption and ice prior to use, **Figure 45.64**.

Domestic ice makers do not make ice like commercial ice makers, which use augers or water flowing over inverted evaporators. Domestic ice makers use time more than any other method to determine the sequence of events, but some use electronic circuitry to control the operation of the ice maker. A solenoid valve in the water line opens for a predetermined time to fill the tray. Once the tray is filled and enough time has passed for the water to freeze into cubes, the ice maker will harvest the ice. Harvesting the ice is most commonly accomplished by a rotating "rake" that pushes the cubes from the tray. A small electric resistive heater loosens the cubes for harvest. This heater is attached to the bottom of the ice tray and, when energized, causes the tray to heat up. This melts the ice closest to the tray and allows the rake to remove the finished cubes. When they turn loose, the gear motor moves them to the storage area and the process starts again. This is repeated until the ice bin is full, **Figure 45.65**.

The amount of ice a domestic ice maker produces depends on a number of factors, including the temperature of the appliance's freezer compartment. The heat load on the appliance and the number of times the door is opened also affect the rate of ice production. Keeping the freezer

(B)

Figure 45.65 The water-filled tray freezes. When the control circuit determines that the water is frozen, the heater energizes. Then the fingers push the ice out of the tray to the storage bin. When the bin is full, the bail switch is moved to the right and will not return; production stops.

filled with frozen product keeps the temperature in the box more stable and actually helps to increase the efficiency of the appliance. A typical domestic ice maker produces between 3 and 5 pounds of ice a day, depending on the model and the conditions just mentioned. When first installed, it may take up to a full day before the unit begins to make ice.

45.9 WIRING AND CONTROLS

A wiring diagram should be permanently fastened to each refrigerator box, normally on the back. Most of the time, the diagram is placed inside a plastic sleeve that is permanently mounted to the back of the appliance, **Figure 45.66**. These wiring diagrams are usually either pictorial or linear. The line diagram, also commonly referred to as a ladder diagram, shows each separate circuit as a separate "rung" on a ladder. The pictorial diagram typically shows the location of each component in addition to all of the wires in the appliance, **Figure 45.67**. The line diagram is used to illustrate how the circuit functions by showing all power-passing and power-consuming devices between the two lines, **Figure 45.68**. It is especially useful for troubleshooting purposes, as each load can be easily identified as well as all of the controls and switches that are wired in series with it. Keep in mind that these are 115 V appliances, so there will be one hot wire and one neutral to operate the equipment and a ground (green wire) for the frame or box ground protection.

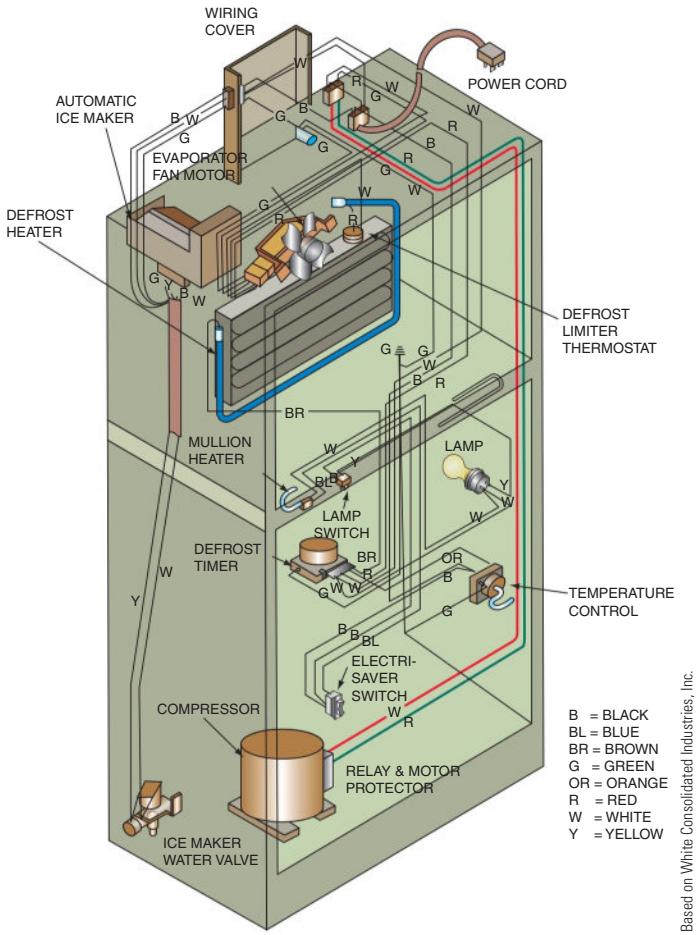
The components of the typical refrigerator that are under electrical control include the following:

- Compressor
- Defrost components
- Various heaters—butter and panel or mullion

Figure 45.66 Wiring diagram on back of the appliance.

Photo by Eugene Silberstein

Figure 45.67 A pictorial wiring diagram.



- Lights for the interior
- Evaporator fan
- Ice maker
- Condenser fan

Except for automatic defrost controls, controls for freezers are simple. A typical freezer has only two: a thermostat and a door switch for turning off the light (and possibly a fan on some models). As with any control circuitry, the technician must know what the manufacturer's intent was when the system was designed.

COMPRESSOR CONTROLS

The space-temperature thermostat, also referred to as the cold control, **Figure 45.69**, controls the compressor. It is a line-voltage device that passes line power to the compressor start/run circuit. It is a make-on-a-rise-in-temperature device.

Several methods are used to control the operation of the compressor. In fully automatic defrost refrigerators, the thermostat, which controls compressor operation, is positioned so that the sensor is in the path of the freezer's supply air. The thermostat in refrigerators with two evaporators is

Figure 45.68 A line wiring diagram.

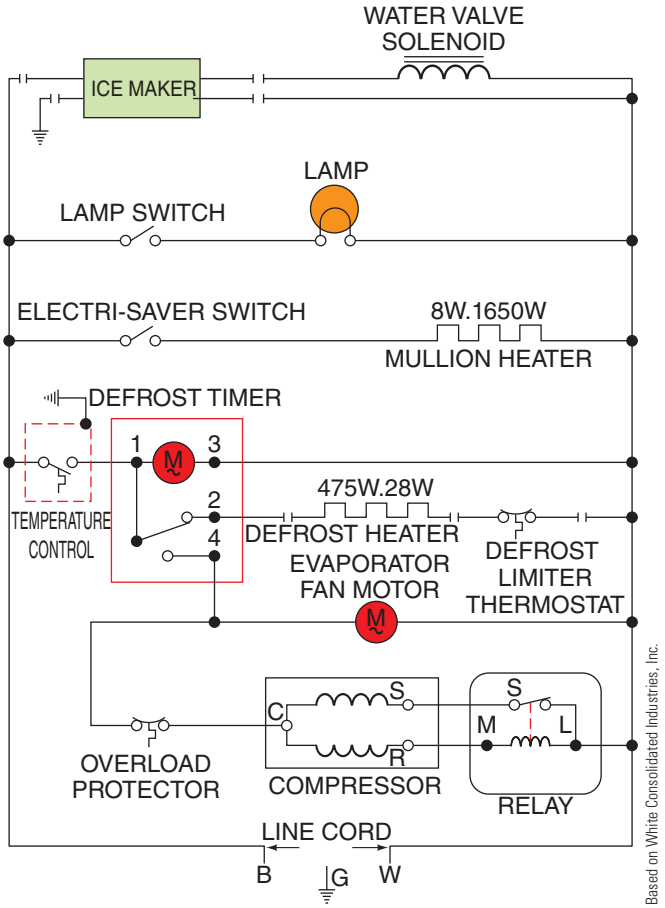

Figure 45.69 The thermostat or cold control.

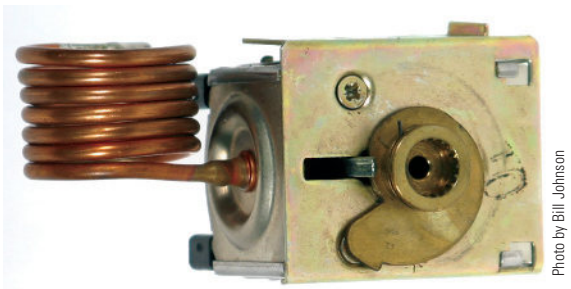

positioned so that it senses the temperature of the evaporator coil in the refrigerator compartment of the unit. On refrigerators that are designed for manual defrost, the thermostat senses the temperature of the evaporator coil, which is located in the freezer compartment of the unit. Refrigerator thermostats often have a large dial with graduated numbers, which typically run from 1 to 10 and have no relation to actual temperatures. The dial may bear the label "colder" with an arrow pointing in the direction where the numbers will yield colder temperatures. This control must be electrically rated and have contacts that are able to stop and start the compressor for years of service.

No matter which control method is used, the compressor is still shut off by a thermostat based on some condition inside the refrigerated box with the intent of keeping both the frozen-food compartment and the fresh-food compartment at the correct temperature. The thermostat is adjustable and can be considered a remote-bulb thermostat, since the sensing element can be uncoiled and positioned to sense the air temperature at a point that is a fair distance from the thermostat itself. Inside the sensing bulb of refrigeration thermostats is a fluid that exerts pressure against the bottom of a diaphragm or bellows, **Figure 45.70**. The atmosphere is on the other side of the bellows. If the atmospheric pressure is much lower than normal, the control setting must be calibrated for a new pressure, such as when a refrigerator is located at a high altitude. Altitude adjustment varies from one manufacturer to another, so the manual should be consulted.

COMPRESSOR START CIRCUIT. The compressor receives power from the thermostat circuit when its contacts close. A current magnetic relay, **Figure 45.71**, or a PTC device, **Figure 45.72**, are often used to assist in the starting of the compressor. Most new appliances use a PTC device to assist in compressor starting. The starting components and their circuits are typically located in the back in the vicinity of the compressor. **Figure 45.71** shows the current magnetic relay as it would be observed on the appliance.

The current magnetic relay, also referred to as a CMR, is a device that senses the amount of current flowing through the run winding of the circuit and, in response to this current, will open or close the contacts on the device. The CMR has a low-resistance coil and a normally open set of contacts. The coil is wired in series with the run winding, and the contacts are wired in series with the start winding, **Figure 45.73**.

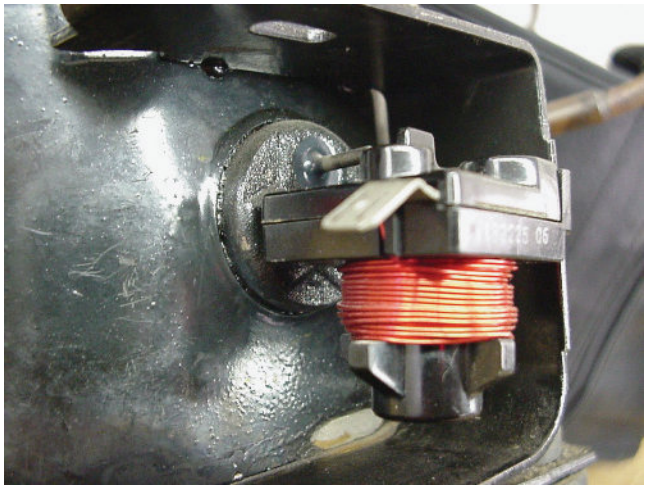
Figure 45.71 Current relay installed on compressor.



Courtesy Ferris State University. Photo by John Tomczyk

When the compressor motor is initially energized, only the run winding is in the active circuit since the contacts on the CMR are in the open position. With only the run winding energized, the motor cannot start because the motor relies on an imbalance in magnetic fields to start. This causes the motor to draw locked-rotor amperage. As discussed earlier in the electric motors portion of the text, a motor's locked-rotor amperage is about five to seven times greater than the normal running amperage of the motor.

While drawing locked-rotor amperage, a strong magnetic field is generated by the coil of the relay. This magnetic field pulls the contacts of the CMR closed, energizing the start winding on the compressor motor. With both windings energized, the compressor motor starts and the amperage draw of the motor drops to its normal operating current. When this happens, the amperage draw of the compressor drops, the strength of the magnetic field in the CMR coil weakens and the CMR contacts open by gravity. This removes the start winding from the circuit and the motor continues to operate with only the run winding energized.

The PTC device is also quite popular on domestic refrigerators and freezers. The PTC, or positive temperature coefficient, is a device whose resistance changes with changes in heat. Since heat is generated when there is current flow through a circuit, this device can be used to add or remove circuit resistance depending on the amount of current flowing through the compressor circuit. **Figure 45.74** shows the wiring of a PTC. Notice that it is wired across the R (run) and S (start) terminals on the compressor motor. When the motor has been off and the PTC device is cool, the resistance of the PTC is very low. This way, when the compressor motor is energized, both the start and run windings are energized and the motor starts. As the motor is operating, current is flowing through the PTC and it quickly warms up. After a very short time, the resistance of the PTC rises to a point that, in essence, prevents current from flowing through the start winding.

Figure 45.73 Wiring diagram of a compressor using a current relay.

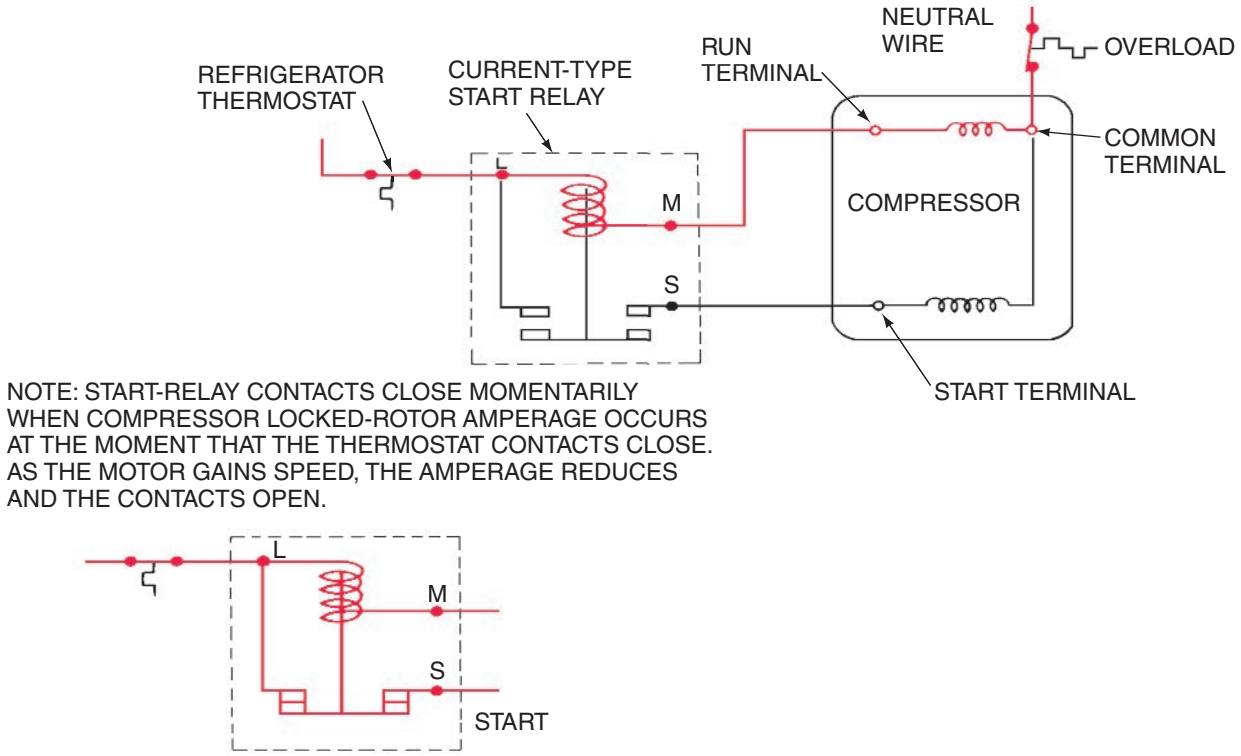

Figure 45.74 Wiring diagram of a compressor with a PTC device.

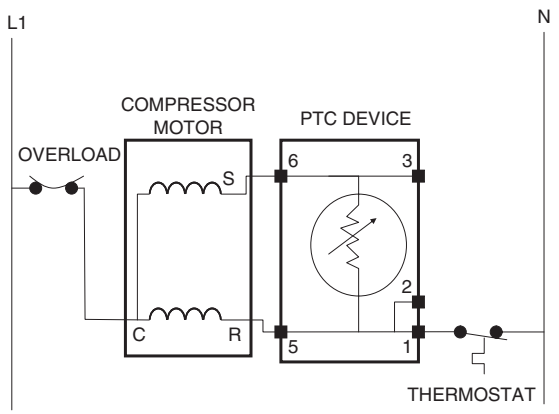
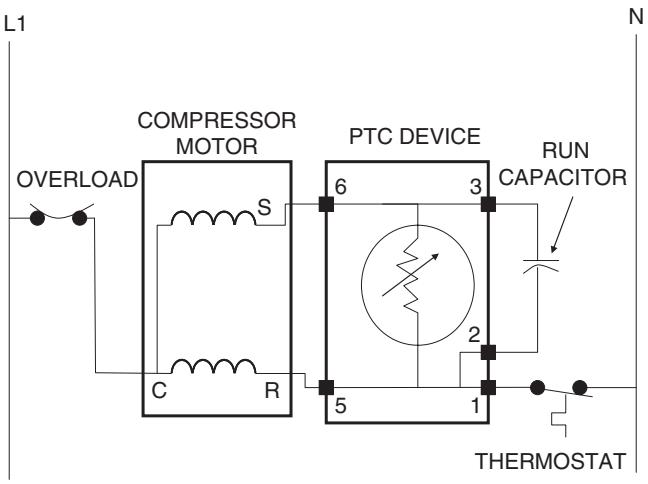


Quite often, a run capacitor will be wired in parallel with the PTC device, **Figure 45.75**. When this is the case, the PTC acts as a closed switch when the motor is initially energized and the run capacitor is bypassed. After a short time, the resistance of the PTC increases and current flow through the device stops. When the PTC "opens," current cannot bypass the run capacitor, which is now a part of the active circuit. The motor now operates as a permanent split capacitor (PSC) motor. Be sure to refer back to the units on motors and motor starting to brush up on these concepts.

Figure 45.75 Wiring diagram of a compressor with a PTC device and a capacitor.



COMPRESSOR WIRING DIAGRAMS. **Figure 45.76** shows a simplified ladder wiring diagram for a domestic refrigerator. Toward the top of the diagram is the compressor and the circuitry that controls its operation. From the diagram we can see that the compressor will operate only when there is power to the unit, the thermostat is calling for refrigeration, and the defrost timer is in the refrigeration mode. (The defrost timer will be discussed in more detail in the next section.)

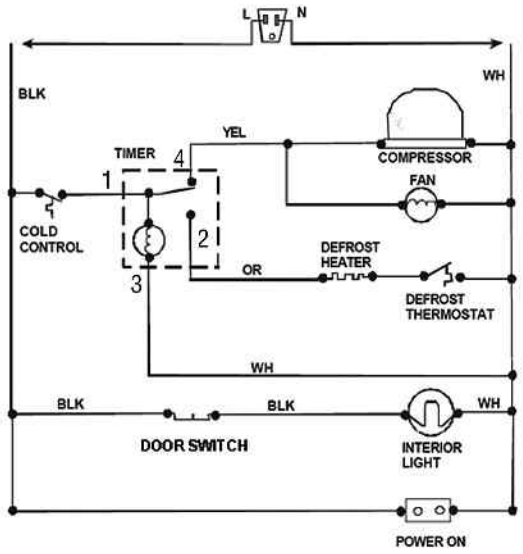
Figure 45.76 Ladder diagram of a domestic refrigerator.



Using the ladder diagram makes troubleshooting the compressor circuit much easier. For example, if the unit is being supplied with the proper line voltage and there is no voltage being supplied to the compressor, we can conclude, assuming the wiring is intact, that either the thermostat or the defrost timer is not allowing current to flow. It may be that the thermostat is not calling for refrigeration or the defrost timer is not calling for refrigeration, or it may be that one of these components is defective. Since the thermostat and the defrost timer are the only components in series with the compressor motor circuit, these are the only devices that will prevent power from reaching the compressor circuit. It is important to note that the compressor starting relays are not included in this diagram, as they are included as part of the compressor. When troubleshooting a system, be sure not to overlook these starting components.

DEFROST CYCLE

All refrigerators have freezing compartments, so they are low-temperature refrigeration systems. Low-temperature refrigeration systems operate with an evaporator coil temperature below 32°F, and for this reason, the evaporator will gather frost. This frost must be removed from the evaporator coil to maintain the coil's efficiency and also to ensure that air is able to pass through the coil. Ice acts as an insulator, so when ice forms on the evaporator coil, the rate of heat transfer between the air in the refrigerated space and the refrigerant is reduced. Automatic defrost is called *frost-free* by many manufacturers, customers, and service people. It is desirable because manual defrosting is a chore and often is not done when needed. *Automatic defrost will help the refrigeration system to operate more efficiently because the frost will be kept off the coil.*

Automatic defrost is controlled by either a mechanical defrost timer, **Figure 45.77**, or an electronic, solid-state, defrost timer, **Figure 45.78**. The mechanical defrost timer is made up of a timer motor, a normally open set of contacts, and a normally closed set of contacts, **Figure 45.79**. The defrost timer motor is often wired so that it is energized

Figure 45.77 Defrost timer.

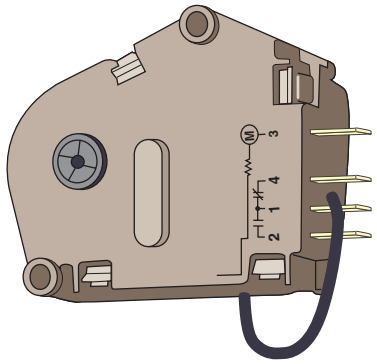


Figure 45.78 Electric, solid-state timer.

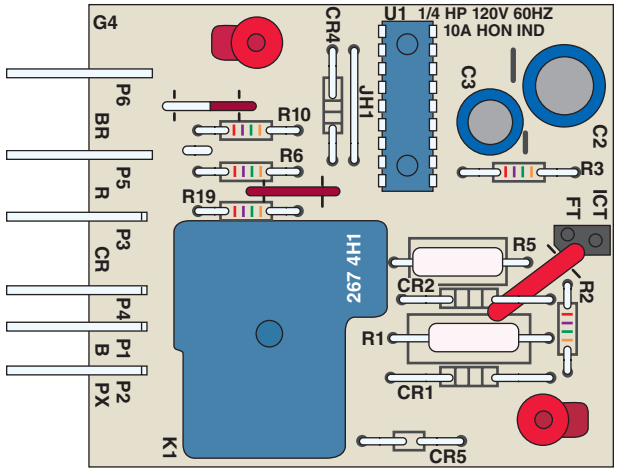

Figure 45.79 Wiring diagram of a mechanical defrost timer.

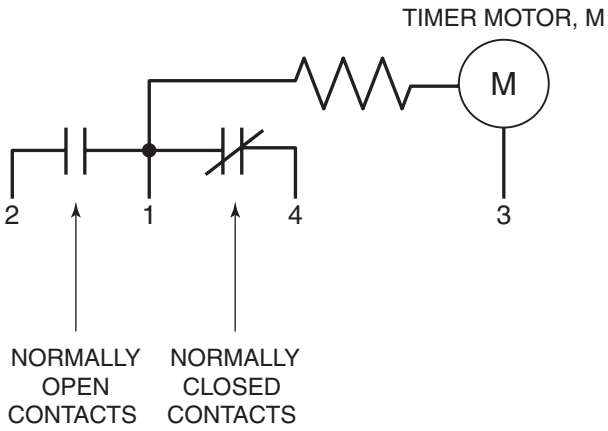

Figure 45.80 Timer wiring for refrigerator defrost.

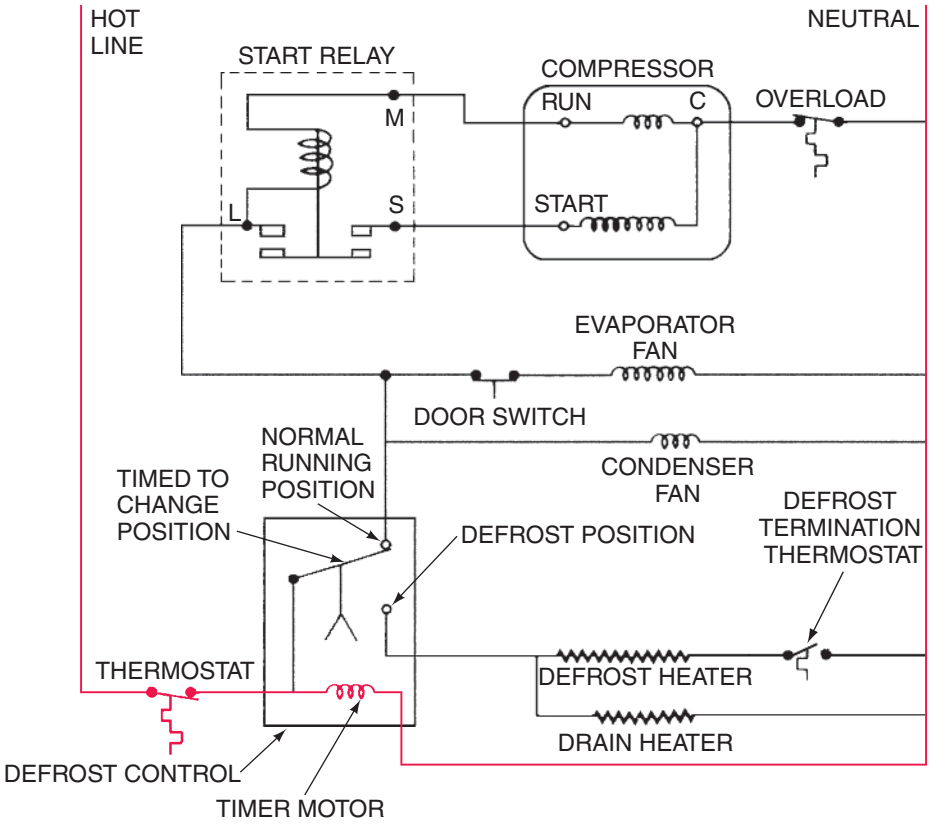

whenever the compressor is operating. When the timer motor is energized, internal gears rotate to keep track of the total run time of the compressor. After the desired run time has elapsed, the defrost cycle is initiated. The normally closed contacts are used to energize the refrigeration cycle when the refrigerator is cooling. The normally open contacts are used to energize the defrost mode of operation.

In **Figure 45.79**, we can see that the timer motor, M, is connected to terminals 1 and 3 on the timer. The timer is connected to terminal 1 by means of the jumper wire that is attached to the device. The normally open set of contacts is located between terminals 1 and 2, and the normally closed set of contacts is located between terminals 1 and 4. From the label on the timer we can see that for every 8 hours of compressor run time, the unit will go into defrost for a period that is determined by the manufacturer. The many different defrost timers available have different combinations of run and defrost times.

Among the several methods manufacturers use to start defrost is compressor running time. By wiring a defrost timer in parallel with the compressor, the time circuit only advances when the compressor runs, **Figure 45.80.** Compressor running time is directly associated with door openings, infiltration, and warm food placed in the box. In the wiring diagram in **Figure 45.80**, it should be noted that the defrost timer motor is wired in series with the refrigerator's thermostat. This means that the defrost timer motor will only be energized when the thermostat is calling for compressor operation. The defrost cycle may be terminated by two methods, time or temperature. Some units use a termination thermostat, **Figure 45.81**, that is backed up by the timer. If the thermostat does not terminate defrost, the timer will act as a safety feature.

Figure 45.81 Defrost termination thermostat.

Electric heat defrost is accomplished by electric heaters located close to the evaporator to melt the ice, **Figure 45.82.** When the unit calls for defrost, the compressor and the evaporator fan stop and the heaters are energized. This condition is maintained until the end of the defrost cycle. Drain pan heaters may be energized when electric heat defrost is used to keep the condensate from freezing as it leaves the drain pan.

DEFROST TIMER WIRING DIAGRAMS. As discussed in the previous paragraphs, the defrost timer is made up of the timer motor as well as normally open and normally closed sets of contacts. Assuming that the manufacturer intends for the appliance to go into defrost after a predetermined period of compressor run time, the timer motor will be wired in series with the cold control or refrigerator thermostat, **Figure 45.83.** It can be seen from the wiring diagram that the timer motor is identified by terminals 1 and 3 and that power cannot be supplied to the timer motor unless the cold control is in the closed position. When the cold control is in the open position, the timer motor is deenergized and the internal gears on the timer stop turning. The normally closed contacts are the contacts that energize the compressor and evaporator fan motor in the refrigeration mode and deenergize these components when the system is in defrost. These contacts are identified by terminals 1 and 4 in **Figure 45.84.**

The normally open contacts energize the defrost heater when the system goes into defrost. They also deenergize the heater when the system is operating in the refrigeration mode. These contacts are identified by terminals 1 and 2 in **Figure 45.85.** Notice that there is a defrost termination switch wired in series with the defrost heater. This component is a bimetal device that will open its contacts if it senses that there is no ice on the evaporator coil. Although the system is still technically in the defrost cycle, as indicated by the defrost timer, the defrost termination switch deenergizes the heater because its operation is not needed. This reduces the amount of unnecessary heat that is added to the box which would have to be removed later when the compressor cycles back on. This device also prevents the evaporator from overheating during defrost and causing damage to the appliance cabinet.

Figure 45.82 Electric heaters for defrost.

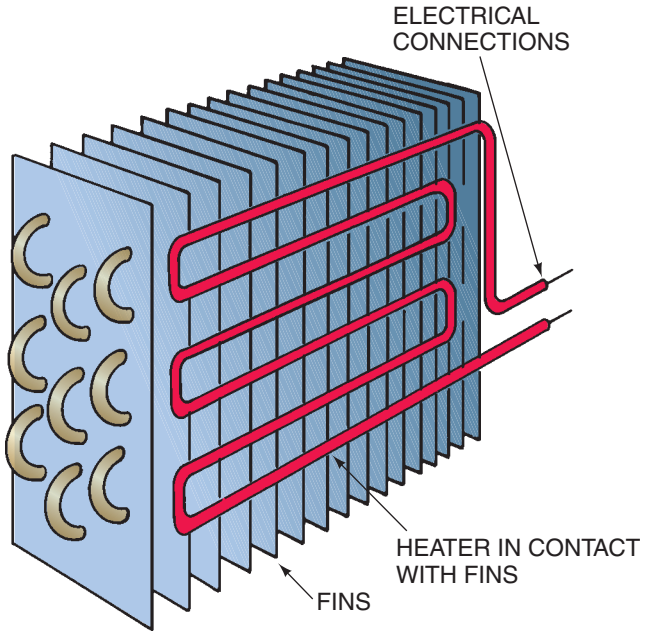

Figure 45.83 Defrost timer motor wired in series with the thermostat.

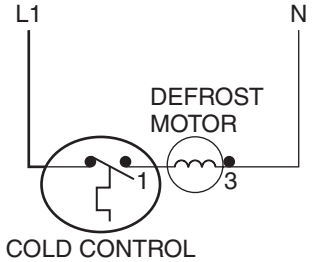

Figure 45.84 On this timer, the normally closed contacts are between terminals 1 and 4. These contacts energize the compressor circuit.

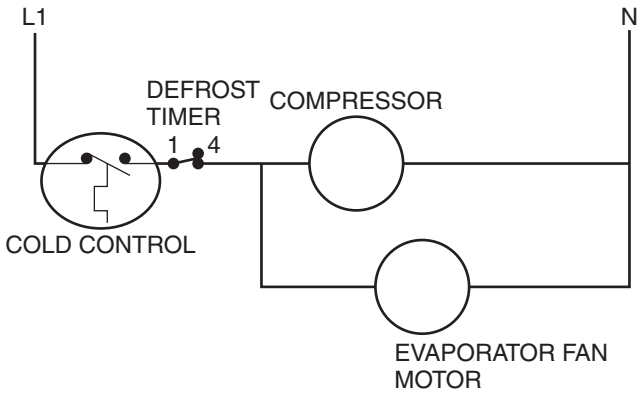

Figure 45.85 On this timer, the normally closed contacts are between terminals 1 and 2. These contacts energize the defrost heater circuit.

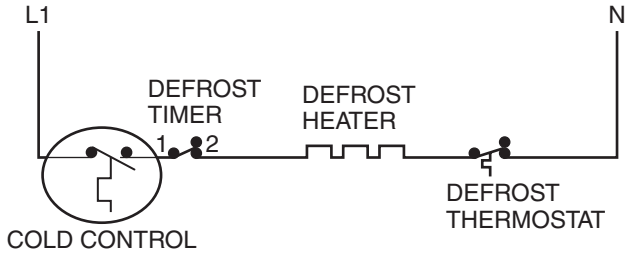


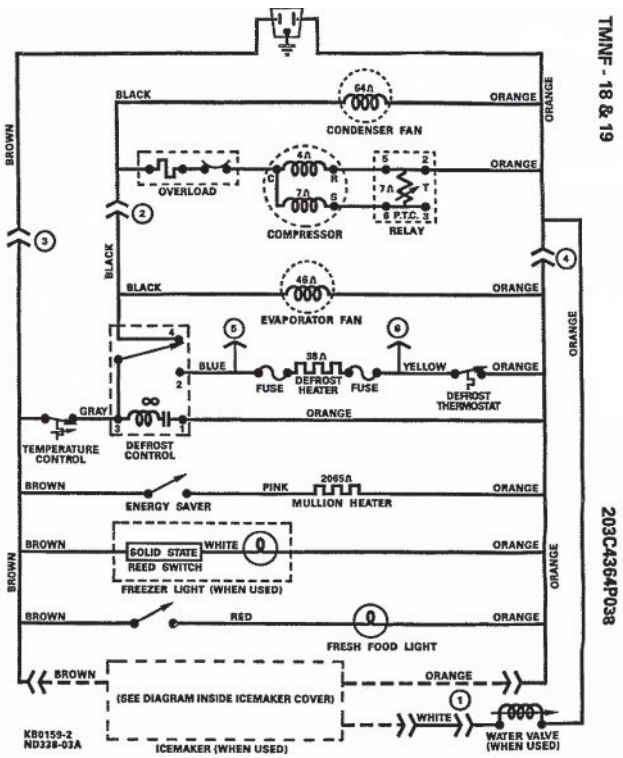
SWEAT PREVENTION HEATERS

Most sweat prevention heaters are small, electrically insulated wire heaters that are mounted against the cabinet walls at the door openings. Their function is to keep the outside cabinet temperature above the dew point temperature of the room so that the box will not sweat. *Some units may have energy-saver switches that allow the owner to switch part of the heaters off if the room humidity is low.* **Figure 45.86** shows the wiring diagram of a refrigerator/freezer with an energy-saver switch. Notice from the diagram that the mullion heater will be energized whenever the energy-saver switch is closed, regardless of whether or not the compressor is operating. If the appliance owner understands the feature and how best to use it, money can be saved.

There are, however, conflicting opinions with regard to the whether the energy-saver switch on refrigerators actually provides monetary savings over the long term. It can be argued that it costs money to keep any heater on, but because of the extremely high resistance of the heaters, the actual operating cost is very low. Most manufacturers simplify the two switch positions by giving them such labels as "HUMID" (which turns the heaters on) and "SAVE ENERGY" (which turns the heaters off). Most appliance owners are not aware of how the switch will save them money but are eager to conserve energy and money and so choose the "Save Energy" setting. Although this may be fine in the winter months when the humidity is low, problems can arise when the more humid summer months arrive. In very dry climates, the heaters may not be needed at all.

With humid air and cool refrigerator cabinet surfaces, condensate can form on the door, resulting in dripping water, which is a nuisance. The main problem is not the water dripping on the outside of the box, but the water that can build up on the interior of the refrigerator panels as well. The insulation can get wet, and over time, the wet insulation can sag, leaving bare spots with no insulation in the walls. This can lead to an increase in heat seepage through the box walls, which, in turn, can lead to increased compressor run time and an increase in energy consumption. For this reason, many industry professionals recommend that the sweat prevention heaters be powered at all times.

Figure 45.86 Wiring diagram of a refrigerator/freezer equipped with an energy-saver switch.



LIGHTS

Most refrigerators have lights mounted in the fresh- and frozen-food compartments. These lights are typically controlled by door switches that close a circuit when the door is opened. The wiring diagram in **Figure 45.87** shows circuits for both the freezer compartment and the fresh-food (refrigerated) compartment of the appliance.

REFRIGERATOR FAN MOTORS

In mechanical-draft refrigerators, two types of fans are used: one for the condenser and one for the evaporator. Condenser fans are usually prop types with shaded-pole motors. Small squirrel-cage centrifugal blowers may be used for the evaporator.

The evaporator fan, used on frost-free models only, may run all the time except in defrost, so in a few years it may have many operating hours, but it is typically reliable. The fan is located in the vicinity of the evaporator, usually under a panel that may be easily removed for service. The motor is often an open type with no covers over the windings. These fans have permanently lubricated bearings that require no service, **Figure 45.88**. The condenser fan is located under the refrigerator in the back and is typically a shaded-pole motor with a prop-type fan. It is permanently lubricated also but is covered, not open, **Figure 45.89**.

These small fan motors are simple to troubleshoot. If there is power to the motor leads and the motor will not turn, either the bearings are tight or the motor is defective. Most domestic refrigerator and freezer evaporator and condenser fan motors will operate whenever the compressor is operating. This means that these motors will cycle on whenever the box thermostat or cold control is calling for refrigeration and the defrost timer is not in the defrost mode. The wiring diagram in **Figure 45.87** shows that the condenser and evaporator fan motors are wired in parallel with the compressor

circuit, so all three components will cycle on an off together during normal system operation. All three components will cycle "off" during the defrost cycle.

ICE MAKER WIRING

The ice makers found in domestic refrigerators are add-on options and are supplied with constant power. The ice maker has its own controls built right into it, so all that needs to be done is mount it, plug it in, and make certain that the water line is connected to the refrigerator as instructed. No field wiring is required to install the ice maker, except for plugging it into the plug provided for the wiring harness. The wiring diagram in **Figure 45.87** shows an ice maker and

where it is connected to the circuit. Notice that there are no controls or switches external to the component itself that will affect the operation of the device.

45.10 SERVICING THE APPLIANCE

The technician should make every effort to separate problems into definite categories. Some problems are electrical and some are mechanical. It is also important to know the type of appliance. For example, when servicing freezers, the technician does not have to think about the fresh-food compartment—only the low-temperature compartment. Also, the type of box determines the type of service. For example, a box that has a forced-draft evaporator will have a fan motor that can be a source of problems.

Unit 5, "Tools and Equipment," describes tools and equipment used by technicians for the servicing of refrigeration equipment. A poorly equipped technician works at a disadvantage. Lack of proper instruments may prevent discovery of the problem, and the customer's equipment or property can be damaged or the technician may be injured if, for example, the correct equipment for moving a refrigerated box is not used. A professional is well equipped. The sections that follow address a number of service-related issues regarding the domestic refrigerator and freezer.

ELECTRICAL PROBLEMS

Electrical problems in a domestic refrigerator or freezer are relatively easy to diagnose. This is because the appliance has relatively few electrical loads and switches and all of the components are located within its cabinet. In addition, a complete wiring diagram is attached to the appliance, usually on the back. Be sure to locate this very important document before attempting to repair the unit. One very important thing to know is the sequence of operations for the particular unit being worked on. Knowing what is supposed to happen when can save a lot of time when troubleshooting the system. For example, if the compressor and condenser fan motor are wired to cycle on and off together, troubleshooting the problem will be a breeze if the condenser fan is operating and the compressor is not. The unit is being supplied with power because the condenser fan motor is operating. Also, the cold control is closed and operational because it is feeding power to the condenser fan motor. It is not difficult to conclude that the problem lies with the compressor, its wiring, or its associated starting components.

Here are a few things to keep in mind when troubleshooting the electrical circuits of a refrigerator or freezer:

- Have the wiring diagram handy.
- Observe what the appliance is doing and what it is not doing.
- Observe what appliance components are operating and those that are not.
- Know the sequence of operations of the appliance.
- Know the difference between a load (power-consuming device) and a switch (power-passing device).
- Know how to correctly use a voltmeter and ohmmeter.
- When testing resistance or continuity, make certain that the circuit power is disconnected and that the circuit or component being tested is completely removed/disconnected from the circuit to prevent false/feedback readings.
- When possible, unplug the appliance and discharge all capacitors to reduce the risk of electric shock.
- Make certain all electrical connections are tight.
- Make certain that all electrical wires are as far away as possible from wet locations, such as where condensate may drip or accumulate.
- Make certain that all electrical wires are as far away as possible from rotating components, such as fan motors.
- When replacing an electrical component, use an exact replacement whenever possible.

MECHANICAL PROBLEMS

Mechanical problems in domestic refrigerators and freezers often involve the refrigerant circuit and the compressor. Mechanical problems include system leaks, system undercharge, system overcharge, and compressor-related issues. The sections that follow are geared toward the mechanical portion of system evaluation and provide valuable service-related procedures to properly identify and remedy mechanical problems in the appliance.

CABINET PROBLEMS. In order for the refrigerant to correctly circulate through the evaporator and condenser, domestic refrigerators must be leveled according to the manufacturer's specifications. If it is not level, the ice maker may overflow when filled with water, and condensate may not completely drain during defrost. The leveling screws or wheels are on the bottom of the box or cabinet. Leveling feet may be adjusted with a wrench or a pair of adjustable pliers. Wheels have leveling adjustments to raise and lower them, **Figure 45.13**. If the floor is too low, spacers may need to be added at the lowest point so that all four feet or wheels are touching the floor or spacers. Vibration may make the refrigerator, as well as its contents (rattling glass containers, for example), noisy if all four points do not touch with equal pressure. Also, if the box is not level, the door or doors may not close correctly or may tend to swing open, **Figure 45.90**. With magnetic gaskets, it is important that the box not be sloped down and toward the front.

The door gets the most abuse of any part of the box because it is opened and closed so many times. It also may have a lot of weight in it due to food storage, so it must have strong hinges. Many refrigerator doors have bearing surfaces

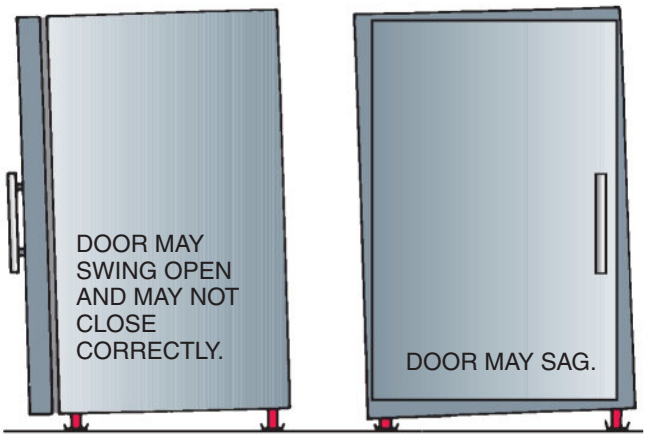
Figure 45.90 If the box is not leveled per the manufacturer's instructions, the doors may not function correctly.



built into these hinges that may need changing after excessive use, **Figure 45.91.** Wires and water piping may be threaded through the door hinges to furnish power and water to circuits that may operate ice or water dispensers located in the door, **Figure 45.92.** These connections may wear with use and require service. As door gaskets age, they may need replacement. The various manufacturers use different gaskets that may require special tools that help in removing the old gaskets and installing the new ones. The manufacturer's directions should be followed when changing gaskets to ensure that the door is properly aligned and the gaskets fit properly.

MOVING THE APPLIANCE. A refrigerator or freezer is among the heaviest and most awkward types of equipment to move.

Figure 45.91 Hinges may have bearing surfaces to make door opening easier.

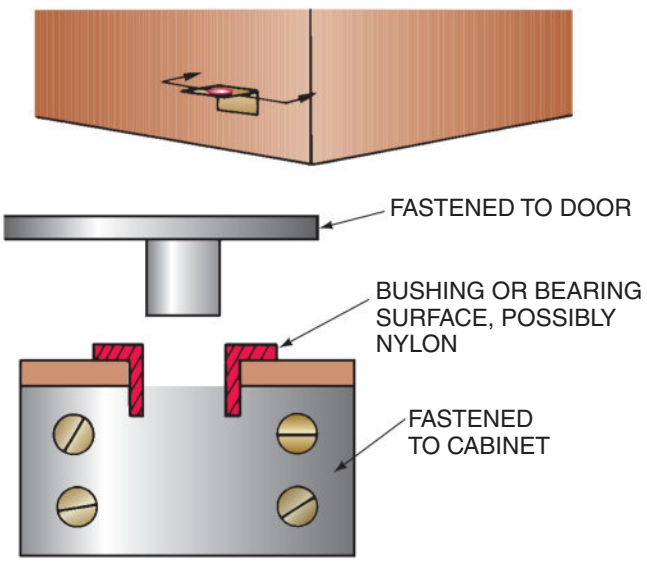


Figure 45.92 Power circuits and tubing for water may be connected to the door through the hinges.

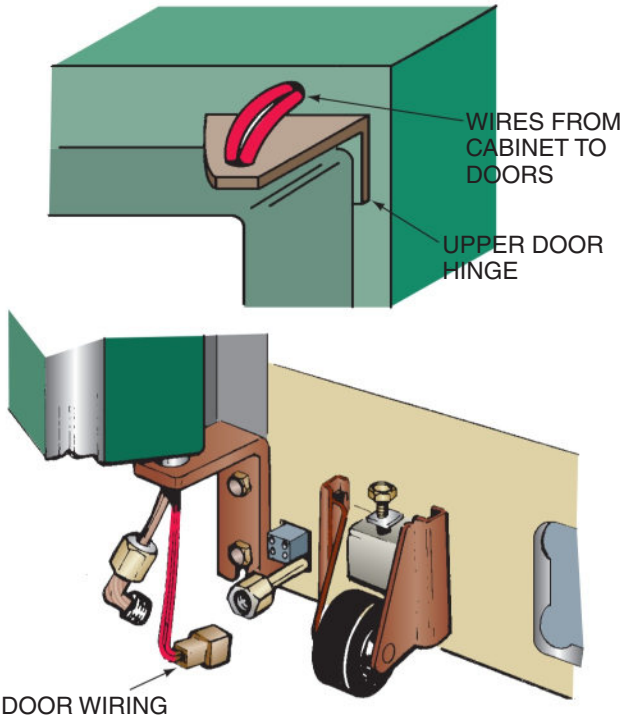

SAFETY PRECAUTION: *Technicians must use great care when lifting and moving any heavy object and think out the safest method. They should use special tools and equipment at all times and wear appropriate back brace belts when moving and lifting objects,* **Figure 45.93.**• When it is necessary to lift, it should

Figure 45.93 Use a back brace to lift objects. Use legs, not the back; keep the back straight.

be done with the legs, not the back, and the back should be kept straight. Because freezers are frequently located in tight places and often need to be moved upstairs or downstairs, the surroundings or the freezer may be damaged when moving it. The correct moving devices must be used. **NOTE:** *Because of oil migration, never lay a freezer on its side.*•

MOVING UPRIGHT APPLIANCES. To move upright boxes, refrigerator hand trucks with wide belts are used, **Figure 45.94**. The trucks must be positioned in such a manner that they do not damage the condenser or let the door swing open, **Figure 45.95**. If possible, the box should be trucked from the side where the door closes. When repositioned, the box must be on a solid foundation.

Freezers or refrigerators should not be moved with food in them, although they may be moved far enough away from the wall for service without removing the food if this is done carefully. If the box is located on a floor that must be protected, the technician is responsible for knowing how to accomplish the move without causing damage to the floor or freezer. If the box does not have wheels, a small rug or mat inserted under the legs will slide it across a fine-finished floor without causing damage to the floor. The box should be slightly tilted to one side while someone slides the mat under the feet. Then the box must be tilted to the other side to get the mat under the other feet. This method can be used only where there is room to tilt the unit, **Figure 45.96**. If there is no tilt room, the box may have to be pulled out from the wall far enough for the mat to be placed under the front feet—and then it may be pulled out from the wall far enough for service.

Figure 45.94 Refrigerator hand trucks.

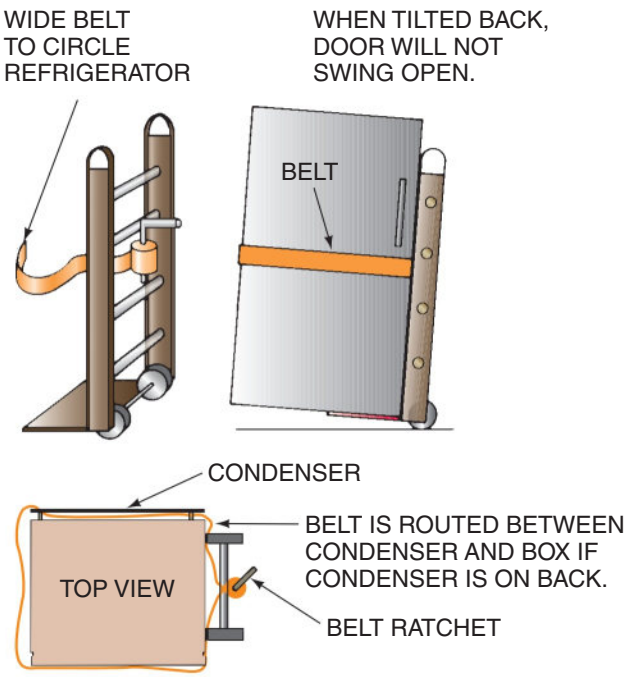

Figure 45.95 Pull the belt between the condenser and the box when the condenser is in the back.

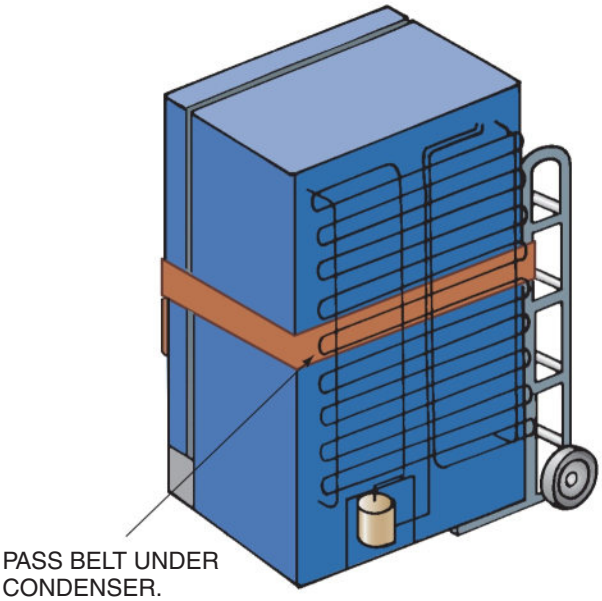

Figure 45.96 Enough room is available to tilt the box and place a mat under the feet.

The front feet may be screwed upward one at a time and a mat placed under them—and then screwed back out if no side or backward tilt is possible, **Figure 45.97**. Care should be used when placing a mat under the feet. **SAFETY PRECAUTION:** *Avoid putting hands under the box. A screwdriver or stick may be used to slide the mat under the feet,* **Figure 45.98**.•

Figure 45.97 The feet may be screwed upward, one at a time, to work the mat under the feet.

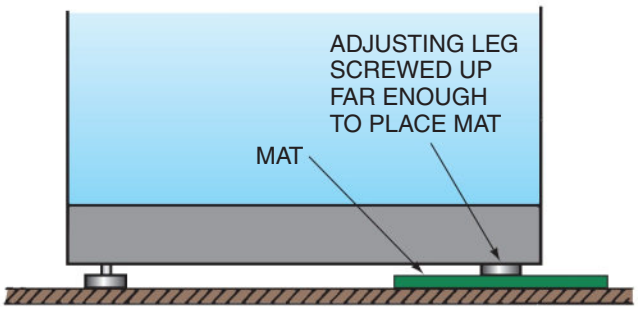

Figure 45.98 Use a small stick or long screwdriver, not hands, to place the mat.

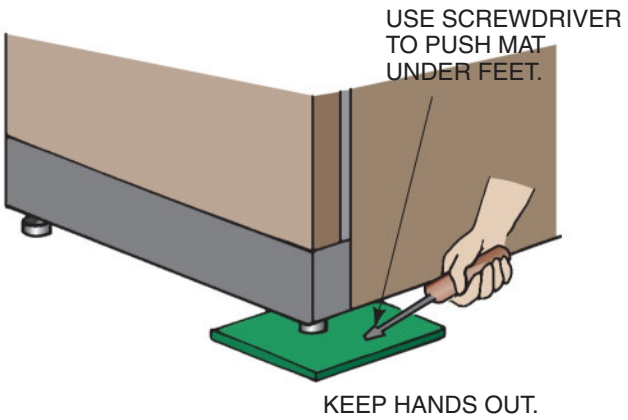
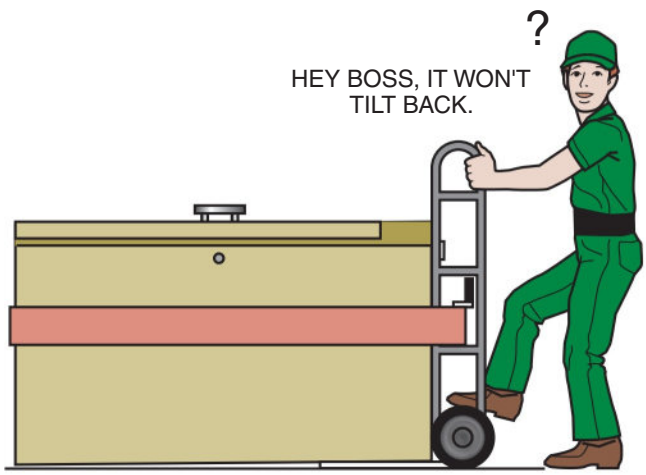


MOVING CHEST-TYPE FREEZERS. Chest-type freezers are more difficult to move than upright refrigerators or freezers. They may be larger, take up more floor space, and contain more food. Two-wheel refrigerator hand trucks will not work as well on chest freezers because they are longer than they are tall, **Figure 45.99**. When a chest freezer must be moved out from the wall for service, the same guidelines apply as for an upright refrigerator or freezer. By carefully using a pry bar resting on a piece of plywood, a mat can be placed under the feet, **Figure 45.100**. Two four-wheel dollies, **Figure 45.101**, may be used when the chest freezer is to be moved from one room to another. The freezer must carefully be raised to the level of the dollies. This requires at least two people and caution. Chest freezers for domestic use are sized so that they will fit through standard doors, but care should be used when moving the dolly wheels over the door's threshold.

Figure 45.99 Refrigerator hand trucks will not work on a chest freezer.



GAUGE CONNECTIONS

Domestic refrigerated appliances do not have factory-installed gauge ports like commercial refrigeration or air-conditioning systems. The system is hermetically sealed at the factory, and gauges may never have to be installed on it. When a system has been charged correctly, it should never have to be adjusted, as long as the appliance remains leak-free.

Leaks, field analysis requiring pressure readings, and field repair of components are the only reasons for installing gauges. Many service technicians have a tendency to routinely install gauges. This is poor practice, especially when dealing with domestic refrigeration appliances, since many have refrigerant charges amounting to only a few ounces. Taking a high-pressure reading from the liquid line on a

Figure 45.100 A mat can be placed under a chest freezer by using a pry bar.

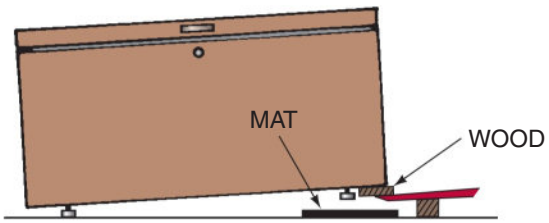


Figure 45.101 The use of two dollies with four wheels each is a good choice for moving a full chest freezer.

domestic appliance can cause enough refrigerant to leave the system and enter the gauge hoses to adversely affect the operation of the unit. Many systems start with the correct charge, but as a result of a technician taking pressure readings, operate with a deficiency of refrigerant, causing system problems. Gauges should be installed on the system only as a last resort, and when installed, great care should be taken to ensure that the system remains free of contaminants. Some methods for determining system problems without the use of gauges are discussed in the next section, "Low Refrigerant Charge."

All gauge manifolds and gauge hoses must be leak-free, clean, and free from contaminants. It is good practice for a technician to have a set of gauges for each type of refrigerant commonly encountered. The gauge manifold should be stored with pressure in the hoses to reduce the possibility of manifold contamination. It may be desirable to remove the Schrader valve depressors furnished in the gauge hoses and use special adapters for depressing Schrader valve stems, **Figure 45.102**. This provides unobstructed gauge hoses for quick evacuation of a wet or damp system. Low-loss fittings must also be used on gauge hoses.

Some manufacturers provide a service port arrangement in which an attachment may be fastened to the compressor for taking gauge readings, **Figure 45.103**. Others do not furnish any service ports, so field service ports may be installed in the field in the form of line tap valves, **Figure 45.44**, following the manufacturer's instructions. Always, the correct valve size based on the line size should be used. **NOTE:** *If there is a chance that the system pressure may be in a vacuum, either purge the gauge hoses with clean refrigerant or shut the unit off and let the pressures equalize before installing a low-side line tap valve; otherwise, atmosphere will enter the system.* When installing a line tap valve on the high-pressure side of the system, it is best to install it on the compressor process tube, where it may be soldered on or removed by pinching off the process tube between the valve and compressor housing, **Figure 45.104**. All line tap valves left in the active part of the system must be soldered to the tubing. A saddle-type line tap valve must be removed from the unit after service is complete.

If repairs are made to components in the refrigerant cycle or a refrigerant charge is lost completely, it is best to use the process tubes on the compressor for pressure readings. Fittings with Schrader valves may be soldered to the process tubes for the service work and evacuation, **Figure 45.105**. These tubes may be capped, or they may be pinched off using a special pinch-off tool, **Figure 45.106**, and soldered shut. A special pinch-off tool is necessary because refrigerant lines cannot be pinched off with general purpose pliers.

Figure 45.102 Remove the Schrader valve depressors from gauge hoses and use the special fitting on the right to depress the valve cores.

LOW REFRIGERANT CHARGE

If a refrigeration unit had the correct charge when it left the factory, it will maintain that charge until a leak develops. If a unit does have a low refrigerant charge, every effort should be made to determine the cause. A low refrigerant charge results in reduced appliance capacity, increased compressor run time, warmer-than-normal box temperatures, low operating pressures, high evaporator superheat, and low condenser subcooling.

Figure 45.104 Locate the high-pressure line tap valve on the hot gas line, not the liquid line. When finished, the line can be pinched off and soldered shut.

One service technique that many experienced service technicians use to determine whether the charge is approximately correct in a system (before connecting gauges) requires only that the unit be stopped and restarted. The unit is shut off and the pressures allowed to equalize, which takes about 5 min. Before the compressor is restarted, the technician places a hand on the suction line where it enters the compressor in such a manner that the line temperature may be sensed by touch. The compressor is then started. If the suction line gets cold for a short time, the chances are the refrigerant charge is correct. This occurs because a small amount of liquid is pulled from the evaporator into the suction line and the line gets cold for a short period of time. In addition, inspecting the evaporator coil can give an indication of a proper system charge. If the evaporator coil has a full frost on it, the system is very likely not undercharged. However, if the coil is only partially frosted, at the inlet of the evaporator, an undercharge should be suspected. Checking the amperage draw of the compressor, **Figure 45.107**, can also provide useful information regarding the charge. If the amperage draw of the compressor is very low as compared to the amperage rating on the compressor, an undercharge is possible.

All refrigerators currently being manufactured in the United States use R-134a. If a technician suspects a low charge, even after the items mentioned before have been checked, the compressor should be stopped and uncontaminated gauges installed on the system. It is good practice to wait 5 min before installing the gauges. This will allow the unit pressures to equalize and lower the possibility of having the low side of the system in a vacuum, which may be the case as long as the compressor is running. The compressor may then be restarted. If the system low-pressure gauge reads in a vacuum (below atmosphere) for a period of time, about 15 min, the unit is probably low on refrigerant or the capillary tube may be restricted. (Note that it is not uncommon for a refrigerator to operate in a vacuum for a short period of time after start-up.)

Figure 45.107 Taking a current reading at the compressor.

A small amount of refrigerant may be added to the system and the pressures observed again. **SAFETY PRECAUTION:** *High-pressure readings should be taken when adding refrigerant because a restricted capillary tube will cause high head pressure readings if refrigerant is added. This problem cannot be determined from a low-pressure reading only. If a high-pressure reading is not possible, attach a clamp-on ammeter to the compressor common wire and do not allow the compressor amperage to rise above the running-load amperage (RLA) rating of the compressor. If it does, shut it off.* •

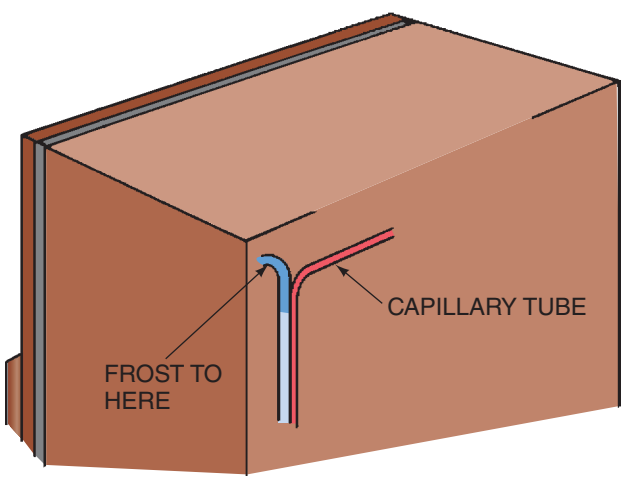
4R *Manufacturers recommend that a low charge be fixed by finding the leak, removing and recovering the charge, and repairing the leak. A measured charge may then be transferred into the system.* 4R Some experienced service technicians may successfully add a partial charge by the frost-line method. This method is used to add refrigerant while the unit is operating, and it works as follows. A point on the suction line leaving the refrigerated box is located where the frost line may be observed, possibly where the suction line leaves the back of the box, **Figure 45.108.** Refrigerant is added very slowly by opening and closing the gauge manifold low-side valve until frost appears at this point. Then no more is added. The suction pressure may be 10 to 20 psig at this time and should reduce to about 2 to 5 psig just before the refrigerator thermostat shuts the compressor off. Using the frost-line method of charging a domestic refrigerator is a slow, tedious process that is not recommended unless just topping off a charge. The recommended method is to start from a deep vacuum and measure the charge into the system using either a charging cylinder or accurate scales, because the charge is critical to about ¼ ounce. 4R *If the frost line creeps toward the compressor as the box temperature reduces, refrigerant may be recovered slowly through the low side until the frost line is correct.* 4R

The typical operating conditions for the low-pressure side are fairly straightforward. The conditions are based on the coldest coil, the freezer coil. The typical low temperature for the freezer is 0°F. The refrigerant in the evaporator would typically be 12°F colder than the food temperature, so the refrigerant would boil at about −12°F. The corresponding pressures would be about 1.1 psig for R-134a when the thermostat is ready to shut the compressor off. If the box temperature were set to a lower point, the pressures would move downward. When it is time for the compressor to start, the pressures would be higher. Typically, the temperatures may fluctuate between 0°F and +5°F with corresponding pressures. **NOTE:** *Many units will operate in a vacuum for a short period of time after start-up. This condition will last until the refrigerant feeds through the capillary tube from the condenser and the system charge is in balance. This is particularly true if a unit is charged on the high-pressure side after evacuation.* •

One sure-fire way to determine if the system is operating with less than a full charge of refrigerant is to evaluate the evaporator superheat and condenser subcooling of the unit. If a system is undercharged, due to either a leak or improper charging, the evaporator superheat will be high and the condenser subcooling will be low. Consider an R-134a domestic refrigerator that is operating with a low-side pressure of 9.7 in. Hg and a high-side pressure of 104.4 psig. If the evaporator outlet temperature is 10°F and the condenser outlet temperature is 85°F, we have enough information to calculate the evaporator superheat and the condenser subcooling. The evaporator superheat is calculated by subtracting the evaporator saturation temperature, obtained from the T/P chart, from the evaporator outlet temperature. In this case, we get 10°F − (−30°F), or 40 degrees of evaporator superheat. This by itself does not tell us if the system is short of refrigerant or if the capillary tube is clogged, as both of these conditions will result in higher-than-normal superheat. We take a look at the condenser subcooling next.

The condenser subcooling superheat is calculated by subtracting the condenser outlet temperature from the condenser saturation temperature. In this case, we get (90°F − 85°F), or 5 degrees of condenser subcooling. Low condenser subcooling indicates that there is a deficiency of refrigerant on the high side of the system. Since this system has high evaporator superheat, which indicates a deficiency of refrigerant on the low side of the system, and low condenser subcooling, we can conclude that the system is operating with a deficiency of refrigerant. We will still have to determine if this deficiency is a result of a leak or of improper charging.

Figure 45.108 Checking the refrigerator charge using the frost-line method.



REFRIGERANT OVERCHARGE

The refrigerator may have either a natural-draft or induced-draft condenser. Induced-draft condensers are more efficient and their head pressure will typically be lower than that of a natural-draft condenser. If too much refrigerant is added to a refrigerator, the head pressure will be too high. Typical head pressures for static condensers should correspond to

a condensing temperature that is 30°F to 35°F higher than room temperature at design operating conditions. Refrigerators that use mechanical, induced-draft condensers typically would condense refrigerant at a temperature that is about 20°F higher than room temperature.

For example, if the room temperature at the floor level is 70°F, the head pressure on a unit with a static condenser should be between 124.2 psig and 135 psig for R-134a, **Figure 45.109.** (Refer to the temperature/pressure chart in Unit 3, Figure 3.40.) Head pressure higher than 136 psig is too high.

NOTE: *Be sure to check the load on the refrigerated space before drawing any final conclusions. Head pressures will be higher during a hot pulldown of the refrigerated space,* **Figure 45.110.**

Figure 45.109 Typical head pressure for an R-134a appliance.

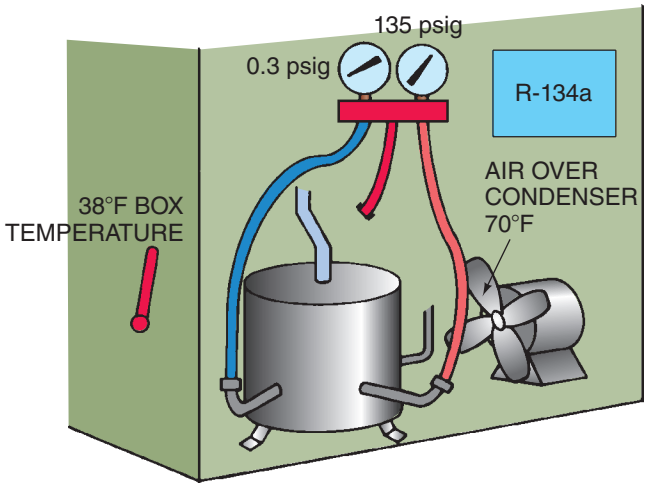

Figure 45.110 Head pressure under an abnormally high load.

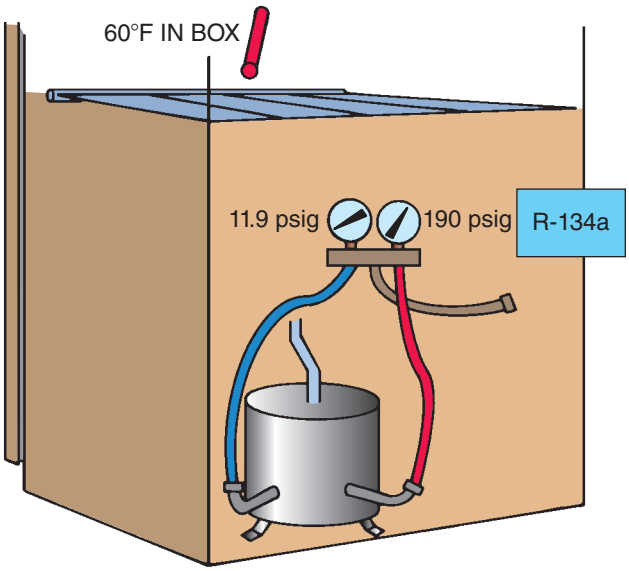

If the compressor is sweating around the suction line, there is too much refrigerant. The suction pressure will also be too high with an overcharge of refrigerant. Dirty condenser coils, defective condenser fan motors and box lights that fail to turn off can also be the cause for high operating pressures, so it is important to investigate these as well.

A technician can determine if the system is operating with a refrigeration overcharge by evaluating the evaporator superheat and condenser subcooling of the unit, just as was done in the case of the refrigerant undercharge. If a system is overcharged, the evaporator superheat will be low and the condenser subcooling will be high. Consider an R-134a domestic refrigerator that is operating with a low-side pressure of 22 psig and a high-side pressure of 171 psig. If the evaporator outlet temperature is 28°F and the condenser outlet temperature is 80°F, we have enough information to calculate the evaporator superheat and the condenser subcooling. The evaporator superheat is calculated by subtracting the evaporator saturation temperature from the evaporator outlet temperature. In this case, we get (28°F − 25°F), or 3 degrees of evaporator superheat. Low superheat is an indication that there is too much refrigerant in the low side of the system. Since low evaporator superheat indicates that the evaporator is not absorbing heat fast enough, this condition can also be caused by a faulty defrost system or a faulty evaporator fan. In either case, the amount of heat being transferred from the air in the box to the refrigerant would be reduced, causing the low superheat condition. By evaluating the condenser subcooling, the cause for system malfunction can be narrowed down.

Condenser subcooling is calculated by subtracting the condenser outlet temperature from the condenser saturation temperature. In this case, we get (120°F − 80°F), or 40 degrees of condenser subcooling. High condenser subcooling indicates that there is an excess of refrigerant on the high side of the system. Since this system has high condenser subcooling, which indicates an excess of refrigerant on the high side of the system, and low evaporator superheat, we can conclude that the system is operating with an excess of refrigerant.

FINDING AND REPAIRING REFRIGERANT LEAKS

Because domestic refrigerators and freezers typically contain only a small amount of refrigerant, even a very small amount of refrigerant lost from a household refrigerator will affect the performance of the appliance. In some instances, a low refrigerant charge that occurred in the factory may be discovered when the refrigerator is put into service, since it is very likely that the appliance will not refrigerate properly from the start. If the appliance does function when it is initially put into service, it is very unlikely that the leak occurred at the factory. In any event, refrigerant leaks should be located and repaired for both environmental and system operational reasons.

Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

REFRIGERANT LEAKS. When the box has run for some period of time and a leak occurs, it may be hard to locate in the field. Very small leaks may be found only with the best leak-detection equipment, such as electronic leak detectors, **Figure 45.111**. Many technicians prefer to move the unit to the shop and provide the customer with a temporary replacement. They can then repair the defective unit at their own pace when there is no food in it. However, removing the appliance and providing a loaner refrigerator involves a great deal of appliance transporting. A well-trained technician with a properly stocked service vehicle should be able to perform the required repairs on site.

In the event of a leak, there might not be enough refrigerant in the system to effectively leak check the unit. In this case, the system pressure must be increased by using nitrogen, **Figure 45.112**. **SAFETY PRECAUTION:** *Do not raise the pressure above the manufacturer's specified low-side working pressures. This is usually 150 psig.* **SAFETY PRECAUTION:** *Never operate the compressor on an appliance that is charged with nitrogen!* Once the leak has been located and repaired, it is important to properly leak check, evacuate, and recharge the system. *The EPA allows that a trace of system refrigerant be mixed with nitrogen for leak detection purposes. This nitrogen/refrigerant mixture can be released to the atmosphere as stated in Section 608 of the Clean Air Act of 1990.*

EVAPORATOR LEAKS. The use of a sharp tool when defrosting the unit manually may cause a leak in the evaporator. When this occurs in an aluminum evaporator, it may be repaired. Leaks in aluminum may be repaired with special solders. But soldering a puncture leak may be difficult because of location and the contraction and expansion of the evaporator. Leaks may also be repaired with the proper epoxy. Special epoxy products are available that are compatible with refrigerants.

After cleaning the surface according to the epoxy manufacturer's directions, the epoxy is applied to the hole while the unit is in a slight vacuum, about 5 in. Hg. This will pull a small amount of epoxy into the hole and form a mushroom-shaped mound on the inside of the pipe, **Figure 45.113**. The

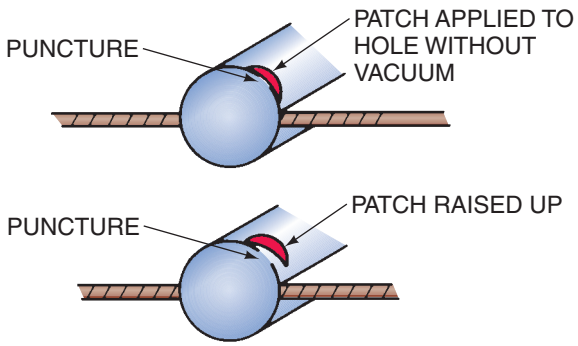
Figure 45.114 The pressure inside may push the patch off the puncture under some circumstances. This may occur during storage when the low-side pressure is high.



mound will prevent the patch from being pushed out when the refrigerator is unplugged and the low-side pressure rises to the pressure corresponding to the room temperature. However, the pressure inside a refrigerated box located outside where it may reach 100°F may rise to 124 psig for R-134a, which may be enough to push a plain patch off the hole, **Figure 45.114.** Care also should be taken not to allow too much epoxy to be drawn into the hole or a restriction may occur. Another method of fixing the leak may be to use a short sheet metal (self-tapping) screw and epoxy in the hole. The vessel must have enough room inside for the screw for this to work. After cleaning the puncture and the screw according to the epoxy manufacturer's recommendations, the epoxy is applied to the hole and the screw is tightened so that the head is snug against the hole to hold the epoxy under high pressure, **Figure 45.115.**

CONDENSER LEAKS. Refrigerator condensers are made of steel. Leaks usually do not occur in the middle of the tube, but at the end where connections are made or where a tube has vibrated against the cabinet, causing a hole. This part of the system operates under the high-pressure condition, and a small leak will lose refrigerant faster than the same size leak

Figure 45.115 A screw may be used in some cases to hold the epoxy in the puncture hole.

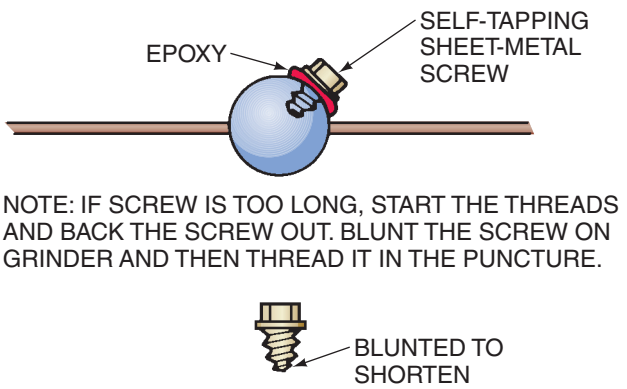


Figure 45.116 A small leak in the high-pressure side of the system will cause a greater refrigerant loss than a leak on the low-pressure side.

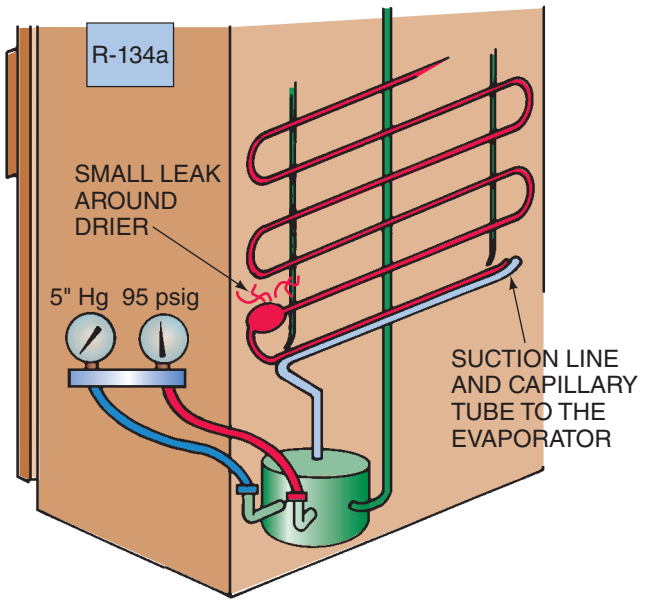

on the low-pressure side, **Figure 45.116.** Wherever the leak occurs in steel tubing, the best repair is solder. The correct solder must be used, one compatible with steel; usually it has a high silver content. When flux is used, it must be cleaned away from the connection after the repair is made. Always leak check after the repair is made. When the condenser is located under the refrigerator, it is often hard to gain access for leak repair. The box may be tilted to the side or back to do the repair, **Figure 45.117.**

Some refrigerators and freezers are manufactured as hot-wall appliances, in which the condenser is embedded in the insulation of the box cabinet. When configured this way, locating a leak in the condenser is difficult at best, since major damage can be done to the appliance cabinet. If a hot-wall condenser is suspected of leaking, the following procedure will confirm if such is indeed the case:

1. Recover refrigerant from the system.
2. Disconnect the condenser piping from the filter drier.
3. Pinch and solder closed the open ends created in step 2.
4. Remove the discharge line connection from the compressor.
5. Seal the compressor's discharge port.
6. Connect an access port to the discharge line.
7. Using dry nitrogen, pressurize the condenser through this access port to a pressure of about 200 psig to 250 psig.
8. Monitor the pressure in the condenser. A drop in pressure indicates a leak in the condenser coil.

When a condenser leak is confirmed in a hot-wall refrigerator or freezer, it is recommended that the existing condenser be abandoned and replaced with a chimney condenser located

at the back of the appliance. **SERVICE NOTE:** *If a condenser replacement is needed, be sure that it is compatible with the existing appliance.*•

COMPRESSOR CHANGEOUT

4R Compressors may be changed in a refrigerator by recovering the refrigerant charge and removing the old compressor. 4R A new compressor should be at hand before the old one is removed. This is especially important for R-134a appliances, as the oils used in conjunction with this refrigerant are hygroscopic, meaning they attract moisture, so keeping the system open too long can contaminate the appliance. An exact replacement is the best choice but may not be available. A diagram of the tube connections and the mounting should be available to help connect it correctly. Remember, several lines, including suction, discharge, suction access, and discharge access, may all be the same size, **Figure 45.118**.

Figure 45.118 A compressor may have three lines coming from the shell.

Photo by Bill Johnson

4R The best way to remove the lines from the old compressor is to recover the charge and pinch the lines off close to the compressor, **Figure 45.119**, *or cut them using a very small tubing cutter. 4R* If the old tubing is removed with a torch, the tubing ends should be cleaned using a file to remove excess solder, being careful not to allow filings to enter the system. **SAFETY PRECAUTION:** *Some of the lines may contain oil, which may flame up when the lines are separated with a torch. A fire extinguisher should always be at hand.*• The old tubes should be filed until they are clean and will slide inside the compressor fittings, **Figure 45.120**. Approved sand tape (sand tape with nonconducting abrasive) should be used to further clean the tubing ends. They must be perfectly clean with no dirty pits, **Figure 45.121**. Dirt trapped in pits will expand into the solder connection when heated, **Figure 45.122**, and cause leaks.

The new compressor should then be set in place in the compressor compartment to compare the connections on the box with those on the compressor. When certain that the

Figure 45.119 Pinch the old lines close to the compressor shell using side-cutting pliers.

Figure 45.120 The old tubing must be cleaned of all old solder; a file may be needed.

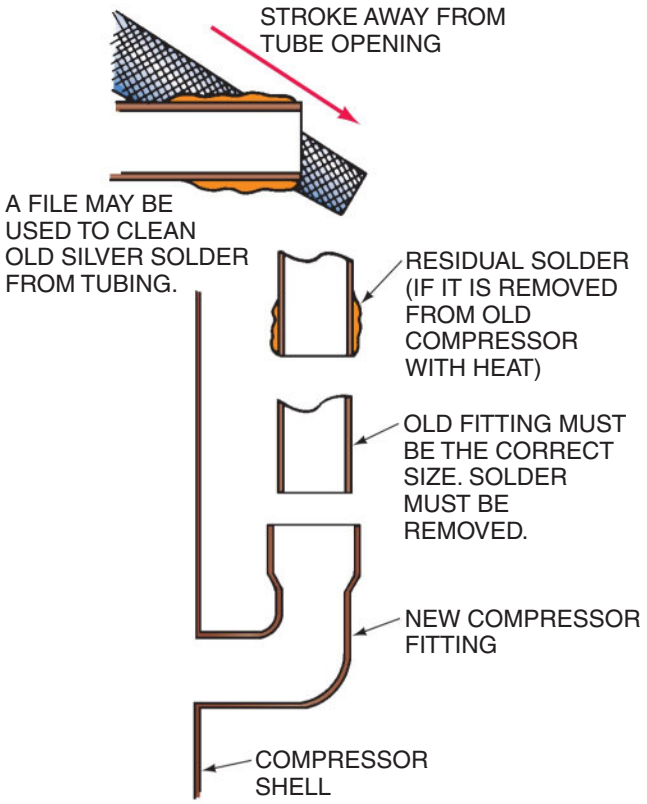

Figure 45.121 All pits in steel tubing must be cleaned.

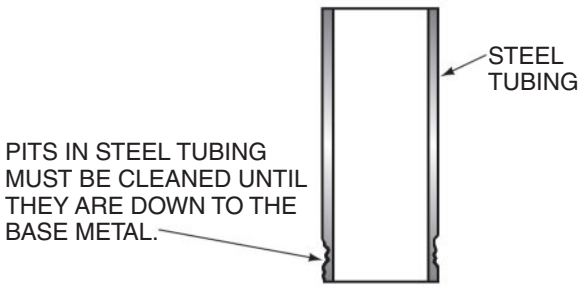

Figure 45.122 Dirt trapped in pits will expand when heated and cause leaks.

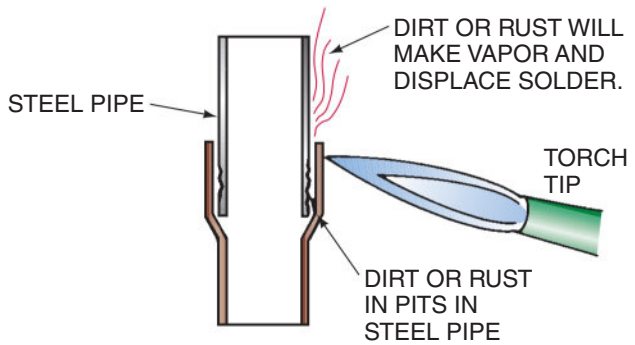

connections line up correctly, remove the new compressor from the compartment. Remove the plugs from the compressor lines and clean the tubing ends, **Figure 45.123**. **NOTE:** *Take care not to allow anything to enter the compressor lines.* Set the new compressor in place and connect all lines. Flux may be applied if this is the last time the lines are to be connected before soldering. **SAFETY PRECAUTION:** *Solder the connections carefully, being particularly careful not to overheat the surrounding parts or cabinet. A heat shield may be used to prevent the heat of the torch flame from touching the surrounding components and cabinet.* Use the minimum of heat recommended for the type of connection being made. While soldering the compressor to the lines, it is a good time to also solder process tubes to the compressor. Sometimes a "tee" fitting is soldered into the suction and discharge lines with a Schrader fitting, **Figure 45.124**.

Figure 45.123 Remove the plugs from the compressor lines and clean the tubing ends.

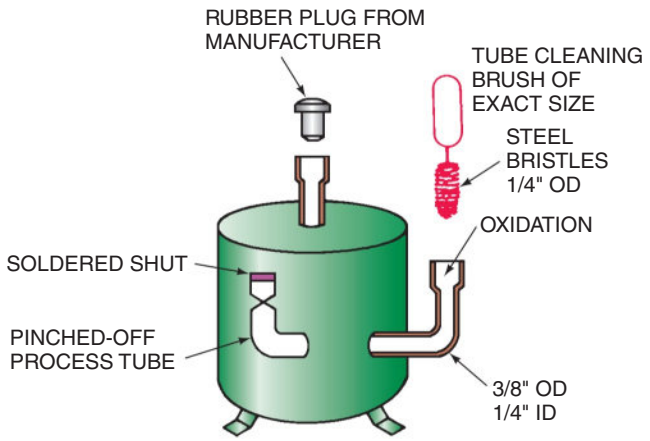

Figure 45.124 A "tee" fitting may be soldered in the suction and discharge lines for service connection while the system is open.

A filter drier should be added to a system open long enough to change a compressor. The refrigerator manufacturer may recommend using a liquid-line drier of the correct size. If an oversized liquid-line drier is used, additional refrigerant charge must be added. After the compressor is installed, it is recommended that the system first be swept with nitrogen and then the drier installed. This prevents contamination of the drier with whatever may be in the system. This sweep may be accomplished by cutting the liquid line or the suction line, wherever the drier is going to be installed. Connect the gauge manifold to the service ports and a cylinder of nitrogen. Allow vapor to flow first into the high side of the system. This will force pressure into the high side, then through the capillary tube, through the evaporator, and out the loose suction line (this example is for suction-line installation), **Figure 45.125**. The vapor will flow very slowly from the suction line because it must move through the capillary tube, but it will sweep the entire system, except the compressor, which is new.

Now open the whole system to the atmosphere by leaving the gauge valves open so that there will be no pressure buildup, **Figure 45.126**, and connect the drier. Close the gauge manifold valves immediately after completing the solder connection so that when the vapor in the system cools it will not shrink and draw air inside. When the new compressor is in place with process tubes, leak check the whole assembly at maximum low-side working pressure. Again, the low-side working pressure may be used as the upper limit for pressure testing. If a unit holds 150 psig of nitrogen pressure overnight, it is leak-free.

SYSTEM EVACUATION

When the system is proved leak-free, a vacuum may be pulled on the entire system with confidence. Unit 8, "System Evacuation," covers evacuation procedures. Briefly, removing the

Figure 45.125 Purging or sweeping a system.

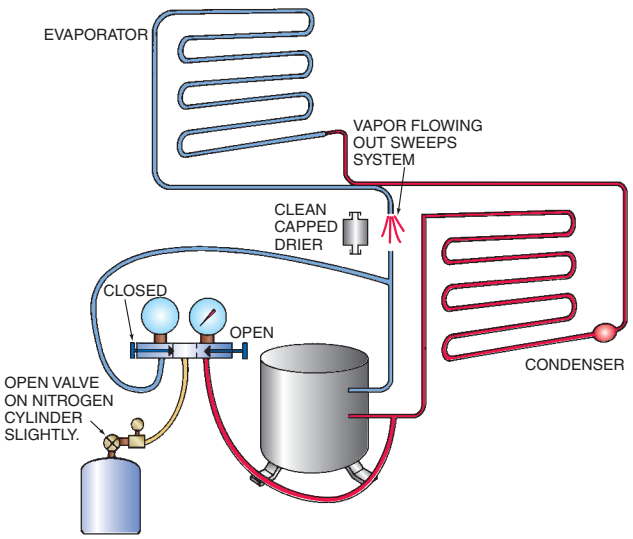

Figure 45.126 Be sure to open gauges before attempting to solder the drier in the suction line.

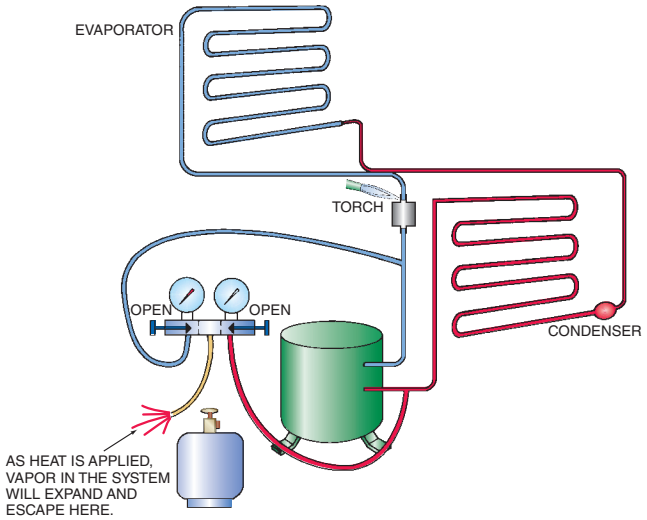

Schrader valve stem from the service stems and using gauge hoses without Schrader valve depressors will speed the vacuum. In triple evacuation, the first two vacuums may be performed and then the pressure in the system may be brought up to about 5 psig above atmospheric. The Schrader valve stems may then be installed along with Schrader valve depressors and a final evacuation performed. When a deep vacuum is achieved, the charging cylinder or accurate electronic scales may be attached and the measured charge allowed into the system.

Special evacuation procedures will be required when a system has had moisture pulled inside, because the moisture will move from the evaporator through the suction line to the compressor crankcase. When the compressor is restarted, moisture may be trapped under the oil, **Figure 45.127**. Although the triple evacuation will work to remove the moisture in a relatively short period of time, the following procedure can be used when the unit is in the shop and time is not a factor.

Install full-size gauge connections, such as "tees" in the suction and discharge lines so evacuation is from both

Figure 45.127 Moisture may be trapped under the oil in the compressor.

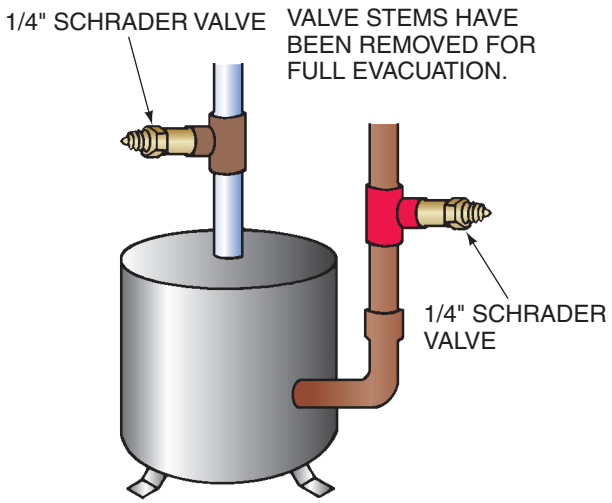
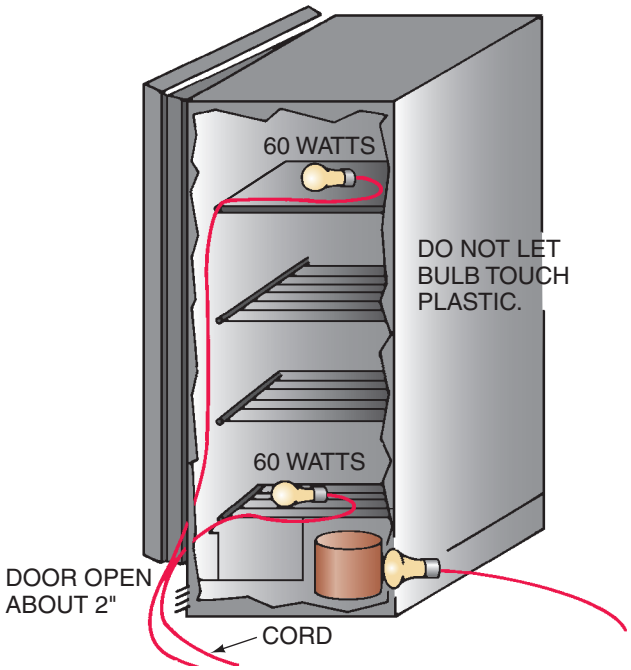
Figure 45.128 Full-size gauge connections must be installed to remove moisture.



sides of the system, **Figure 45.128.** **NOTE:** *Make sure that there are no Schrader depressors in the gauge hoses or fittings on the compressor.* Start a two-stage vacuum pump and apply heat to the compressor crankcase by placing a light bulb next to the compressor. Also place a small light bulb (about 60 W) in both the low- and medium-temperature compartments and partially shut the doors, **Figure 45.129.** **NOTE:** *Do not shut the doors all the way, or the heat will melt the plastic inside the refrigerator.* Allow the vacuum pump to run for at least 8 hours. Break the vacuum using nitrogen and pull another vacuum. This time, monitor it with an electronic vacuum gauge. When a deep vacuum has been achieved, such as 500 microns, break the vacuum with nitrogen to atmospheric pressure and remove the heat. Cut the suction line and install a suction-line filter drier. The liquid-line drier should also be replaced. Pull one more vacuum and charge the unit with a measured charge of refrigerant.

Figure 45.129 Placing light bulbs in a refrigerator to heat the refrigerant circuit but not overheat the plastic.



CAPILLARY TUBE REPAIR

Capillary tube repair may involve patching a leak in the tube because it has rubbed against some other component or the cabinet. You may need to change the drier strainer at the tube inlet, or repair may consist of clearing a partial restriction from the tube or even replacing the tube. Whatever the repair, the capillary tube must be handled with care because it is small and delicate. It can be easily pinched.

When a capillary tube must be cut for any reason, the following is recommended. Using a triangular file, cut a V-notch in the capillary tube, making certain not to cut into the bore of the tube, **Figure 45.130.** Move the file to the underside of the capillary tube and make another V-notch that lines up with the first, **Figure 45.131,** once again making certain not to cut into the bore. Hold the capillary tube with one hand on each side of the notch and gently bend the tube back and forth. The capillary tube will break at the notch and no filings will have entered the tube. **NOTE:** *The full dimension of the inside diameter of the tube must be maintained or it will cause a restriction. Proper care at this time cannot be overemphasized.*

When it is necessary to solder a capillary tube into a fitting, such as into the end of a new strainer, do not apply flux or clean the tube all the way to the end. Allow the outside of the end of the tube to remain dirty because the solder will not flow over the end of the tube if it is not cleaned, **Figure 45.132.** A capillary tube that is broken in two may usually be repaired by cleaning both ends so that the inside dimension is maintained and then pieced together with tubing one size larger, **Figure 45.133.** When a capillary tube has a rub hole in it, it is recommended that the tube be cut in two at this point and repaired as a broken tube.

Figure 45.130 Using a triangular file, cut a V-notch in the capillary tube.

Figure 45.131 By placing the file under the notched capillary tube, another notch is made on the other side of the tube.

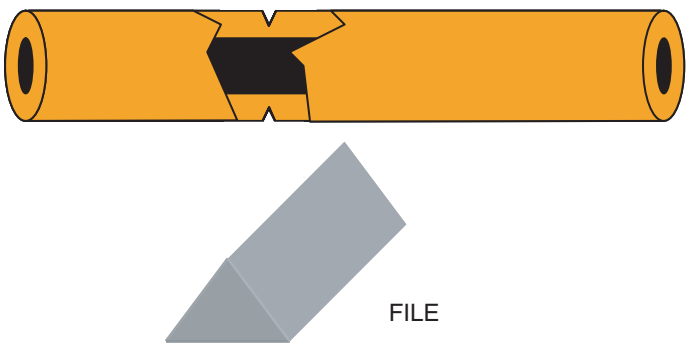

Figure 45.132 Application of flux to a capillary tube to prevent solder from entering the tube.

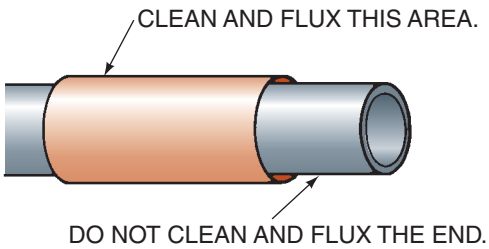

The capillary tube may be changed in some instances, but usually it is not economical because it is fastened to the suction line for a heat exchange between the capillary tube and the suction line. This connection can never be duplicated exactly, but a repair may come very close by insulating the suction line along with the capillary tube under the insulation, **Figure 45.134.**

Figure 45.133 Repairing a broken capillary tube.

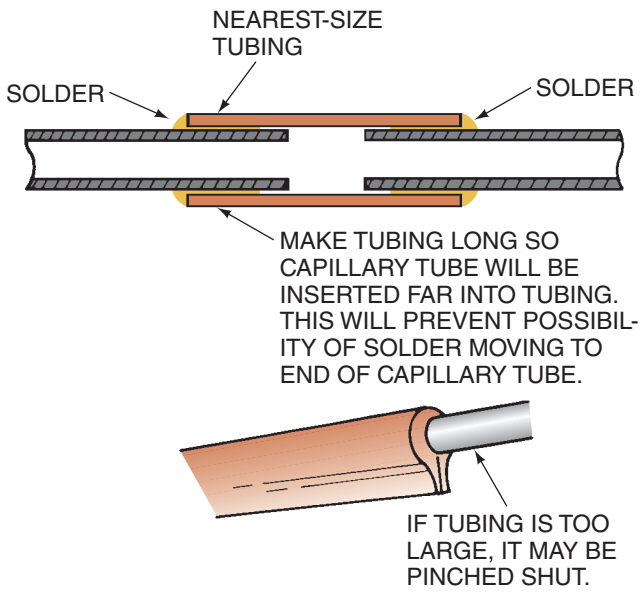

Figure 45.134 The capillary tube may pass close to the suction line under insulation to get some heat exchange.

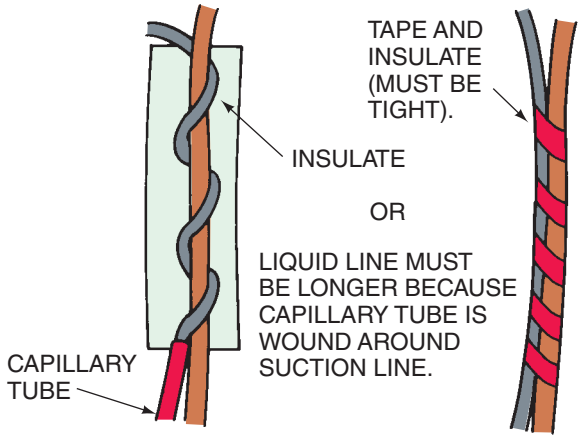

COMPRESSOR PUMPING CAPACITY

One of the most difficult problems to diagnose is a compressor that is pumping to partial capacity. The customer may complain that the unit is running all the time. It may still have enough capacity to maintain the food compartments at reasonable temperatures, but one of the first signs that the compartment temperature is not being maintained is that previously hard ice cream will be slightly soft. Liquids such as water or milk served from the fresh-food compartment also may not seem as cool. When the conditions of running all the time and not maintaining temperature are noticed, either the refrigerator has a false load or the compressor is not operating to capacity. The technician may have to decide which.

First, make sure all door gaskets are in good condition and that the doors shut tight. Then make sure there is no extra load, such as hot food being put in the refrigerator too often, **Figure 45.135**. The light bulb may be on all the time in one of the compartments. Make sure that the condenser has the proper airflow, with all baffles in place for forced draft, **Figure 45.136**, and not under a cabinet if the condenser is natural draft. Make sure that the unit is not in a location that is too hot for its capacity. Any temperature greater than 100°F will usually cause the unit to run all the time, but even so it should maintain conditions. A unit located outside, particularly where it is affected by the sun, will always be a problem because it is not designed to be outside. Another possibility is that the defrost contacts are welded closed, so the appliance is trying to defrost the evaporator and cool the box at the same time. When all of this has been checked and everything proves satisfactory, then suspect the compressor.

Loss of compressor pumping capacity can be caused by poor operating conditions. For example, if the box has been

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 45.135 Extra load on a refrigerator may be caused by defective gaskets, hot food placed in the box too often, or a light bulb burning all the time.

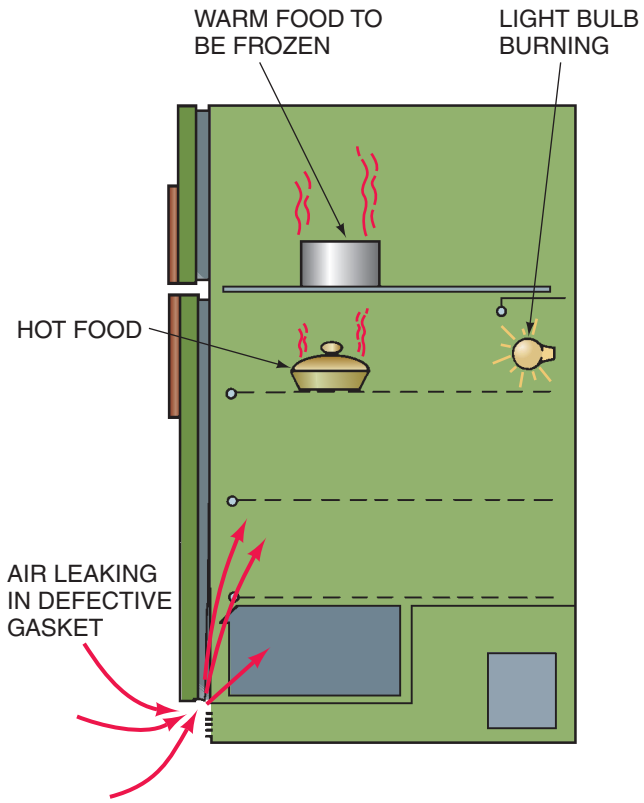

Figure 45.136 Make sure that all baffles are in place in the condenser area for correct airflow.

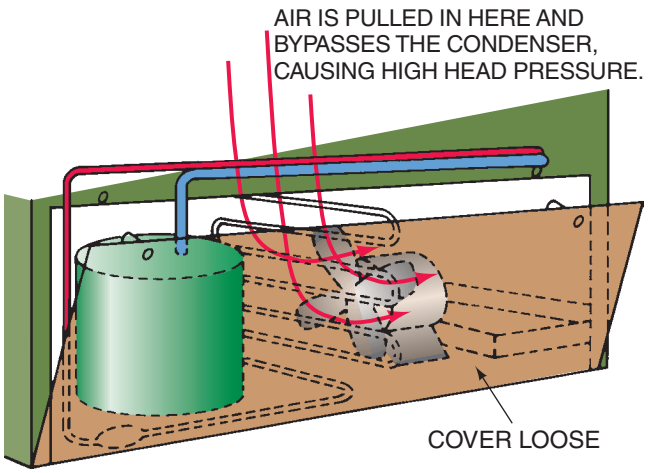

operating with an extremely high head pressure due to a dirty condenser or an inoperable condenser fan motor or if it has been operating in a very hot location for a long time, the compressor valves could be leaking due to valve wear. When this happens, the compressor does not pump the correct quantity of refrigerant gas and a loss of capacity occurs. Before even thinking about compressor capacity loss, always make sure that the condenser is clean and that both types of condensers have unobstructed airflow. The condenser must be able to dissipate the heat, or capacity loss is ensured. Induced-draft condensers must have all cardboard partitions in place, or air may recirculate across the condenser and cause overheating.

After operating conditions are checked, gauges should be fastened to the system to check the suction and discharge pressures. Do not forget to let the pressures equalize before attaching the gauges. If it is available, use the manufacturer's literature to check the performance, or call the distributor of the product or another technician who may have had considerable experience with the type of appliance. Declaring a compressor defective is a big decision, especially for a new technician, so it may often be best to get a second opinion from an experienced technician.

HVAC GOLDEN RULES

When making a service call to a residence:

- Make and keep firm appointments. Call ahead if you are delayed. The customer's time is valuable also.
- Keep customers informed if you must leave the job for parts or other reasons. Customers should not be upset when you inform them of your return schedule if it is reasonable.

Added Value to the Customer

Here are some simple, inexpensive procedures that may be included in the basic service call:

- Clean the condenser.
- Make sure that the condenser fan is turning freely (if applicable).
- Check the refrigerator light and replace it if needed.
- Make sure the evaporator coil has no ice buildup.
- Make sure the box is level.

45.11 SERVICE TECHNICIAN CALLS

SERVICE CALL 1

A customer calls and tells the dispatcher that a new refrigerator is sweating on the outside of the cabinet between the side-by-side doors. *The problem is a defective connection at the back of the refrigerator in a mullion heater circuit.*

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Arriving at the job, the technician makes certain to park in the street, not in the customer's driveway. When the customer opens the door, the technician shakes hands and greets the customer by name. Explaining to the technician that the appliance is new, the customer is a little upset that it is not working as expected. The technician apologizes for the inconvenience and assures the homeowner that he would do whatever he could to remedy the problem.

Making his way to the refrigerator, the technician lays down a drop cloth on which he places his toolbox. He can see right away that a mullion heater is not heating. The house temperature and humidity are normal because the house has central air-conditioning. The technician dreads pulling the panels off to get to the heater between the doors if it is defective because this is a difficult, time-consuming job. In addition, the appliance is brand new and the technician does not want to void the warranty. A look at the diagram on the back of the refrigerator reveals a junction box at the back corner of the unit where the mullion heater wires are connected before running on to the front. He unplugs the refrigerator and locates the junction box and the heater wires. The connection seems loose, but the technician wants to be sure, so he takes the connection apart. An ohm check of the heater circuit proves the heater has a complete circuit. He reconnects the wires in a secure manner, plugs in and starts the refrigerator, and checks the power at the connection. Power is available from the neutral wire to the hot wire going to the heater. To make sure, the technician takes an amperage reading of the heat circuit and determines that current is flowing and feels confident the problem has been corrected.

The technician explains the situation to the customer and informs him that it is very possible that the wiring came loose during the shipping process. Before leaving the home, the technician explains some of the energy-saving features on the appliance.

SERVICE CALL 2

A homeowner who lives in a rural area calls. This customer had recently purchased a freezer and placed in it an entire butchered, quick-frozen steer. *The problem is that the condenser fan motor has failed, and the freezer compressor is running all the time. The food is still frozen hard, but the temperature is beginning to rise.*

Before arriving at the job, the technician verifies with his office that the appliance is new and still under warranty. When the customer answers the door, the technician introduces himself and presents the company's business card. The customer explains that the freezer is not working as expected. The technician apologizes for the inconvenience as the customer brings him over to the unit.

The technician notices right away that the condenser fan is not running. The thermometer in the box reads 15°F. No time can be wasted. After the unit is unplugged, the box is moved away from the wall to give access to the fan motor. The fan motor turns freely, so the technician removes one motor lead and performs an ohm check. The motor has an open circuit through the windings, **Figure 45.137**. The technician does not have a new motor with him and he must go get one. He asks the customer whether a floor fan is available that may be used to cool the condenser until he can obtain a new fan motor. She has one, so the technician places the fan where it can blow over the condenser coil and plugs it in, **Figure 45.138**. The fan is allowed to operate for a while to remove some of the excess heat from the condenser. Then the freezer is plugged in, and the compressor starts. The technician leaves to get the new fan motor.

When the technician returns to the job about 3 hours later, the freezer is still running. The thermometer inside reads 1°F, so the freezer temperature is going down. Unplugging the freezer, the technician replaces the fan motor, reinstalls all panels with the proper fasteners, and plugs the freezer in. The compressor and the new condenser fan start. The technician pushes the freezer back against the wall and cleans up any scuff marks on the floor left by the appliance. The technician once again apologizes for the problem and thanks the customer for choosing his company for service.

Figure 45.137 A motor with an open circuit through the windings.

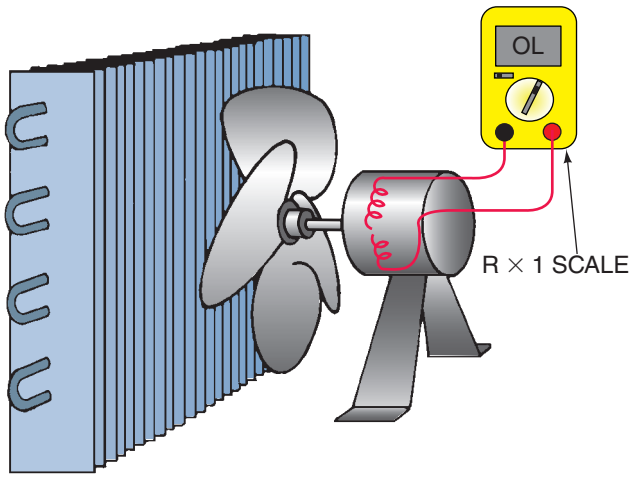

Figure 45.138 A fan placed where it can temporarily pass air over the condenser.

SERVICE CALL 3

A customer calls to report that the freezer is running all the time. *The problem is that this freezer has a vertical condenser on the back and it is covered with lint. The freezer is located in the laundry room. It is summer, and the laundry room is hot from the summer heat and the clothes drier.*

When the technician arrives at the job, he notices that his work shirt is soiled from his previous job. He changes into a spare, clean shirt he keeps in his truck before approaching the customer's house. Ringing the bell, he steps back and waits for the customer to answer. The customer is very happy that the technician has arrived so quickly. She leads the technician inside, shows him to the freezer, and explains the problem.

The technician checks the temperature of the box with a thermometer. It is already evident that the box is not cold enough because the ice cream is not hard. The technician places the temperature probe between two packages and closes the door. In about 5 min the instrument shows 14°F. While the temperature of the probe was pulling down, the technician had a look at the surroundings. It is evident that the condenser is dirty and the room is hot, **Figure 45.139.** He pulls the freezer out from the wall and uses a vacuum cleaner brush to remove the lint from the condenser. The technician then slides the box back to the wall.

The technician can do no more and gives the owner the following directions: "Do not dry any more clothes until the next morning." The customer purchases a small, dial-type thermometer, and places it in the food compartment. The technician calls the next morning to ask what the temperature indication is. It is −5°F, so the box is working fine. He also instructs the customer how to slide the unit from the wall and clean the condenser coil periodically and suggests that the freezer be relocated so that it is not in the same room as the washer and dryer.

SERVICE CALL 4

A customer calls to report that the refrigerator in the lunchroom is not cooling correctly. It is running all the time and the box does not seem cool enough. *The problem is that the defrost timer motor is burned out and will not advance the timer into defrost. The evaporator is frozen solid.*

When the technician arrives he opens the freezing compartment inside the top door. He hears the evaporator fan running but can feel no air coming out of the vents. A package of ice cream is soft, indicating the compartment is not cold enough. The technician removes the cover to the evaporator and finds it frozen, a sure sign of lack of defrost.

Shutting the compartment door, the technician pulls the box from the wall. The timer is in the back and has a small window for observing rotation of the timer motor. It can be seen that the timer is not turning. A voltage check of the timer terminals shows voltage to the timer motor. The winding is checked for continuity; it is open and defective.

The technician opens the refrigerator door and removes the food, placing it in another box nearby. He locates a small fan in such a manner as to blow room air into the box for rapid defrost, **Figure 45.140,** and asks the customer to put towels on the floor to absorb the water that will drip as the frost begins to melt. The manager is informed of the problem and the cost for repair. Once the repair cost is approved, the technician informs the manager that since it will take a couple of hours to melt the ice, he is going to make another service call on the way to the supply house for a defrost timer.

On returning, the technician replaces the defrost timer. The evaporator is thawed, but the pan underneath the unit is full and must be emptied. After it is emptied, the pan is cleaned, sanitized, and replaced; the evaporator cover is replaced, and the unit is started. The coil begins to cool. Since it will take some time for the box to cool down to the

Figure 45.139 A dirty chimney-type condenser.

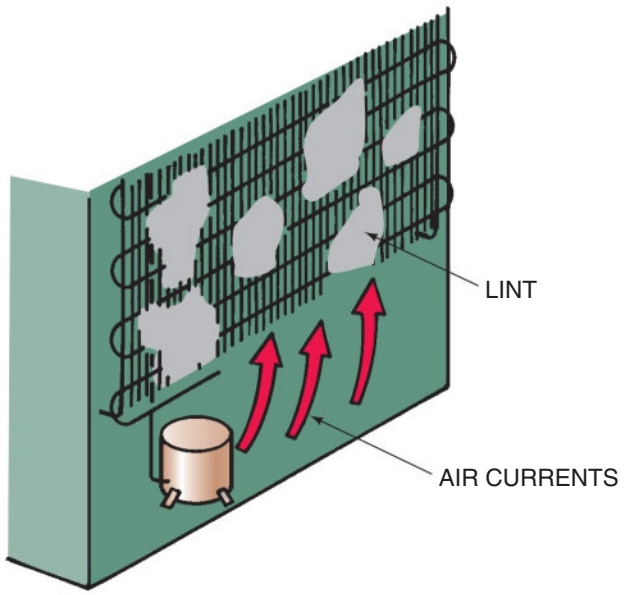

Figure 45.140 A room fan may be used for rapid defrost.

desired temperature, the technician recommends that the food be left in the other box until the next day.

Upon determining that the timer motor was defective, the technician could have simply replaced the timer and brought the system into defrost without having to manually defrost the evaporator. In addition, the motors on mechanical defrost timers rarely go bad due to the extremely low power consumption of the motor. The main reason for mechanical defrost timer failure is the jamming of the plastic gears within the timer.

SERVICE CALL 5

A homeowner reports that the refrigerator is running all the time and not shutting off. *The problem is that the door gaskets are defective and the door is out of alignment. The customer has four children.*

The customer explains the problem to the technician when he arrives and introduces himself. The technician can easily see the problem when he opens the refrigerator door. The gaskets are badly worn and daylight is visible under the door when looking from the side. The technician writes down the model number of the refrigerator and tells the owner the cost of the repair and that a trip to the supply house will have to be made to get the right gaskets. Since the supply house is about 2 hours away, they agree that the repair would be completed the next day.

The technician returns to the job with the new gaskets and replaces them following the manufacturer's recommendations. The door does not close tightly at the bottom, so the technician removes the internal shelving and adjusts the brackets in the door so that it hangs straight. Although he cannot be certain, the technician assumes that the children might have been constantly opening and closing the door or, even worse, have been swinging on the door, which would take it out of alignment. In a very professional manner, the technician informs the customer that improper use of the appliance can result in damage to the appliance or even personal injury. The technician completes his paperwork, obtains payment for the repair, and leaves for his next service call.

SERVICE CALL 6

A customer calls to say that his freezer shocked him when he touched it and the water heater located beside it at the same time. *The problem is that the freezer has a slight ground circuit due to moisture behind the box. The house is old and only has two-pronged wall outlets.* These are ungrounded, and an adapter has been used to plug the freezer into the wall outlet. The water heater is wired straight to the electrical panel, where it is grounded. The customer is advised not to touch the box. It cannot be unplugged or loss of food may result.

The technician listens attentively as the customer informs him of the situation with the appliance. He thanks the homeowner for the information and asks to be shown to the freezer. The technician uses a volt-ohmmeter to check the voltage between the freezer and water heater, duplicating the customer's experience, **Figure 45.141.** The voltmeter indicates 115 V. This could be a dangerous situation. The technician removes the fuse to the freezer circuit and pulls the freezer away from the wall. When it is unplugged, the technician discovers at least half of the problem—a two-prong plug. If the unit were connected through a three-prong plug and grounded, the ground would have flowed through the green ground wire.

The technician then fastens one lead of the ohmmeter to the hot plug and the other to the ground (green) plug for the freezer. He measures 25,000 ohms between the hot wire and the cabinet, **Figure 45.142.** If the cabinet had been properly grounded, the current flow through this circuit would have blown the fuse and would have flowed to the ground through the green ground wire, **Figure 45.143.** The technician must now find the circuit. The compressor is disconnected while the meter is still connected; the reading remains the same, **Figure 45.144**.

The technician eliminates the circuits one at a time, until he discovers that the junction box at the bottom of the unit is damp due to water dripping from a very slight leak in a water heater valve. The technician tightens the valve packing gland and the leak stops. A hair drier is used to dry the junction box, and the ground is eliminated. The technician has a talk with the homeowner about the circuit and the danger involved.

Before the technician leaves, an electrician is called to properly ground this circuit and several more that have the same potential problem. The technician has done all that can be expected. It would not have been acceptable to leave the job without knowing an electrician was already coming to make the system safe.

NOTE: *Typically, when there is a shock problem the very first thing to check is a short-to-ground in the compressor. If not that, the next most common cause is, oddly enough, that the appliance insulation got saturated over time. This is usually because the owner turned off the mullion heater trying to save energy and the wet insulation shorts out a wiring harness embedded in the walls.*

SERVICE CALL 7

A customer reports that beef frozen two weeks ago has no flavor, is dry, and seems to be tough. *The problem is that this is a new freezer—and was sold to a person with no experience in freezing food. The customer bought a fresh side of beef and took it home to freeze it in the new freezer. Ordinarily, the technician would not get involved in this problem, but the customer is an old one and relations must be maintained.*

The night before his call, the technician asks the customer to thaw a steak overnight so that it can be checked in the morning. When he arrives, the technician sees a puddle of water and blood under the steak and begins to ask questions. The customer explains how the meat was frozen. She picked it up at a packing house and made three stops before getting it home; the weather was hot. The packing-house clerk tried to get her to let the packing house to freeze the

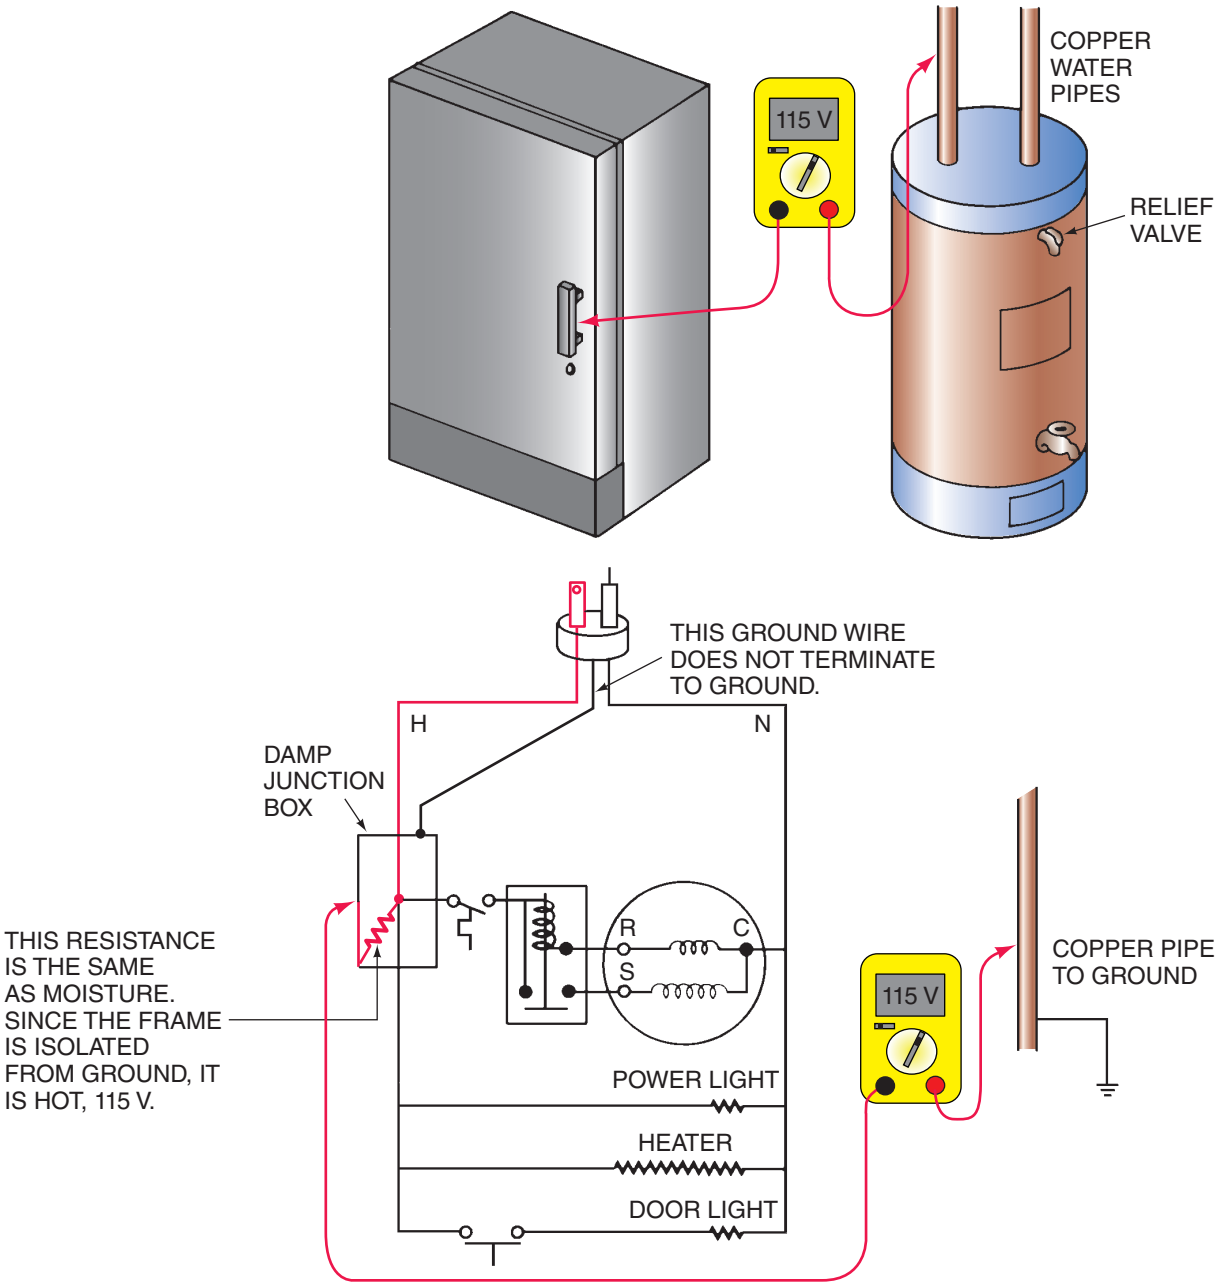
Figure 45.141 To determine the cause of the shock, a meter is being substituted for a person in the circuit.



meat, but she thought of her own new freezer and felt that it would do a better job.

The whole side of beef was put in the freezer at one time, about 200 lb, packaged in small parcels. The technician asks to see the owner's manual. In the manual, it plainly states that the capacity of this 15 ft^3 freezer is 40 lb. The customer therefore has a freezer full of meat that will not be of the best quality. This is partly the salesperson's fault for not explaining the capabilities of the freezer. The technician goes over the manual with the owner.

SERVICE CALL 8

A customer reports that the refrigerator is running all the time. It is cool but never shuts off. This refrigerator is under warranty. *The problem is that a piece of frozen food has fallen and knocked the door light switch plunger off, causing the light in the freezer to stay on all the time. This is enough increased load to keep the compressor continuously.*

The customer informs the technician of the problem when he arrives. After looking the refrigerator over, the

Figure 45.142 A resistance of 25,000 Ω is measured between the hot wire and the cabinet.

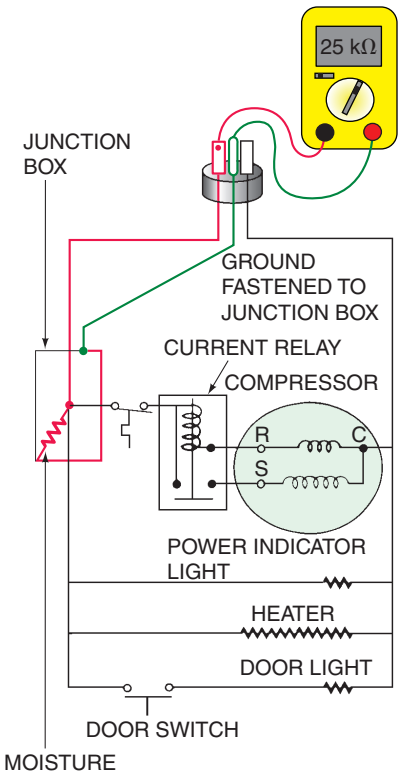

Figure 45.143 If this circuit had been properly grounded, a fuse might have blown.

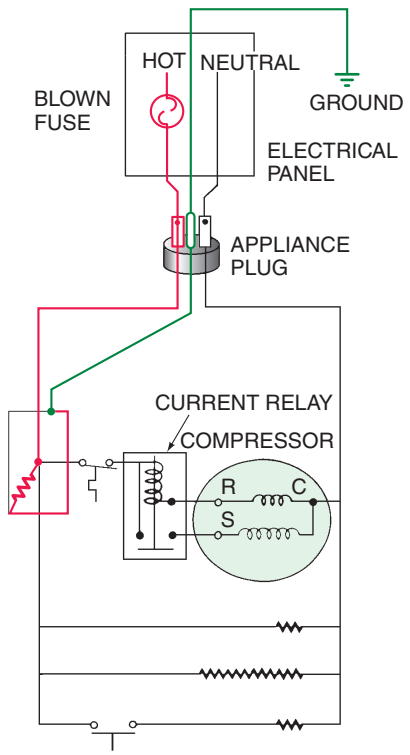

Figure 45.144 When the compressor is disconnected, the ground circuit is still present.

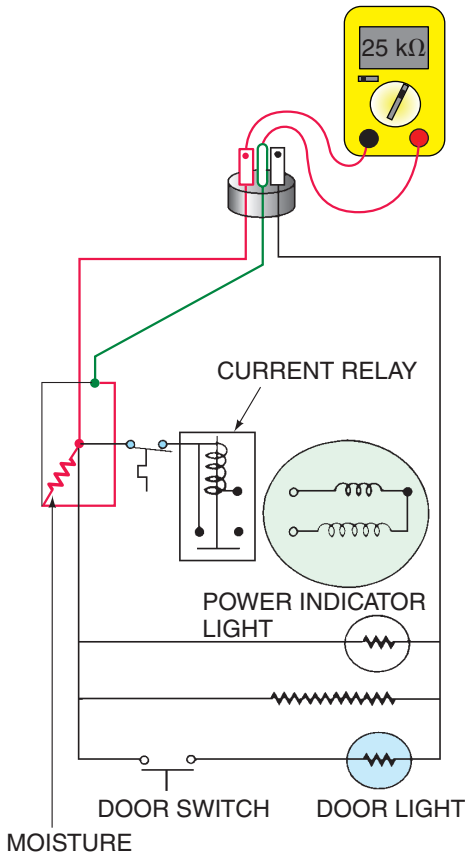

technician does not see any frost buildup on the evaporator. He questions the owner about placing hot food in the refrigerator or leaving the door open. This does not seem to be the problem. The customer says the refrigerator is always running. It should be cycling off in the morning, no matter how much load it has.

It seems like the compressor is not pumping, or maybe there is an additional load on it. The unit has electric defrost, and the evaporator coil seems to be clean of frost. The technician opens the freezer door and notices that the light switch in the freezer is missing the plunger that touches the door when it is closed, **Figure 45.145.** The light is staying on all the time.

The technician informs the customer that a switch will have to be ordered from the manufacturer. Until a switch can be obtained, the light bulb in the freezer is removed. The technician returns the next day with a switch and replaces it. The owner tells the technician that the refrigerator was not running at breakfast time, so the diagnosis was good.

SERVICE CALL 9

An apartment-house tenant has an old refrigerator that must be defrosted manually. The ice was not melting fast enough so the tenant used an ice pick, which punctured the evaporator. She heard the hiss of the refrigerant leaking out but decided to continue anyway. *The problem is that the refrigerant leaked out, and when the refrigerator was restarted, water was pulled into the system.* (Without refrigerant the low-pressure side of the system will pull into a vacuum.) When the refrigerator would not cool, the tenant called the management office. This would normally be a throwaway situation, but the apartment house has 200 refrigerators like this one and a repair shop.

The technician takes a replacement refrigerator along after reading the service ticket. This has happened many times—so many that a definite procedure has been established. The food is transferred to the replacement box and the other one is trucked to the shop in the basement.

The technician solders two process tubes into the system, one in the suction line and the other in the discharge line, **Figure 45.146.** Pressure is added to the circuit using nitrogen, and the leak is located. It is in the evaporator plate, so the repair procedure will be to patch with epoxy. The technician allows the nitrogen pressure to escape from the system, and cleans the puncture with a nonconductive sand tape. He uses a solvent recommended by the epoxy manufacturer to remove all dirt and grease from the puncture area and then connects a vacuum pump to the service ports. **NOTE:** *The service ports have no Schrader valve plungers and the gauge hoses have no Schrader valve depressors; they have been removed for the time being.*

The technician starts up the vacuum pump and allows it to run until 5 in. Hg is registered on the suction compound gauge and then valves off the gauges. Then mixing the epoxy (remember, this is a two-part mixture and it must be used very fast or it will harden, usually within 5 min), he spreads some over the puncture hole. The vacuum pulls a small amount into the hole to form the mushroom shape mentioned earlier in the text, **Figure 45.147.** The vacuum pulls a hole through the center of the epoxy patch, causing more epoxy to spread over the hole. The epoxy is now becoming solid. The gauges are opened to the atmosphere to equalize the pressure on each side of the patch, and the epoxy is allowed to dry.

The epoxy is allowed to dry for several hours; meanwhile, other service tasks are performed. Nitrogen is used to pressure the system to 100 psig. The epoxy patch is checked for a leak using soap bubbles. The service stems are also checked for leaks, and there are none. The tricky part of the service procedure comes next. This technician knows the procedure well and knows from experience that a step must not be skipped.

The pressure is allowed to escape from the system, and the vacuum pump is started without stems or depressors in the Schrader fittings. This allows the gauge hose to operate at full bore. A 60-W bulb is placed in the freezer compartment and one in the fresh-food compartment. **SAFETY PRECAUTION:** *The doors are shut only partially.* A 150-W bulb is placed so that it touches the compressor crankcase, **Figure 45.148.** None of these bulbs should ever be in contact with plastic because it will melt. As part of the triple evacuation process, once the first vacuum has been reached, the technician breaks the vacuum to about 2 psig pressure using nitrogen and disconnects the vacuum pump.

Figure 45.146 Process tubes soldered into the suction and discharge lines offer the best service access.

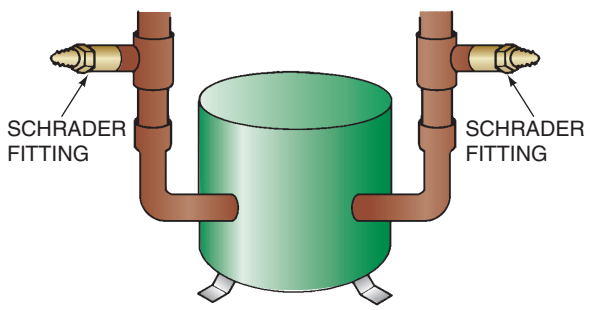

Figure 45.147 The vacuum is used to pull a small amount of epoxy into the evaporator puncture.

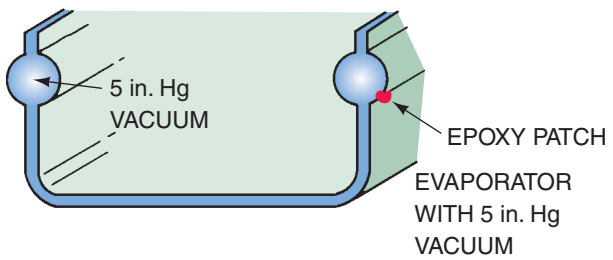
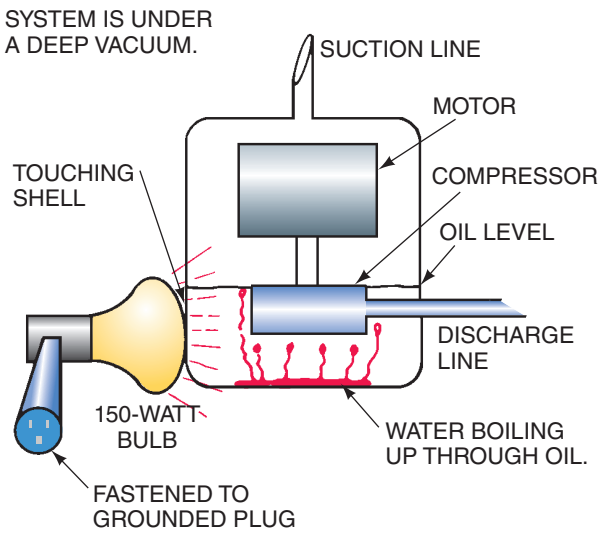


Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 45.148 Heat is applied to the compressor to boil any moisture from under the oil.



The vacuum pump is removed to the workbench and the oil is replaced. The vacuum pump is now started and allowed to run until the second stage of the the evacuation is completed. Once the vacuum level has been reached again, the vacuum is again broken to about 5 psig using nitrogen. The gauge hoses are removed one at a time, and the Schrader valve stems and depressors are added back to the gauge hoses.

A suction-line filter drier is installed in the suction line and the system is pressured back to 100 psig using nitrogen to leak check the drier connection. This may seem like a long procedure, but the service technician has tried shortcuts before, and they do not work. The most obvious one would be to cut the drier into the circuit at the beginning, but it would become contaminated before the refrigerator is started if cut into a wet system. The liquid-line drier should be changed at this time, as it has become saturated. It has been partially reactivated with the evacuation, but changing it will ensure that all moisture is removed. The vacuum pump is started for the third and final evacuation and allowed to run until the required vacuum is reached and maintained as determined by a micron gauge. During these waiting periods, the technician may have other service duties to perform.

The high-side line is pinched off and soldered shut; the refrigerant is charged into the system (see Unit 10, "System Charging"). The refrigerator is started to pull the last of the charge into the system. The suction line is disconnected and a cap is placed on the Schrader valve. The discharge line port is soldered shut so the next time a gauge reading is needed, a suction-line port is available, but no discharge port. This is common; there is less chance of a leak under the low-side pressure than under the high-side pressure.

SERVICE CALL 10

A customer who has been on vacation calls. While the family was gone, the freezer had warmed and thawed. *The problem is that a compressor wire has been damaged.*

The technician arrives with a helper. It is obvious that the freezer will have to be moved. They unload it and dispose of the spoiled food. After that, the technician and helper move the freezer to the carport. They wash the box with ammonia and water, several times, and leave the door open to allow the sun to shine in.

Now the technician starts to investigate the problem. When the box is plugged in, the compressor does not start. A close examination shows that the common wire going to the compressor has been hot, **Figure 45.149.** The box is unplugged and after being examined more closely, the wire is found to be burned in two in the junction box. The wire is replaced with the proper connectors and the correct wire size. The box is plugged in again and the compressor starts. The technician can hear refrigerant circulating and feels that the box is now in good working order.

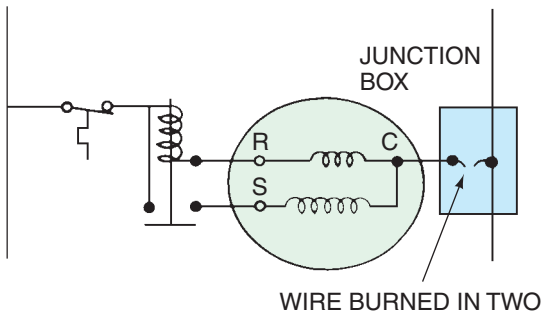
This box smells so bad that the technician advises the homeowner to try the following to remove the smell:

- Leave the box open for several days.
- Then close it and place some activated charcoal, furnished by the technician, inside and start the box.
- If odor is still present, spread several pans of ground coffee inside the box and leave the freezer running for several more days.
- Then wash the freezer inside with warm soda water—about a small package to a gallon of water—and let it run with more coffee grounds inside, for several days. If this does not remove the odor, the box may need replacing. This seems like a long procedure, but a new freezer is expensive and the old one should be saved if possible.

SERVICE CALL 11

A customer calls indicating that the freezer is not running and is making a clicking sound from time to time. *The problem is that the customer has added some appliances to the circuit*

Figure 45.149 The insulation and wire are burned.



Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

and the voltage is low. A small 115-V electric heater has been added to the mother-in-law's bedroom, and she is operating it all the time. The voltage is only 95 V at the wall outlet while the heater is operating. This is not enough voltage to start the freezer compressor. The homeowner has an old system with fuses and has replaced the 15-A fuse with a 20-A fuse. The owner is advised to shut the freezer off until the technician arrives and to keep the door to the freezer shut.

When the technician arrives, the homeowner tells him about the clicking sound and that the freezer is not running. As the customer had implied, the compressor is not operating. The technician places a temperature probe between two packages; after about 5 min., the temperature reads 15°F. There is no time to spare. The technician decides to check the amperage and the voltage at start-up. He fastens an ammeter around the common compressor wire and plugs a voltmeter into the other plug in the wall outlet. The voltage is 105 V; this is low to begin with, **Figure 45.150**. The technician plugs the box in and watches the voltmeter and the ammeter. The compressor does not start and the voltage drops to 95 V, so he unplugs the freezer before it trips the overload, **Figure 45.151.** It is time to look further into the house circuits.

The technician asks the owner whether any additional load has been added to the house; she mentions the heater in the mother-in-law's room, which turns out to be a 1500-W heater. By itself it should draw 13 A (Watts = Amperes × Volt;

Figure 45.150 There are only 105 V in the circuit before the freezer is plugged in. The freezer will be an additional load on the circuit.

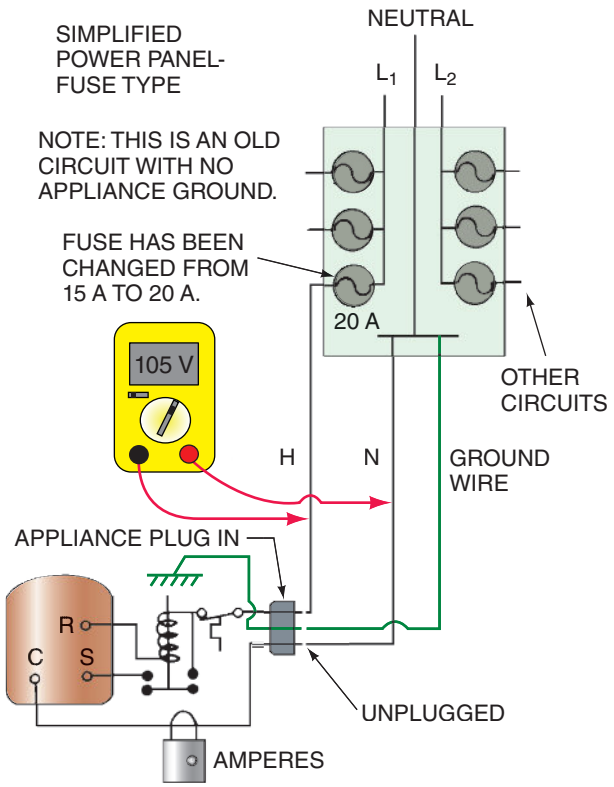


Figure 45.151 When the unit is plugged in, the voltage drops to 95 V and the compressor will not start.

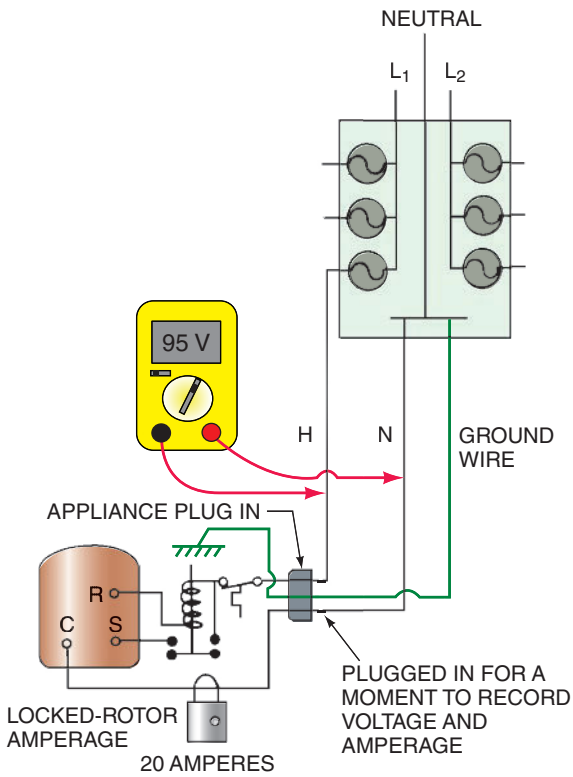

solved for amperes, this would be Amperes = Watts divided by Volts, or Watts = 1500 divided by 115 = 13 A). However, the house has only 110 V at the main, so 1500 W divided by 110 V = 13.6 A for the heater under these circumstances, **Figure 45.152.** The fuse being used on this circuit is a 20-A fuse. The rest of the circuits with the same wire size have 15-A fuses. A voltage check at the main electrical panel shows 110 V. With just the electric heater operating, the circuit is losing 5 V.

The technician unplugs the electric heater and measures the voltage at the freezer outlet; it is 110 V. Obviously, the electric heater must be moved to another circuit, a circuit by itself, and a smaller heater would be a better choice. Upon examining the heater, the technician discovers that it can be operated in a lower mode that consumes 1000 W, which should be enough heat for the small room. It would pull 9.1 A (1000 W divided by 110 V = 9.1 A). Every little bit of savings helps—this place is operating at near maximum capacity.

The heater is plugged into another circuit at the lower output, 1000 W. Then the freezer is plugged in and it starts; while it is running the voltage is 105 V, **Figure 45.153.** This is slightly above the −10% allowed for the motor voltage. The rated voltage is 115 V; 115 × 0.10 = 11.5. The rated voltage of 115 V minus 11.5 V is 103.5 V, which is the minimum voltage that can be used. Before, when the freezer and the heater were on the circuit at the same time, the freezer would not start.

The technician replaces the 20-A fuse with a 15-A fuse and advises the owner that an electrician should be consulted to rework the electrical system in the house. The owner did not realize the circuits were operating at near capacity.

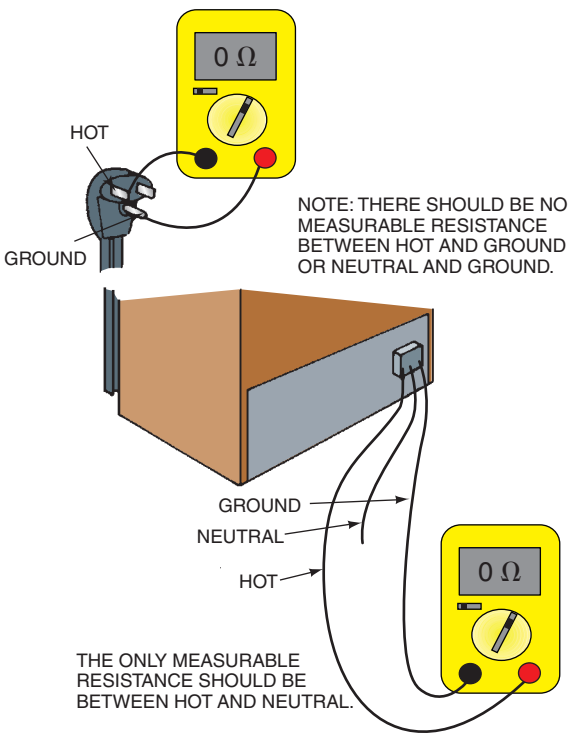
SERVICE CALL 12

A customer reports that the refrigerator has shut off; it tripped a breaker. When he tried to reset the breaker, it tripped again. The dispatcher advises the customer to unplug the refrigerator and reset the breaker because there may be something else on the circuit that he may need. *The problem is that the compressor motor is grounded and tripping the breaker.*

The technician takes with him a helper, a refrigerator to loan the customer, and a hand truck. He suspects a bad electrical problem. This unit is under warranty and will be moved to the shop if the problem is complicated.

The technician introduces himself and his helper to the customer and informs him that a loaner refrigerator is on the truck should it be needed. The customer thanks the technician for thinking of this and shows him where the unit is. Using an ohmmeter at the power cord, the technician checks for a ground. He reads 0 ohms, indicating a short circuit, when he touches one meter lead to the line prong on the plug and the other to the ground prong on the plug, **Figure 45.154**.

Figure 45.154 Checking the unit for a grounded circuit using the appliance plug.



The refrigerator is moved away from the wall to see whether the ground can be located. It could be in the power cord and, if so, it could be repaired on the spot. Removing the leads from the compressor, the compressor terminals are checked with one lead on a compressor terminal and the other on the cabinet or one of the refrigerant lines. The compressor shows 0 Ω to ground, **Figure 45.155.** It has internal problems and must be changed.

The technician and the helper move the refrigerator to the middle of the kitchen floor and put the spare refrigerator in place. The food is transferred to the spare refrigerator, which is cold because it was plugged in at the shop. The faulty refrigerator is trucked to the shop and unloaded. The technician knows that the refrigerant in the box may be badly contaminated. *The refrigerant is properly recovered and stored in a recovery cylinder used for contaminated refrigerants.* The service technician decides to change the compressor and the liquid-line drier and add a suction-line drier.

The refrigerator is set up on a workbench for easier access. The compressor is changed and process tubes soldered in place with ¼-in. fittings on the ends. (**Schrader fittings will not be used in this example to demonstrate how a system is totally sealed after an evacuation.**) The liquid line is cut and the old drier is removed. The technician then fastens the gauge hoses to the process tubes. No Schrader stems or depressors are installed or used. Nitrogen is used to purge the system from the suction line back through the evaporator and capillary tube, which is loose at the drier. Nitrogen under pressure is blown through the high side and out of the liquid line that is attached to the liquid-line drier, **Figure 45.156.** The purge method used in this system differs because there is no moisture present, just contaminated refrigerant and oil

Figure 45.155 Using the compressor frame or lines to check for an electrical ground circuit.

Figure 45.156 Purging the system at the suction-line drier connection before soldering the drier in the line.

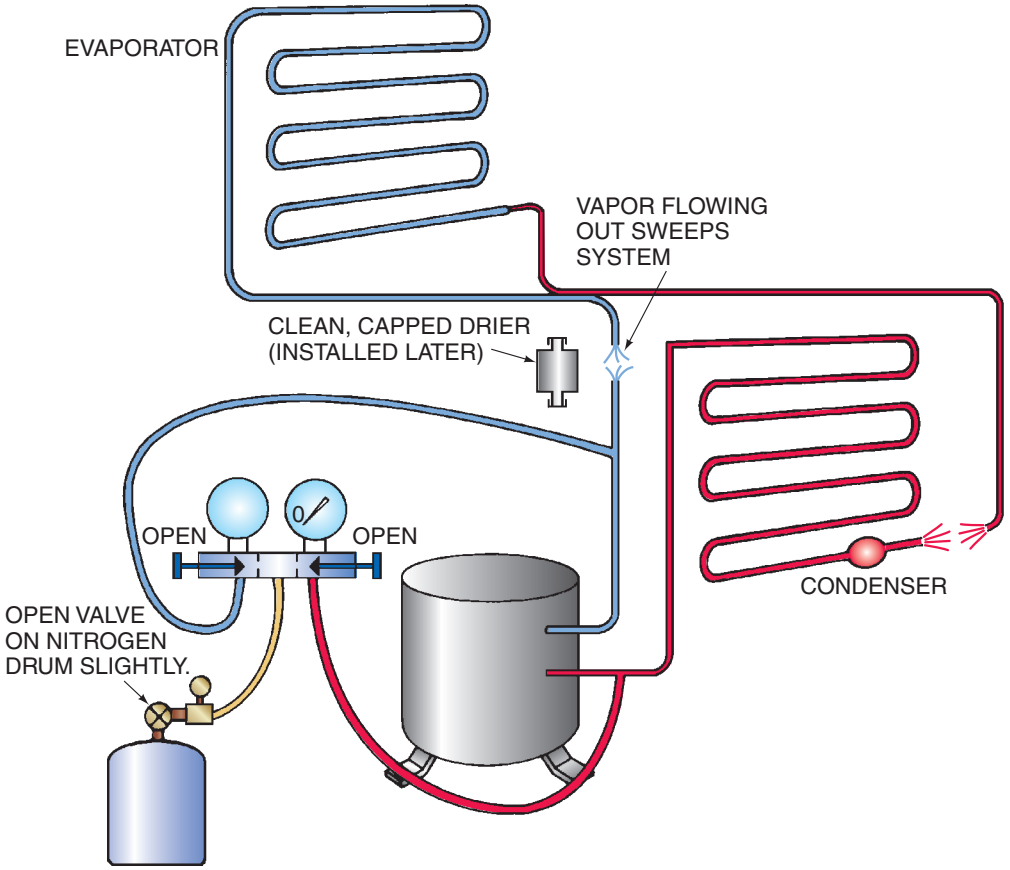

Figure 45.157 Typical pressure while the box is pulling down.

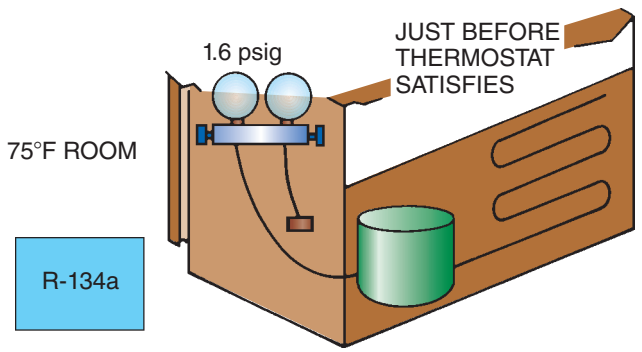
and possibly smoke from the motor ground in the system. Purging can remove the large particles, and the driers will remove the rest. After this step, the liquid-line drier and then the suction-line drier are soldered in place.

The system is leak checked and triple evacuated. At the end of the third evacuation, the discharge service tube is pinched off using a pinch-off tool. The system is charged with a measured charge and started. The low-side pressure is observed to be correct during the pulldown of the box, **Figure 45.157.** The box is allowed to run for 24 hours before it is returned to the customer.



SUMMARY

- Heat enters the refrigerator through the walls of the box by conduction, by convection, and by warm food being placed in the box.
- Refrigerators and freezers are designed to operate indoors and should not be subjected to extreme temperatures.
- Refrigerators and freezers must be level.
- Evaporators can be natural draft or forced draft.
- The evaporator in the household refrigerator operates at the low-temperature condition, yet maintains food at the correct temperature in the fresh-food compartment.
- Sharp objects should never be used when manually defrosting the evaporator.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Evaporators may be of the flat-plate type or fan-coil type.
- Plate-type evaporators may be designed as a shelf or the evaporator plate may be the wall of the box interior.
- Evaporators may be manually defrosted or have an automatic defrost feature.
- Many compressors have a suction line, a discharge line, a process tube, and two oil cooler lines, all of which protrude from the shell.
- Most residential refrigerators and freezers do not have service ports.
- Most domestic refrigerators use the capillary tube metering device.
- Current model refrigerators have a magnetic strip gasket with a compression seal around the door or doors.
- Door gaskets must fit tightly or air leaks will occur, causing the compressor to run excessively and frost to build up inside the cabinet.
- The space-temperature thermostat controls the compressor.
- Most cabinet heaters used to prevent frost and moisture are small, electrically insulated wire heaters that are mounted against the cabinet walls near the door openings.
- The fans used for induced-draft condensers are typically prop-type with shaded-pole motors.
- The fans used for mechanical-draft evaporators can be small squirrel-cage centrifugal blowers.
- Ice makers are located in the low-temperature compartment and freeze water into ice cubes.
- The condenser should be able to condense refrigerant at 20°F to 35°F higher than the ambient air. The more efficient the condenser, the closer the condensing temperature is to the air passing over it.
- The service technician should not routinely install gauges on a domestic refrigerator or freezer, but should explore all other troubleshooting techniques before installing gauges.
- A very small amount of refrigerant lost from a refrigerator will affect the performance. Very small leaks may be found only with the best leak detection equipment.
- An epoxy may be used to seal a leak in an aluminum evaporator.
- Condenser tubing is usually made of steel. Leaks in these tubes should be repaired with the appropriate solder.
- When a leak has been repaired, a triple evacuation should be pulled on the entire system.
- Under certain conditions capillary tube metering devices may be repaired.
- Normally, a wiring diagram is fastened to the back of the cabinet. This should be studied before servicing the freezer.
- *Refrigerant should be recovered and never exhausted into the atmosphere.*

REVIEW QUESTIONS

1. The typical temperature inside the fresh-food compartment in a domestic refrigerator is
   A. 25°F to 30°F.
   B. 30°F to 35°F.
   C. 35°F to 40°F.
   D. 40°F to 45°F.
2. The operating condition for the single compressor in a household refrigerator is the lowest box temperature, which is typically
   A. 0°F
   B. −20°F
   C. 20°F
   D. 40°F
3. When the air temperature in a domestic freezer is 0°F, the plate-type evaporator temperature may be as low as
   A. −30°F.
   B. −12°F.
   C. −6°F.
   D. 0°F.
4. Typical head pressures should correspond to a condensing temperature _____°F higher than room temperature at design operating conditions.
   A. 5–10
   B. 10–15
   C. 20–35
   D. 35–45
5. Using the temperature/pressure chart in Unit 3, the psig for R-134a at −5°F would be _____.
6. Using the pressure/temperature chart in Unit 3, the psig for R-134a at 100°F would be _____.
7. If a forced-draft evaporator fan motor is wired in parallel with the compressor, when will it run?
8. Frost accumulates on the evaporators of forced-draft refrigerators because
   A. they are generally located within a house.
   B. they are generally located in high-humidity areas.
   C. they are low-temperature appliances.
   D. there is a heat exchange with the suction line.

9. The defrost cycle in a domestic refrigerator may be terminated by two methods: _____ and _____.
10. Upright freezers are generally _____ (more or less) efficient than a chest freezer.
11. What are the two types of evaporators found in household refrigerators?
12. Refrigerators currently being manufactured in the United States are using _____ as their refrigerant.
13. Condensers in these refrigerators are all _____ cooled.
14. Home freezers are air-cooled and may have _____ or _____ type condensers.
15. Induced-draft condensers are typically used with units that have _____ defrost.
    A. automatic
    B. manual
16. The capillary tube metering device is usually fastened to the _____ for heat exchange.
    A. suction line
    B. compressor discharge line
    C. liquid line
17. The refrigerant flow through the fixed-bore capillary tube metering device is determined by the bore of the tube and the _____ of the tube.
18. If the compressor has liquid refrigerant returning to it, it will _____ on the side.
    A. be hot
    B. be warm
    C. sweat
19. Some freezers may have _____ heaters to prevent sweat on the cabinet.
20. Welded _____ sealed compressors are normally used in household refrigerators.
21. Special heaters called _____ heaters are often located around the doors to keep the door facing above the dew point temperature to avoid sweating.
    A. defrost
    B. condensate
    C. mullion or panel
    D. oil
22. Two types of wiring diagrams are the _____ and the _____ diagrams.
23. Two fans are provided in refrigerators when forced draft is used: one for the _____, and one for the _____.
24. The adjustment device used for low atmospheric pressure conditions is called the _____ thermostatic adjustment control.
    A. positive temperature coefficient
    B. altitude
    C. dual-voltage
    D. condenser coil
25. What happens to the temperature of the refrigerant in the compressor discharge line when the head pressure increases?

UNIT 46

ROOM AIR CONDITIONERS

OBJECTIVES

After studying this unit, you should be able to

- describe the various methods of installing window air-conditioning units.
- discuss the variations in the designs of window and through-the-wall units.
- list the major components in the refrigeration cycle of a window cooling unit.
- describe the heating cycle in the heat pump or reverse-cycle room air conditioner.
- describe the controls for room air-conditioning (cooling) units.
- describe the controls for room air-conditioning (cooling and heating) units.
- discuss service procedures for room air conditioners.
- list the procedures to be followed to determine whether or not to install gauges.
- state the proper procedures for charging a room air conditioner.
- list the types of expansion valves that may, under some conditions, be substituted for the capillary tube.
- state the components that may require electrical service.

SAFETY CHECKLIST

- ☑ Wear back brace belts when lifting or moving any appliance.
- ☑ Lift with your legs, keeping your back straight. Whenever possible, use appropriate equipment to move heavy objects.
- ☑ Observe proper electrical safety techniques when servicing any appliance or system. Ensure that electrical power to the unit is off except when needed for troubleshooting.
- ☑ Wear goggles and gloves when transferring refrigerant into or out of a room air-conditioning unit.
- ☑ When performing service on window units, make sure that all loose clothing and hair are secured because they could become entangled in rotating fans and shafts.

46.1 AIR-CONDITIONING AND HEATING WITH ROOM UNITS

Room units are used to provide comfort cooling, and sometimes heating, to an individual room or relatively small open area in a structure. Room air-conditioning units are constructed of components that have been discussed in detail earlier in this book. When a particular component or service technique is mentioned, refer to the appropriate sections of the text for the necessary details. Systems and components characteristic of room units are discussed in this unit.

Single-room air-conditioning can be accomplished in several ways, but each involves the use of package (self-contained) systems of some type. A common type is the room air-conditioning window unit for cooling only, **Figure 46.1**. Variations of this type of unit include electric strip heaters in the airstream with controls for heating and cooling, **Figure 46.2**. If there is adequate air circulation

between multiple rooms, it may be possible to use a single unit to condition more than one room.

46.2 ROOM AIR-CONDITIONING—COOLING

The manufacturer's design objectives for room units are efficiency of space and equipment and a low noise level. Most units are as compact as current manufacturing and design standards will allow. The intent is to get the most capacity from the smallest unit.

Cooling-only units may be either window or through-the-wall types, **Figure 46.3**. They are much the same, typically having only one double-shaft fan motor for the evaporator and the condenser. The capacity of these units may range from about 4000 Btu/h (1/3 ton) to 24,000 Btu/h (2 tons). Some units are front-air discharge and some are top-air discharge, **Figure 46.4**. Top-air discharge is more common in through-the-wall units; the controls are located on top. Frequently,

Figure 46.3 (A) Window and (B) through-the-wall-type units.

Source: Friedrich Air Conditioning Co.

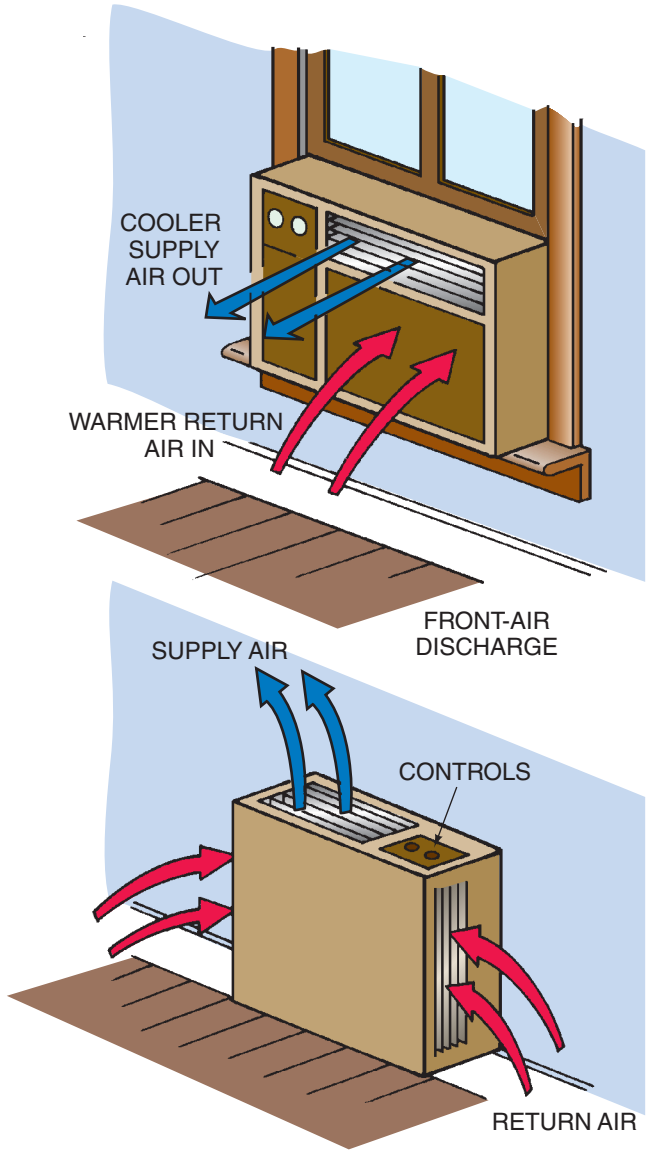
Source: Friedrich Air Conditioning Co.

(B)

Figure 46.4 Some room units are front-air discharge and some are top-air discharge.



these top-air discharge units are installed in motels where individual room control is desirable. The controls are built-in so that the unit may be serviced in place or changed for a spare unit and repaired in the shop.

Window and wall units are designed for easy installation and service. Window units have two types of cases or sleeves. In one type, the case or sleeve is fixed to the chassis of the unit. This is referred to as a wrap-around sleeve. In order to service this type of air conditioner, the entire unit must be removed from the window or wall. The term chassis is used to reference the assembly of all of the components that make up the air-conditioning system. The second type of window

Figure 46.7 The case lifts off the roof-mount unit.

Photo by Bill Johnson

unit has a slide-out chassis. With this type of unit, the sleeve or case is secured to the window opening and the chassis slides in and out, **Figure 46.5**. The sleeve configuration is important from a service standpoint. For units in which the case is built on the chassis, the entire unit including the case must be removed for service. A slide-out chassis may be pulled out of the case for simple service.

Several companies make a roof-mount unit for travel trailers and motor homes, **Figure 46.6**. This type of unit may also be seen in gas station attendant booths. The case on this unit lifts off the top, **Figure 46.7**. The controls for this type of unit are located inside the conditioned space, **Figure 46.8**.

46.3 THE REFRIGERATION CYCLE—COOLING

The most common refrigerant used in older room units is R-22. However, newly manufactured units contain R-410A, which does not contain chlorine and, as a result, does not deplete ozone. R-410A does, however, have a high global warming potential, GWP, and, as a result, is classified as a super-polluter. R-410A will be the only refrigerant discussed in this Unit. When other refrigerants are encountered, the temperature/pressure chart in Unit 3, "Refrigeration and Refrigerants," may be consulted for the pressure conversions. The operating temperatures will be the same.

The basic refrigeration cycle utilized in a window or room unit consists of the same four major components as those described in Unit 3: an evaporator to absorb heat into the system, **Figure 46.9**; a compressor to pump the heat-laden refrigerant through the system, **Figure 46.10**; a condenser to reject

the heat from the system, **Figure 46.11**; and an expansion device to control the flow of refrigerant, **Figure 46.12**. Although commonly found on domestic refrigerators and freezers, heat exchangers between the metering device (capillary tube) and the suction line are not typically found on window air conditioners, **Figure 46.13**. The complete refrigeration cycle is illustrated in **Figure 46.14**.

Cooling units are considered high-temperature refrigeration systems, meaning the evaporator coil is intended to operate above freezing to prevent condensate from freezing on the surface of the coil. Typically, the evaporators operate with a saturation temperature of about 35°F. Central air conditioning systems operate with a design evaporator saturation temperature of about 40°F. Room units boil the refrigerant much closer to freezing, so more care must be taken to prevent freezing of the evaporator.

The evaporator is typically made up of copper or aluminum tubing with aluminum fins. The fins may be straight or spiny, and all are in close contact with the copper tubing for the best heat exchange. The evaporator coil may be a

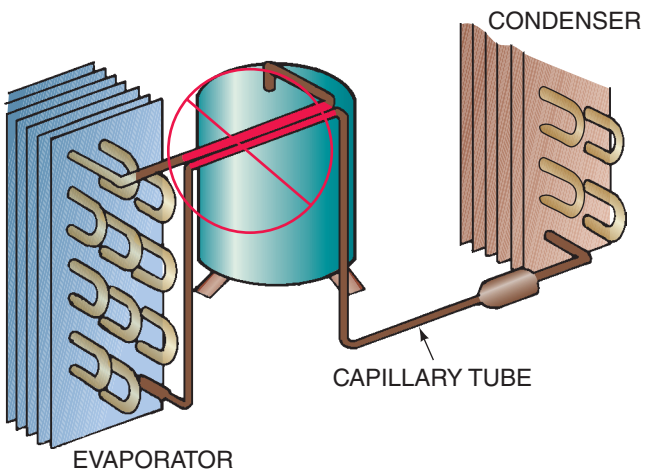
Figure 46.13 Although found on domestic refrigerators and freezers, window air conditioners do not typically utilize suction-to-capillary-tube heat exchange.



single circuit or can be manufactured with multiple, parallel refrigerant circuits, **Figure 46.15**. Evaporators are small and designed for the maximum obtainable heat exchange. Fins that force the air to move from side to side and tubes that are staggered to force the air to pass in contact with each tube are typical, **Figure 46.16**.

The evaporator typically operates below the dew point temperature of the room air for the purpose of dehumidification, so condensate forms on the coil. The condensate falls into a pan beneath the coil, **Figure 46.17**, and is generally drained back to the condenser section where it is evaporated. **Figure 46.18** shows a typical evaporator with temperatures and pressures.

The compressor for room units is a typical hermetically sealed air-conditioning compressor, **Figure 46.19**. The compressor may be reciprocating, **Figure 46.19**, or rotary,

Figure 46.14 Refrigeration cycle component.

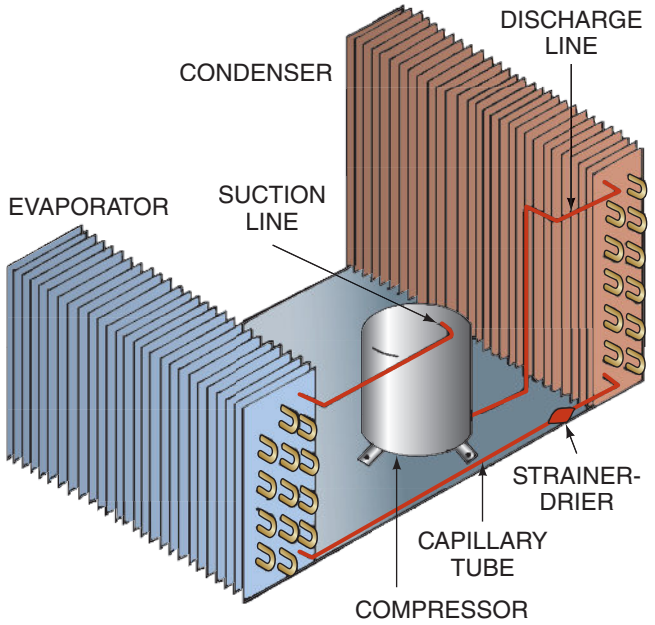


Figure 46.20. Most, if not all, new room air-conditioning units use rotary compressors. Compressors are described in detail in Unit 23, "Compressors".

Similar to the evaporator, condensers are typically copper or aluminum tubes with aluminum fins, **Figure 46.21**. The condenser is responsible for rejecting heat from the system, and some of this heat can be used to evaporate the condensate from the evaporator section. The evaporation of condensate is generally accomplished by using the heat from the discharge line and a slinger ring on the condenser fan blade, **Figures 46.22** and **46.23**. *Evaporating the condensate keeps the unit from dripping and improves the efficiency of the condenser.*

46.4 HEAT-PUMP-STYLE ROOM UNITS

Some window and through-the-wall units have reverse-cycle capabilities similar to the heat pumps discussed in Unit 43, "Air Source Heat Pumps." They can absorb heat from the outdoor air in the winter and reject heat to the indoors. This is accomplished with a four-way reversing valve. The valve is used to redirect the suction and discharge gas at the proper time to provide heat or cooling, **Figure 46.24**. Check valves are used to ensure correct flow through the correct metering device at the proper time. A study of Unit 43 will help in understanding the basic heat-pump cycle because the same principles are involved. The following is a description of a typical cooling cycle, illustrated in **Figure 46.25**.

During the cooling cycle, the refrigerant leaves the compressor discharge line as a hot gas. The hot gas enters the four-way valve and is directed to the outdoor coil, where the

Figure 46.15 Some typical evaporator circuits.

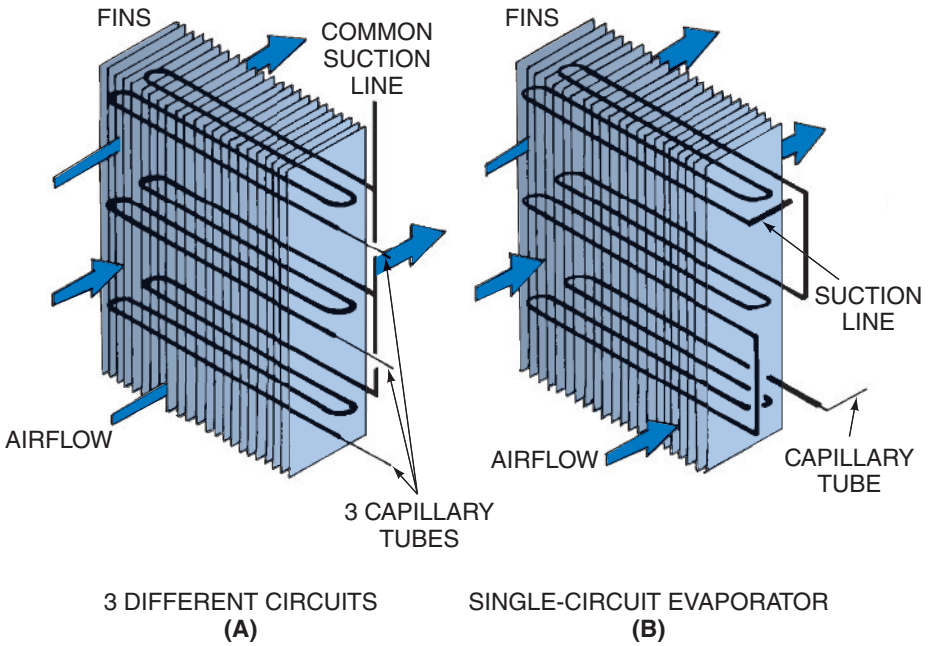

Figure 46.16 Some fins force the air to have contact with the fins and tubes.

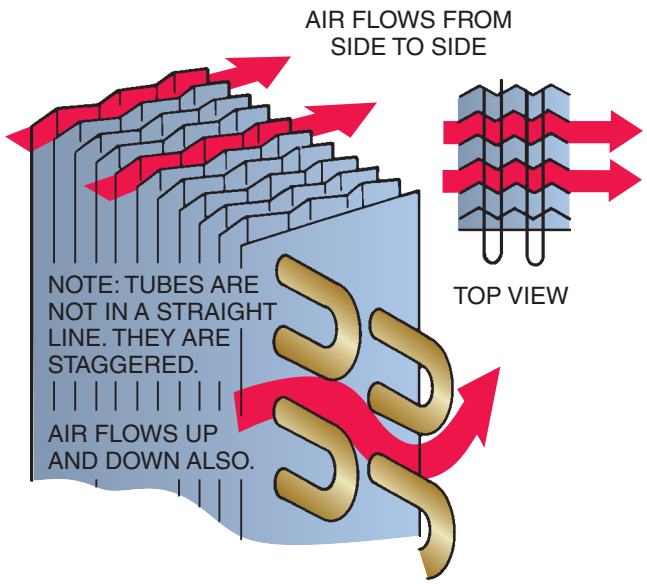
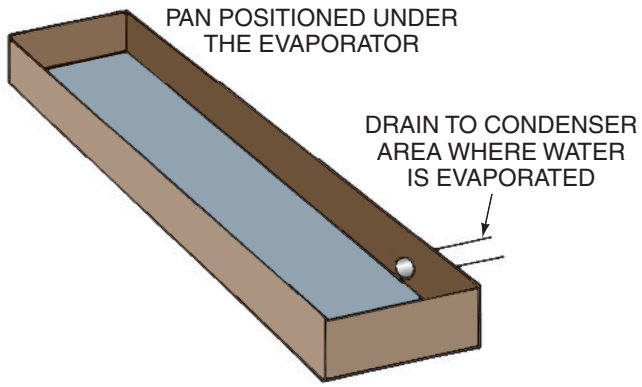


heat is rejected to the outdoors. The refrigerant is condensed to a liquid, leaves the condenser, and flows to the indoor coil through the capillary tube. The refrigerant is expanded in the indoor coil, where it boils to a vapor, just as in the cooling cycle in a regular cool-only unit. The cold, heat-laden vapor leaves the evaporator and enters the four-way valve body. The piston in the four-way valve directs the refrigerant to the suction line of the compressor, where the refrigerant is compressed and the cycle repeats itself.

Figure 46.17 A condensate pan.



The heating cycle may be followed in **Figure 46.26**. The hot gas leaves the compressor and enters the four-way valve body as in the cooling cycle. However, the piston in the four-way valve is shifted to the heating position, and the hot gas now enters the indoor coil. The indoor coil functions as the condenser and rejects heat to the conditioned space. The refrigerant condenses to a liquid and flows out of the indoor coil through the capillary tube to the outside coil. The refrigerant expands and absorbs heat while boiling to a vapor. The heat-laden vapor leaves the outdoor coil and enters the four-way valve, where it is directed to the compressor suction line. The vapor is compressed and moves to the compressor discharge line to repeat the cycle.

Figure 46.21 A finned-tube condenser.

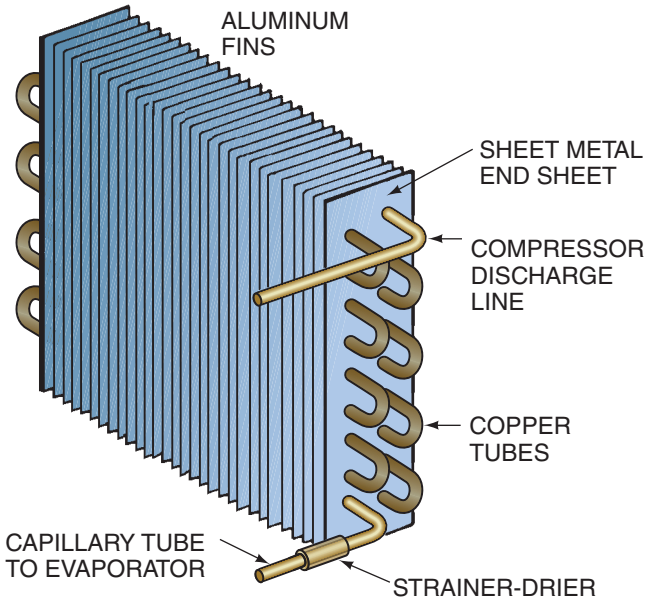

Figure 46.22 Moisture evaporated with the compressor discharge line.

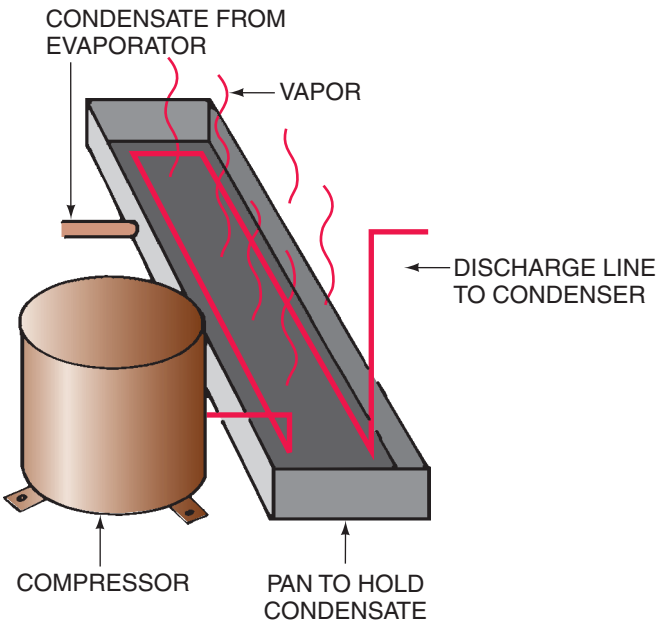

The compressor found in a heat-pump system is not a conventional air-conditioning compressor. It has a different cylinder displacement and horsepower. The compressor must have enough pumping capacity for low-temperature operation. The unit evaporator also operates below freezing during the heating cycle, and frost will build up on it. Different manufacturers handle this frost buildup in different ways, so the technician will have to consult their literature. A defrost cycle may be used to defrost this ice, for example.

Figure 46.23 The slinger ring attached to the condenser fan blade.

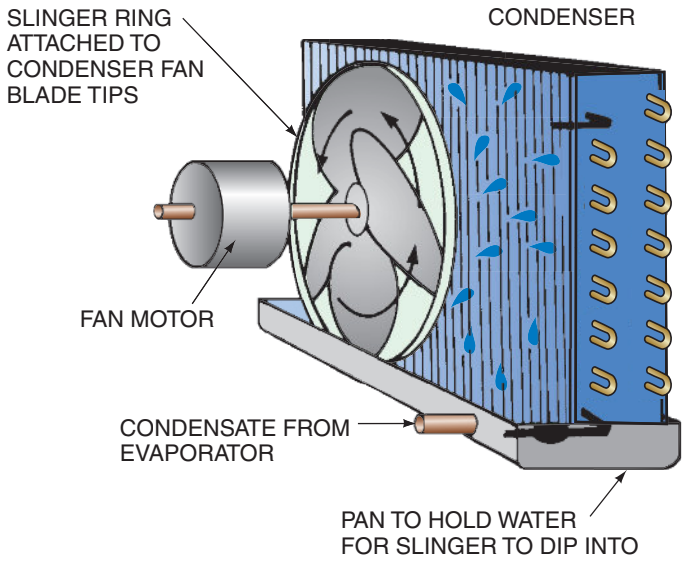

Figure 46.24 The four-way reversing valve for a heat pump.

Photo by Eugene Silberstein

Another point to remember is that the capacity of a heat pump is less in colder weather, so supplemental heat—commonly electrical strip heat—will probably be provided. Supplemental heat may also be used to prevent the unit from blowing cold air during the defrost cycle.

46.5 INSTALLATION

There are two types of installation for both cooling and cooling-heating room units: window installation and wall installation. The window installation may be considered temporary because a unit may be removed and the window restored to its original use. The wall installation is permanent because a hole is cut in the wall and must be patched if the unit is removed. In a window installation, when a unit becomes old and must be changed for a new one a new unit that fits the

Source: Friedrich Air Conditioning Co.

(B)

window would probably be available. A new unit that fits a hole in a wall may not be available.

Window installations are for either double-hung or casement windows, **Figure 46.27**. Units for double-hung windows are the most popular because there are more of these types of windows. Units may be installed in other types of windows, such as a picture window or jalousie window, but doing so requires a great deal of carpentry skill. A special unit is manufactured for casement window installation, **Figure 46.28**.

Some general guidelines should be followed in every installation. On the inside, the proper electrical outlet must be located within the length of the cord furnished with the unit. Extension cords are not recommended by manufacturers. The proper electrical outlet also must match the plug on the end of the cord, **Figure 46.29**. Window units may be either 115- or 208/230-V operation and should be on a circuit by themselves. Usually, a 115-V unit is chosen to avoid having to install an electrical circuit, but this choice is often made without investigating whether the existing circuit

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Figure 46.28 A window unit installed in a casement window.

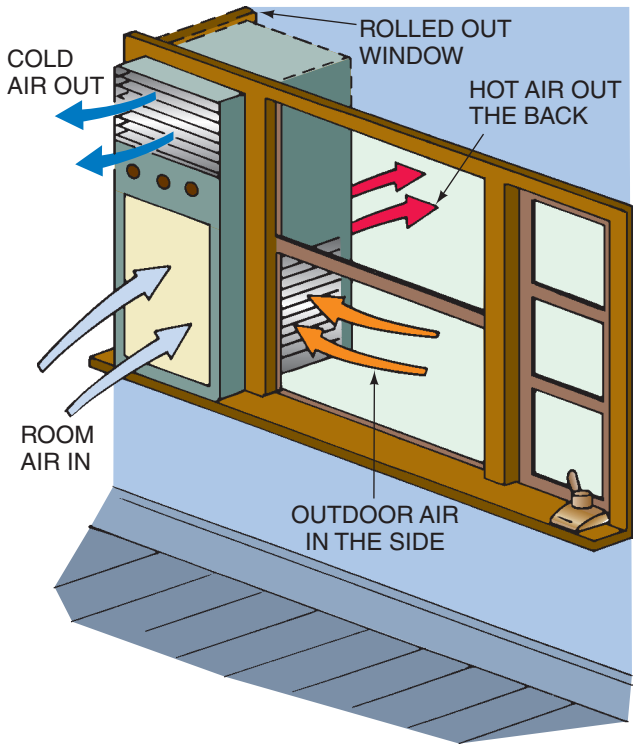

Figure 46.29 The proper outlet must be used that matches the plug.

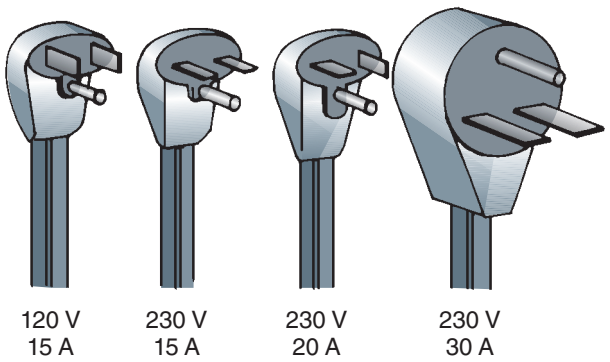

already has some load on it. For example, a 115-V electrical outlet may be part of the lighting circuit and a television and several lamps may be on the same circuit. The addition of a window air conditioner of any size may overload the circuit, **Figure 46.30**.

Investigating the electrical circuit to see what extra capacity is available is necessary. This may be accomplished by turning on all the lights in the room nearest the intended outlet, and possibly the lights in the adjacent room, and then turning off the breaker that controls the outlet. The current load from the lights may be totaled by adding them mathematically or using an ammeter on the wire to the circuit. If a 15-A circuit is already using 10 A, a window unit consuming 6 A will overload the circuit. A typical 5000 Btu/h unit will pull about 7 A in a 115-V circuit. An inexperienced homeowner who buys a unit at the department store and installs it may be in trouble. If the unit does run on a slightly overloaded circuit, the television picture may roll over every time the unit compressor starts, **Figure 46.31**.

Other considerations on the inside of the room are the best window to use and the air direction. A window that will give the best total room circulation may not be the best choice because it may be next to the easy chair in a den, by the bed in a bedroom, or behind the dining table, **Figure 46.32**. Some people will purchase a large window unit for several rooms. The unit must be able to circulate the air to the adjacent rooms or the thermostat will shut the unit off and cool only one room. A floor fan may be used to move the air from the room with the unit, **Figure 46.33**. Through-the-wall units in motels usually seem to be located on the outside wall, under the window and where the chair or chairs and table are located. This is the best practical place for the unit, but not necessarily the best for the occupants. However, there may be no place in a small room other than on an outside wall, **Figure 46.34**.

A unit located where air will recirculate—for example, behind drapes—will be a problem in any installation. Air will continually recirculate to the return-air grille and be cold enough to satisfy the thermostat, shutting the unit off. Some small units have no thermostat, only an ON-OFF switch. These may freeze the evaporator solid with ice, **Figure 46.35**. The airflow should usually be directed upward, as cold air will fall, **Figure 46.36**. This will also keep the supply air from mixing with the return air and freezing the evaporator or satisfying the thermostat.

Windows must be wide enough for the unit and must open enough so that the unit can be set on the window ledge, **Figure 46.37**. Smaller units are of a size that when placed on the window ledge, they will almost balance. In larger units, the compressor is located more to the rear, causing the unit to have a tendency to fall out of the window unless half of it is extended into the room. This, of course, is not desirable. Most manufacturers provide a brace kit to support the back of the unit, **Figure 46.38**. The bracket takes the pressure off the upper part of the window by placing the load on the bracket. A window unit never completely fills the window. Each new unit comes with a kit to aid in neatly filling the gap. The kit may contain telescoping side panels or panels matching the unit color that may be cut to fit. Also, the space between the partly raised movable window section and the upper part of the window must be insulated. Usually a foam strip is furnished for this purpose, **Figure 46.39**.

Figure 46.37 The window must open wide enough for the unit to fit.

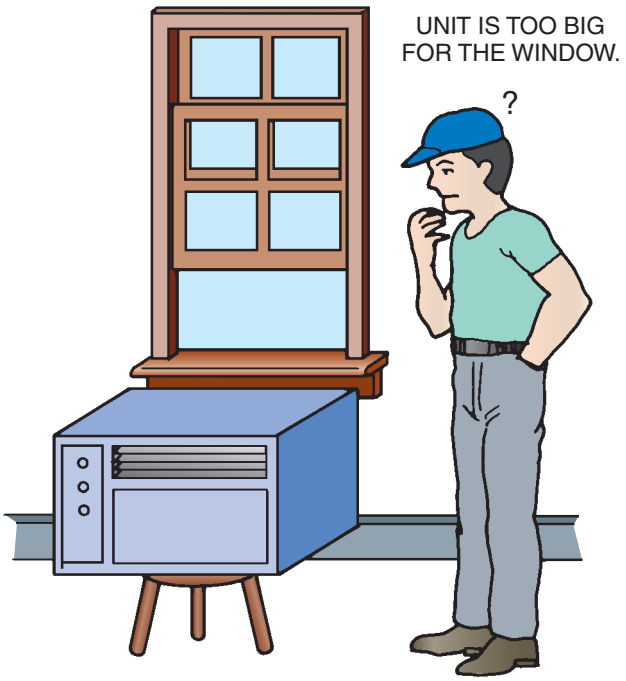

Figure 46.38 Larger units may be located farther to the rear so that they do not protrude into the room. A brace kit should be used.

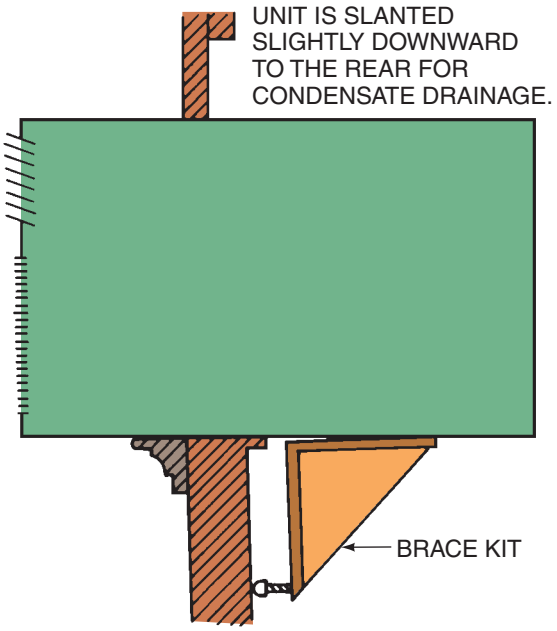
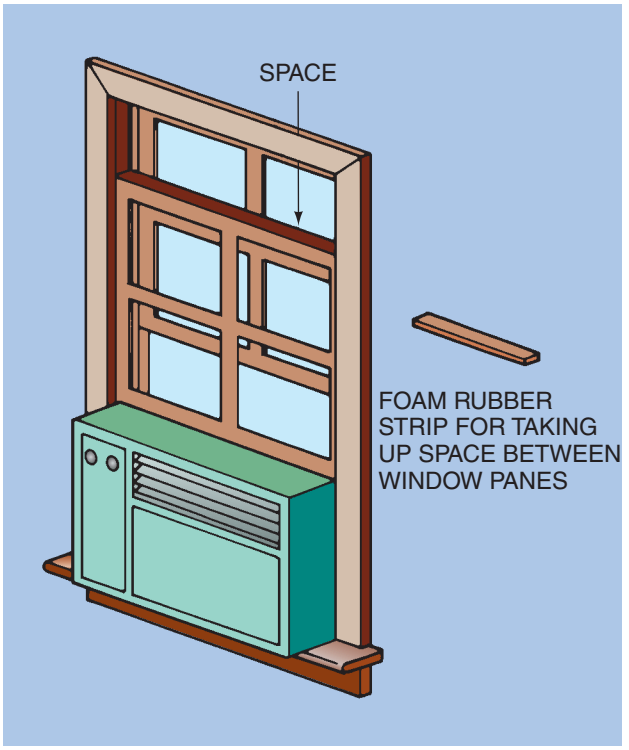


Directions are included with each new unit. Be sure to follow them and use all of the appropriate mounting hardware supplied with the unit. Units installed without the proper braces or window kits tend to vibrate, **Figure 46.40**. A properly braced unit will typically slant slightly to the rear for proper condensate drainage. When the weight is supported at the back, the pressure on the window is relieved and vibration is reduced.

Figure 46.39 A foam strip to fill the gap between the window sections.



Most units evaporate the condensate, but some allow it to drain out the back. This condensate should drain to a proper location, such as a flower bed, the lawn, or a gutter, **Figure 46.41**. Properly sized units operating under a normal load will be able to completely evaporate the condensate without having the unit drip. However, when there is an excessively high load on the system, even properly sized units may drip. Sometimes condensate is allowed to drip on a sidewalk. This is not good, as algae may form and the walkway could become slick, **Figure 46.42**. The unit must also be installed in such a manner that air can circulate across the condenser and not recirculate. It must be allowed to escape the vicinity and not heat the surroundings. Window units have been located with the condenser in a spare room, such as at a business location, **Figure 46.43**. This is poor practice because the unit heats the air, and high operating conditions will occur. Recirculation will cause high head pressure and high operating cost, **Figure 46.44**. In addition, there should be no obstructions located close to the air discharge.

Figure 46.40 An awkward installation because the bracket kit has been lost.

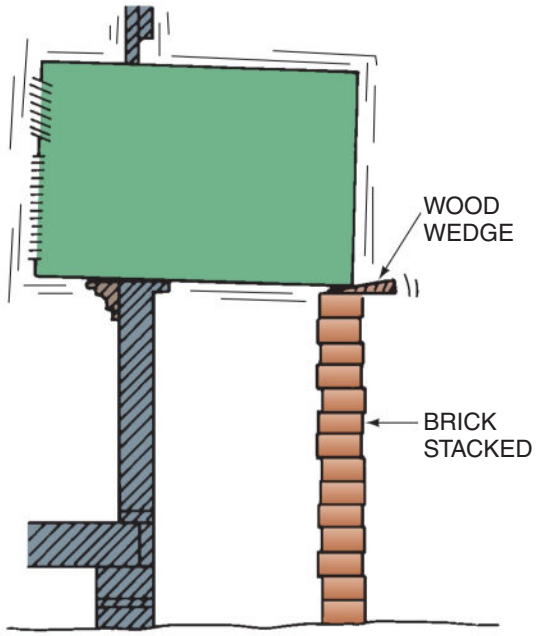

Figure 46.41 The condensate should drain to the proper place.

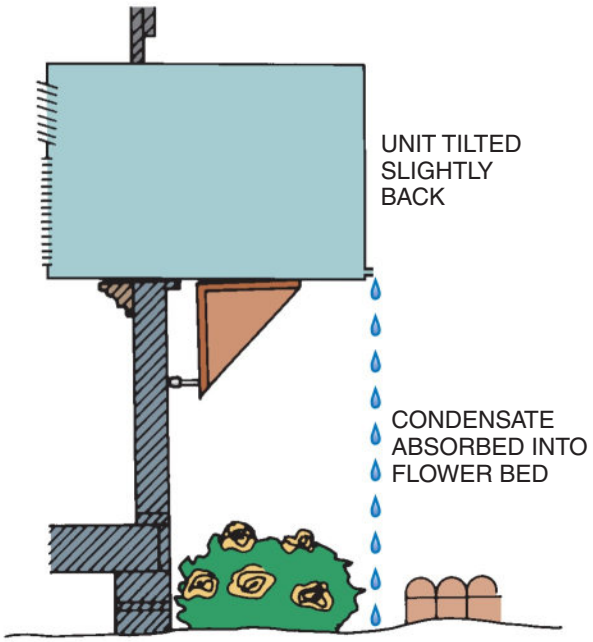

Figure 46.42 Condensate on a walkway can be dangerous.

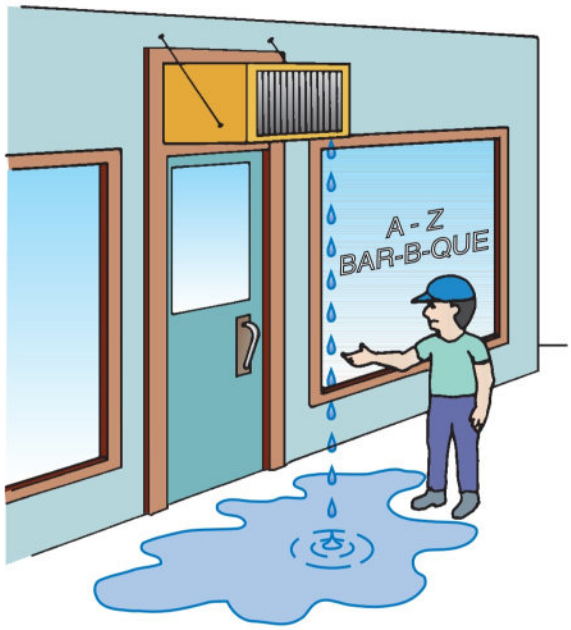

Figure 46.43 The heat must be able to escape from around the unit. Units with the condenser in an adjacent room will not operate efficiently.

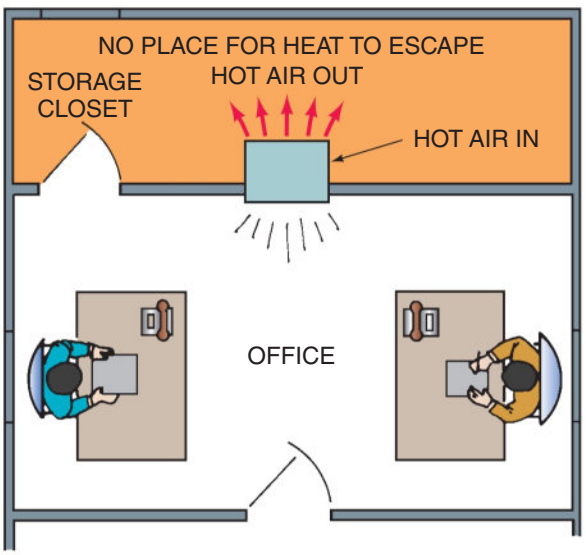

Through-the-wall units typically protrude into the room only a slight amount with the bulk of the unit on the outside, **Figure 46.45**. When these units are installed in a motel, the outdoor portion protrudes into the walkway slightly. If condensate is not completely evaporated, it will run across the walkway and cause a hazard. Through-the-wall units may be installed while the building is under construction. This is accomplished by installing wall sleeves and covering the openings until the unit is set in place, **Figure 46.46**. The wiring is run to the vicinity of the unit, and the unit is connected when installed. It is important that holes of the correct size be cut. The wall sleeve should be purchased from the manufacturer in advance to ensure this.

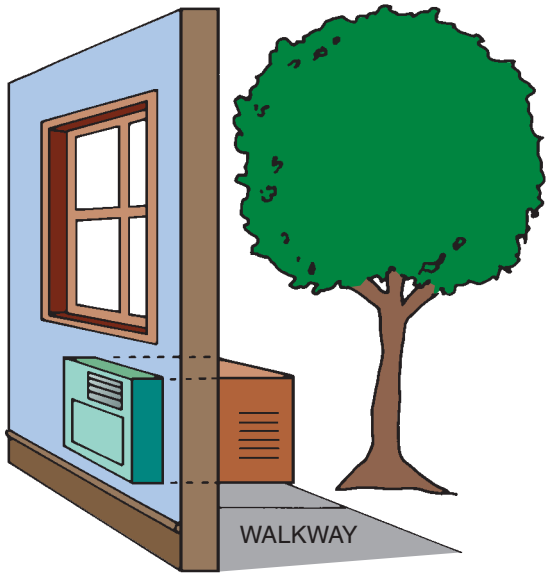

Figure 46.46 Wall sleeves may be installed in advance of the unit.

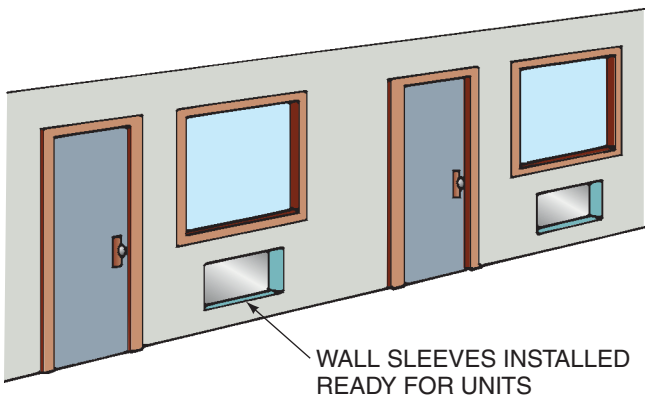

46.6 CONTROLS FOR COOLING-ONLY ROOM UNITS

Room units that provide only cooling are plug-in appliances furnished with a power cord. Most of the time, all of the controls are contained in the unit, as there is no wall-mounted thermostat as in the case of central air-conditioning. Many new room units, however, do come supplied with wireless remote controls so that the user can turn the unit on and off, as well as change the temperature setting in the space without having to approach the unit. In all cases, the room thermostat sensor is located in the unit's return airstream, **Figure 46.47**. A typical room unit may have a selector switch to control the fan speed and provide power to the compressor circuit, **Figure 46.48**. The selector switch may be considered

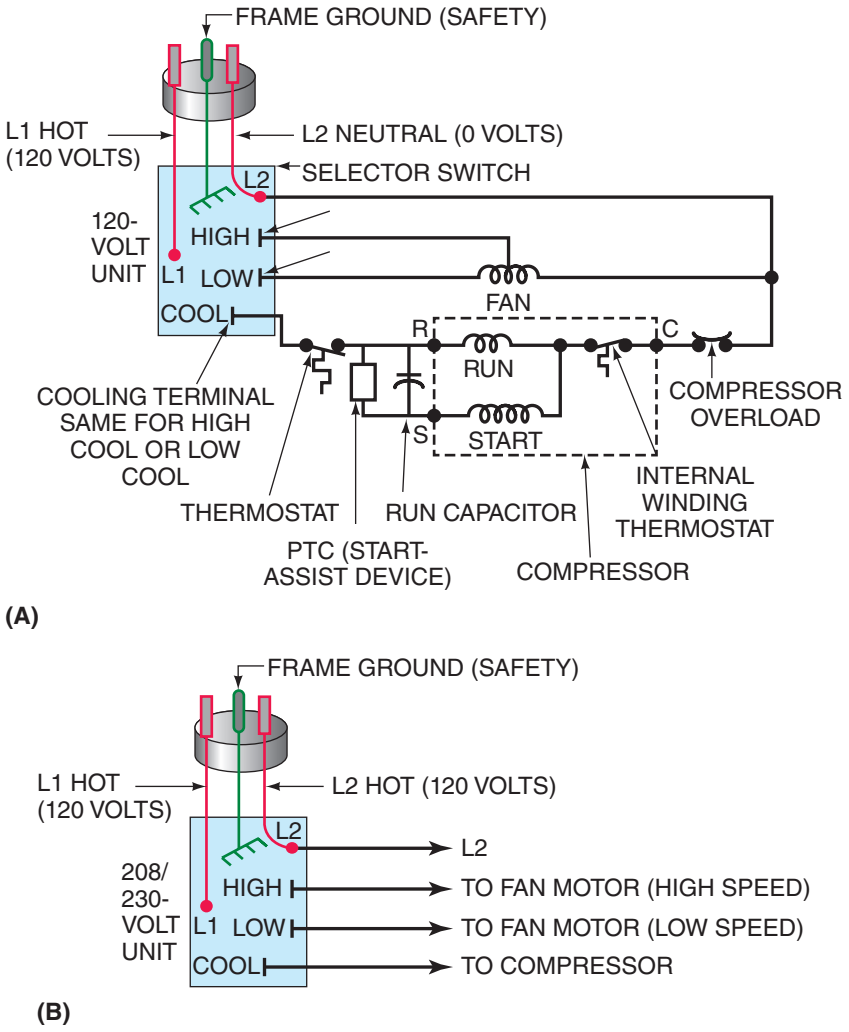
Figure 46.49 Typical selector switch terminal designations for (a) 120- and (b) 208/230-V units.

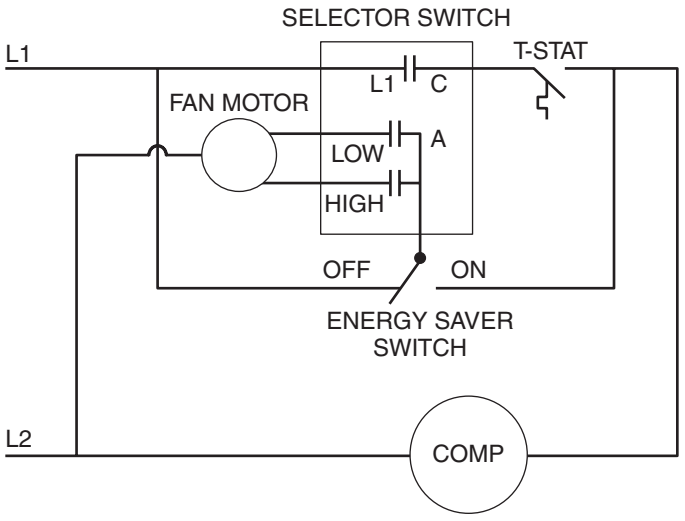


a power distribution center. The power cord will usually be wired straight to the selector switch for convenience. Therefore it may contain a hot, grounded neutral and a frame safety (green) ground wire for a 115-V unit. A 208/230-V unit will have two hot wires and a ground, **Figure 46.49**. The ground or neutral wire for 115-V service is routed straight to the power-consuming device. The hot wire is connected directly to the other side of the power-consuming device.

Many combinations of selector switches will allow the owner to select fan speeds, high and low cool, exhaust, and fresh air. High and low cool is accomplished with fan speed. Because the unit has only one fan motor, a reduction in fan speed slows both the indoor and the outdoor fan. This reduces the capacity and the noise level of the unit.

Some units are equipped with energy-saver switches. The purpose of this switch is to allow the user to determine if the fan motor should cycle on and off with the compressor. The basic circuit for an air conditioner equipped with this control is shown in **Figure 46.50**. In this diagram, contacts L1-C

Figure 46.50 Control switch wiring for a room unit equipped with an energy-saver switch.



will close whenever the selector switch is set to the COOL position. With the energy-saver switch in the OFF position, power from L1 will be fed to Terminal A all the time, whether or not the unit is set to COOL or if the space thermostat is calling for compressor operation. This means that, with the energy-saver switch in the OFF position, the fan will operate independently of the thermostat and cooling contacts on the switch, **Figure 46.51**. With the energy-saver switch in the ON position, power from L1 will be fed to Terminal A only when the selector switch is calling for cooling and the space thermostat is calling for compressor operation, **Figure 46.52**. If the energy-saver switch is in the ON position *and* the selector switch is set to COOL *and* the space thermostat is calling for cooling, Terminal A will be powered and the indoor fan will operate, **Figure 46.53**. If the thermostat is satisfied, both the compressor and the fan will cycle off.

Some newer units have electronic wireless remote controls. They often have cool and fan speed options, and 24-hour ON-OFF timers. The exhaust and fresh-air control is a lever that positions a damper to bring in outdoor air or exhaust indoor air, **Figure 46.54**. The selector switch sends power to various circuits (including the compressor start circuit) to start the compressor.

Figure 46.51 With the energy-saver switch OFF, the fan motor operates independently of the compressor.

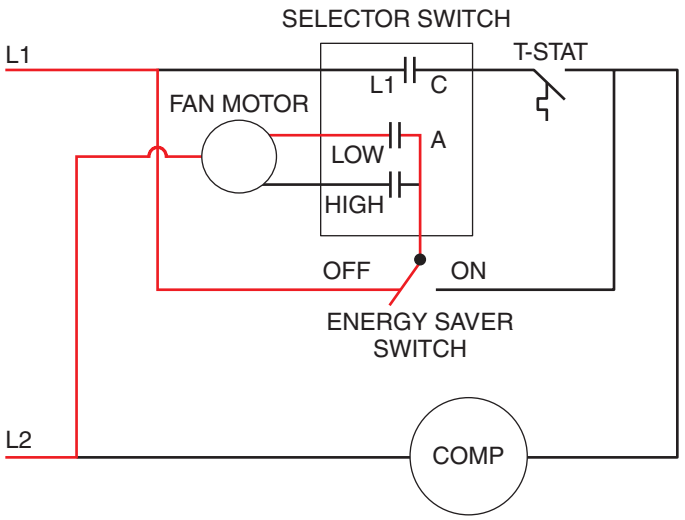


Figure 46.52 With the energy-saver switch ON, the fan motor can only operate when compressor operation is called for.

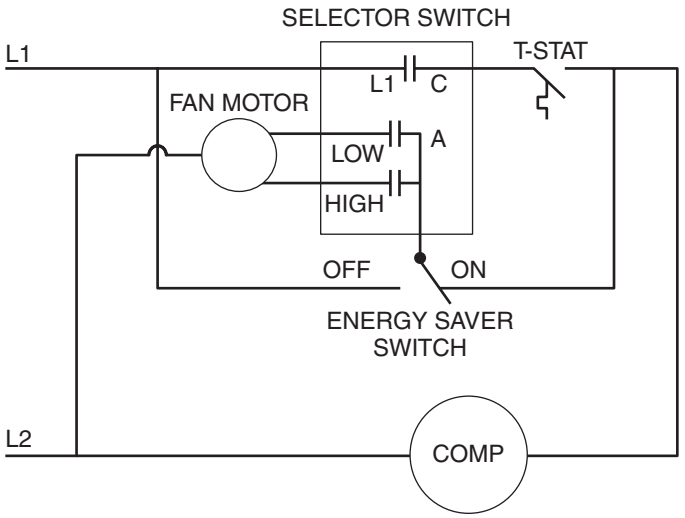

Figure 46.53 Diagram showing the path of electric current when the compressor is operating and the energy-saver switch is on.

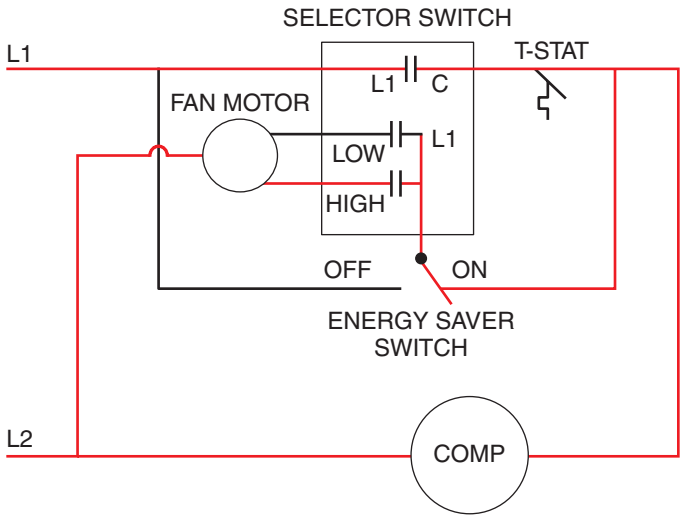

Figure 46.54 Exhaust and fresh air are accomplished with a damper operated from the front of the unit.

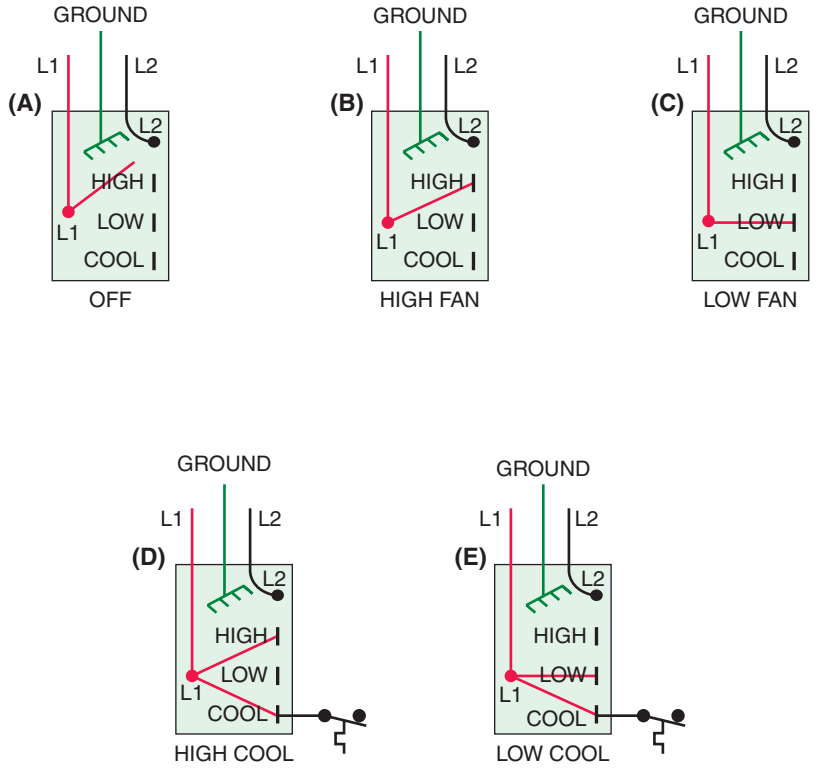
Figure 46.55 Some selector switch wiring configurations.

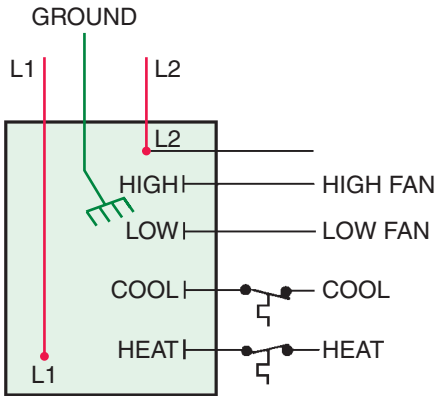


Motor starting was discussed in Unit 19, "Motor Controls," and will not be further discussed here. **Figure 46.55** shows some selector switch and compressor diagrams with explanations.

46.7 CONTROLS IN COOLING AND HEATING UNITS

Combination cooling and heating units may be either plug-in or through-the-wall appliances. Through-the-wall units usually are furnished with an electrical service. The cooling controls for cooling and heating units are the same as previously discussed for the cooling cycle. Typically, a selector switch changes the unit from cooling to heating. When the unit has electric strip heat, the selector switch merely directs the power to the heating element through the thermostat, **Figure 46.56**. If the unit is a heat pump, it will have a selector switch to select heating or cooling. The cooling cycle should be a typical cycle with the addition of the four-way valve. In the heating cycle, defrost may have to be considered. Many newer units with strip heat have electronic controls. In these units a thermostat usually controls the heating elements to maintain constant room temperature, and they may have digital touch-pad controls with remotes and a 24-hour ON-OFF timer.

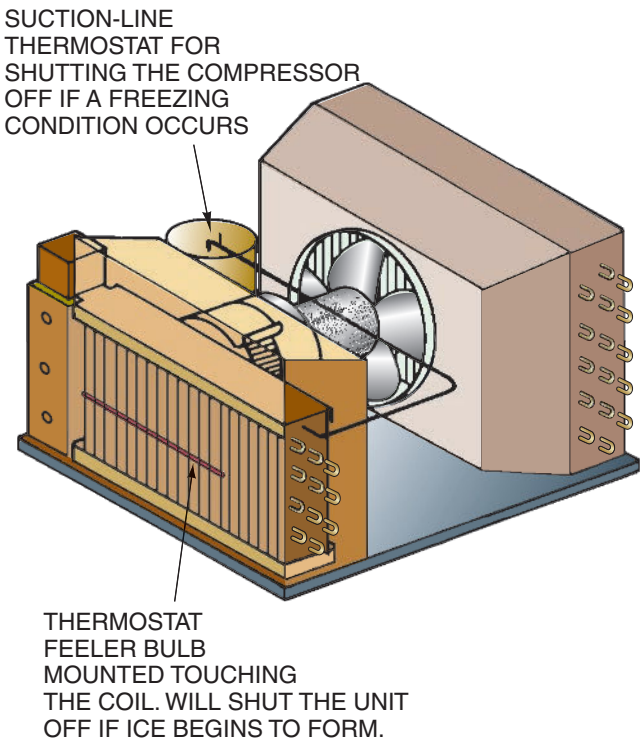
Figure 46.56 The selector switch directs the power to the heating or cooling circuits.



46.8 MAINTAINING AND SERVICING ROOM UNITS

Maintenance of room units basically involves keeping the filters and coils clean. In the later models, the motor is typically permanently lubricated. If the filter is not maintained, the indoor coil will become dirty and cause the unit to operate at low suction pressures. While in the cooling mode, the

Figure 46.57 Freeze protection for a room unit.



coil is already operating at about 35°F. If the coil temperature drops below this, ice will begin to form. Some manufacturers provide freeze protection that will shut the compressor off and allow the indoor fan to run until the threat of freezing is over. This may be done with a thermostat located on the indoor coil or a thermostat mounted on the suction line, **Figure 46.57**.

Service may involve mechanical or electrical problems. Mechanical problems usually arise in the fan motor and bearing or refrigerant circuits. All room units have a critical refrigerant charge, and gauges should be installed only after there is some proof that they are needed. The system will normally be sealed and for gauges to be installed line tap valves or the installation of service ports on the process tubes will be required. Line tap valves and their use is discussed in Unit 45, "Domestic Refrigerators and Freezers." **Figure 46.58** shows an example of a line tap valve. Line tap valves, such as the one shown in **Figure 46.58**, must be removed from the system after use. Since these valves leak, leaving one installed on a room unit is a violation of Section 608 of the Clean Air Act of 1990.

NOTE: *Be sure to follow the valve manufacturer's instructions.*

A bench test at the workshop is often performed on room units. Before installing gauges, the technician should perform the following test when a low charge is suspected. Because the condenser and the evaporator operate in air that is the same temperature, the condenser airflow may need to be reduced to move any refrigerant from the condenser due to low head pressure. A full explanation of condenser operation and charging

Figure 46.58 A line tap valve.

Photo by Eugene Silberstein

under low ambient conditions is discussed in Unit 29, Section 29.6, "Calculating the Correct Head Pressure for Air-Cooled Equipment." Refer to **Figure 46.59** while reading the following:

- Remove the unit from its case.
- Make sure that air flows through the coils. For temporary testing, cardboard may be positioned over places where panels force air to flow through the coils.

Figure 46.59 Testing for a low charge before installing gauges.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Start the unit in HIGH COOL.
- Let the unit run for about 5 min and observe the sweat on the suction line. It should come close to the compressor. The evaporator should be cold from bottom to top.
- Cover a portion of the condenser to force the head pressure to rise. If the room is cool, a portion of the charge may be held in the condenser. The condenser airflow may be blocked to the point that the air leaving it is hot, about 110°F.
- With the head pressure increased, allow the unit to run for 5 min; the sweat line should move to the compressor. If the humidity is too low for the line to sweat, the suction line should be cold. The evaporator should be cold from bottom to top. If only part of the evaporator is cold (frost may form), the evaporator is starved. This may be a result of a restriction or a low charge.
- If the compressor is not pumping to capacity and the charge is correct, the coil will not be cold anywhere, only cool. An ammeter may be clamped on the common wire to the compressor and the amperage compared to the full-load amperage of the compressor.

When this test indicates that the charge is low, because the suction line is not cold or sweating, gauges should be installed.

When the charge is low, the leak should be found. If the unit has never had a line tap or service port installed and has operated for a long period of time without a problem, it can be assumed that the leak has just occurred. An electronic leak detector may be used to help locate the leak. Turn the unit off and allow the pressures to equalize. Make sure there is enough refrigerant in the unit to properly leak check. If the system temperature and pressure relationship indicates there is no liquid present, there is so little refrigerant in the system that what is left could be considered trace refrigerant for leak-checking purposes. If the leak cannot be found with the unit off, dry nitrogen may be used to increase the pressure to the pressure at which the unit was leak tested at the factory. Be sure to check the nameplate on the unit for this information. Once the leak has been located, the nitrogen and refrigerant trace can be released to the atmosphere. After the leak has been repaired, the unit must be pressure tested, properly evacuated and recharged.

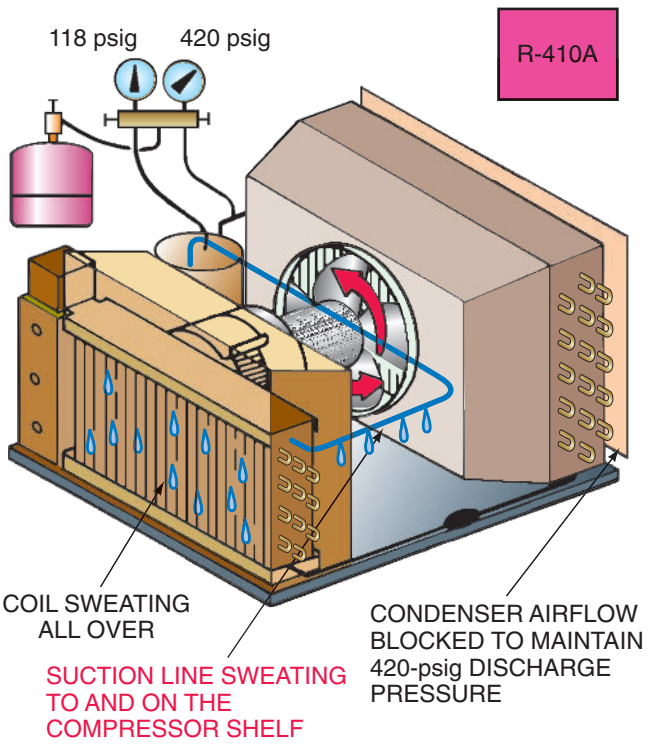
4R *The correct method of charging a unit is to remove and recover the remaining charge, evacuate the unit, and measure in the correct charge printed on the nameplate.* 4R **SAFETY PRECAUTION:** *Do not start the unit with a nitrogen charge in it because high pressure will occur and the motor will quickly overheat due to lack of cooling.* Technicians should use accurate scales similar to the one in **Figure 46.60** to measure the charge. At times, the technician may want to adjust the charge rather than start from the beginning. A charge may be adjusted by using the following method, which, together with **Figure 46.61**, illustrates the procedure:

- Install suction and discharge gauge lines.
- Purge the gauge lines and connect them to the correct refrigerant cylinder.

Figure 46.60 Charging scale.

Scale provided by Fieldpiece Instruments. Photo by Eugene Silberstein

Figure 46.61 Charging a unit by sweat line.



- Make sure that air is passing through the evaporator and the condenser coils; cardboard may be used as temporary panels.
- Start the unit in HIGH COOL.
- Watch the suction pressure and do not let it fall below atmospheric pressure into a vacuum; add refrigerant through the suction gauge line if the pressure falls too low.
- Adjust the airflow across the condenser until the head pressure is 420 psig and corresponds to a condensing temperature of 120°F for R-410A. Refrigerant may have to be added to obtain the correct head pressure.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Add refrigerant vapor at intervals with the head pressure at 420 psig until the compressor suction line is sweating at the compressor. As refrigerant is added, the airflow will have to be adjusted over the condenser or the pressure will rise too high. Note also that the evaporator coil should become colder toward the end of the coil as refrigerant is added.
- The correct charge is verified after about 15 min of operation at 420 psig and by a cold (probably sweating) suction line at the compressor. The suction pressure should be about 118 psig and the compressor should be operating at near full-load amperage.

When a system must be evacuated, the same procedures are used as those discussed in Unit 8, "Leak Detection, System Evacuation, and System Cleanup." The larger the evacuation ports, the better. Unit 45, "Domestic Refrigerators and Freezers," has a complete evacuation procedure for refrigerators and freezers; this same procedure would apply here.

The capillary tube may be serviced in much the same manner as described in Unit 45, "Domestic Refrigerators and Freezers." If the head pressure rises and the suction pressure does not and refrigerant will not fill the evaporator coil, there is a restriction. In this case, the technician must make sure the compressor has a starting relay and capacitor or it may not start. Thermostatic and automatic expansion valves do not equalize during the off cycle. This is a workable situation for a room unit, but not a refrigerator.

It may be difficult to remove the fan motor in many units. They are so compact that the fans and motor are in close proximity to the other parts. The evaporator fan is normally a centrifugal type (squirrel cage design) and the condenser fan is typically a propeller type. The condenser fan shaft usually extends to a point close to the condenser coil. Often there is not room to slide the propeller fan to the end of the shaft, **Figure 46.62**. Either the fan motor must be raised up or the condenser coil moved, **Figure 46.63**. The evaporator fan wheel is normally locked in place with an Allen-head setscrew that must be accessed through the fan wheel with a long Allen wrench, **Figure 46.64**.

Electrical service requires the technician to be familiar with the electrical power supply. All units are required to be grounded to earth. This involves running a green or bare copper ground wire to every unit from the grounded neutral bus bar in the main control panel. Ground wires provide a safety circuit to protect the service technician and others from electrical shock hazard. The electrical service

Figure 46.63 The condenser may be moved back or the fan motor may be raised in order to remove the fan blade.

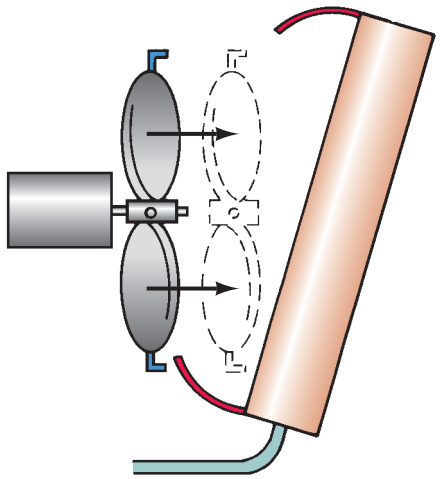


Figure 46.62 Often the condenser fan is hard to remove from the shaft because of the clearance between the condenser and fan.

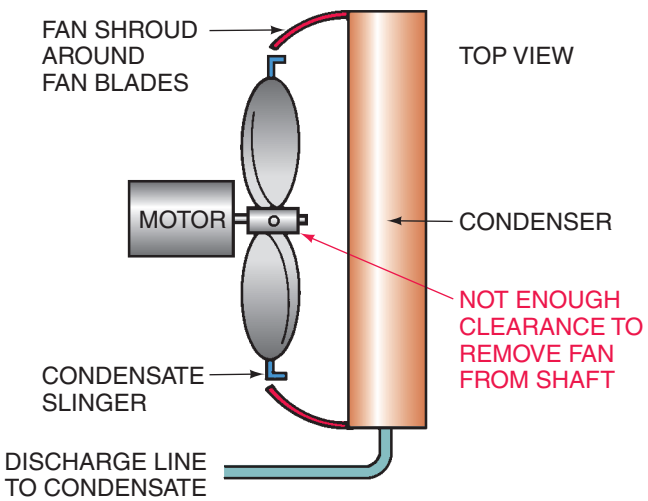

Figure 46.64 An Allen-head setscrew may be loosened by inserting a long Allen wrench through the blades.

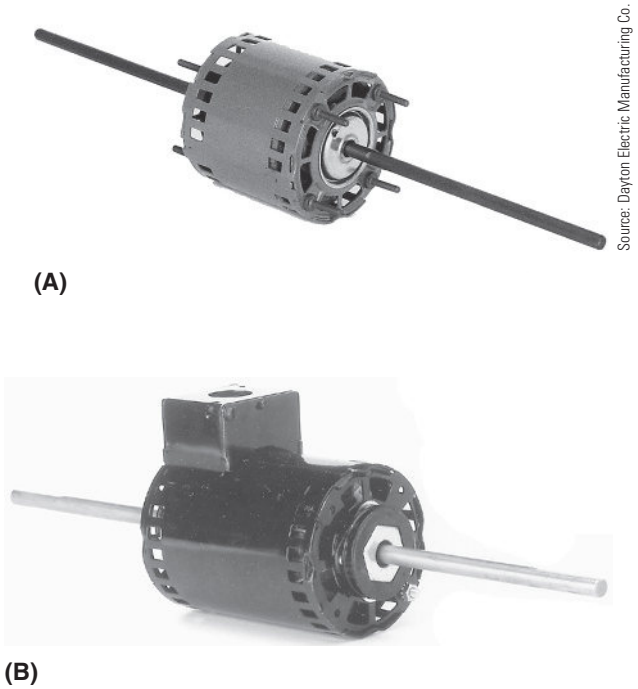
Figure 46.65 Fan motors. (A) Shaded pole. (B) Permanent split capacitor.



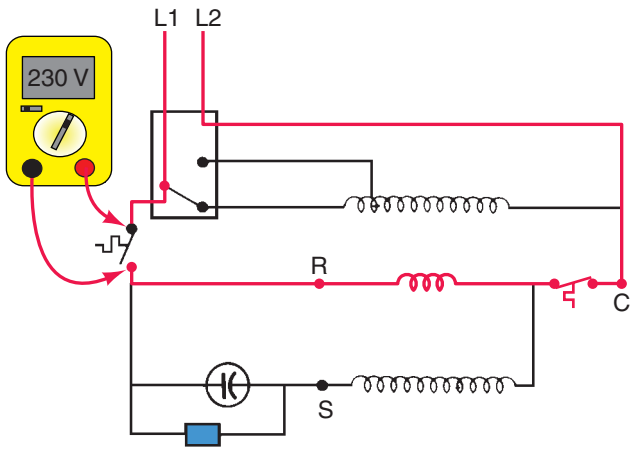
must be of the correct voltage and have adequate current-carrying capacity. The example described in Section 46.5, "Installation," describes what typically happens if the circuit was not planned to operate an air-conditioning unit.

Electrical service may involve the fan motor, the thermostat, the selector switch, the compressor, and the power cord. The fan motor will be either a shaded-pole or a permanent split-capacitor type, **Figure 46.65**. These motors are discussed in detail in Section 4.

The thermostat for room units is usually mounted with the control knob in the control center and the remote bulb is located in the vicinity of the return air. These thermostats are the line-voltage type discussed in Unit 13, "Introduction to Automatic Controls." Since most units operate with the fan running continuously anytime the selector switch is set for cooling or heating, there is a moving airstream over the thermostat at all times.

It is important to remember that the thermostat is a switch that passes power to the compressor start circuit. If the thermostat is suspected of not passing power to the compressor start circuit, unplug the unit (shut off the power and lock the circuit out if wired direct) and remove the plate holding the thermostat. The plate may be moved forward far enough to place the voltmeter leads on the thermostat terminals. Turning the power back on, put the selector switch at the HIGH-COOL position and observe the voltmeter reading. If there is a voltage reading across the thermostat, the thermostat contacts are open, **Figure 46.66**.

Figure 46.66 If the meter reads voltage, the thermostat contacts are open.



The selector switch may have the same defect as the thermostat and the trouble may be found in a similar way. The selector switch is usually mounted on the same panel as the thermostat. If the selector switch is suspected of not passing power, turn the power off and remove the panel. Secure it in such a manner that the unit may be started. The selector switch is checked in a slightly different way, using the common terminal and the power lead. To verify that power is being supplied to the switch, connect the test leads of the voltmeter to the L1 and L2 Terminals on the switch. If power is being supplied to the switch, the meter should read line voltage, **Figure 46.67**. If the HI COOL mode is to be checked, the selector switch should be set to HI COOL and the temperature setting on the thermostat should be set to a point that is well below the actual temperature in the space. Voltage readings should then be taken between the L2 Terminal and the HIGH FAN Terminal, **Figure 46.68a**, and between the L2 Terminal and the COOL Terminal, **Figure 46.68b**. If the switch is operating properly, both of these voltmeter readings should be line voltage. If the switch is not operating properly, either the voltage reading between Terminal L2 and the HIGH FAN terminal, **Figure 46.69a**, or the voltage reading between Terminal L2 and the COOL terminal, **Figure 46.69(B)**, will be 0 volts. If this is the case, the switch needs to be replaced.

Compressor electrical problems may be in either the starting circuit or the compressor itself. Room units use single-phase power. Compressors are often started with a capacitor or with the help of a positive temperature coefficient device (PTC) described in Unit 17, "Types of Electric Motors." Electrical troubleshooting and capacitor checks are discussed in Unit 20, "Troubleshooting Electric Motors." A review of these units will help in understanding motors and their problems.

Power cord problems usually occur at the end of the cord where it is plugged into the wall plug. Loose connections that occur because plugs do not fit well or the plug or power cord has been stepped on and partially unplugged are the big problems. The power cord should make the best connection possible at the wall outlet. Sometimes the cord may need support to relieve the strain from the connection, **Figure 46.70**. If the cord becomes hot to the point of discoloration or the plug swells, the plug should be changed. The wall receptacle may need inspection to make sure that damage has not occurred inside it. If the plastic is discolored or distorted, the receptacle should be changed; installing a new plug will not help and the problem will recur.

Figure 46.70 A power cord may need support.

HVAC GOLDEN RULES

When making a service call to a residence:

- Try to park your vehicle so that you do not block the customer's driveway.
- Always carry the proper tools and avoid extra trips through the customer's house.
- Ask the customer about the problem. The customer can often help you solve the problem and save you time.

Added Value to the Customer

Here are some simple, inexpensive procedures that may be added to the basic service call.

- Clean or replace the air filters.
- Advise customers about proper operation; for example, tell them not to allow conditioned air to recirculate into the return air.
- If removal of the unit is necessary, obtain the proper assistance and use dropcloths to prevent dirt from the unit from falling on the floor.

46.9 SERVICE TECHNICIAN CALLS

SERVICE CALL 1

A customer in an apartment reports that the window unit in the dining room, used to serve the kitchen, dining room, and living room, is freezing solid with ice every night. The tenants both work during the day. They shut the unit off in the morning and turn it on when they get home from work. The air temperature is 80°F inside and outside by the time they turn the unit on. *The problem is that the head pressure is too low during the last part of the cycle, starving the evaporator and causing it to operate below freezing.*

The apartment house technician arrives late in the afternoon when the tenants get home. The technician asks them to describe how they are using and setting the controls on the unit to get an idea about what the problem might be. The tenants show him how the thermostat is set each night. The technician explains that the outdoor temperature is cooler than the temperature in the apartment by the time the unit is turned on and that a better approach may be to leave the unit on LOW COOL during the day and to raise the thermostat setting several degrees, letting the unit run some during the day. A call back a few days later verifies that the unit is performing well using this approach. The unit had no problem; it was lack of operator knowledge.

SERVICE CALL 2

A customer calls to indicate that the air conditioner in the guest bedroom is not cooling the room. The coil behind the filter has ice on it. This sounds like a low-charge situation. *The problem is that a drape is partially hanging in front of the unit, causing the air to recirculate. The supply air louvres are also pointing downward.*

Wiping his feet before entering the apartment, the technician makes his way to the unit. He notices that the drape hangs in front of the unit and explains that the drape will have to be kept out of the airstream. Also, the air discharge is pointed down, causing the air to move toward the return-air inlet. This is adjusted.

Just to be sure that the unit does not also have a low charge, the technician pulls it out of the case and places it on a small stool so it can be started. The technician notices that when the unit is started, air blows out of the top of the blower compartment and bypasses the indoor coil, so he places a piece of cardboard over the fan compartment to force the air through the coil. He starts the unit again and partially blocks the condenser to force the head pressure higher. After the unit has run for a few minutes, the suction line starts to sweat back to the compressor.

If the unit had a low charge, ice would form on the bottom of the coil because there would not be enough refrigerant to fill it. If the coil were dirty or the airflow blocked, the coil might ice all over, even to the compressor. The compressor might sweat excessively because the refrigerant wouldn't be boiled to a vapor and liquid would enter the compressor. This unit has never had gauges installed, so it has the original charge and it is still correct. The technician stops the unit, pushes it back into its case in the window, and cleans the filter. The unit is started and left operating normally.

SERVICE CALL 3

A customer calls to report that his room air conditioner is not cooling so it has been turned off. *The problem is a leak in the high-pressure side of the system.*

The technician asks the owner about the problem he is having with the unit, explaining that he will look at the unit and make every effort to resolve the problem. He then starts the unit. The compressor runs, but it does not cool. The technician turns the unit off and slides it out of its case onto a stool and restarts the compressor. He feels the discharge line and notices that it is cool to the touch. The technician tells the customer that the unit will have to be taken to the shop for further evaluation. He then brings in a hand truck as well as materials to seal the opening left by the removed air conditioner. He informs the customer that he will receive a call as soon as there is more information about the unit.

At the shop, the unit is moved to a workbench, and a line tap valve is installed on the suction process tube. When the

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

gauges are fastened to the line tap valve, no pressure registers on the gauge. The system is out of refrigerant. The technician allows a very small amount of R-410A, the refrigerant for the system, to flow into the unit and then increases the pressure to about 100 psig with dry nitrogen. No leak can be heard, so an electronic leak detector is used, which locates a leak on the discharge-line connection to the condenser. The nitrogen, along with the trace of R-410A, is released from the unit. The process tube is cut off below the line tap valve connection. A 1/4-in. flare connection is soldered to the end of the process tube and a gauge manifold connected to the low side; the discharge line leak is repaired using a high-temperature, silver-bearing brazing rod.

After removing the torch from the connection, the gauge manifold valve is closed to prevent air from being drawn into the system when the vapor inside cools and shrinks. When the connection is cooled, nitrogen is introduced to the system and the leak is checked again, this time with a liquid leak detection solution. There is no leak. The nitrogen is released from the unit, and the system is ready for evacuation.

The vacuum pump is attached to the system and started. While the system is being evacuated, the technician moves the electronic scales to the system and prepares for charging. Because the service connection is on the low-pressure side of the system, the charge will have to be in the vapor state to prevent liquid refrigerant from entering the compressor. The unit is designed for 18.5 oz of refrigerant. The 30-lb cylinder should deliver enough refrigerant to keep the pressure from dropping during charging. When the appropriate level on the vacuum gauge, 500 microns, has been reached and held, the vacuum pump is disconnected from the unit and the center hose on the gauge manifold is connected to the refrigerant cylinder. The center hose on the manifold is purged of air, and the correct charge is allowed into the system.

If the charge will not move into the system, the technician may start the compressor to lower the low-side pressure where refrigerant will move from the cylinder into the system. **NOTE:** *DO NOT allow the system to operate in a vacuum. If it tries to go into a vacuum, shut the compressor off for a few minutes.* When the correct charge is established, the unit is started. It is cooling as it should.

The technician takes the unit back to the customer and places it in the window, starts it, and makes sure that it operates correctly. Before leaving, the technician asks the customer if there are any questions about the unit.

SERVICE CALL 4

A customer in a warehouse office reports that the window unit cooling the office is not adequately cooling the space. *The problem is a slow leak.*

When the technician looks at the unit, he determines that it definitely has a low charge; the evaporator coil is cold only halfway to the end. He pulls the unit out of the case and sets it on a stool. The technician points out that the unit is old and needs replacing. The customer asks if there is anything that can be done to get them through the day.

The technician fastens a line tap to the suction line and connects a gauge line; the suction pressure is 90 psig. The unit has R-410A, which should yield an evaporator temperature of 26°F. The unit is showing signs of frost on the bottom of the coil. This is an old unit, so the technician decides to add refrigerant to adjust the charge. It is about 80°F in the room. The condenser airflow is blocked until the leaving air is warm to the hand. Refrigerant is added until the suction line sweats to the compressor. The gauges are removed and the unit is placed back in the case, but the leak was not found. The company requests that a new unit be installed the next day. 4R *When the old unit is discarded, the refrigerant will have to be recovered before it is scrapped.* 4R

Classroom Discussion: How would you have handled this call? What would you have done with the line tap valve? Are any laws being violated?

SERVICE CALL 5

A new unit sold last month is brought to the shop for the technician to repair. The service repair order reads, "no cooling." *The problem is that the compressor is stuck and will not start.*

The technician checks to make sure the selector switch is in the OFF position and plugs the unit into a 230-V wall plug. This workbench is set up for servicing appliances so it has an ammeter mounted on it. The technician turns the fan to HIGH FAN; the fan runs. He then turns the selector switch to LOW FAN and the fan still runs. The amperage is normal, so the technician turns the selector switch to HIGH COOL, keeping a hand on the switch. The fan speeds up but the compressor does not start. The thermostat is not calling for cooling. When the thermostat is turned to a lower setting, the compressor tries to start. The ammeter registers locked-rotor amperage and does not fall back. The technician turns the unit off before the compressor overload reacts and disconnects the power cord.

Removing the unit from the case, the technician looks for the compressor terminal box. He removes the box cover and installs a hard-start kit on the compressor. The technician tries to start the compressor with the hard-start kit. It will not start; the compressor is stuck and must be changed.

4R *The technician installs a line tap valve on the suction process tube. Before piercing the refrigerant line, the technician leak tests the line tap valve. It is leak-free, so he pierces the refrigerant line and starts to recover the refrigerant. While the refrigerant is being recovered slowly, a new compressor, a 1/4-in. flare fitting for the process tube, and a suction-line drier are brought from the supply room. The technician removes the compressor hold-down bolts. When the refrigerant has been recovered, he uses an air-acetylene torch with a high-velocity tip to remove the suction and discharge lines.* 4R

The old compressor is removed and the new one set in place. Since the compressor failed, the technician decides to test the unit for acid and also install a suction line filter drier along with the new compressor for extra protection. The acid test results showed that the system was not acidic, but the technician still opted to install a suction line drier, just in case. The suction line is altered to get it ready for the installation of the suction-line drier. Before that is done, the compressor discharge line is brazed in place, and then the 1/4-in. flare fitting is installed on the process-tube connection (the process tube was cut off below the line tap connection). The suction line filter drier is soldered in place and then the suction line is brazed to the suction port of the compressor. A gauge line is fastened to the 1/4-in. flare connection. A small amount of R-410A is added to the system (to 5 psig), then nitrogen is used to pressure the system to 150 psig. A leak check is performed on all fittings; the unit is leak-free.

The small amount of refrigerant vapor and nitrogen is purged and the vacuum pump is fastened to the gauge manifold and started. When the vacuum pump has obtained a deep vacuum according to the micron gauge, the correct charge is weighed into the unit. The technician reconnects the compressor wiring while the vacuum pump operates so the unit will be ready to start. The technician plugs in the cord and turns the selector switch to HIGH COOL; the compressor starts. He allows the unit to run for 30 min and it operates satisfactorily. The process tube is pinched and cut off below the 1/4-in. flare fitting. The process tube is closed on the end and soldered shut.

SERVICE CALL 6

A customer reports that a window unit servicing the den and kitchen has tripped the breaker. This is a fairly new unit, 6 years old. The owner is told to shut the unit off and to not reset the breaker. *The problem is that the unit compressor is grounded.*

The technician introduces himself to the customer and asks about the problem with the unit and the circuit breaker. He decides to give the unit an ohm test before trying to reset the breaker and start the unit. The multimeter is set to read resistance, and the technician unplugs the unit, fastens one ohmmeter lead to each of the hot prongs (L1 and L2) on the 230-V plug, **Figure 46.71**, and turns the unit selector switch to HIGH COOL. There is a measurable resistance; all appears to be well. Before plugging the unit in, one more ohm test is necessary for the complete picture, a ground test. The multimeter is once again set to read resistance, and one test lead is connected to L2, while the other is connected to the ground prong on the plug. The meter reads 0 resistance; there is a ground in the unit somewhere, **Figure 46.72**. It could be in the fan motor or the compressor. Pulling the unit from its case, the technician disconnects the compressor terminals and touches one lead of the meter to the discharge line and the other to the common terminal; the meter reads 0 resistance. The compressor has the ground circuit. The customer is informed of the problem and given the price of repairing the unit.

Figure 46.71 The unit has a ground circuit according to the ohmmeter.

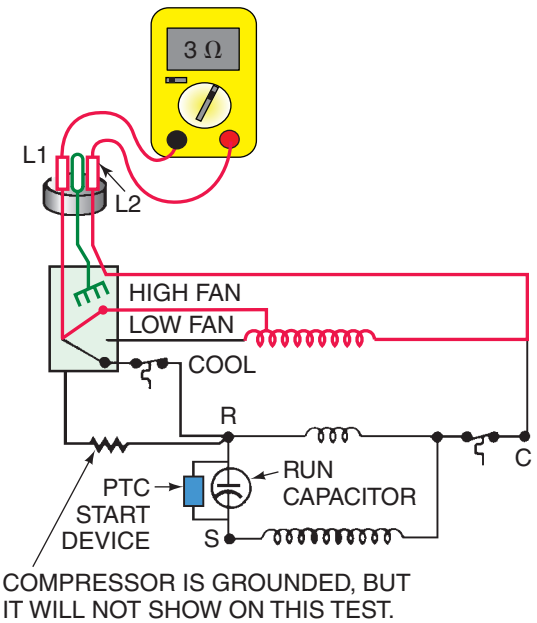

Figure 46.72 The ground circuit is through the compressor.

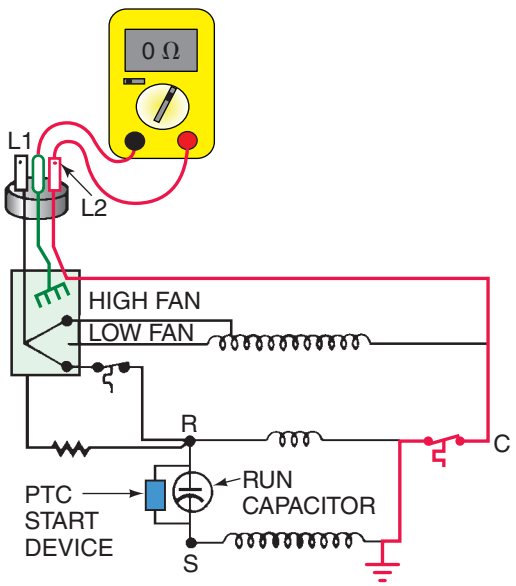

The technician takes the unit to the shop. The technicianobtains a liquid-line drier, a suction-line drier, a 1/4-in. "tee" fitting for the liquid line, a compressor, and a 1/4-in. fitting for the process tube. After the refrigerant is removed from the unit, the technician cuts the compressor discharge line at the compressor with diagonal pliers. He then cuts the suction line with a small tube cutter and removes the

Figure 46.73 The system is purged using the "tee" fitting installed in the liquid line.

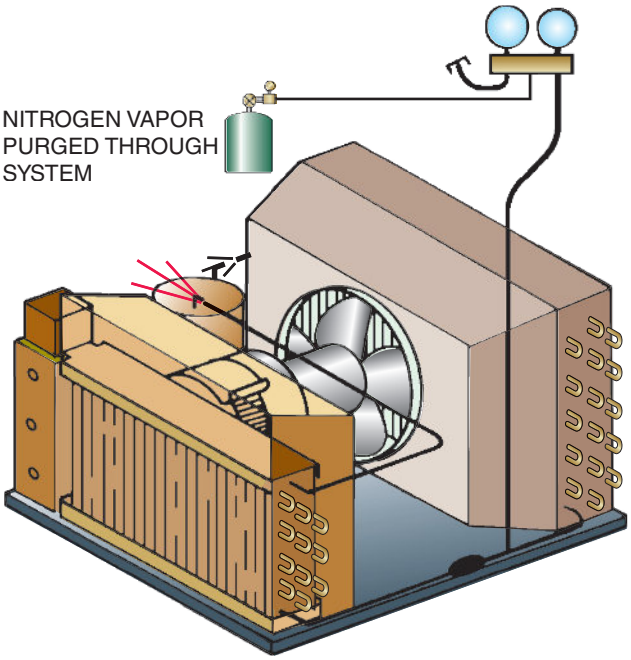

Figure 46.74 Liquid is charged into the system; this saves time.

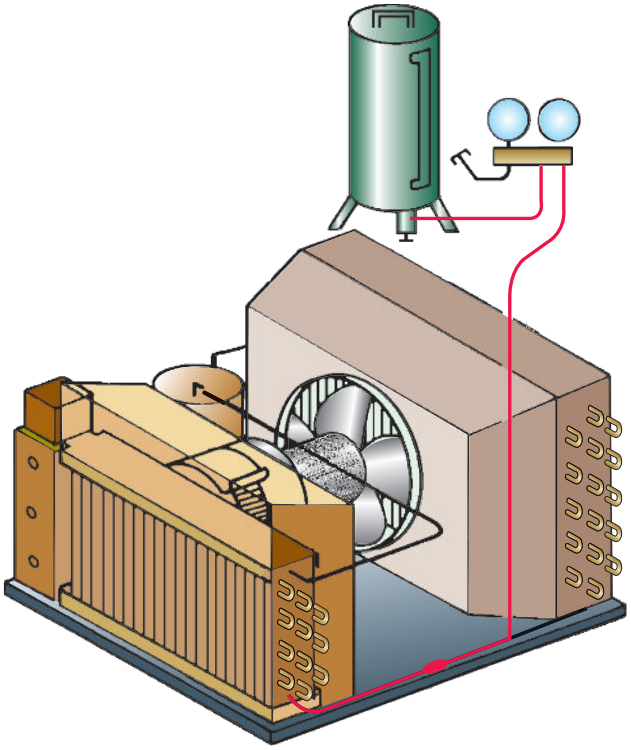

compressor from the unit. A "tee" fitting is installed in the liquid line, and a gauge line fastened to the "tee" fitting allows nitrogen to purge the unit, **Figure 46.73**. This will push much of the contamination out of the unit.

The technician sets the new compressor in place and solders the discharge line to the new compressor. The suction line is cut to the correct configuration for the suction-line drier. The liquid line is now cut, just before the strainer entering the capillary tube, and the new small drier is installed. The suction-line drier and the 1/4-in. fitting for the process tube are soldered in place. The gauges are fastened to the process port and the "tee" fitting in the liquid line. The unit is pressured with a small amount of R-410A (to 5 psig) and nitrogen is added to push the pressure up to 150 psig. The unit is then leak checked with an electronic leak detector. After the leak checking, the trace refrigerant and nitrogen are purged from the system. The vacuum pump is then connected and started. While the unit is being evacuated, the technician checks the run capacitor and relay. The capacitor is good, the coil on the relay has a measurable resistance, and the contacts look good.

The charge for the unit is 18 oz; adding the capacity of the small liquid-line drier, 1.9 oz, the total charge is 19.9 oz (this information should be packed in with the drier directions but not all manufacturers do so). When a 500-micron vacuum is obtained according to the micron gauge, the charge is added. The charge is in a charging cylinder, as explained in Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting," which has a liquid valve. The high-pressure gauge line is connected to the liquid line on the unit, and the charge is allowed to enter the system through the liquid line in the liquid state, **Figure 46.74**. When the complete charge is inside the unit, the liquid-line valve is pinched off and soldered shut.

The unit is started and allowed to run while the technician is monitoring the suction pressure and amperage. The unit is ready to be returned to the customer.

SUMMARY

- Room air conditioners may be designed to be installed in windows or through the wall.
- These units may be designed for cooling only, cooling and heating with electric strip heat, or cooling and heating with a heat pump cycle.
- The four major components in the cooling cycle for these units are the evaporator, compressor, condenser, and metering device.
- The heat pump cycle uses the four-way valve to redirect the refrigerant.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- The heat pump compressor is different from one found in a cooling-only unit. It must have enough pumping capacity for low-temperature operation.
- Before installing a unit, the technician should make sure that the electrical service is adequate.
- When installing these units, the technician should make sure there is no possibility of direct recirculation of air through the unit.
- The selector switch is the primary control for room air-conditioning units.
- The primary maintenance for these units involves keeping the filters and coils clean.
- Gauges should be installed for service only when it is determined that it is absolutely necessary.
- Electrical service may involve the fan motor, thermostat, selector switch, compressor, and power cord.

REVIEW QUESTIONS

1. A typical room air-conditioning unit has _____ (one or two) fan motors.
2. The most common refrigerant used in the past for window units was
   A. R-12.
   B. R-22.
   C. R-134a.
3. The line that carries refrigerant into the metering device is the
   A. suction line.
   B. discharge line.
   C. liquid line.
4. Typically room air-conditioning unit evaporators boil the refrigerant at
   A. 15°F.
   B. 25°F.
   C. 35°F.
   D. 45°F.
5. True or False: Typically, window air conditioners utilize automatic defrost.
6. The evaporator tubing is normally made of _____ or _____.
7. Compressors in these units are _____ sealed compressors.
8. The refrigerant in the capillary tube is _____ at the outlet than at the inlet.
   A. warmer
   B. colder
   C. the same temperature
9. Room units that use the heat pump cycle absorb heat from outdoors in the winter and reject the heat indoors by using a _____ reversing valve.
   A. two-way
   B. three-way
   C. four-way
   D. five-way
10. True or False: A window-unit heat pump compressor is the same as a conventional window-unit air-conditioning compressor.
11. The room temperature sensor is located in the _____ airstream.
    A. return
    B. supply
12. A 208/230-V unit will have _____ hot wire(s) and a ground.
    A. A. one
    B. B. two
    C. C. three
13. Describe the operation of the exhaust and fresh-air control.
14. Why should gauges be installed only after there is evidence that they are needed?
15. A head pressure of 420 psig with R-410A corresponds to a saturation temperature of _____.
    (Use the temperature/pressure relationship chart, **Figure 3.15**.)
    A. 100°F
    B. 110°F
    C. 120°F
    D. 130°F
16. In a normally operating R-410A window unit, the suction pressure should be approximately 110 psig, which converts to _____°F.
17. During the heat pump heating cycle, the hot gas from the compressor discharge line is directed to the
    A. indoor coil.
    B. outdoor coil.
18. What are two methods used to evaporate condensate from the evaporator?

UNIT 47

HIGH-PRESSURE, LOW-PRESSURE, AND ABSORPTION CHILLED-WATER SYSTEMS

OBJECTIVES

After studying this unit, you should be able to

- list different types of chilled-water air-conditioning systems.
- describe how chilled-water air-conditioning systems operate.
- state the types of compressors often used with high-pressure refrigerant water chillers.
- describe the operation of a centrifugal compressor in a high-pressure chiller.
- explain the difference between direct-expansion and flooded chiller evaporators.
- explain what is meant by approach temperature in a water-cooled condenser.
- state two types of condensers used in chilled-water systems.
- explain subcooling.
- list the types of metering devices used in high-pressure chillers.
- list the types of refrigerants typically used in low-pressure chillers.
- state the type of compressor used in low-pressure chiller systems.
- describe the metering devices used in low-pressure chiller systems.
- explain the purge system used on a low-pressure chiller condenser.
- describe the absorption cooling system process.
- state the refrigerant generally used in large absorption chillers.
- state the compound normally used in salt solutions in large absorption chillers.
- state the type of electric motors typically used on chiller air-conditioning systems.
- discuss the various start mechanisms for these motors.
- describe a load-limiting device on a chiller motor.
- discuss various motor overload protection devices and systems.

SAFETY CHECKLIST

- ✔ Wear gloves and use caution when working around hot steam pipes and other heated components.
- ✔ Use caution when working around high-pressure systems. Do not attempt to loosen fittings or connections when the system is pressurized. Follow recommended procedures when using nitrogen.
- ✔ Follow all recommended safety procedures when working around electrical circuits.
- ✔ Lock and tag disconnect boxes or panels when power has been turned off to work on an electrical system. There should be one key for this lock, and it should be in the technician's possession.
- ✔ Never start a motor with the door to the starter components open.
- ✔ Check pressures regularly as indicated by the manufacturer of the system.

Chilled-water systems are used for larger central air-conditioning applications because of the ease with which chilled water can be circulated in the system. If refrigerant were piped to all floors of a multistory building, there would be too many possibilities for leaks, not to mention the expense of the refrigerant to charge such a large system. The design temperature for boiling refrigerant in a coil used for cooling air is 40°F. If water can be cooled to approximately the same temperature, it can also be used to cool or condition air, **Figure 47.1**. This is the logic behind circulating chilled-water systems. Water is cooled to about 45°F and circulated throughout the building to air-heat exchange coils that absorb heat from the building air. Water used in this way is called a secondary refrigerant. Water is much less expensive to circulate than refrigerant, **Figure 47.2**.

Figure 47.1 Water circulating in a fan coil unit for cooling a room.

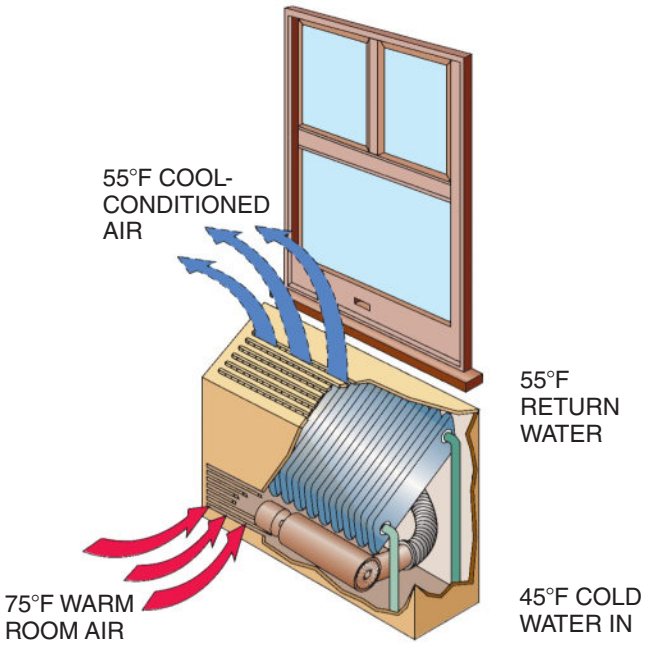

Figure 47.2 Water is circulating throughout the building to the fan coil units. It is considered to be a secondary refrigerant.

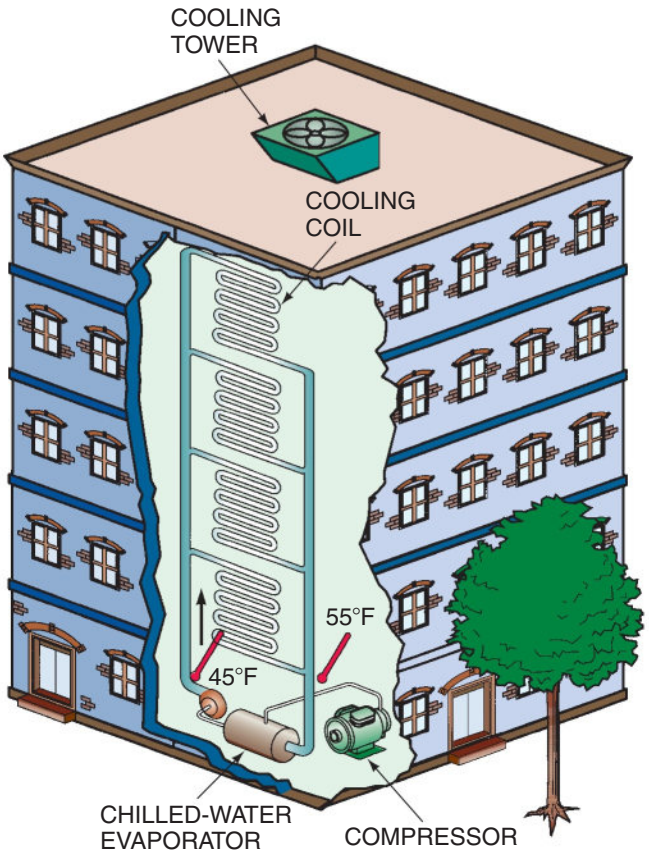

Chilled water circulated through a building is typically 45°F. *Lower water temperatures may be used to make the building side of the chilled-water system more efficient.* Many systems chill water to 42°F, and with the addition of electronic controls, some manufacturers are actually able to furnish 34°F chilled water. *The colder the circulating water, the smaller the terminal equipment—the coils and fans—can be. Also, with colder water, the interconnecting piping for the entire system can be smaller, which saves on piping supplies, fittings, and insulation for the entire system as well as on labor. Also, smaller fans and pumps save on electricity, because they consume less power.*

All installations must deal with variable loads. The load on the equipment is not constant. In a residential system, it is typical to just turn the unit off when the desired conditions are met. In large installations, it is not wise to simply cycle the compressor or chiller on and off as the load on the structure increases and decreases, because much of the wear-and-tear on the equipment occurs when the chiller is started. The motor bearings are not as well lubricated at start-up as they are when the compressor is running, so the motor is stressed when the compressor is started up. In most comfort-cooling installations, the load varies during the season as well as during the day. We saw in Unit 36, "Refrigeration Applied to Air-Conditioning," that when a system is designed for very high temperature conditions, the equipment will run at full load only a small percentage of the time. The rest of the time it will run at reduced load. At times, the equipment will need to operate at 40% or 50% of its capacity; other times that it will need to run at only 15% or 20% of its capacity in mild weather.

Manufacturers have developed many capacity-control methods for their equipment. Some chillers manage reduced capacity with variable-speed, or unloading, compressors. Variable-capacity control for each type of chiller will be discussed in the appropriate sections of this unit. Manufacturers usually rate chiller capacities and efficiencies at full-load operation. With energy costs rising and the increased emphasis on system efficiency and reduced environmental impact, manufacturers have implemented technologies to achieve efficient operation at part load. In the past, equipment did not typically operate as efficiently at part load.

47.1 CHILLERS

A chiller refrigerates circulating water. As the water passes through the evaporator section of the machine, often referred to as the chiller barrel, the temperature of the water is lowered. This chilled water is then circulated throughout the building, where it picks up heat. The typical design temperatures for a circulating chilled-water system are 45°F for water furnished to the building and 55°F for water returned to the chiller from the building, so the building heat adds about 10°F to the water supplied by the chiller. Upon returning to the chiller, the heat is removed from the water, which is then recirculated through the building.

Cooling buildings is not the only application for water chillers, although most of this unit will cover comfort-cooling chillers—a thorough discussion of all chiller applications would be beyond the scope of this text. Many industries use chillers for process cooling. Some chillers are designed to circulate water and glycol (antifreeze) mixtures at temperatures well below freezing. These are used, for example, in the plastic-molding manufacturing business. Milk bottles are manufactured by the process of injecting hot plastic into a mold, and the mold must be cooled to solidify the plastic. When a water valve is opened at the correct time in the process, the plastic milk bottle is water-cooled slightly until solid and is then ejected from the mold. The flow of chilled water is stopped and the mold is ready to make another bottle. The chilled water allows this process to happen very quickly.

The textile industry is another example of process cooling. Mills use huge amounts of chilled water to maintain the conditions that allow thread to move fast through the machines. If the temperature and humidity are held at the correct levels, maximum production can be accomplished. In the years before chilled water was used, mills could only operate at full capacity about 3 months of the year. With chilled water, ideal conditions can be maintained 24 hours a day for 365 days a year. Many mills run 24 hours a day year-round, allowing one week annually for maintenance.

There are two basic categories of chillers: the compression cycle chiller and the absorption chiller. The compression chiller uses a compressor to provide the pressure differences inside the chiller to boil and condense refrigerant. The absorption chiller uses a salt solution and water to accomplish the same result. These chillers are very different and are discussed separately. Manufacturers of both types provide different design features, but all of them attempt to build a reliable, low-cost chiller that will last a long time.

47.2 COMPRESSION CYCLE IN HIGH-PRESSURE CHILLERS

The compression cycle chiller has the same four basic components as a typical air conditioner: a *compressor*, an *evaporator*, a *condenser*, and a *metering device*. These components are generally larger, however, in order to handle more refrigerant, and they may use a refrigerant different from that used in air conditioners.

The heart of the compression cycle refrigeration system is the compressor. As mentioned in Unit 3, "Refrigeration and Refrigerants," there are several types of compressor. Those common in water chillers are the *reciprocating*, *scroll*, *screw*, and *centrifugal* compressors. Photos of these can be found in Unit 23, "Compressors." The compressor is the component in the system that both lowers the suction pressure and increases the discharge pressure. It can be thought of as a *vapor pump*. The compressor lowers the evaporator pressure to the desired boiling point of the refrigerant, which is about 38°F for a chiller. It then builds the pressure in the condenser to the point that vapor will condense to a liquid for reuse in the evaporator. The typical condensing temperature for a chilled-water system equipped with a water-cooled condenser is about 105°F. The technician can use temperatures to determine whether a typical chiller is operating within design parameters for pumping and compressing the vapor to meet the needs of a particular installation.

Compression cycle chillers may be classified as either *high-pressure* or *low-pressure systems*. Following is a discussion of high-pressure chilled water systems.

47.3 RECIPROCATING COMPRESSORS IN HIGH-PRESSURE CHILLERS

Large reciprocating compressors in water chillers operate in the same way as those used in any other application, with a few exceptions. A review of Unit 23, "Compressors," will help you to understand how these compressors function. Reciprocating compressors range in size from about ½ hp to approximately 150 hp, depending on the application. Many manufacturers use multiple smaller compressors instead of a single, larger pump. Reciprocating compressors are classified as positive displacement pumps and cannot pump liquid refrigerant without risk of damage. Several refrigerants have been used in reciprocating compressor chillers, most commonly R-500, R-502, R-12, R-134a, and R-22. *Because of ozone depletion and global warming concerns, environmentally friendly alternative refrigerants like R-134a and certain HFC refrigerant blends are now favored.*

Large reciprocating compressors have many cylinders in order to produce the pumping capacity needed to move large amounts of refrigerant. Some of these compressors have as many as 16 cylinders, thus the machine becomes one with many moving parts and much internal friction. If one cylinder of the compressor fails, the whole system will go off-line. If one compressor fails in a multiple-compressor system, the others can carry the load, so multiple compressors give some protection from total failure. This is the reason, as well as for capacity control, that many manufacturers choose to use multiple smaller compressors in their systems.

All large chillers must have some means for controlling capacity or the compressor will cycle on and off. This is not satisfactory because most compressor wear occurs during start-up before adequate oil pressure is established. A better design approach is to keep the compressor running but operate it at reduced capacity. Reduced-capacity operation also smooths out temperature fluctuations that occur from

shutting off the compressor and waiting for the water to warm up to bring the compressor back on.

CYLINDER UNLOADING AND VARIABLE-FREQUENCY DRIVES

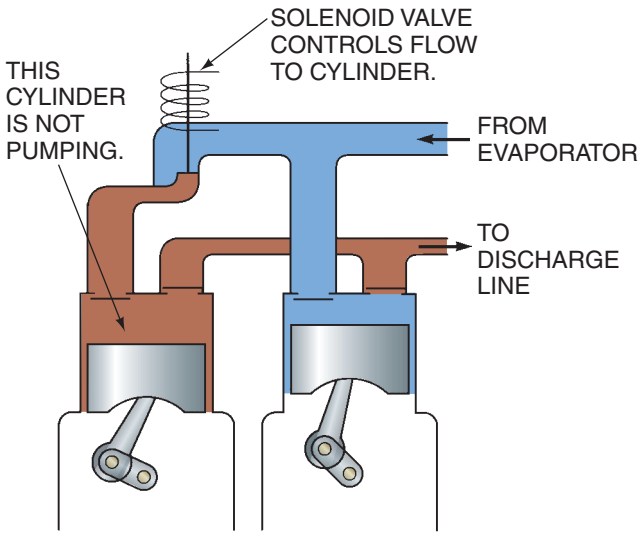
Reduced capacity for a reciprocating compressor is accomplished through *cylinder unloading* and *variable-frequency drives* (VFDs). For example, suppose the chiller for a large office building uses a 100-ton compressor with eight cylinders and the chiller has 12.5 tons of capacity per cylinder. When all eight cylinders are pumping, the compressor has a capacity of 100 tons ($8 \times 12.5 = 100$). As the cylinders are unloaded, the capacity is reduced. For example, the cylinders may unload in pairs, which would be 25 tons per unloading step. The compressor may have four unloading steps, which would give it four different capacities: 100 tons (eight cylinders pumping), 75 tons (six cylinders pumping), 50 tons (four cylinders pumping), and 25 tons (two cylinders pumping).

In the morning when the system first starts, the building may need only 25 tons of cooling. As the temperature outside rises and as people begin to enter the building, the chiller may need more capacity and the compressor will automatically load two more cylinders for 50 tons of capacity. As the heat load on the structure continues to rise, the compressor can load up to 100% capacity, or 100 tons. If the building—a hotel, for example—stays open at night, the compressor will start to unload as the outside temperature drops. It will unload down to 25 tons; if this is too much capacity, the chiller will then shut off. *When the chiller is restarted, it will start up at the reduced capacity, lowering the starting current.* A compressor cannot be unloaded to 0 pumping capacity because it would not be able to move any refrigerant through the system to return the oil in the system. *Usually compressors will unload down to 25% to 50% of their full-load pumping capacity.*

A big advantage of cylinder unloading is that the power needed to operate the compressor is reduced as capacity is reduced. The reduction in power consumption is not in direct proportion to compressor capacity, but the power consumption is greatly reduced at part load. In addition to the reduction in workload by cylinder unloading, the compression ratio is reduced; when a cylinder is unloaded, the suction pressure rises slightly and the head pressure is reduced slightly. Cylinder unloading is accomplished in several ways; **blocked suction unloading** and **suction-valve-lift unloading** are the most common.

BLOCKED SUCTION UNLOADING. Blocked suction is accomplished by placing a solenoid valve in the suction passage to the cylinder being unloaded, **Figure 47.3**. If the refrigerant gas cannot reach the cylinder, no gas can be pumped. If a compressor has four cylinders and the suction gas is blocked to one of them, the capacity of the compressor is reduced by 25% and the compressor then pumps at 75% capacity. Power consumption also decreases by approximately 25%. Power consumption is related to the amperage draw of the compressor. Amperage is typically measured in the field by using a clamp-on ammeter. When a compressor is running at half capacity, the amperage will be about half the full-load amperage. (The power consumption of a compressor is actually measured in watts. Using amperage as a measure of compressor capacity is close enough for field troubleshooting.)

Figure 47.3 Blocking the flow of refrigerant to one of the cylinders in a reciprocating compressor will unload that cylinder's load from the system.



SUCTION-VALVE-LIFT UNLOADING. If the suction valve is lifted off the seat of a cylinder while the compressor is pumping, the cylinder will stop pumping. Gas that enters the cylinder will be pushed back out into the suction side of the system on the upstroke. There is very little resistance to the refrigerant being pumped back into the suction side, so it requires almost no energy. As in the example of blocked suction, power consumption will be reduced. One of the advantages of lifting the suction valve is that the gas that enters the cylinder will contain oil, and good cylinder lubrication will occur even while the cylinder is not pumping. Compressor unloading could be accomplished by letting hot gas back into the cylinder, but this is not practical because power output will not be reduced. When the gas has been pumped from the low-pressure side to the high-pressure side of the system, the work has been accomplished. Also, allowing hot gas back in would overheat the cylinder by making it compress the hot gas again.

Except for cylinder unloading, the large reciprocating chiller compressor is the same as smaller reciprocating compressors. Most compressors over 5 hp have pressure-lubricating systems. The lubricating pressure is provided by an oil pump that is typically mounted on the end of the

compressor shaft and driven by the shaft, **Figure 47.4**. The oil pump picks up oil in the sump at evaporator pressure and delivers it to the bearings at about 30 to 60 psig greater than suction pressure, called net oil pressure, **Figure 47.5**. The compressors also have an oil safety shutdown in case of oil pressure failure, which has a time delay of about 90 sec to allow the compressor to get started and to establish oil pressure before it shuts the compressor off.

VARIABLE-FREQUENCY DRIVES. Variable frequency drives, VFDs, electronically alter the frequency of alternating-current (AC) sine waves through a device called an inverter. Today, compressor motors can operate within a wide range of speeds that can vary capacity without shutting off. *The speeds used are in conjunction with electronic expansion valves that also have an almost unlimited ability to vary refrigerant flow to the evaporator. The condenser water pump and the chilled-water pumps may also have VFD drives that can vary the water flow. The system flow rates must be synchronized by computer and take into account the desired system conditions to prevent problems and maintain minimum and maximum flow rates for all the devices that are being coordinated.* See Unit 17, "Types of Electric Motors," for details.

Figure 47.4 The pressure lubrication system for a reciprocating compressor. Notice that the oil pump is on the end of the shaft. The oil is picked up from the sump and pumped through the drilled passages to all moving parts.

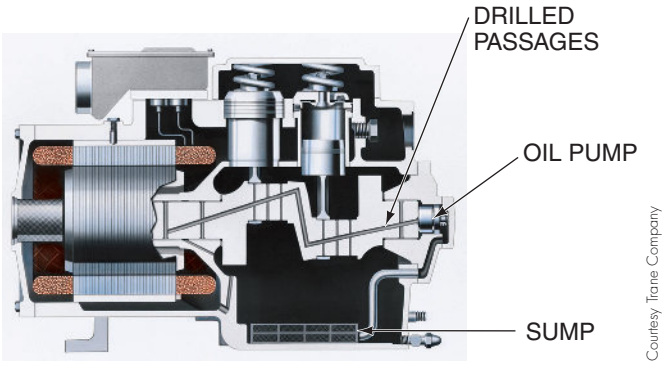

Figure 47.5 The oil pump's inlet pressure is the same as the system's suction pressure in the crankcase. The oil pump then increases the oil pressure to the pump's discharge pressure.

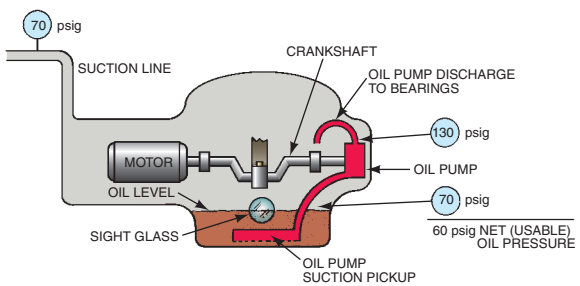

47.4 SCROLL COMPRESSORS IN HIGH-PRESSURE CHILLERS

The scroll compressor is a welded, hermetic, positive displacement compressor. The scroll compressors in chillers are larger than those described earlier in this text. They are in the 10- to 25-ton range but operate the same as the smaller compressors. See **Figure 47.6** for an illustration of a scroll compressor. When these compressors are used in chillers, the capacity control of the chiller is maintained by cycling the compressors off and on in increments of 10 and 25 tons. For example, a 25-ton chiller would have a 10- and a 15-ton compressor and would have capacity control of 10 and 15 tons. A 60-ton chiller may have four 15-ton compressors and be able to operate at 100% (60 tons), 75% (45 tons), 50% (30 tons), and 25% (15 tons).

Some of the advantages of the scroll compressor include the following:

1. Efficiency
2. Quietness
3. Fewer moving parts
4. Size and weight
5. Ability to pump small amounts of liquid refrigerant without compressor damage

Figure 47.6 The check valve in a scroll compressor prevents discharge pressure from flowing back through the compressor when the compressor shuts down.

The scroll compressor offers little resistance to refrigerant flow from the high side of the system to the low side during the off cycle. A check valve is provided to prevent backward flow when the system is shut down, **Figure 47.6**. Lubrication of the scroll compressor is provided by an oil pump at the bottom of the crankshaft. The oil pump picks up oil and lubricates all moving parts on the shaft.

One type of chilled-water system that utilizes scroll compressors is the reverse-cycle chiller. This type of system, which is becoming more popular, has the ability to provide both heated and chilled water for many different applications, **Figure 47.7**. Uses for this type of system include

- Swimming pool heating
- Commercial aquariums
- Radiant heating
- Ice/Snow-melting
- Conventional chilled-water comfort cooling

Systems such as the one shown in **Figure 47.7** have multiple scroll compressors, allowing them to function efficiently and effectively during both high- and low-load periods. These are packaged chillers, so no refrigerant lines need to be installed in the field. However, interconnecting water lines do need to be installed and all local codes must be followed when doing so. As with any chilled-water system, the water that circulates through the system's heat exchangers must be treated. This will help ensure that the amount of scaling and corrosion on the interior heat exchanger surfaces is minimized, prolonging the useful life of the equipment.

Figure 47.7 A reverse-cycle (heat pump) chilled-water system with multiple scroll compressors.

47.5 ROTARY SCREW COMPRESSORS IN HIGH-PRESSURE CHILLERS

Most of the major manufacturers are building rotary screw compressors for larger-capacity chillers, which use high-pressure refrigerants. The rotary screw compressor is capable of handling large volumes of refrigerant with few moving parts, **Figure 47.8**. A positive displacement compressor, this type of compressor is

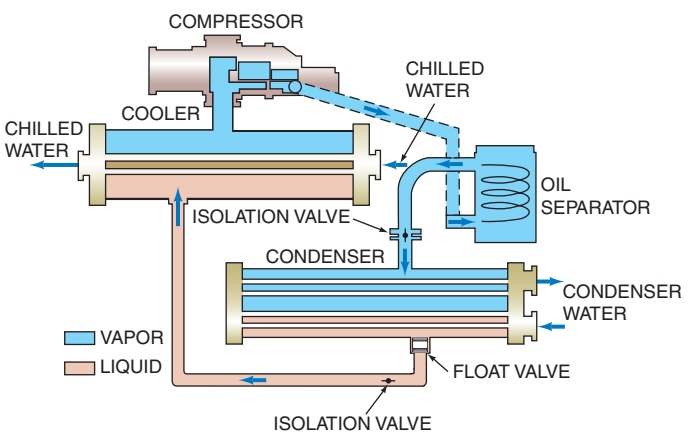
able to handle *some* liquid refrigerant without compressor damage, unlike the reciprocating compressor, which cannot handle liquid refrigerant. Rotary screw compressors are manufactured in sizes from about 50 to 700 tons of capacity and are reliable and trouble-free.

Manufacturers build both *semihermetic rotary screw compressors* and *open-drive compressors*. The open-drive models are direct drive and must have a shaft seal to contain the refrigerant at the point where the rotating shaft penetrates the compressor shell. It is common practice to start up open-drive compressors regularly during the off-season to keep the shaft seal lubricated. Long periods of system downtime can cause the shaft seal to dry out and shrink somewhat, allowing refrigerant to leak from the system.

Capacity control for a rotary screw compressor may be accomplished by means of a *slide valve* that blocks the suction gas before it enters the rotary screws in the compressor or by means of compressor VFD speed control. The slide valve is typically operated by differential pressure in the system. *The slide valve may be moved to the completely unloaded position before shutdown so that on start-up, the compressor is unloaded, reducing the inrush current. Most of these compressors can function from about 10% load to 100% load with sliding graduations because of the nature of the slide valve unloader.* This is in contrast to the step capacity control of a reciprocating compressor, which unloads one or two cylinders at a time.

Screw compressors pump a great deal of oil while compressing refrigerant, so they typically have an oil separator to return as much oil to the compressor reservoir as possible, **Figure 47.9**. The oil is moved to the rotating parts of the compressor by means of pressure differential within the compressor instead of an oil pump. Oil is also accumulated in the oil reservoirs and moved to the parts that need lubrication by means of gravity. The rotating screws are close together but do not touch. The gap between the screws is sealed by oil that is pumped into the rotary screws as they turn. This oil is separated from the hot gas in the discharge line and returned to the oil sump through an oil cooler. This separation is necessary because if too much oil reaches the system, a poor heat exchange will occur in the evaporator and cause loss of capacity. The natural place to separate the oil from the refrigerant is in the discharge line. Manufacturers use different methods for this process, but all use some means of oil separation.

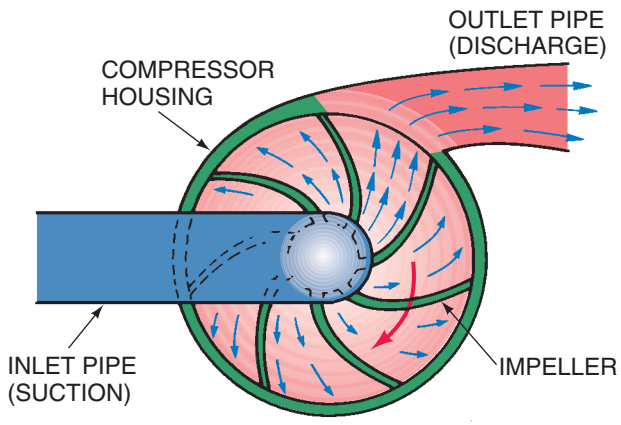
Figure 47.9 An oil separator for a rotary screw compressor.



47.6 CENTRIFUGAL COMPRESSORS IN HIGH-PRESSURE CHILLERS

The centrifugal compressor applies only centrifugal force to the refrigerant to move it from the low- to the high-pressure side of the system, **Figure 47.10**. It functions like a large fan that creates a pressure difference from one side of the compressor to the other. Although it does not exert a great deal of force, it can handle a large volume of refrigerant, and some companies manufacture centrifugal compressors for use in high-pressure systems. In high-pressure systems, the compressor is turned very fast by means of a gearbox or multiple stages of compression to provide the pressure difference from the evaporator to the condenser. Typical motor speeds in direct-drive reciprocating, scroll, and rotary screw compressors are near 3600 rpm. In centrifugal systems, a gearbox is used to speed the compressor up to higher rpm levels when faster speeds are needed. Some single-stage centrifugal compressors use speeds of about 30,000 rpm. The gearbox used to obtain the high speeds of the centrifugal compressor adds some friction to the system that must be overcome; it causes a slight loss of efficiency due to the horsepower needed to turn the gears. There are typically two gears: The drive gear is the larger of the two, and the driven gear is the smaller and turns the fastest. **Figure 47.11** illustrates a gearbox.

Figure 47.10 Centrifugal action is used to compress refrigerant.



THE TURNING IMPELLER IMPARTS CENTRIFUGAL FORCE ON THE REFRIGERANT, FORCING THE REFRIGERANT TO THE OUTSIDE OF THE IMPELLER. THE COMPRESSOR HOUSING TRAPS THE REFRIGERANT AND FORCES IT TO EXIT INTO THE DISCHARGE LINE. THE REFRIGERANT MOVING TO THE OUTSIDE CREATES A LOW PRESSURE IN THE CENTER OF THE IMPELLER WHERE THE INLET IS CONNECTED.

The gearbox and impeller of the centrifugal compressor have bearings that support the weight of the turning shaft. The bearings are typically made of a soft material known as babbitt. The babbitt is backed and supported by a steel sleeve. A single-stage compressor must also have a thrust bearing to counter the thrust of the refrigerant entering the compressor impeller. The thrust bearing counters the sideways movement of the shaft due to the force of the entering refrigerant.

If the head pressure becomes too high or the evaporator pressure too low, the centrifugal compressor cannot overcome the pressure difference and stops pumping. The motor and compressor still turn, but refrigerant stops moving from the low- to the high-pressure side, and the compressor may make a loud whistling sound, called a "surge." Even though this is a loud noise, it will normally not cause damage to the compressor or motor unless allowed to continue for a long time. If damage does occur due to prolonged surge times, it is likely to be borne by the thrust surface of the bearings or the high-speed gearbox. The clearances in the impeller of a centrifugal compressor are critical, **Figure 47.12**. The parts must be very close together or refrigerant will bypass from the high-pressure side of the compressor to the low-pressure side.

A separate motor and oil pump provide lubrication for the centrifugal compressor. A three-phase fractional horsepower motor (usually 1/4 hp to 3/4 hp) is located inside the oil sump and runs in the refrigerant and oil atmosphere. A three-phase motor is used so that there will be no internal motor start switch, as in a single-phase motor. This allows the oil pump to start before the centrifugal motor and establish lubrication before the compressor and gearbox start to turn. It also allows the oil pump to run as the centrifugal impeller and gearbox coast down at the end of a cycle when the machine is shut off. Enough oil is also in the reservoirs to prevent bearing and gear failure during a coast down in the event of a power failure. The oil pump, usually a gear-type positive displacement pump, would normally furnish a net oil pressure of about 15 psig to the bearings and, with some compressors, to an upper sump where oil is fed by gravity to the bearings and gearbox during a coast down because of power failure, **Figure 47.11**. There are many methods of routing the oil, but the oil must have enough pressure to reach the farthest bearings with enough pressure to circulate the oil around them.

The lubrication system for a centrifugal chiller is sealed; oil is not intended to be mixed with the refrigerant and separated for recovery as in the reciprocating, scroll, or rotary screw systems. If the oil does get into the refrigerant, it is difficult to remove because only vapor should leave the evaporator. When refrigerant in the evaporator becomes saturated with oil, heat exchange becomes less efficient. Oil-logged refrigerant must be distilled to remove the oil. This is a long, time-consuming process, so the intent of the manufacturer is to keep the two separated. A heater in the oil sump prevents liquid refrigerant from migrating to the sump when the system is off, **Figure 47.11**. The heater typically maintains the oil sump at about 140°F. Without this heater, the oil would soon become saturated with liquid refrigerant. But even with the heater operating, some liquid migrates to the sump and the oil may have a tendency to foam for a few minutes immediately after the compressor is started. The operator should keep an eye on the oil sump and run the compressor at reduced load until any foaming in the oil is reduced. Foaming oil contains liquid refrigerant that is boiling off and is not a good lubricant until the refrigerant is boiled away.

When a chiller is operating, the oil is heated as it lubricates the moving parts and also absorbs heat from the bearings to cool them. If it is not cooled, the oil will become overheated, so an oil cooler is in the circuit during operation. The oil typically is pumped from the oil sump through a filter and an oil cooler heat exchanger where either water or refrigerant removes some of the heat from the oil, **Figure 47.11**. The oil cooler cools the oil from a sump temperature of 140°F–160°F to about 120°F. The oil will then pick up heat again while lubricating.

Capacity control in the centrifugal compressor is accomplished by means of guide vanes at the entrance to the impeller eye. These guide vanes, usually pie-shaped devices arranged in a circle, can rotate to allow full flow or reduced flow down to about 15% or 20%, depending on the clearances in the vane mechanism, **Figure 47.13**. The guide vanes also serve another purpose in that they help the refrigerant enter the impeller eye by starting it in a rotation pattern that matches the rotation of the impeller. The guide vanes are often called the prerotation guide vanes. They are controlled by electronic or pneumatic (air-driven) motors that vary the capacity of

the centrifugal compressor. The controller sends either a pneumatic air signal or an electronic signal to the operating motor of the inlet guide vane, which is either a pneumatic or electronic motor. When the building load begins to be satisfied, the controller tells the vane motor to start closing the vanes. The capacity control motor is controlled by the temperature of the entering or leaving chilled water, depending on the engineer's design. If the guide vanes are closed, the compressor pumps at only 15% to 20% of its rated capacity. When open all of the way, the compressor pumps 100%. A 1000-ton chiller can operate from 150–200 tons to 1000 tons of capacity in any number of steps. The guide vanes can also be used for two other purposes—to prevent motor overload and to start the motor at reduced capacity to reduce the current on start-up.

When a chiller is operating at a condition in which the chilled water is above the design temperature—for example, when a building is hot on a Monday morning start-up—the compressor motor would run under an overloaded condition. At that time, the return chilled water may be 75°F instead of the design temperature of 55°F. A control known as a *load limiter* on the chiller control panel will sense the motor amperage and partially close the guide vanes to limit compressor amperage to the full-load value. When the controls have established that the compressor motor is up to speed, the control system will take over and rotate the vanes to the correct position for the application. When the compressor starts, the prerotation guide vanes are closed and do not open until the motor is up to speed. Therefore, the compressor starts up unloaded, which reduces the power required to start the compressor.

Some centrifugal compressors are hermetically sealed and some have open drives, **Figure 47.14**. The motors of hermetically sealed compressors are refrigerant-cooled. **Figure 47.15** shows a liquid-cooled motor. Liquid refrigerant is allowed to flow around the motor housing. Systems with open-drive motors use the air in the equipment room to cool the motor. The heat from a large motor is considerable and must be exhausted from the equipment room. The rotation of the motor in many centrifugal chillers is critical. If the motor is started in the wrong direction, some chillers can be damaged, as will be discussed later in this unit.

47.7 EVAPORATORS FOR HIGH-PRESSURE CHILLERS

The evaporator is the component that absorbs heat into a system. In the evaporator, liquid refrigerant is boiled to a vapor by the circulating water. This portion of a chilled-water system is often called the chiller barrel. For water chillers, the heat exchange surface is typically copper. Other materials may be used if corrosive fluids are being circulated for manufacturing processes. In typical smaller air-conditioning systems, air is on one side of the heat exchange process and liquid or vapor refrigerant on the other. The rate of exchange between air and vapor refrigerant is only fair. The exchange between air and liquid refrigerant is better, and the best heat exchange is between water and liquid refrigerant. This is what gives the water chiller part of its versatility. The heat exchange surface can be small and still produce the desired results.

DIRECT-EXPANSION EVAPORATORS

The evaporators used in high-pressure chillers are either direct-expansion evaporators or flooded evaporators. **Direct-expansion evaporators** are also known as dry-type evaporators, meaning they have an established superheat at the evaporator outlet, and they normally use thermostatic expansion devices to meter the refrigerant. They are used on smaller chillers, of up to approximately 150 tons for older types and to about 100 tons for more modern chillers. Refrigerant in direct-expansion chillers is introduced into the end of the chiller barrel and water is introduced into the side of the shell, **Figure 47.16**. The water is on the outside of the tubes, where baffles cause it to come in contact with as many tubes as possible for the best heat exchange. The problem with this arrangement occurs when the water side of the circuit gets fouled or dirty. The only way the chiller can be cleaned is with chemicals because it cannot be cleaned with brushes. It is in this way that these chillers differ from those

in which the water circulates in the tubes and the refrigerant circulates around the tubes—as with flooded chillers.

FLOODED EVAPORATOR CHILLERS

Flooded chillers introduce refrigerant at the bottom of the chiller barrel and the water circulates through the tubes. There are some advantages to this arrangement because the tubes may be totally submerged in the refrigerant for the best heat exchange, **Figure 47.17**. The tubes may also be physically cleaned in several different ways. **Figure 47.18** shows tubes being cleaned with a brush. The water side of an evaporator should not become dirty with this system unless the chiller is being used in an open process, such as a manufacturing operation. Most chillers use a closed water circuit that should remain clean unless there are many leaks and water must be continually added. Flooded chillers use much more refrigerant charge than direct-expansion chillers, so leak monitoring must be part of regular maintenance with high-pressure systems.

Figure 47.18 *Cleaning the tubes in a condenser by using a power brush and flushing with water.*

Courtesy Goodway Tools Corporation

Water introduced into the end of the chiller is contained in water boxes. Water boxes with removable covers are known as marine water boxes, **Figure 47.19**. Water-box covers with attached piping that must be detached to remove the covers are known as standard covers, **Figure 47.20**. The water box is used to direct the water by means of partitions. For example, water may need to pass through the chiller one, two, three, or four times to achieve different purposes. Thus a manufacturer can use one chiller with combinations of water boxes and partitions for different applications.

Water passing through a chiller once is in contact with the refrigerant for only a short period of time. Using two, three, or four passes keeps the water in contact longer but also creates more pressure drop and more pumping horsepower, **Figure 47.21**. In a two-pass chiller, the design water temperatures are typically 55°F for inlet water and 45°F for outlet water.

Figure 47.19 Marine water boxes allow the technician to clean the tubes by removing the water-box cover; piping does not have to be disconnected.

Figure 47.20 Standard water-box covers with piping connections.

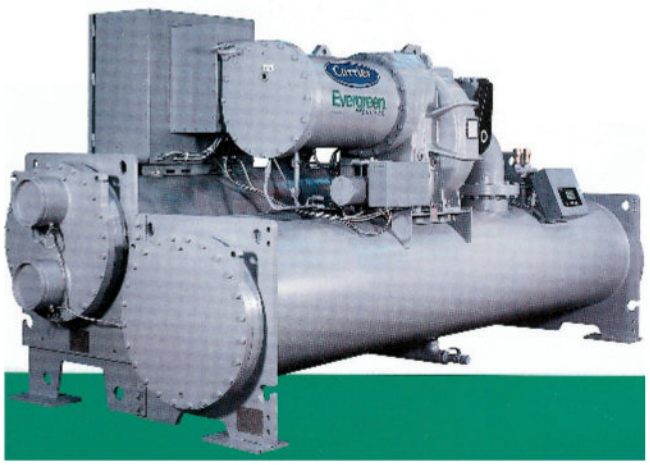

Figure 47.21 Heat exchangers for evaporators or condensers that are one-, two-, three-, and four-pass shells.

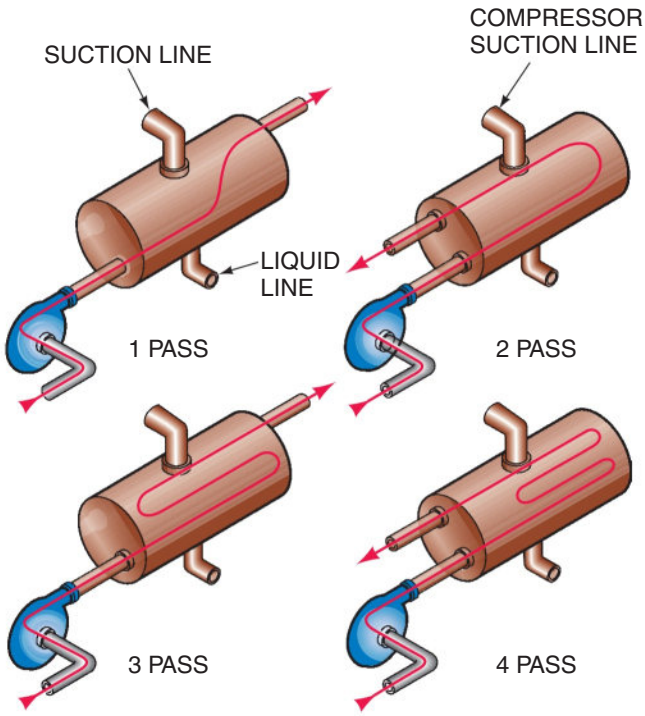
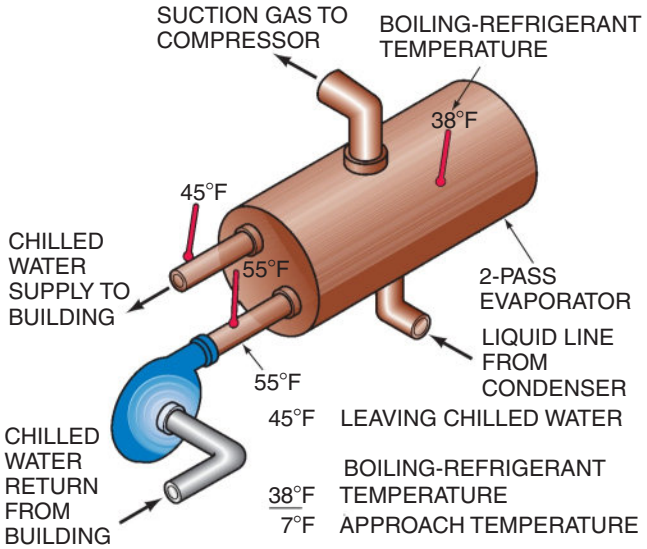


The refrigerant is absorbing heat from the inlet water, and its boiling temperature is typically about 7°F cooler than that of the leaving water. The inlet temperature is called the approach temperature, **Figure 47.22. The approach temperature is very important to the technician when troubleshooting chiller performance.** If the chiller tubes become dirty, the approach temperature becomes greater because the heat exchange rate between the refrigerant and the water will decrease. If the water cannot give up heat to the refrigerant, the temperature of water will be higher than desired and the saturation temperature of the refrigerant will be lower than desired.

Figure 47.22 Approach temperature for a two-pass chiller.



The approach temperature is different for chillers with a different number of passes. Direct-expansion chillers have only one pass of water (with baffles to sweep the tubes), and the approach temperature may be about 8°F. Chillers with three-pass evaporators will have an approach temperature of about 5°F, and chillers with four passes may have an approach temperature of 3°F or 4°F. The longer the refrigerant is in contact with the water, the lower the approach temperature will be. Flooded chillers generally have a means of measuring the actual refrigerant temperature in the evaporator, either with a thermometer well or as a direct readout on the control panel. Direct-expansion chillers typically have a pressure gauge on the low-pressure side of the system; the pressure must be converted to temperature to determine the evaporating refrigerant temperature. When a chiller is first started up, a record known as an operating performance log should be kept. Data should be recorded when the chiller is at full-load conditions. Often, equipment manufacturers rather than the contractor choose to start up larger chillers because of the cost of warranty. They will update the entries in the operating log and keep it on file for future reference. **Figure 47.23** is an example of an equipment manufacturer's log sheet.

When water is boiled in an open pot and the heat is turned up to the point that the water is boiling vigorously, water will splash out of the pot. Refrigerant in a flooded chiller acts much the same way; the compressor removes vapor from the chiller cavity, which will accelerate the process due to vapor velocity. Liquid eliminators are often placed above the tubes to prevent liquid from carrying over into the compressor suction intake at full load, **Figure 47.17**. In a flooded chiller, the suction gas is often saturated as it enters the suction intake of a compressor, unlike in a direct-expansion chiller where the gas will always have some superheat when leaving the evaporator.

Evaporators are constructed as a shell with end sheets to hold the tubes. *The heat exchange qualities of both direct-expansion and flooded tube surfaces may be improved by machining fins on the outside of the tubes. Direct-expansion evaporator tubes may have inserts that cause the refrigerant to sweep the sides of the tube, or the inside of the tube may be rifled like the bore of a rifle,* **Figure 47.24.** These features cause slight pressure drops, but the improvements are worth the drop. Typically, the tubes are made leak-free in the tube sheets by a process called rolling. Grooves are cut in the hole in the tube sheet into which the tube fits. After the tube is inserted in the hole, it is expanded into the grooves by being rolled with a roller for a leak-free connection, **Figure 47.25**. Some chiller evaporators may have tubes that are silver-soldered at the tube sheet. These tubes would be hard to repair by replacing them, compared to the ones that are rolled in place.

Evaporators have a working pressure for the refrigerant and the water circuits. High-pressure chillers must be able to accommodate the refrigerant used, generally R-22, R-410A, or R-134a. Newer, environmentally friendly, alternative refrigerants may also be used in newer equipment. The water side of the chiller may have one of two working pressures, 150 or 300 psig. The 300-psig chillers are used when the chiller is to be located on the bottom floor of a tall building where the water column will create a high pressure

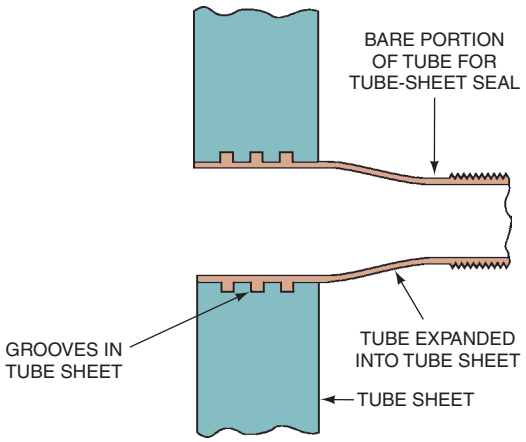
Figure 47.25 The tubes are rolled into the tube-sheet grooves to make a leak-free connection between the refrigerant side and the water side.



from the standing column of water. Unit 37, "Air Distribution and Balance," indicates that 1 psi of pressure will support a column of water 2.31 ft high. A column of water 1 ft high will exert a pressure of 0.433 psig (1 psi/2.31 ft = 0.4329, or 0.433 psi/ft). A chiller with a 300-psig working pressure can have only 693 ft of water standing above it, which would create a pressure of 300 psig (300 psi/0.433 ft/psi = 692.8 ft). Each story of a multistory building is about 12 ft, so this chiller could serve a building that is only 58 stories high (692.8/12 = 57.5 stories). Chillers can be located on the upper floors of multistory buildings. Service becomes more difficult, but not many other options exist.

Evaporators are leak tested after manufacture. If proven to be leak-free, they are then insulated. Many larger chillers are insulated with rubber foam insulation that is glued directly to the shell. Smaller chillers may be insulated by being placed in a skin of sheet metal with foam insulation applied between the chiller shell and the skin. A repair requires the skin to be removed and the foam cut away. The skin can be replaced later and foam insulation added back to insulate the chiller barrel. Some evaporators may be located outside, as is the case with an air-cooled package chiller, so freeze protection for the water in the shell is necessary. Resistance heaters can be added to the chiller barrel under the insulation. The heaters may be wired into the chiller control circuit and energized by a thermostat if the ambient temperature approaches freezing and water is not being circulated.

47.8 CONDENSERS FOR HIGH-PRESSURE CHILLERS

The condenser is the component that transfers heat out of the system. The condenser for high-pressure chillers may be either water-cooled or air-cooled. Both will absorb the heat and transfer it out of the system, usually to the atmosphere. In some manufacturing processes, the heat may be recovered and used for other purposes.

WATER-COOLED CONDENSERS

Water-cooled condensers used for high-pressure chillers are the shell-and-tube type with the water circulating in the tubes and the refrigerant around the tubes. The shell must have a working pressure to accommodate the refrigerant used and a water-side working pressure of 150 to 300 psig, like the evaporators mentioned earlier. The hot discharge gas is normally discharged into the top of the condenser, **Figure 47.26**. The refrigerant is condensed to a liquid and drips down to the bottom of the condenser, where it gathers and drains into the liquid line. As with evaporators, the heat exchange can be improved by use of extended surfaces on the refrigerant side of the condenser tube, **Figure 47.24**. The inside of the condenser tubes may also be grooved, as with the evaporator tubes, for improved water-side heat exchange.

Condensers must also have a method for piping the water into the shell. There are two basic types of connections to the water box that is attached to the condenser shell. In a standard water box, the piping is attached to the removable water box and some of the piping must be removed before the inspection cover can be removed on the piping end. A marine water box has a removable cover for easy access to the piping end of the machine. Tube access is more important for the condenser than the evaporator in most installations because the water in the cooling tower is open to the atmosphere and more likely to carry dirt and other foreign matter into the condenser.

Some comfort-cooling installations serve both cooling and heating needs at the same time. While the outside of the building may need heat in the winter, the inside or core of the building may be generating heat from lighting and equipment that needs to be removed. These installations may have what is known as double-bundled condensers, which are two condensers in one shell. *When the heat can be used for the building perimeter, the warm condenser water can be circulated in the heating circuit.* When the heat needs to be transferred to the outside, the other condenser may be used and the heat transferred to the cooling tower. With this type of installation, the temperature of the water from the condenser may not be warm enough, so the water temperature may be increased with a boiler. *The net result is that the water entering the boiler is preheated with the heat from the building interior.*

CONDENSER SUBCOOLING

The design condensing temperature for a water-cooled condenser is around 105°F on a day when 85°F water is supplied to the condenser and the chiller is operating at full load. The saturated liquid refrigerant would be 105°F. Many condensers have subcooling circuits that reduce the liquid temperature to below 105°F. If the entering water at 85°F is allowed to exchange heat from the saturated refrigerant, the liquid-line temperature can be reduced. *If the water can be reduced to 95°F, a considerable amount of capacity can be gained for the evaporator, which can increase the machine capacity by about 1%/°F of*

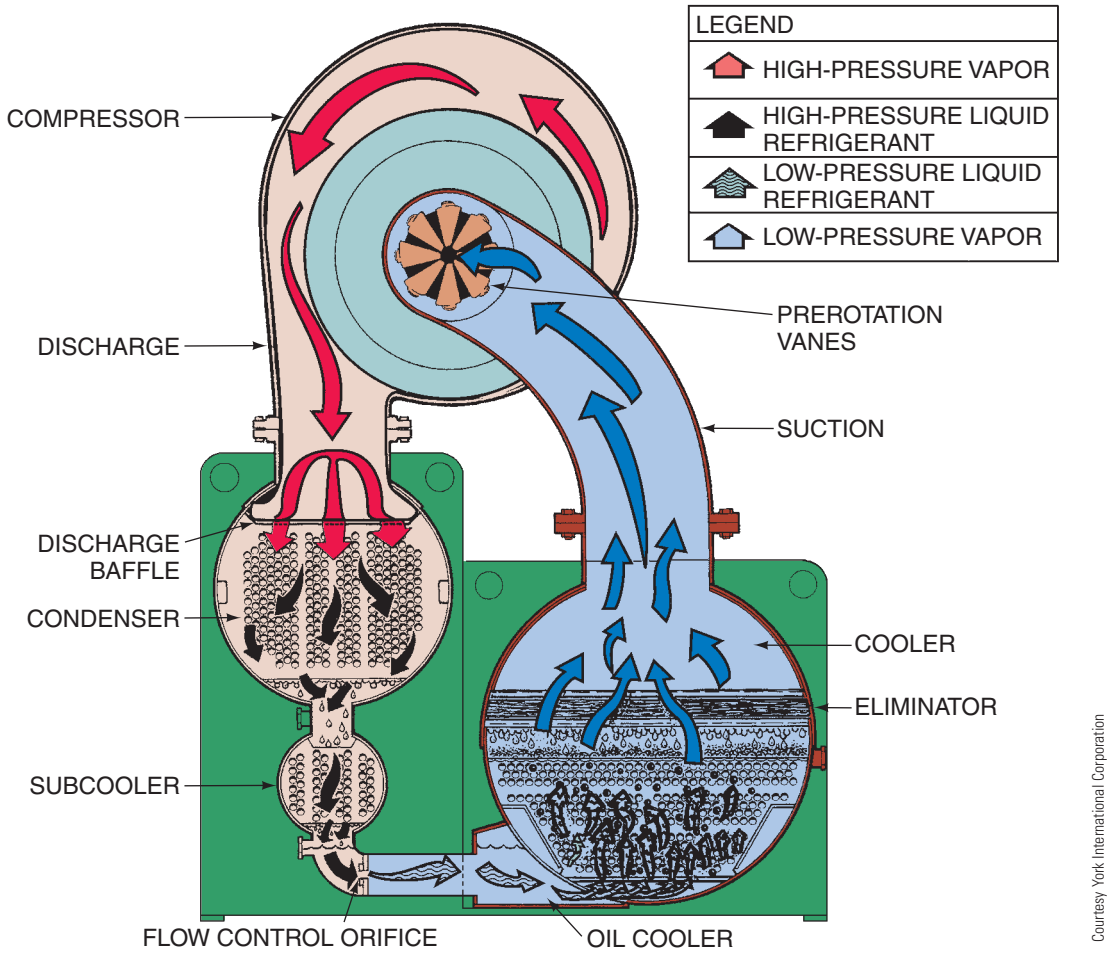
Figure 47.26 *The subcooling circuit improves the efficiency of the chiller.*



subcooling. For a 300-ton chiller, 10°F subcooling would increase the capacity about 30 tons with very little energy use. To subcool refrigerant, it must be isolated from the condensing process with a separate circuit, **Figure 47.26**, so the only expense for subcooling is the extra circuit in the condenser.

As in the evaporator, there is an approach relationship between the refrigerant condensing temperature and the leaving-water temperature in the condenser. Most water-cooled condensers are two-pass condensers and are designed for 85°F entering water and 95°F leaving water with a condensing temperature of about 105°F, **Figure 47.27**. This is an approach temperature of 10°F, and it is important to the technician. Other condensers may be configured as one-, three-, or four-pass with different approach temperatures. As with evaporators, the longer the refrigerant is in contact with the water, the lower the approach temperature will be. The original operating log will reveal what the approach temperature was at start-up. It should be the same for similar conditions at a later date, provided the tubes are clean.

Because the condenser rejects heat from the system, its capacity to do so determines the head pressure for the refrigeration process. There must be some pressure in the condenser to push the refrigerant through the expansion device. The head

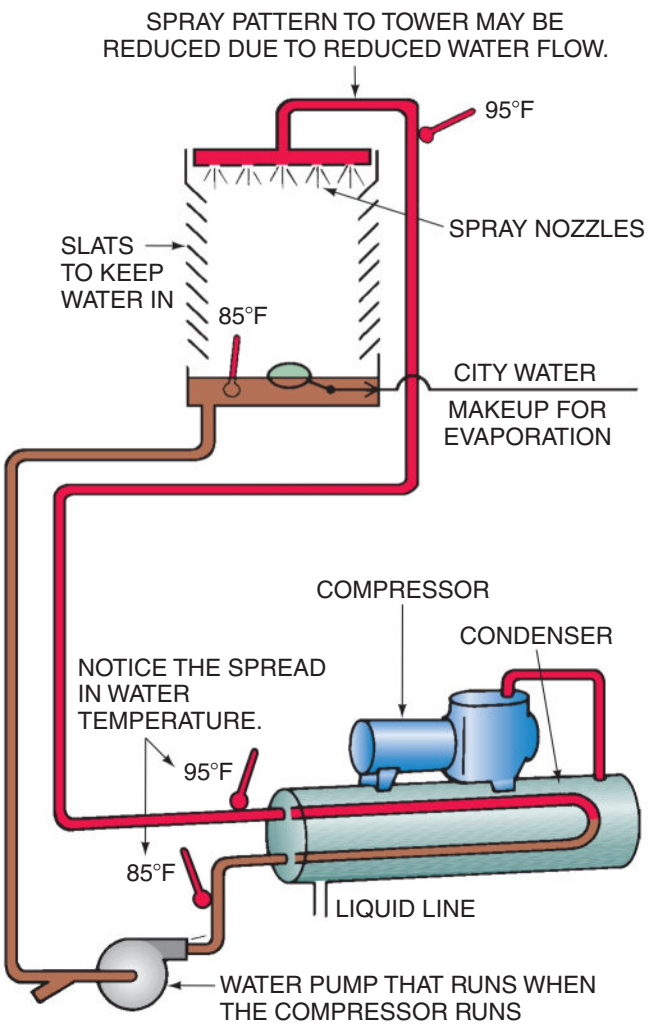
pressure must be controlled. If it becomes too low, problems may occur at start-up and in very cold weather when there is still a call for air-conditioning. When there is a call to start up a water-cooled chiller and the water in the cooling tower is cold, the head pressure may become so low that the suction pressure will be low enough to trip either the low-pressure control (direct-expansion chillers) or the evaporator freeze control (flooded chillers). Continued operation will also cause oil migration in many machines. A bypass valve is typically located in the condenser circuit to bypass water during start-up to prevent nuisance shutdowns due to cold condenser water. This same bypass may be used during normal operation. (This is discussed in more detail in Unit 48, "Cooling Towers and Pumps.") The heat from the refrigerant is transferred into the water circulating in the condenser circuit and in a typical installation the heat must then be transferred to the atmosphere. This is done by means of a cooling tower, **Figure 47.28**, which are discussed in Unit 48.

Figure 47.28 Heat moves from the refrigerant to the water and then into the atmosphere from the cooling tower.



AIR-COOLED CONDENSERS

The tubes in which the refrigerant circulates in air-cooled condensers are generally constructed of copper with aluminum fins on the outside of the tubes to provide a larger heat exchange surface, **Figure 47.29**. These air-cooled heat exchange surfaces have been used for many years with great success. Some manufacturers furnish copper-finned tubes or special coatings for the aluminum fins in locations where salt air may corrode the aluminum. The coils are positioned differently by manufacturers to suit their own design purposes, some horizontally and some vertically. Many air-cooled condensers use multiple fans that can be cycled on and off for head pressure control.

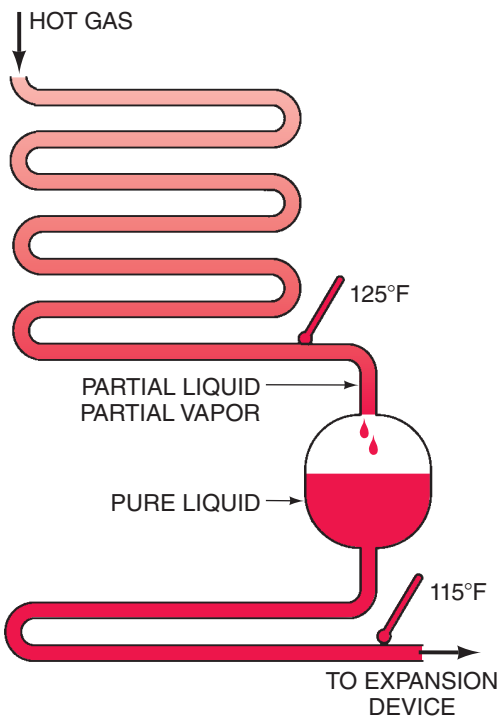
Air-cooled condensers range in size from very small to several hundred tons. They eliminate the need for cooling towers and the problems often associated with water-cooled equipment and are popular because they require less maintenance. Systems using air-cooled condensers do not operate at the same condensing temperatures and head pressures as water-cooled condensers. Water-cooled condensers typically condense at about 105°F. Air-cooled condensers condense at 20°F to 30°F higher than the entering air temperature, depending on the condenser surface area per ton of condenser. For example, an R-134a chilled-water system with a water-cooled condenser would have a head pressure about 135 psig (105°F compares to 135 psig). An air-cooled condenser on a 95°F day would have a head pressure that could range from 157 psig (95°F + 20°F = 115°F) to 185 psig (95°F + 30°F = 125°F). This is a considerable difference in head pressure and will increase the operating cost of the chiller. Various types of head pressure control for air-cooled condensers are discussed in Unit 25, "Special Refrigeration System Components."

SUBCOOLING CIRCUIT

Subcooling in an air-cooled condenser is just as important as in a water-cooled unit. *It gives the unit more capacity by about 1%/°F of subcooling.* Subcooling is accomplished in an air-cooled condenser by means of a small reservoir in the condenser to separate the subcooling circuit from the main condenser, **Figure 47.30**. *A condenser operating on a 95°F day can expect to achieve 10°F to 15°F of subcooling.*

Figure 47.30 *The subcooling circuit in an air-cooled condenser.*



Many units accomplish the subcooling process by flooding the bottom of the condenser with refrigerant. This would be something like an overcharge of refrigerant, except that the condenser has additional tubes to hold the extra charge. The technician must be aware of this subcooling circuit to charge the unit to the correct subcooling level, or the unit will not operate at rated capacity. Often, there is a sight glass in the reservoir and charge is added until a level of refrigerant appears in the reservoir. Sometimes there is a sight glass in the condenser end sheet to show the level of charge in the condenser. Otherwise, the technician must use a temperature lead attached to the liquid line to determine the subcooling temperature while adding refrigerant. This is accomplished by converting head pressure to condensing temperature and adding refrigerant until the liquid line is lower in temperature than the condensing temperature. For example, the condensing temperature may be 125°F. To arrive at a subcooling of 15°F, the technician would charge the unit until the liquid-line temperature is 110°F. This is a much longer process than using a sight glass and there is much more room for technician error.

47.9 METERING DEVICES FOR HIGH-PRESSURE CHILLERS

The metering device holds liquid refrigerant back and meters it into the evaporator at the correct rate. Four types of metering devices may be used for large chillers: thermostatic expansion valves, orifices, high- and low-side floats, and electronic expansion valves.

THERMOSTATIC EXPANSION VALVES

The *thermostatic expansion valve* (*TXV*) was discussed in detail in Unit 24, "Expansion Devices." The TXVs used with chillers are the same, only larger. The TXV maintains a constant superheat at the end of the evaporator; usually this is 8°F to 12°F of superheat. The more superheat, the more vapor there will be in the evaporator and the less heat exchange will occur. The more liquid the evaporator has, the better the heat exchange, so TXV valves are not used except on smaller chillers, up to about 150 tons.

ORIFICES

The orifice is a fixed-bore metering device that is merely a restriction in the liquid line between the condenser and the evaporator, **Figure 47.31**. These devices are trouble-free because they have no moving parts. The flow of refrigerant through an orifice is a constant at a given pressure drop. A greater pressure difference will produce more flow. Greater loads produce a higher head pressure, and when the head pressure is allowed to rise, more flow will occur. Any chiller with an orifice for a metering device has a critical charge. The unit must not be overcharged or liquid refrigerant will enter

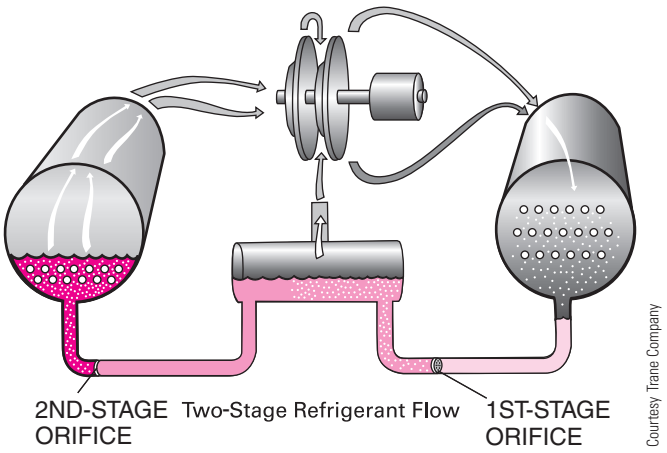
Figure 47.31 An orifice metering device.



the compressor inlet. This could be detrimental to a reciprocating compressor, so orifices may not be used with these compressors. Small amounts of liquid refrigerant, often in the form of wet vapor, will not harm the scroll, rotary screw, or most centrifugal compressors.

FLOAT-TYPE METERING DEVICES

There are two types of float-type metering devices: the **low-side float** and the **high-side float**. The low-side float rises and throttles back the refrigerant flow when the liquid refrigerant level rises in the low side of the chiller, **Figure 47.32**. It is located at the correct level to produce the amount of refrigerant required for the chiller. The high-side float is located in the liquid line entering the evaporator. When the level of refrigerant is greater in the liquid line, it is because the evaporator needs liquid refrigerant and the float rises, allowing liquid refrigerant to enter, **Figure 47.33**.

Floats can be a problem if they rub against the side of the float chamber, which will cause resistance or rub a hole in

Figure 47.32 A low-side float.

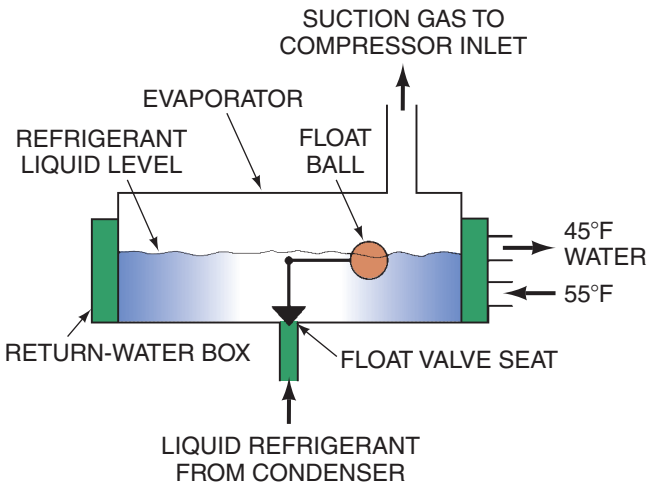


Figure 47.33 A high-side float.

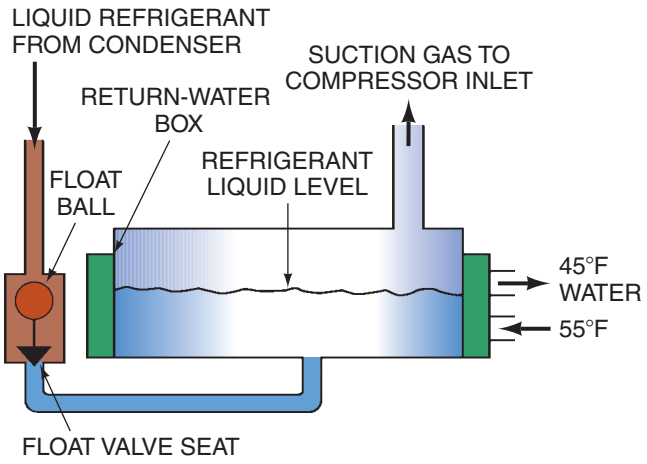

the float. The float will sink if a hole develops. In the case of the low-side float, the line will open and allow a full flow of refrigerant to the evaporator; no refrigerant will be held back from the liquid line and the bottom of the condenser. If a hole wears in the high-side float, it will sink and block the flow of liquid refrigerant to the evaporator.

The refrigerant charge is critical when either the low- or high-side floats are used. An overcharge with a low-side float will back refrigerant up into the liquid line and condenser. An overcharge of refrigerant with a high-side float will flood the evaporator.

ELECTRONIC EXPANSION VALVES

The electronic expansion valve used with large chillers is similar to the one explained in Unit 24, "Expansion Devices". In the line, it looks much like a solenoid valve, **Figure 47.34**. Expansion valves operate by means of a thermistor to monitor the refrigerant temperature. The thermistor sensor can be inserted in the evaporator piping. The liquid does not touch the sensor; an electronic circuit is used instead. The sensing element operates much like a thermometer except its readout is not temperature. A pressure transducer gives the electronic circuit a pressure reading that can be converted to temperature. The pressure reading from the evaporator converted to temperature along with the actual suction-line temperature can measure the real superheat and make close control possible.

An advantage of the electronic expansion valve is the versatility of the electronic control circuit, which makes it able to handle a wider variation in load than a typical TXV. It can also be used to allow more refrigerant to flow under low head pressure conditions during low-ambient operation. This is particularly helpful in air-cooled units when the weather is cold. The electronic expansion valve can allow maximum liquid refrigerant flow due to its large liquid-handling capacity.

The ability to allow maximum flow on a cold day gives the condenser much more capacity to pass on to the system. For example, if it is 40°F outside and the building is calling

Courtesy Trane Company

for cooling, the condenser can condense the refrigerant at about 60°F to 70°F. This is a head pressure of 58 to 71 psig for R-134a. This would not be enough head pressure for a typical TXV. But an electronic expansion valve (because of its flow capability) can use this low pressure to feed the evaporator. If the refrigerant is then subcooled 10°F more, the evaporator can be furnished with 50°F to 60°F liquid refrigerant. *The compressor is only required to pump from an evaporator pressure of approximately 33 psig (corresponding to 38°F evaporator boiling temperature for R-134a) to 71 psig maximum head pressure.* This is a big difference from a typical summer condition where the evaporator suction pressure may be 33 psig and the head pressure 185 psig (corresponding to a condensing temperature of 125°F) for R-134a.

Electronic expansion valves are often called step-control valves because they can modulate flow in so many increments. **Figure 47.35** is a photo of a step-control expansion valve along with an illustration that shows the motor turning a shaft with a needle and seat to modulate flow through the valve seat. **Figure 47.36** shows an exploded view of the valve with all of its intricate parts. **Figure 47.37** is a wiring diagram of how a valve may be wired into the circuit. Notice that there are two sensors (thermistors): one on the inlet of the coil and one on the outlet. There is no pressure connection for checking superheat; temperature difference is used to do that. The valve also has an optional pumpdown feature. It can be closed when the system thermostat is satisfied and the refrigerant can be pumped into the condenser. The valve reopens at the beginning of the next cycle to allow refrigerant to flow naturally during the ON cycle. The pumpdown cycle is used for any system that might suffer if liquid refrigerant is pumped into the compressor at the beginning of a new cycle because the refrigerant had migrated to the evaporator during the OFF cycle.

47.10 LOW-PRESSURE CHILLERS

Low-pressure chillers have all of the same components as high-pressure chillers: a compressor, an evaporator, a condenser, and a metering device. Many of the features and operations of low-pressure centrifugal chillers are the same or similar to those found on or with high-pressure units. Older low-pressure chillers typically have used R-11 or R-113 as refrigerants. Newer low-pressure chillers and those that have been converted use R-123; for special applications, some use R-114. *As of July 1, 1992, it became unlawful to vent CFC and HCFC refrigerants into the atmosphere. As of November 15, 1995, it became unlawful to vent HFC refrigerants and any other alternative refrigerant into the atmosphere. January 1, 1996 was the total phaseout date for CFC refrigerants, which made it unlawful to manufacture or import any CFC refrigerant. R-11, R-113, and R-114 are all low-pressure, CFC refrigerants. R-123 is an HCFC refrigerant.* **Figure 47.38** shows a temperature/pressure chart for these low-pressure refrigerants.

47.11 COMPRESSORS FOR LOW-PRESSURE CHILLERS

All low-pressure chillers as well as some high-pressure chillers use centrifugal compressors. The speed of centrifugal compressors in low-pressure chillers ranges from a motor's synchronous speed (3600 rpm) for direct-drive compressors to very high speeds (about 30,000 rpm) in gear-drive machines. The turning of the impeller of a centrifugal compressor creates a low-pressure area in the center where the suction line is fastened to the housing, **Figure 47.39**. The compressed refrigerant gas is trapped in the outer shell, known as the volute, and is guided down the discharge line to the condenser, **Figure 47.40**.

Systems with centrifugal compressors can be manufactured to produce more pressure by including more than one compressor and operating them in series, called multistage, or operating one stage of compression at a high speed. Single-stage compression can be accomplished using a single compressor that turns at a high speed, up to about 30,000 rpm. A gearbox is used with a 3600-rpm motor to step up the speed of the compressor, **Figure 47.11**. The advantage of this arrangement is lower size and weight.

With multistage compressors, the discharge from one compressor actually becomes the suction for the next compressor, **Figure 47.41**. It is common for compressors in air-conditioning applications to have up to three stages of compression. **Figure 47.39** shows a modern three-stage compressor that can be used with either R-11 or R-123. One of the advantages of multistage operation is that the compressor can be operated at slow speed, typically the speed of the motor, about 3600 rpm.

Refrigerant vapor can also be drawn off the liquid leaving the condenser to subcool the liquid entering the evaporator metering device. The vapor is drawn off using the intermediate compressor stages, so the liquid temperature corresponds to the pressure of the compressor intermediate suction pressure; it is less than the pressure corresponding to the condensing temperature. *The subcooling process*

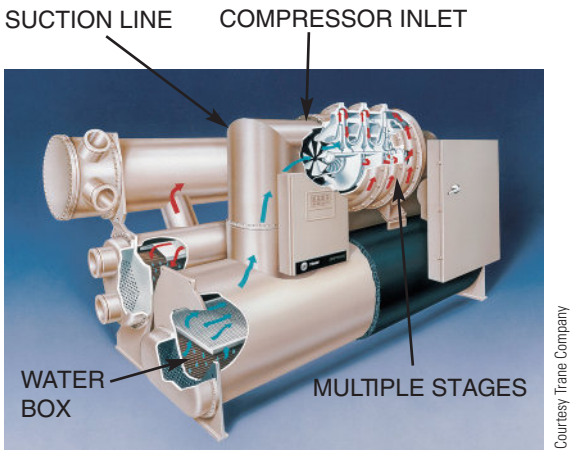
gives the evaporator more capacity for its respective size at very little additional pumping cost. This process is called an economizer cycle, **Figure 47.41**.

The amount of compression needed depends on the refrigerant used. For example, most centrifugal compressors in chillers use two-pass evaporators and two-pass condensers. If the evaporator has a 7°F approach temperature, the evaporator would boil the refrigerant at 40°F in a chiller with 47°F

Figure 47.39 A multiple-stage compressor and chiller.



leaving water. **NOTE:** *We are using 47°F water to get an evaporator temperature of 40°F for use with a typical temperature/pressure chart. If the condenser has a 10°F approach temperature, is receiving 85°F water from the tower, and has 95°F leaving water, the condenser should be condensing the refrigerant at about 105°F,* **Figure 47.27**. The compressor must overcome the following pressures to meet the requirement for this system:

Refrigerant Type	Evap Press 40°F	Cond Press 105°F
R-113	24.4 in. Hg Vac	6.4 in. Hg Vac
R-11	15.6 in. Hg Vac	11.1 psig
R-123	18.1 in. Hg Vac	8.1 psig
R-114	0.44 psig	35.3 psig
R-500	46 psig	152.2 psig
R-502	80.5 psig	231.7 psig
R-12	37 psig	126.4 psig
R-134a	35 psig	134.9 psig
R-22	68.5 psig	210.8 psig

Notice that for R-113 the compressor has only to raise the pressure from 24.4 in. Hg Vac to 6.4 in. Hg Vac; this is only 18 in. Hg Vac (or 18/2.036 = 8.84 psig). With R-502 in the system, the compressor would have to raise the pressure from 80.6 psig to 231.7 psig, or 151.1 psig, so a different compressor would have to be used for R-502. Compressors do not raise the pressure the same amount nor do they operate in the same pressure ranges. The R-113 compressor operates in a vacuum on both the high- and low-pressure sides of the system, and the R-502 compressor operates under a discharge pressure of 231.7 psig. The physical thickness of the shell of the two compressors would be very different. The comparison should give you some idea of the different applications for centrifugals. Although **Figure 47.42** is a cutaway view of a high-pressure chiller shell, it is similar to most low-pressure chillers. Low-pressure chillers must be able to accommodate the refrigerant used—typically, R-113, R-11, or R-123. Because the chillers are low pressure, the refrigerant

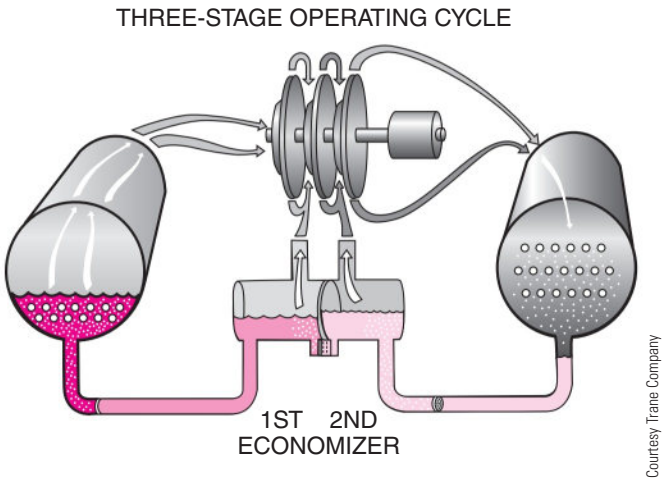

Figure 47.42 A cutaway view of a high-pressure chiller shell. Low-pressure shells are much like this.

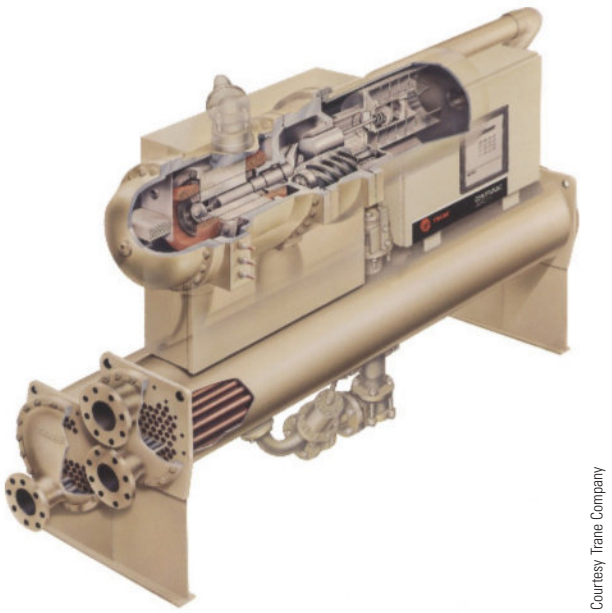

side of the shell does not have to be as strong as those of high-pressure chillers and can be much lighter in weight because of the lower pressures.

The evaporator on a low-pressure system has a working pressure for the refrigerant circuit and for the water circuit.

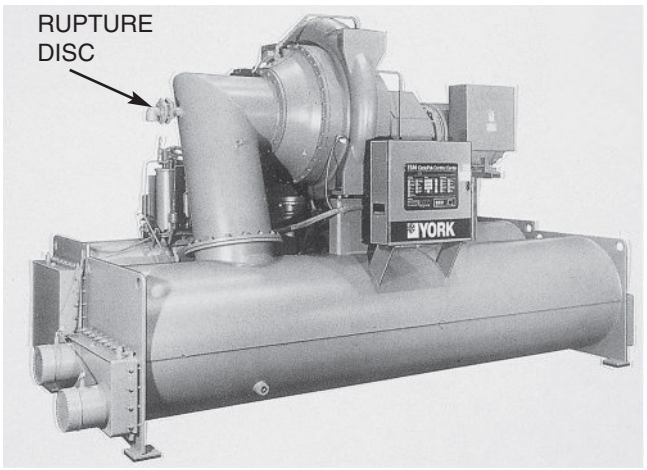
Figure 47.43 A rupture disc mounted on the suction line of the compressor. These rupture discs are typically set at 15 psig. The disc is on the suction side, so it is under low pressure during operation. If the shell were to be subject to fire or if a technician tried to overpressure the shell for leak-testing purposes, the disc would blow out and protect the shell from splitting.



Courtesy York International Corporation

The low-pressure system may have a refrigerant working pressure as low as 15 psig. The system has a refrigerant safety device called a rupture disc; its relief pressure is 15 psig, and it is located in the low-pressure side of the system, on the evaporator section or the suction line, **Figure 47.43**. This device prevents excess pressure on the shell. If a fire occurs or a technician uses too much pressure, the shell is safe from rupture.

47.12 CONDENSERS FOR LOW-PRESSURE CHILLERS

The condenser is the component that rejects heat from the system. The condensers for low-pressure chillers are water-cooled. As in high-pressure systems, the heat is usually transferred to the atmosphere. In some manufacturing processes, the heat may be recovered and used for other purposes. The water-cooled condensers used in low-pressure chillers are the shell-and-tube type; water circulates in the tubes and the refrigerant circulates around the tubes. The shell must have a working pressure to accommodate the refrigerant used and a water-side working pressure of 150 to 300 psig. The hot discharge gas enters at the top of the condenser, **Figure 47.40**.

Because it is the condenser that rejects heat from the system, its capacity to do so determines the head pressure for the refrigeration process. In low-pressure chillers, the condenser is usually located above the evaporator. The compressor lifts the refrigerant to the condenser level in the vapor state. When it is condensed to a liquid, it flows by gravity with very little pressure difference to the evaporator through the metering device. The head pressure must be controlled so that it does not drop too low below the design pressure drop.

Water-cooled condensers may also have a subcooling circuit. The purpose of the subcooling circuit is to lower the liquid refrigerant temperature to a level below the condensing temperature. This is accomplished by means of a separate chamber in the bottom of the condenser where the entering condenser water (at about 85°F) can remove heat from the condensed liquid refrigerant (at about 105°F). This gives the system more efficiency, **Figure 47.26**.

47.13 METERING DEVICES FOR LOW-PRESSURE CHILLERS

The metering device holds liquid refrigerant back and meters the liquid into the evaporator at the correct rate. Two types of metering devices are typically used for low-pressure chillers, the orifice and the high- or low-side float, which were discussed previously in the section on high-pressure chillers.

47.14 PURGE UNITS

When a low-pressure refrigerant is used in a centrifugal system, the low-pressure side is always in a vacuum when operating. If the system uses R-113, the entire system is in a vacuum. This means that any time there is a leak, the system is in a vacuum and so air will enter the machine, **Figure 47.44**. Air may cause several problems. The oxygen and moisture in

Figure 47.44 When a low-pressure chiller leaks while in a vacuum, atmosphere enters the chiller shell.

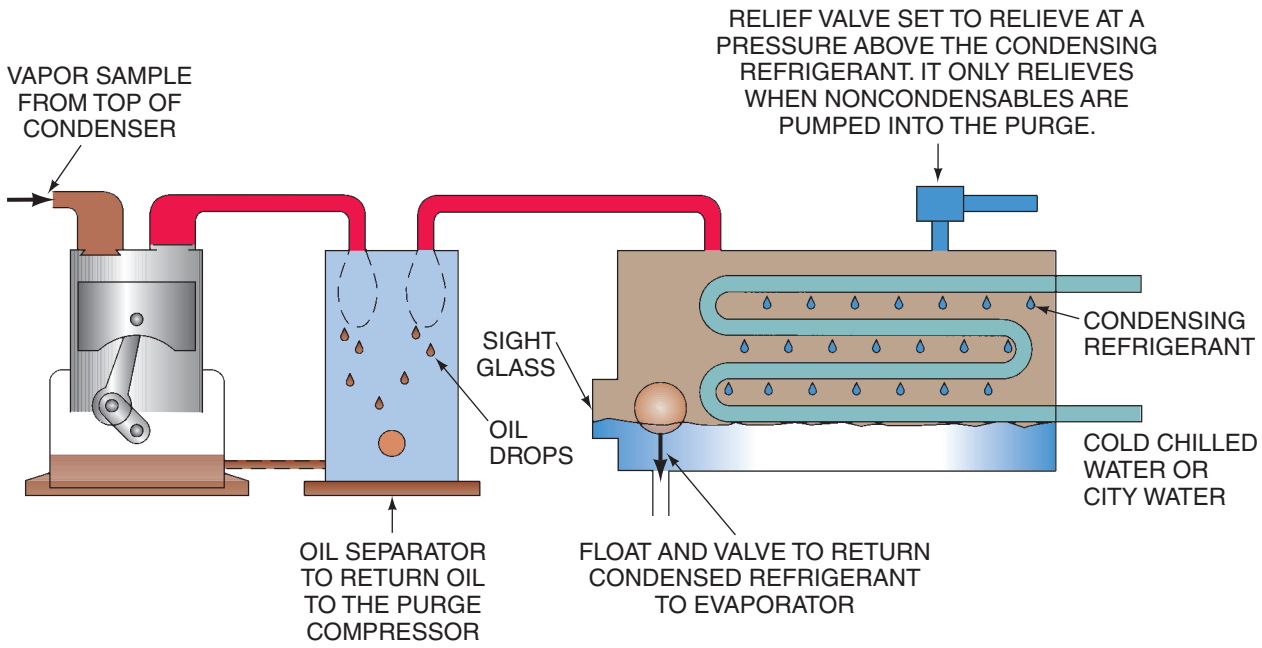
Figure 47.45 A simplified purge unit in operation.



the air will mix with the refrigerant, which will create a mild acid that will eventually attack the motor windings and cause damage, or motor burn. While the machine is running, air will move to the condenser but will not condense. This will cause the head pressure to rise. If much air enters the system, the head pressure will rise to the point that the machine will either "surge" or shut down due to high head pressure.

When air moves to the condenser, it will collect at the top and take up condenser space. This air can be collected and removed with a purge system. The purge is a separate device, often with its own compressor, that collects a sample of whatever is in the top of the condenser and tries to condense it in a separate condenser. If the product from the top of the condenser can be condensed, it is refrigerant and it will be returned to the system at the evaporator level, **Figure 47.45**. If the sample cannot be condensed, the purge pressure will rise and a relief valve will allow the sample to be exhausted to the atmosphere.

There are several types of purge systems, but they all perform the same function, some more efficiently than others. Some equipment relieves purge pressure by means of a pressure switch and a solenoid valve. A counter tells the operator when the purge is functioning. The operator can use this as a guide for determining when a system has a leak and air is entering. When too many purge reliefs occur, the system is considered to have a leak. Some purge systems use the difference in pressure from the high-pressure side of the system to the low-pressure side to create the same pressure difference that a purge compressor would create—they use a condenser to condense any refrigerant from the sample. *Older purge systems were not efficient, and a high percentage of the sample that was discharged to the atmosphere contained refrigerant. This is considered poor practice today because of environmental concerns and the price of lost refrigerant. Modern-day purges must be efficient and allow only a small fraction of 1% refrigerant loss during the relieving process.* **Figure 47.46** shows one of the modern purge systems that releases only a very small amount of refrigerant when relieving the pressure. The vapor is discharged to the atmosphere only when air is present. A leak-free system will contain no air and the purge system will not be called upon to function.

47.15 ABSORPTION AIR-CONDITIONING CHILLERS

Absorption refrigeration process is considerably different from the compression refrigeration process discussed in the preceding sections. The absorption process uses heat as the driving force instead of a compressor. *When heat is plentiful or economical, or when it is a by-product of some other process, absorption cooling can be attractive. For example, in a manufacturing process that uses steam, which is often at 100 psig, it must be condensed before it can be reintroduced to the boiler.* In the absorption system process, condensing steam is a natural choice for chilling water for air-conditioning. *In this case, chilled water for air-conditioning can be furnished at an economical cost, basically for the cost of operating all the related pumps, because no compressor is involved.* In other cases, natural gas is an inexpensive fuel in the summer. The gas company is looking for ways to market gas then because its winter quota may depend on how much gas it can sell in the summer. Some gas

companies may offer incentives to install gas appliances that consume fuel in the off-peak summer months. 4R *Absorption refrigeration equipment also operates in a vacuum and contains non-CFC refrigerants.* 4R

Equipment for an absorption system looks much like a boiler except that it has chilled-water piping and condenser-water piping routed to it in addition to the piping for steam or hot water. Oil or gas burners are part of the system if the chiller is direct-fired. **Figure 47.47** shows several absorption systems from different manufacturers. The small machines are considered package machines, meaning they are completely assembled and tested at the factory and shipped as one component. They are all built in one shell or a series of chambers, so the range of sizes available may be limited because the equipment must be moved as a single component. The machines are rated in tons and come in sizes of approximately 100 to 1700 tons. A 1700-ton system is extremely large. The large-tonnage machines may be manufactured in sections for ease of rigging and moving into machine rooms, **Figure 47.48**. These sections are usually assembled in the factory to achieve proper alignment, except for the welds that must be accomplished in the field.

The absorption process is very different in some respects from the compression cycle refrigeration process but also similar in others. It is helpful to reach an understanding of the compression cycle before trying to understand the absorption cycle. In compression cycle chillers, the boiling temperature for the refrigerant is controlled by the pressure above the boiling liquid, and it is the compressor that controls this boiling pressure. **Figure 47.49** shows a refrigeration system using water as the refrigerant. The water must be boiled at 0.248 in. Hg absolute, or 0.122 psia, to boil the water at 40°F. **Figure 47.50** shows a limited temperature/pressure chart for water. This refrigeration cycle would be workable using a compressor except that the volume of vapor rising from the boiling water is excessive. The compressor would have to remove 2444 ft^3 of water vapor for every pound of water boiled at 40°F. **Figure 47.51** shows a limited specific-volume chart for water at different temperatures. A compressor is obviously impractical in a refrigeration system using water as the refrigerant.

The term *absorption* means "to attract moisture." The absorption machine uses water as the refrigerant and does not use a compressor to create the pressure difference. Instead, it uses the fact that certain salt solutions have enough attraction for water that they can be used to create a pressure difference. You may have noticed that a grain of salt on a hot, humid day

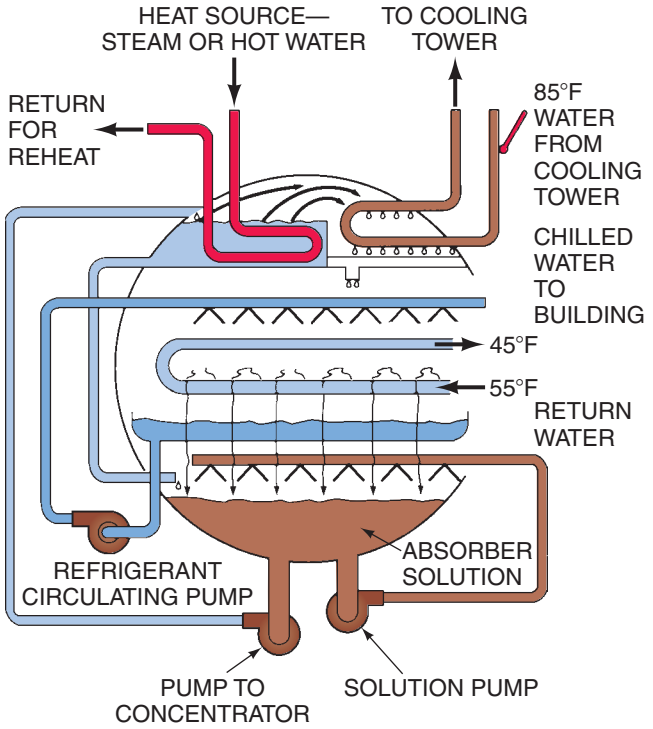
will attract moisture to the point that it will become wet, **Figure 47.52.** This same concept is used in an absorption refrigeration system to reduce the pressure of the water to a point where it will boil at a low temperature. A type of salt solution

Figure 47.53 A simplified absorption refrigeration cycle.



called lithium-bromide (Li-Br) is the absorbent (attractant) for the water in absorption cooling systems. The liquid solution of Li-Br is diluted with distilled water—actually, it is a mixture of about 60% Li-Br and 40% water.

A simplified absorption system would look like the one in **Figure 47.53.** The illustration does not show a complete cycle; it is simplified for ease of understanding. The following steps are a progressive description of the absorption cycle.

1. **Figure 47.54** shows the equivalent of the evaporator system. Refrigerant (water) is metered into the evaporator section through a restriction (orifice). It is warm until it passes through the orifice, where it flashes to a low-pressure area (about 0.248 in. Hg absolute, or 0.122 psia). The reduction in pressure also reduces the temperature of the water. The water drops to the pan below the evaporator tube bundle. A refrigerant-circulating pump circulates the water through spray heads, which spray it over the evaporator tube bundle. This wets the tube bundle through which the circulating water from the system passes. The heat from the system water within the tube bundle evaporates the refrigerant. Water is constantly being evaporated and must be made up through the orifice at the top.
2. **Figure 47.55** shows the absorber section, which would be the equivalent of the suction side of the compressor in a compression cycle system. The salt solution (Li-Br) spray is a very low pressure attraction for the evaporated water vapor so it readily absorbs into the spray solution. The solution is then recirculated through the spray heads to give it more surface area for attracting more

Figure 47.54 The evaporator section of an absorption machine.

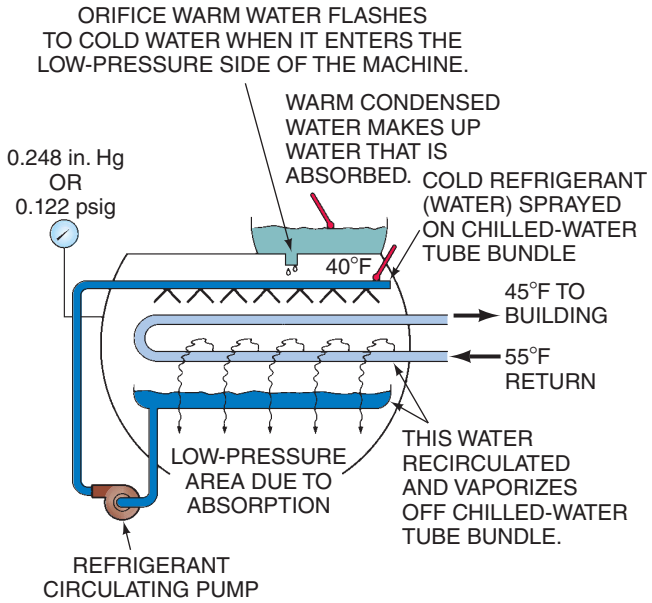

Figure 47.55 The absorber section of an absorption machine.

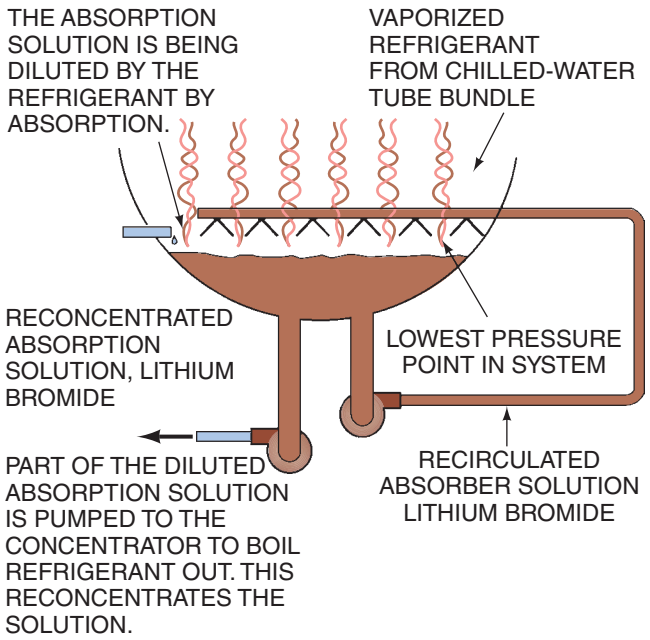
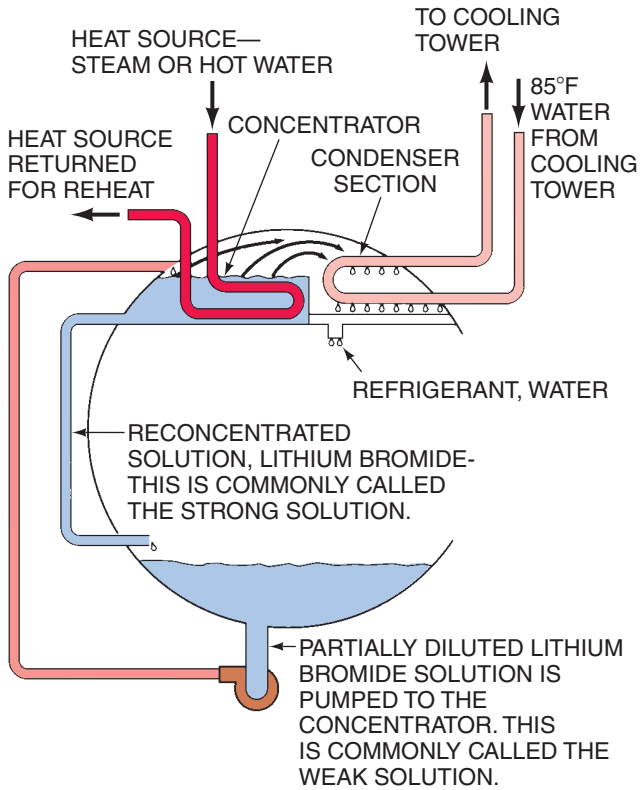


water. As the solution absorbs more water, it becomes diluted. If the excess water is not removed, the solution will become so diluted that it will no longer have any attraction and the process will stop, so another pump constantly removes some of the solution and pumps it to the next step, called the concentrator. This solution that is pumped to the concentrator is called the weak solution because it contains water absorbed from the evaporator.

3. **Figure 47.56** shows the concentrator and condenser segment. The dilute solution is pumped to the concentrator, where it is boiled. Boiling changes the water in the solution to a vapor, and it leaves the solution and is attracted to the condenser coils. The water is condensed to a liquid and is gathered and metered to the evaporator section through the orifice. (In this example, the heat source for boiling the water is either steam or hot water. Direct-fired machines, discussed later, are also available.) The concentrated solution is drained back to the absorber area for circulation by the absorber pump.

Figure 47.56 The concentrator and condenser section of an absorption machine.



As you can see from this description, the absorption process is not complicated. The only moving parts are the pump motors and impellers.

Some other features are added to the absorption cycle to make it more efficient. One of these is shown in **Figure 47.57**. It is a heat exchange between the cooling tower water and the absorber solution in the absorber. This heat exchange removes heat that is generated when the water vapor is absorbed into the solution. **Figure 47.58** shows a heat exchange between the dilute and the concentrated solution. This exchange serves two purposes: It preheats the dilute solution before it enters the concentrator and precools the concentrated solution before it enters the absorber section. It is much like the heat exchange between the suction and liquid line on a household refrigerator. Without this heat exchange, the machine would be less efficient. Some manufacturers have developed a two-stage absorption machine that uses higher-pressure steam or hot water, **Figure 47.59**. The steam pressure may be 115 psig, or

hot water at 370°F. These machines are more efficient than the single-stage machine mentioned earlier.

SOLUTION STRENGTH

The concentration strength of the solutions determines the performance of the absorption chiller. The wider the spread between the dilute and the strong solution, the more capacity the machine has to lower the pressure to absorb the water from the evaporator. If the concentrated solution becomes too concentrated, the solution will become rock salt. If this occurs, the flow of concentrated solution may be partially or totally blocked, which causes the machine to stop cooling. The solution is said to have "become solid" or "crystallized," and service procedures must be performed in order to dissolve the hard salt crystals. The balance between water and Li-Br is delicate.

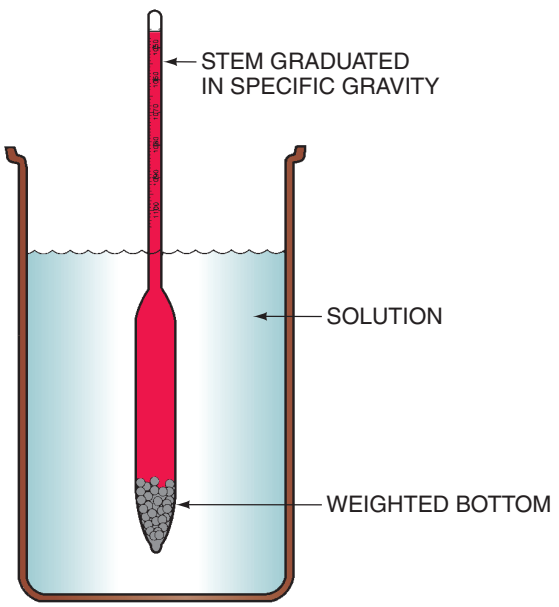
Adjusting the strengths of these solutions is the job of the start-up technician. Some machines are shipped with no charge and the Li-Br is shipped in steel drums to be added in the field. The estimated amount of Li-Br is added first. Distilled water is used as the refrigerant charge and added next. When the charge is adjusted, the technician calls it the trim. A compression cycle system is charged and an absorption system is trimmed.

After a technician trims the machine with the approximate correct amount of Li-Br and water, the machine is started and gradually run up to full load. Full load may be determined by the temperature drop across the evaporator and full steam pressure, which is normally 12 to 14 psig (hot water or direct-fire equipment would be similar). When full load is obtained, the technician pulls a sample of dilute and strong solution and measures the specific gravity using a hydrometer, **Figure 47.60**. Specific gravity is the weight of a substance compared with the weight of an equal volume of water. The technician would know what these specific gravity readings should be from the manufacturer's literature or a Li-Br temperature/pressure chart. Water is either added or removed to obtain the correct specific gravity. This may be a relatively long process in some cases because the technician cannot always obtain full-load operation at start-up. The machine may have to be trimmed to an approximate trim and finished later when full load can be achieved. Some manufacturers furnish a trim chart for a partial load.

SOLUTIONS INSIDE THE ABSORPTION SYSTEM

The solutions inside an absorption system are corrosive. Rust, which is oxidation, occurs where corrosive materials and oxygen are present. The absorption machine is manufactured with materials such as steel and contains a saltwater solution that will cause corrosion if air is present. It is next to impossible to manufacture and maintain a system that can keep air with oxygen away from its working parts.

Figure 47.60 A hydrometer for measuring the specific gravity of absorption solutions.



The system must be kept as clean as possible as the solutions circulate. Some of the passages are very small, such as the spray heads in the absorber. There are many different methods of removing solid materials that may clog any small passages. Filters will stop solid particles, and magnetic devices will attract steel particles that may be in circulation. But even though the liquid circuits have filtration, the solutions in an absorption machine may become discolored. When looking at the fluids in the machine, a technician's first opinion may be that it should be scrapped and a new machine installed. However, the fluids can take on the color of rusty water and still not affect the functioning of the machine. It is normal for the fluids to look very discolored.

CIRCULATING PUMPS FOR ABSORPTION SYSTEMS

There are two distinct fluid flows for the solutions circulating throughout the various parts of the absorption system: the solution flow and the refrigerant flow. Some absorption machines use two circulating pumps, **Figure 47.61**, and some use three, depending on the manufacturer. One manufacturer uses one motor with three pumps on the end of the shaft.

Whatever the number of pumps, they are similar. They are centrifugal pumps and the pump impeller and shaft must be made of a material that will not corrode or the pumps could never be serviced after they have been operated and corrosion has occurred. Special care must be taken not to let the atmosphere enter the pump motors during the pumping process. It is typical for the motors to be hermetically sealed and to operate only within the system atmosphere. The pump itself is immersed in the actual solution to be pumped, but the motor windings are sealed in their own atmosphere where no system solution can enter. Because these motors require cooling, cold refrigerant water from the evaporator or normal supply water in a closed circuit is used for this purpose.

Over a period of time motors must also be serviced. Manufacturers recommend servicing only after many years have passed, but it will eventually be required because moving parts with bearings are involved. Different manufacturers require different procedures, but it is much easier to service the motor and drive if the solution does not have to be removed. However, if it does, the process involves pressurizing the system with dry nitrogen to above atmospheric pressure and pushing the solution out. Once this is accomplished and service completed, the nitrogen must be removed, which takes a long time. Then the system must be recharged.

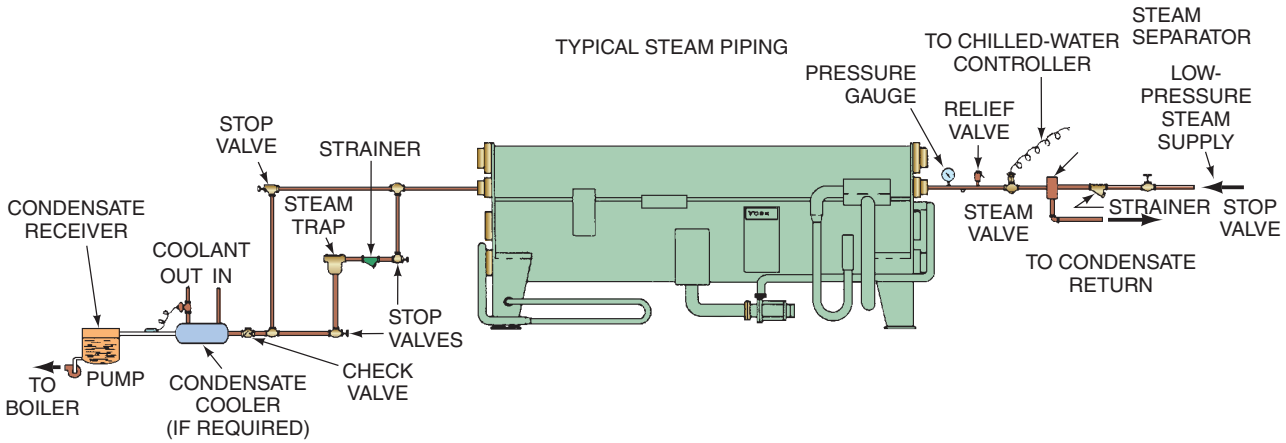
Figure 47.62 *Capacity control using a modulating steam valve.*



Courtesy York International Corporation

CAPACITY CONTROL

The capacity of a typical absorption system can be controlled by throttling back the supply of heat to the concentrator. A typical system that operates on steam uses 12 to 14 psig of steam at full load and 6 psig at half capacity. The steam can be controlled with a modulating valve, **Figure 47.62**. Hot water and direct-fired machines can be controlled in a similar manner. Some manufacturers may provide other means for capacity control, for example, controls for the internal fluid flow in the machine. Reducing the flow of weak (dilute) solution to the concentrator is a practical

control because at reduced load, less solution needs to be concentrated.

CRYSTALLIZATION

Using a salt solution for absorption cooling raises the possibility of the solution becoming too concentrated and actually turning into rock salt. This is called **crystallization** and may occur if the machine is operated under the wrong conditions. For example, if the cooling tower water in some systems is allowed to become too cold while the system is operating at full load, the condenser will become too efficient and remove too much water from the concentrate. This will result in a strong solution that has too little water. When this solution passes through the heat exchanger, it will turn to crystals and restrict the flow of the solution. If left uncorrected, the machine will become completely blocked and will stop cooling. Because this is a difficult problem to overcome when it happens, manufacturers have developed various methods to prevent it. One manufacturer uses pressure drop in the strong solution across the heat exchanger to solve the problem. A valve between the refrigerant circuit and the absorber fluid circuit may be opened to make the weak solution very weak for long enough to relieve the restriction. When the situation is corrected, the valve is closed and the system resumes normal operation. Another manufacturer may recommend shutting the machine down for a dilution cycle when overconcentration occurs.

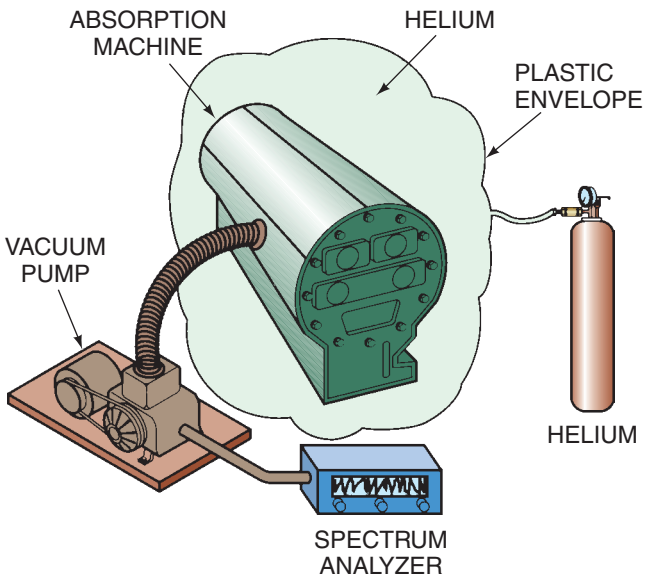
Crystallization can occur for several reasons. Cold condenser water is one cause, and a shutdown of the machine due to power failure while operating at full load is another. An orderly shutdown calls for the solution pumps to operate for several minutes after shutdown to dilute the strong solution. With a power failure, the shutdown is not orderly and so crystallization can occur. Also, at any point where a leak occurs atmospheric air can be pulled into the machine because it operates in a vacuum. Air in the system can also cause crystallization.

PURGE SYSTEM

The **purge** system removes noncondensables from the absorption machine during the operating cycle. All absorption systems operate in a vacuum, so if there is a leak, the atmosphere will enter. Air expands greatly when pulled into a vacuum. Even the amount of air in a soft-drink bottle will affect the capacity of a 500-ton machine. These machines must therefore be kept absolutely leak-free.

Wherever possible, all piping connections are welded at the factory. After the typical packaged absorption machine is assembled, it is put through the most rigid of leak tests, called a mass spectrum analysis, before shipping. In this test, the machine is surrounded with an envelope of helium, the system is pulled into a deep vacuum, and the vacuum pump exhaust is analyzed with a mass spectrum analyzer for any helium, **Figure 47.63**. Helium is a gas with very small molecules

Figure 47.63 Leak checking an absorption machine in the factory. A vacuum is pulled on the machine, which is enclosed in a helium atmosphere. The vacuum pump's exhaust is checked for helium with a spectrum analyzer. Helium has very small molecules and will easily leak through a very small hole.



that will leak in at any leak source. But even with these rigid leak-check and welding procedures, leaks can develop during shipment to the job site. Leaks may also develop after years of operation and maintenance. When a leak occurs, the noncondensables must be removed.

Absorption systems also generate small amounts of noncondensables while in normal operation. A by-product of the internal parts causes hydrogen gas and some other noncondensables to form inside. These are held to a minimum with the use of additives, but they still occur and it is the responsibility of the purge and the operator to keep the machine free of these noncondensables.

Two kinds of purge systems are used on typical absorption cooling equipment: the nonmotorized purge and the motorized purge. The nonmotorized purge uses the system pumps to create a flow of noncondensable products to a chamber where they are collected and then bled off by the machine operator, **Figure 47.64**. This purge works well while the machine is in operation but may not be of much use if the machine were to need service and is pressured to atmosphere using nitrogen. The manufacturer of the machine in **Figure 47.64** offers an optional motorized purge for removal of large amounts of noncondensables. The motorized purge is essentially a two-stage vacuum pump that removes a sample of whatever gas is in the absorber and pumps it to the atmosphere. These vapors are not harmful to the atmosphere. Because the absorber operates in such a low vacuum, this gas sample would contain only noncondensables or water vapor, **Figure 47.65**. The motorized purge requires some maintenance because of the corrosive nature of the vapors that are pulled through the

vacuum pump. The vacuum pump oil must be changed on a regular basis to prevent pump failure. Because vacuum pumps are expensive, they must be properly maintained.

ABSORPTION SYSTEM HEAT EXCHANGERS

Like compression cycle chillers, absorption machines have heat exchangers. Two-stage systems actually have more heat exchangers—the evaporator, the absorber, the concentrator, the condenser, and the first-stage heat exchanger. These are similar to compression cycle heat exchangers, but they also have some differences. They also contain tubes, which are either copper or cupronickel (a tube made of copper and nickel).

The chilled-water heat exchange tubes remove heat from the building water and add it to the refrigerant (water). The chilled-water circuit is usually a closed circuit, so the tubes rarely need maintenance except for water treatment. A flange at the end of the tube bundle allows access through either marine or standard water boxes. This section of the absorption system must have some means of preventing the heat in the equipment room from transferring into the cold machine parts. In some systems this section is insulated; some have a double-wall construction to prevent heat exchange. As in the compression cycle chillers, there is an approach temperature between the boiling refrigerant and the leaving chilled water. This temperature is likely to be 2°F or 3°F in an absorption chiller because the heat exchange is so good, **Figure 47.66**.

The absorber heat exchanger exchanges heat between the absorber solution and the water returning from the cooling tower. The design cooling tower water under full load in hot weather is 85°F. The water from this heat exchange continues to the condenser, where the refrigerant vapor is condensed for reuse in the evaporator. The leaving water is likely to be between 95°F and 103°F on a hot day at full load, **Figure 47.67**. Absorption equipment manufacturers provide thermometer wells located at strategic spots for checking the solution temperatures to assess machine performance and determine if

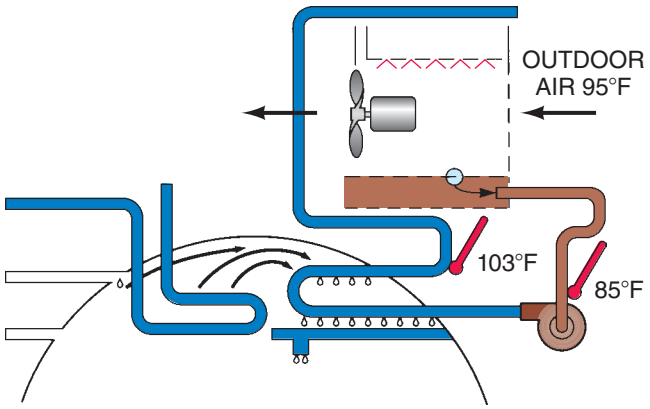

Figure 47.68 The tubes in the absorption chiller are subject to great expansion due to significant temperature differences. Special methods are used to allow for tube expansion.

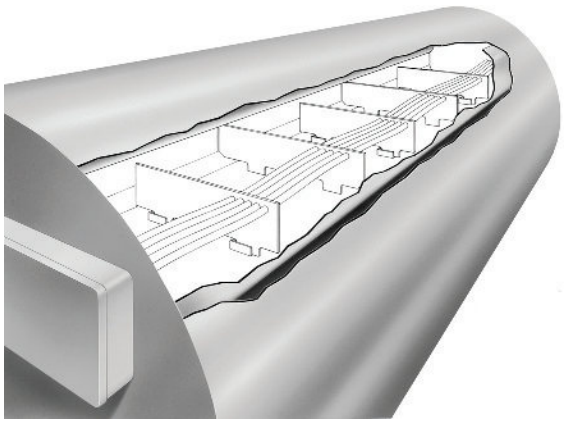

Courtesy Trane Company

the tubes are dirty. The manufacturers provide the correct temperatures and temperature differences for their machines.

The other heat exchange in standard equipment is between the heating medium—steam, hot water, or flue gases—and the refrigerant. This tube bundle may have some high-temperature differences because it may be at room temperature until the system is started and hot water or steam is turned into the bundle. A great deal of stress in the form of tube expansion occurs at this time. Manufacturers claim that a tube can grow up to ¼ in. in length during this process. Different manufacturers deal with this stress in different ways. **Figure 47.68** shows a tube bundle that has the capability of floating to minimize problems.

DIRECT-FIRED SYSTEMS

Some absorption equipment is direct-fired. Gas or oil is the heat source, and some systems are dual-fuel machines for situations where gas demand may require a second fuel. Such machines range in capacity from approximately 100 to 1500 tons. They also may have the ability to either heat or cool by furnishing either hot or chilled water. In some cases, they may be used as one piece of equipment to replace both a boiler and an absorption machine in an old installation. **Figure 47.69** shows direct-fired equipment manufactured by two different companies.

47.16 MOTORS AND DRIVES FOR CHILLERS

All of the motors that drive high-pressure and low-pressure chillers are highly efficient three-phase motors. These motors all give off some heat while in operation, which must be removed from the motor or it will overheat and burn. *Some manufacturers choose to keep the motor in the atmosphere to cool it,* **Figure 47.70.** This reduces the load on the refrigeration system, but the heat air-cooled motors give off to the equipment room must be removed to avoid overheating the room. Typically, the heat is removed with an exhaust fan system. The compressor motor must have a shaft seal to prevent refrigerant from leaking into the atmosphere, **Figure 47.71.** In

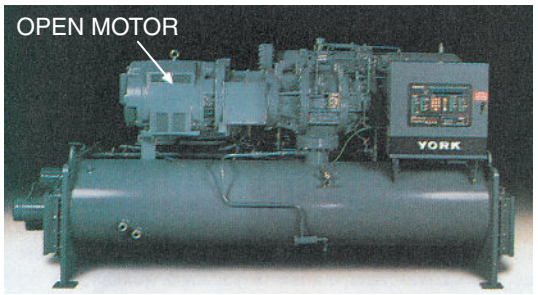
Figure 47.70 An air-cooled, direct-drive compressor motor.



Courtesy York International Corporation

the past, seals have been a source of leaks, but modern seals and correct shaft alignment have improved.

Compressor motors may also be cooled with the vapor refrigerant leaving the evaporator. These compressors, called suction-cooled compressors, are either hermetic or semihermetic. Fully hermetic compressors are the smaller ones and may be returned to the factory for rebuild. Semihermetic compressors and motors may be rebuilt in the field. Compressor motors may also be cooled with liquid refrigerant by allowing liquid to enter the housing around the motor. The liquid does not actually touch the motor or windings; it is contained in a jacket around the motor, **Figure 47.15**.

Large amounts of electrical power must be furnished to the motor through a leak-free connection. Often this is done through a nonconducting terminal block made of some form of phenolic or plastic. The terminals, sealed by O-rings, protrude through both sides of the block, with the motor terminals on one side and the field connections on the other, **Figure 47.72**. The terminal board is sealed to the compressor housing by a gasket. The field connections are checked periodically for tightness. **A loose connection may melt the board and cause a leak to develop**.

The motors used in all types of chillers are expensive and the manufacturer goes to great lengths to protect them by designing them to operate in a protective atmosphere. Part of getting long motor life is to use a good start-up procedure. A motor draws about five times as much amperage at locked rotor on start-up as at full-load amperage. If a motor draws 200 A at full load, it would draw approximately 1000 A at start-up. This inrush of current can cause problems in the electrical service, so manufacturers use several different methods to minimize the inrush of current and power-line fluctuations. A large motor is usually started with a group of components called *starters*. There are several types, the common ones being part-winding, autotransformer, wye-delta (often called star-delta), and electronic start.

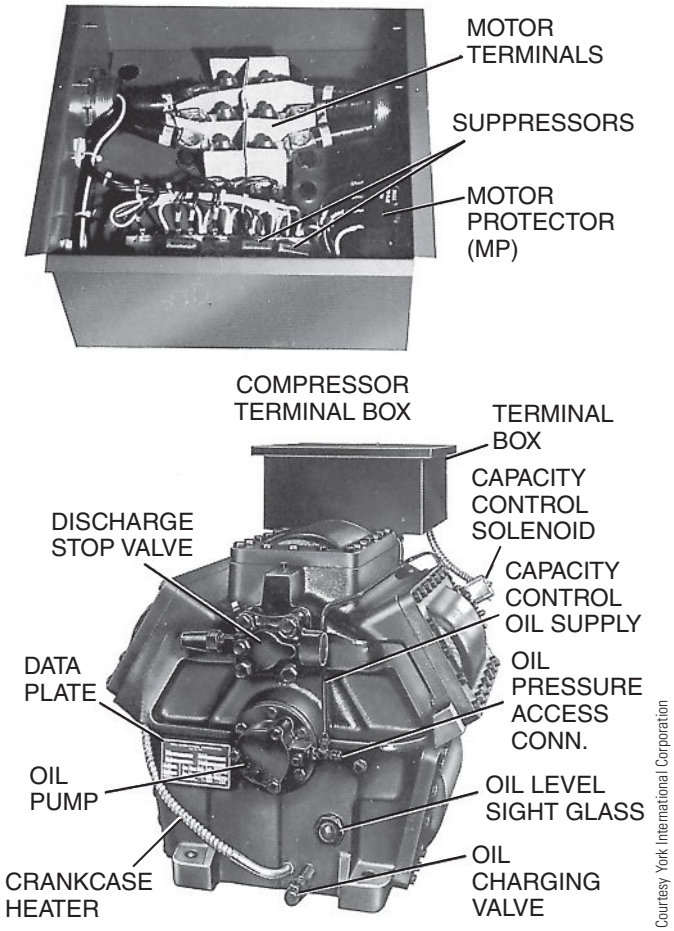
Figure 47.72 The terminal block for a hermetic compressor motor.



PART-WINDING START

Manufacturers often include part-winding start motors when compressor motors reach about 25 hp. These versatile motors normally have nine leads and can be used with two different voltages. The same compressor can be used for 208/230-V and 460-V applications by changing the motor terminal arrangement, **Figure 47.73**, so the start motor actually becomes two motors in one. For example, a 100-hp compressor can have two motors that are 50 hp each. In a 208/230-V application, the motors are wired in parallel and each motor is started separately—first one, then the other—with two motor starters and a time delay of up to about 1 sec between them, **Figure 47.74**. When the first motor starts, the motor shaft begins turning. The second motor then starts to bring the compressor up to full speed, about 1800 or 3600 rpm, depending on the motor's rated speed. *This imposes only the inrush current of a 50-hp motor on the line because when the second motor is energized, the shaft is already turning and so the inrush current is less.* When the compressor motor is used in a 460-V application, the start motors are wired in series and started as one motor across the line,

Figure 47.73 Nine-lead, dual-voltage motor connections.

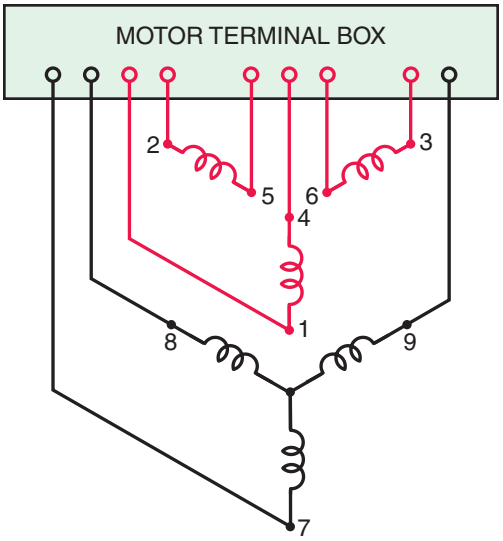


Figure 47.75. At the higher voltage there is much less inrush amperage on start-up. Part-winding start motors are used on compressors of up to about 150 hp.

AUTOTRANSFORMER START

An autotransformer start is actually a reduced-voltage start. A transformer-like coil is placed between the motor and

Figure 47.74 The part-winding start motor wired for 208/230-V.

Figure 47.75 The two motors are now in series for the 460-V application.

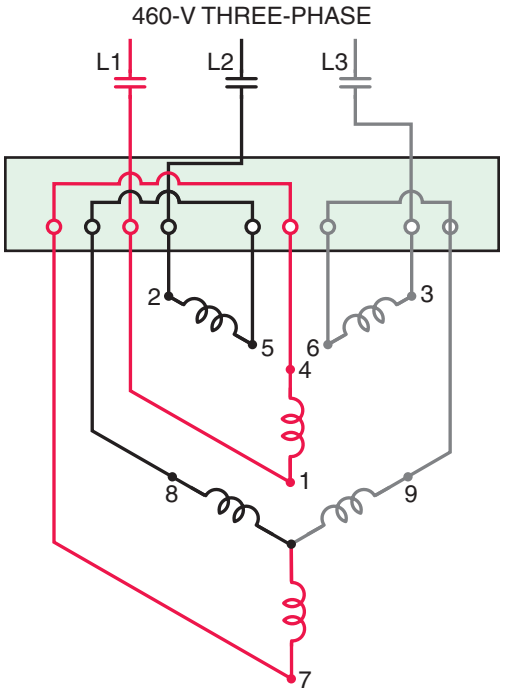

Figure 47.76 An autotransformer starter (motor application).

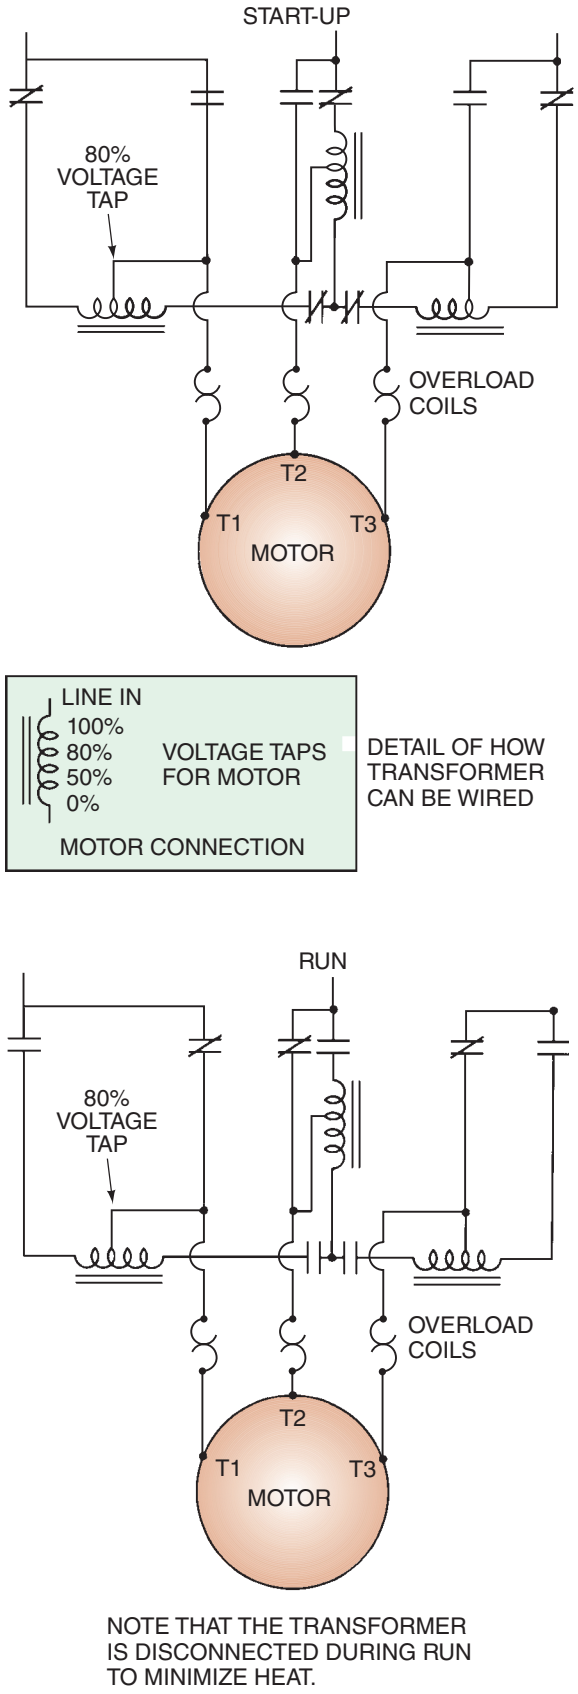

the starter contacts, and the voltage to the motor is supplied through the transformer during start-up. This reduces the voltage to the motor until the motor is up to speed, **Figure 47.76**. When the motor reaches full speed, a set of contacts closes and shorts around the transformer to run the motor at full voltage. The contacts that direct power through the transformer will then open so that current does not go through the transformer when the motor is running. This minimizes heat in the area of the transformer. Because it is starting at reduced voltage, the motor has very little starting torque so autotransformer start is used only in special applications. It is common with large compressors that need little starting torque, such as in centrifugal compressors where the pressures are completely equalized during the off cycle and compression does not start until the compressor is up to speed and the vanes start to open.

WYE-DELTA CONFIGURATION

Wye-delta start, often called star-delta start, is used with large motors; the starter has six leads and a single voltage. *When the motor starts in the wye configuration, it typically draws only about 33% of the current that it would draw starting in the delta configuration,* **Figure 47.77.** After the motor is up to speed, it is transitioned to a delta connection where the motor pulls the load and does the work more efficiently, **Figure 47.78.** The transition from star to delta is accomplished by a starting sequence with three different contactors that are **electrically** and **mechanically interlocked**; two are energized in wye for start-up, then one is dropped out and the other engaged for delta

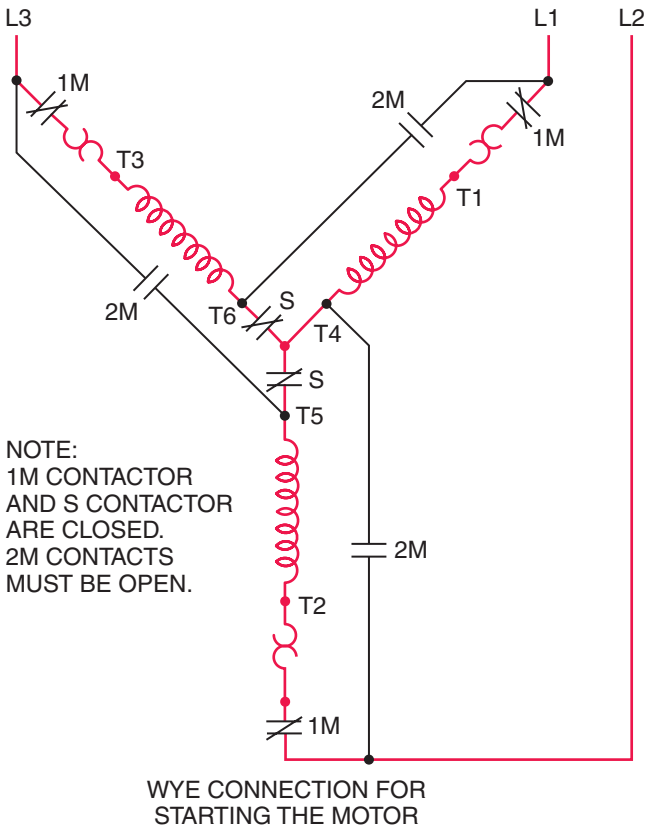
Figure 47.77 Starting a motor using a wye-delta circuit. The motor in this diagram is connected in the wye configuration.



operation. The time the motor operates in the wye connection depends on how long it takes the compressor to get up to speed. Large centrifugal compressors may take a minute or more to get up to speed in wye; then the transition is made to delta.

When the motor starter switches from wye to delta, the wye connection is actually disconnected electrically by means of a contactor. This disconnect is proven both electrically, by the timing of the auxiliary contacts, and mechanically, by means of a set of levers that interlock the contactors. It is then that the delta connection is made. The electrical and mechanical interlock feature is necessary because if the wye connection and the delta connection were to occur at the same time, there would be a dead short from phase to phase that would likely destroy the starter components, **Figure 47.79**.

When the delta connection is made, the motor draws large amperage as it is totally disconnected and then reconnected. This spike in amperage could cause voltage problems in the vicinity of the motor, for example, a computer room located on the same service and close by. Many manufacturers equip the starter with a set of resistors that are electrically connected and act as the load while the transition is being made from wye to delta. This is known as a wye-delta closed transition starter. The starter would be a wye-delta open transition without the resistors. The larger the motor to be started, the more likely it is to have a closed transition starter.

All of the starters mentioned use open contactors to start and stop the motors. The inrush current puts open contacts under a great deal of stress when they are brought together to start a motor. When the motor is disconnected from the line,

Figure 47.78 Once the motor is up to speed, it is changed over to the delta connection shown in this diagram.

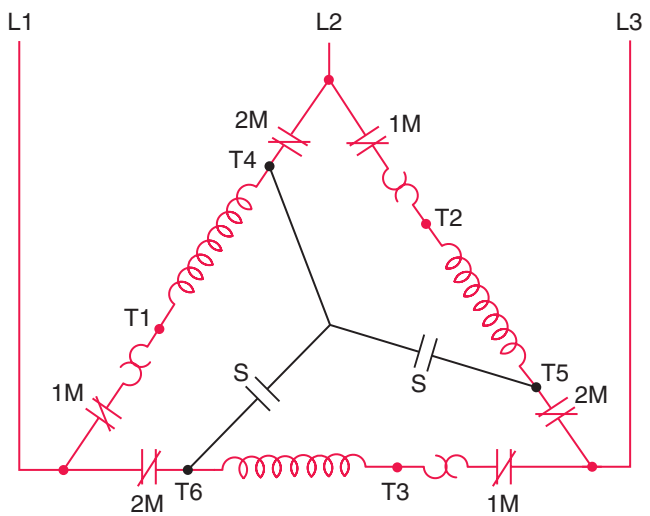


Figure 47.79 When too many of the contacts are closed, a short occurs. This diagram shows a short from line 2 to line 3 because the wye contacts did not open correctly.

an electrical arc tries to maintain the electrical path, much like an electrical welding arc, and the contactor is damaged each time. Due to the arc, the contacts become pitted and so will be able to interrupt the load of a motor only a limited number of times until they must be replaced. **Figure 47.80** shows a new and an old set of contacts for a medium-sized contactor. An arc shield in the starter prevents the arc from spreading to the next phase of contacts when the contacts are opened. This arc shield must be in place when starting and stopping the motor or severe damage may occur.

SAFETY PRECAUTION: *Starting and stopping a large motor using a starter requires a lot of electrical energy to be expended inside the starter cabinet. The operator should NEVER start and stop a motor with the starter door open. If something should happen inside the starter, particularly during start-up, most of this energy may be converted to heat energy, and the result may be molten metal blown toward the door. Do not take the chance—shut the door.*

ELECTRONIC STARTERS

As mentioned, inrush current for a motor can be five times the full-load current. *The inrush current can be greatly reduced by using electronic starters, which are also called soft starters. These starters use electronic circuits to reduce the voltage and vary the frequency to the motor at start-up. The result can be the reduction of a typical draw of 1000 A at locked rotor start-up to 100 A at locked rotor.* The motor is then accelerated up to full speed. This start-up is much easier on all components and reduces power line-voltage fluctuations. Electronic starters are also much smaller and more compact than conventional starters. For example, when an electronic starter is used to replace either an autotransformer or a wye-delta starter, only one component is needed to replace several, **Figure 47.81**.

The electronic starter uses electronic switching devices inside—typically, SCRs—to do the switching instead of electrical open contacts (see Unit 17, "Types of Electric Motors," for an

Figure 47.81 *The electronic contactor used to stop and start the motor offers a soft start and a slow stopping of the motor. There is less inrush current and no voltage spike when the motor is stopped. A set of bypass contacts (conventional contacts) are energized during the running cycle to take the load off of the electronic contactor.*

explanation of how these devices are switched on and off). Once the motor is up to speed and leveled out, the load needs to be taken off these devices so that they will not generate local heat. To do this, a set of open contacts are switched on very quickly after the motor is up to speed and the contacts close, which effectively provides a circuit around the SCRs, **Figure 47.81**.

It is also hard on other electrical circuits when a large electrical load running at full load is just shut off. The power companies' regulation system will allow a voltage spike with an abrupt shutdown. When it is time to stop the motor, the SCRs can be used for a soft coast down by opening the bypass contactor contacts and then ramping the SCRs down with the electronics in the circuit. In the event of a power failure, the system shuts down by means of the bypass contactor.

Troubleshooting all electronic equipment involves following the manufacturer's procedures. A particular sequence must be used. Electronic starters typically issue an error code that is linked to a blinking LED (light-emitting diode) that will tell the technician a fault has occurred and what it is. For example, the light may blink three times, then one time, for a code of 31. The technician then looks up that code to identify the fault. Usually the only tools the technician needs in order to troubleshoot these devices is a good VOM (volt-ohm-milliammeter) and a clamp-on ammeter for checking line amperage to the motor.

MOTOR PROTECTION

The motor that drives the compressor is often the most expensive component in the system. The larger the compressor motor, the more expensive it is and the more protection it should be afforded. Small hermetic compressors in household refrigerators have little protection. Motors in small chillers will have protection like that covered in Unit 19, "Motor Controls." Here we discuss only the motor protection used for large chillers such as rotary screw or centrifugals.

The type of protection depends on the size of the system and the type of equipment. The advances made in electronic devices for monitoring voltage, heat, and amperage have improved the protection offered today compared with that offered several years ago. However, older motor protectors are still in use and will be for many years to come.

LOAD-LIMITING DEVICES. Rotary screw and centrifugal chillers use load-limiting devices to control the motor amperage. They monitor the current the motor is drawing while operating and throttle the refrigerant to the suction inlet of the compressor to prevent the motor from operating at an amperage higher than the full-load amperage.

The load-limiting device controls the slide valve on a rotary screw or the prerotation vanes on a centrifugal, **Figure 47.82**. It is a precision device that is the first line of defense for preventing motor overload and is set at exactly the full-load amperage at initial start-up. It should not give any problems afterwards. For example, assume a motor has a full-load amperage of 200 A. The load-limiting device will be set so as not to exceed full-load amperage, or 200 A. **NOTE:** *Full-load amperage may be derated to a lower value for a system that has high voltage, so the technician cannot always go by the nameplate amperage. The start-up log should be consulted for the derated amperage.* • The load limiter may also have a feature that allows the operator to run the chiller at reduced load manually. Typically for rotary screw chillers, the load may be varied from 10% to 100%. For centrifugal chillers, it may vary from 20% to 100%.

Most buildings are charged for electrical power based on the highest monthly current draw that lasted for some period of time, typically 15 to 30 min. This is called billing

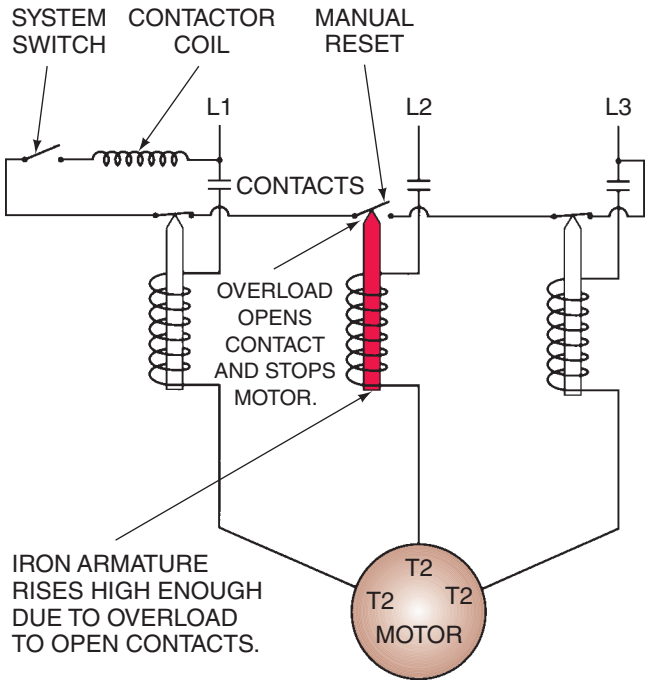
demand power charge and most power companies measure it with a demand meter. Operating the equipment below the billing demand charge would be desirable whenever possible. For example, if an office building did not require cooling during the month until the last day and the operator started the chiller and allowed it to run at full load to reduce the building temperature quickly, this would take more than the time required to drive up the power company demand meter and the building would be charged for the whole month at a rate as though it had operated at full load all month. An operator could have avoided the excess charge by starting the system and operating it at part load, taking longer to reduce the building temperature. For example, the chiller may have the feature that would allow it to run at 40% and take longer to accomplish the task.

Many buildings have computer-controlled power management. This may take over from the chiller's control and operate the chiller at reduced capacity during high peak-load conditions. For example, if the peak power consumption is reached for the month on the 15th and a high air-conditioning load is needed on the 30th of the month, the system will operate above the peak demand set on the 15th, and a higher power bill will result for the entire month. *Rather than allow this to happen, a computerized control may reduce the power consumption in some portion of the building. It is not uncommon to reduce the capacity of the air-conditioning chiller or chillers.* It may be better to allow a temperature rise of a few degrees in the entire building rather than pay a considerably higher power bill for the month. Reduction in demand may be easily accomplished through electronic circuits. This is called *load shedding*, for reducing the load and the demand charge.

MECHANICAL-ELECTRICAL MOTOR OVERLOAD PROTECTION. All motors must have some overload protection. If a motor is allowed to operate at above the full-load amperage for long, the motor windings will be damaged by the heat. Different motors have different types of protection. Overload protection for smaller motors, typically up to about 100 hp, was discussed in Unit 19, "Motor Controls." Mechanical-electrical overload protection for large rotary screw or centrifugal compressors may be a simple dash-pot device. This device operates on the electromagnetic theory that when a coil of wire is wound around a core of iron, the core of iron will move when current flows. With the dash-pot, either the current from the motor or a branch of the current from the motor passing through a coil around an iron core will cause the iron core to rise, **Figure 47.83**.

Large motor overload protectors are typically rated to stop the motor should the current rise to 105% of the motor's full-load rating. For example, in a motor with a rating of 200 A the overload device would be set up to trip at 210 A (200 × 1.05 = 210). The motor will be allowed to run at this amperage for a few minutes before stopping to prevent unwanted overload trips. These motors also have a load-limiting device

Figure 47.83 An iron core and current flow in a compressor overload device.



that limits the motor amperage, so if this device is functioning correctly, the amperage should not be excessive for longer than it takes the electro-mechanical control to react, at which point the amperage should be no more than full load.

The dash-pot overload device gets its name from the fact that it contains a time delay to allow the motor to be started. Without the time delay, the inrush current would trip the device. The time delay is accomplished with a piston that must rise up through a thick fluid (the dash-pot) before tripping, **Figure 47.84**. The overload mechanism is wired into the main control circuit to stop the motor when it is tripped. Overload protections for large motors are manually reset so the operator will be aware of any problem.

ELECTRONIC SOLID-STATE OVERLOAD DEVICE PROTECTION. Solid-state protective devices are wired into the control circuit like the dash-pot but act and react as an electronic control. They have the capability of allowing the motor to start and also monitoring the full-load motor amperage closely. They typically are located in the starter cabinet between the starter and the motor. They are the last line of defense. They are much more compact than the dash-pot overloads and have many more features for close motor overcurrent control, such as the following:

- Motor overload protection
- Phase reversal protection
- Phase failure (single-phase) protection
- Voltage unbalance protection

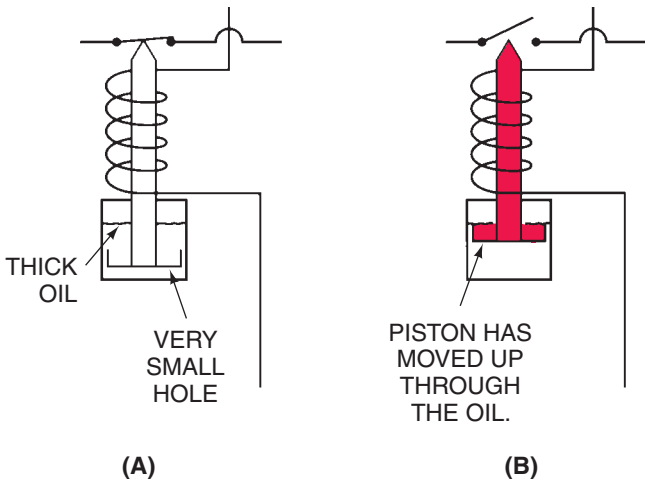
Figure 47.84 A dash-pot of oil gives the overload the time delay needed for motor start-up.



- Manual and automatic reset, often from a remote location
- Ambient temperature compensation
- Trouble codes, much like the electronic contactors

Some of these features are discussed in more detail in the next portion of the text.

ANTI-RECYCLE CONTROL. All large motors should be protected from starting too often over a specified period of time. The anti-recycle timer is a device that prevents the motor from restarting unless it has had enough running time or off time to dissipate the heat from the last start-up. Manufacturers have different ideas as to how much this time should be. Typically, the larger the motor, the more time required. Many centrifugals have a 30-min time period. If the motor has not been started or has not tried to start for 30 min, it is ready for a start. Check the manufacturer's literature for the recycle time for a specific chiller.

PHASE FAILURE PROTECTION. Large motors all use three-phase power. The typical voltages are 208, 230, 460, and 575 V. Higher voltages are used for some applications, such as 4160 V or 13,000 V. Whatever the voltage, all three phases must be furnished or the motor will overload immediately. Electronic phase protection monitors the power and ensures that all three phases are present.

VOLTAGE IMBALANCE. Phase imbalance is caused by the electrical load on the building being unbalanced or the power company supply voltage being out of balance. The voltage to a compressor must be balanced within certain limits. Usually, 2% voltage imbalance is the maximum:

$$\text{Voltage Imbalance} = \frac{\text{Maximum Deviation from Average Voltage}}{\text{Average Voltage}}$$

For example, a technician measures the voltage on a nominal 460-V system to be

Phase 1 to phase 2	475 V
Phase 1 to phase 3	448 V
Phase 2 to phase 3	461 V

The average voltage is

$$\frac{475\text{ V} + 448\text{ V} + 461\text{ V}}{3} = 461.3\text{ V}$$

The maximum deviation from average is

$$475\text{ V} - 461.3\text{ V} = 13.7\text{ V}$$

The voltage imbalance is

$$\frac{13.7}{461.3\text{ V}} = 0.0297, \text{ or } 2.97\%$$

This is more than some manufacturers' maximum allowable. The operating technician should keep an eye on voltage imbalance because it causes the motor to overheat. Some sophisticated electronic systems feature voltage imbalance protection; otherwise, it is up to the equipment operator to monitor.

PHASE REVERSAL. Three-phase motors turn in the direction in which they are wired to run. If the phases are reversed, the motor rotation will reverse. *This can be detrimental to many compressors*. Reciprocating compressors will normally perform in either direction due to their bidirectional oil pumps. Scroll, rotary screw, and centrifugal compressors must turn in the correct direction. Phase protection is often part of the control package for these compressors.

Any compressor with a separate oil pump, such as the centrifugal, will not start under phase-reversal conditions because the oil pump will not pump when reversed. It is not uncommon for the power company to reverse the phases of the power servicing a building or for an electrician to reverse the phases of a circuit within a building. It is very good practice for a building technician to be on the alert for any phase reversal after the building electrical system has been serviced by anyone. A phase meter may be used to determine the proper phasing of the power supply. This meter is a good tool for the heavy commercial or industrial technician to carry.

SUMMARY

- A chiller refrigerates circulating water.
- The compression cycle chiller has the same four basic components as other refrigeration systems discussed previously in this text: a compressor, evaporator, condenser, and metering device.
- R-22, R-134a, and other refrigerants that are environmentally friendly alternatives are used in reciprocating compressor chillers.
- Cylinder unloading is used to control the capacity of a reciprocating compressor.
- Rotary screw compressors are used in larger-capacity chillers using high-pressure refrigerants.
- Rotary screw compressors are lubricated with an oil pump and separate motor.
- The evaporators used in high-pressure chillers are either direct-expansion or flooded evaporators.
- High-pressure chiller condensers may be either water- or air-cooled.
- Many condensers have subcooling circuits that reduce the liquid temperature.
- In the condenser, as in the evaporator, there is an approach relationship between the refrigerant condensing temperature and the leaving-water temperature.
- Air-cooled condensers eliminate the need for water towers.
- Centrifugal compressors may be manufactured so that they can be operated in series; this is called multistage operation.
- For prelubrication of the bearings, the oil pump on a centrifugal compressor is energized before the compressor is started.
- The orifice or the high- or low-side float metering device is typically used in low-pressure chillers.
- When a low-pressure refrigerant is used in a centrifugal compressor, the low-pressure side is always in a vacuum. If there is a leak, air will enter the system.
- Absorption refrigeration is a process that uses heat as the driving force rather than a compressor.
- Water is the refrigerant in an absorption chiller.
- The absorption chiller uses a salt solution consisting of lithium-bromide (Li-Br) as the attractant in the refrigeration process.
- Salt solutions are corrosive, and air must be kept away from them.
- Absorption chillers also have a purge system.
- Motor controls may include motor overload protection devices, load-limiting devices, anti-recycle controls, phase failure protection, and voltage imbalance and phase reversal protection.

REVIEW QUESTIONS

1. When a chiller is used, the secondary refrigerant that circulates in the building is _____.
2. What are the two basic categories of chillers?
3. Three types of compressors are used for chillers: _____, _____, and _____.
4. Blocked suction cylinder unloading is accomplished by
   A. keeping the suction valve closed.
   B. closing the discharge.
   C. closing the suction service valve.
   D. using a device in the low-pressure side of the system to close it off.
5. True or False: The capacity control for a screw compressor is accomplished with cylinder unloading.
6. Which of the following methods are used to control the capacity of a centrifugal compressor?
   A. Cylinder unloading
   B. Prerotation vane control
   C. Blocked discharge
   D. High- to low-side bypass
7. Describe a direct-expansion versus a flooded evaporator.
8. What is the purpose of multiple passes in a chiller evaporator?
9. The approach temperature for the evaporator is
   A. the difference between the suction and head pressures converted to temperature.
   B. the difference between the refrigerant boiling temperature and the suction-line temperature.
   C. the difference between the refrigerant boiling temperature and the inlet water temperature.
   D. the difference between the refrigerant boiling temperature and the leaving-water temperature.
10. What type of water-cooled condenser is used in large chillers?
11. The compressor used in low-pressure chillers is the
    A. centrifugal.
    B. screw.
    C. rotary.
    D. reciprocating.
12. List the types of metering devices used with high-pressure chillers.

13. The subcooling temperature in a condenser can be measured by taking the difference between the
    A. suction pressure converted to temperature and the boiling refrigerant.
    B. boiling temperature and the condensing temperature.
    C. condensing temperature and the leaving-refrigerant temperature.
    D. condensing temperature and the entering-refrigerant temperature.
14. What causes a surge in a centrifugal chiller?
15. Why is it important to keep an operating log on a chiller?
16. Which of the following metering devices is used in low-pressure chillers?
    A. A low- or high-side float
    B. A capillary tube
    C. An automatic expansion valve
    D. A thermostatic expansion valve
17. The purge unit in a low-pressure chiller removes
    A. overcharge of refrigerant.
    B. excess oil.
    C. condensable refrigerant.
    D. noncondensables.
18. In an absorption chiller, _____ is used to create the difference in pressures.
19. The types of energy used to power a typical absorption refrigeration machine are _____ and _____.
20. True or False: Some absorption machines are directly fired with gas or oil.
21. What is the common refrigerant used in absorption refrigeration machines?
22. How is capacity control accomplished with a steam-driven absorption refrigeration machine?
23. True or False: Single-phase induction, run-repulsion start motors are used with centrifugal machines.
24. Describe how a wye-delta motor is started and runs.
25. Why is it important to have phase protection for large motors?

UNIT 48

COOLING TOWERS AND PUMPS

OBJECTIVES

After studying this unit, you should be able to

- describe the purpose of cooling towers used with chilled-water systems.
- state the relationship between the capacity of a cooling tower and the wet-bulb temperature of the outside air.
- explain what is meant by the cooling tower's approach.
- explain what is meant by the cooling tower's range.
- describe and calculate the cooling tower's load.
- state the means by which the cooling tower reduces water temperature.
- describe three types of cooling towers.
- explain the various uses of fill material in cooling towers.
- list the two types of fan drives.
- state the two types of fans used in cooling towers.
- explain the purpose of the sump in a cooling tower.
- explain the purpose of makeup water.
- describe a centrifugal pump.
- describe vortexing.
- explain two types of motor–pump alignment.
- describe chemical-free cooling tower water treatment.
- define scale as it applies to cooling towers.
- describe scale prevention in cooling towers.
- explain what is meant by biofilm as applied to cooling towers.
- explain encapsulation.
- explain electroporation.
- describe particle separation in cooling towers.
- describe bacterial control in a cooling tower.
- explain corrosion control in a cooling tower.

SAFETYCHECKLIST

- ☑ Ensure that all electrical safety precautions are observed when servicing pump motors.
- ☑ Ensure that all guards are in place when working in the area near a turning fan.
- ☑ Do not approach a turning fan that is not properly guarded.
- ☑ Be careful of footing and balance when climbing up to or down from a cooling tower location. Do not move in a way that will cause balance to be lost when working around an elevated tower.
- ☑ When lifting a motor or pump, lift with a straight back and wear a back support belt.

48.1 COOLING TOWER FUNCTION

The heat that is absorbed into the boiling refrigerant in the chiller's evaporator is ultimately rejected by the condenser. In most water-cooled applications, the hot discharge gas from the compressor is desuperheated and condensed with water from the cooling tower. The water from the cooling tower, after absorbing the system heat in the condenser, delivers this heat to the cooling tower where the heat is rejected to the atmosphere. The high-pressure, high-temperature superheated vapor that is pumped from the compressor to the condenser contains heat produced from the compression process as well as heat that is absorbed from the water circulating through the chiller barrel. This heat energy is then transferred to the water that flows between the condenser and the cooling tower. In the cooling tower, air moves across the surface of the water, thereby lowering the temperature of the water in the cooling tower. The cooler water is then circulated back to the condenser so that it can absorb more heat from the refrigerant, **Figure 48.1**. During the water-cooling process in the cooling tower, there is some evaporation, but most of the water is used over and over again.

In vapor-compression refrigeration systems, the condenser must reject more heat than the chiller or evaporator absorbs. Since the cooling tower must reject the heat from the condenser's water circuit, it follows that the cooling tower must also reject more heat than the chiller or evaporator absorbs. The amount of heat energy that must be rejected by the condenser, and ultimately the cooling tower, is very close to the mathematical sum of the amount of heat added to the refrigerant in the chiller barrel and the amount of heat added to the refrigerant during the compression process, **Figure 48.2**. Heat losses and gains in the interconnecting piping, as well as other factors, account for any calculation discrepancies that might arise. The compressor accounts for almost 20% of the heat that must be rejected. This percentage is dependent on the type of compressor used in the cooling process. For example, a 1000-ton chiller would need a cooling tower that could reject about 1250 tons of heat. The additional 250 tons of capacity represents 25% of the chiller's cooling capacity [(250 tons/1000 tons) × 100%] and 20% of the total system capacity [(250 tons/1250 tons) × 100%].

The condenser must be furnished water that is within the design limits of the system, or the system will not perform

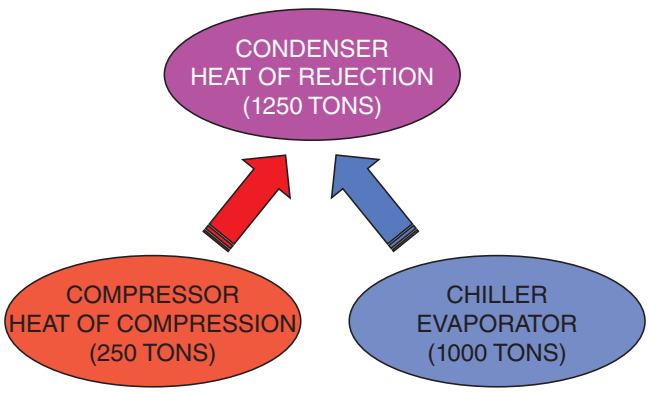

Figure 48.3 The typical cooling tower approach temperature.

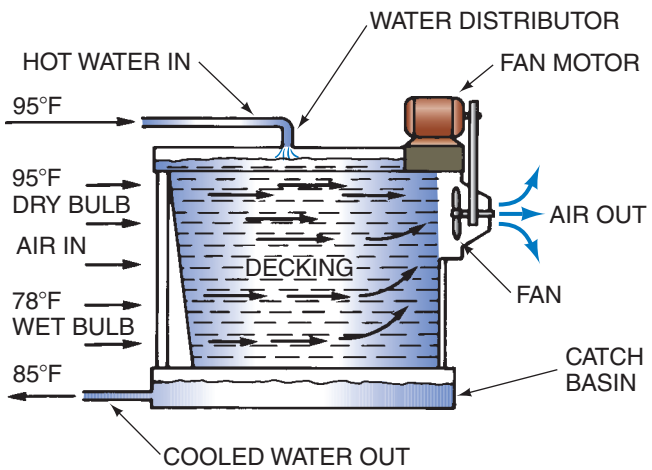

adequately. The design temperature for the water leaving the cooling tower for most refrigeration systems, including the absorption chiller, is 85°F. Using a design outdoor ambient temperature of 95°F dry-bulb and 78°F wet-bulb, the cooling tower can lower the water temperature through the tower to within 7°F of the wet-bulb temperature of the outside air. When the wet-bulb temperature is 78°F, the water temperature leaving the tower would be 85°F, **Figure 48.3**. This occurs even though the air dry-bulb temperature is 95°F.

Most cooling towers work in a similar manner. They reduce the temperature of the water in the tower by means of evaporation. As the water moves through the tower, the surface area of the water is increased to enhance the evaporation process. The different methods used to increase the surface area

of the water is part of what makes one cooling tower different from another. When the water is spread out to create more surface area, it will evaporate faster and be cooled closer to the wet-bulb temperature of the air. The water cannot be cooled below the wet-bulb temperature of the air. A nearly perfect cooling tower could reduce the temperature of the water to the entering wet-bulb temperature; however, the tower would be tremendous in size. Cooling towers produced for HVAC/R applications are typically designed to operate with a 7-degree **approach** temperature. A cooling tower's approach temperature is the temperature difference between the water leaving the tower and the wet-bulb temperature of the air entering the cooling tower.

The heat transfer process within a cooling tower between the water and the air is both latent and sensible. However, the latent cooling process dominates. As the water falls or is sprayed through the cooling tower, a portion of it evaporates. The heat to vaporize a portion of the water comes from the remaining mass of the water. For every pound of water that is evaporated, 970 Btus are absorbed from the remaining water. This is referred to as the latent heat of vaporization of water. The temperature of the remaining mass of the water is now reduced. Evaporation is achieved by water flowing over a fill material in the tower, which breaks it down into smaller droplets with more exposed surface area. As mentioned, the water leaving the cooling tower can be cooled to within 7 degrees of the wet-bulb temperature. In dry climates, the water can exit the cooling tower 10 degrees cooler than the dry-bulb temperature. This phenomenon happens because of the greater amount of evaporation, thus the lower wet-bulb temperatures, in these dryer areas. The temperature difference between the entering and leaving water of the cooling tower is referred to as the **tower range**, and is typically about 10°F.

The cooling tower load in Btu/h can be calculated by the following formula:

$$\text{Cooling Tower Load} = (\text{gpm}) \times (8.33) \times (\text{Tower Range}) \times (\text{Specific Heat of Water}) \times 60$$

where

gpm = Flow rate in gallons per minute of water through the tower

8.33 = Density of water in lb/gal

Specific heat of water = 1 Btu/(lb)(°F)

60 = Conversion between minutes and hours

For example, consider the following conditions:

Entering water temperature = 96°F

Leaving water temperature = 88°F

Flow rate of water = 30 gpm

The tower load can be calculated as follows:

$$\text{Tower load} = (30\ \text{gpm}) \times (8.33\ \text{lb/gal}) \times (96°\text{F} - 88°\text{F}) \times (1\ \text{Btu/(lb)(°F)}) \times (60\ \text{min/hour})$$

Tower load = 120,000 Btu/h = 10 tons

48.2 TYPES OF COOLING TOWERS

Three types of cooling towers are commonly used: the *natural-draft* and *forced- or induced-draft tower* and the *closed-circuit hybrid cooling tower*. The closed-loop hybrid cooling tower has three different operating modes. The larger the installation, the larger and more elaborate the cooling tower.

The natural-draft tower may be anything from a spray pond in front of a building to a tower on top of a building, **Figure 48.4**. The spray pond and natural-draft cooling tower rely on the prevailing winds and will cool the water to a lower temperature when the prevailing winds are greater. The natural-draft tower or spray pond usually has an approach temperature of about 10°F because it relies solely on the blowing wind to provide the cooling effect.

The spray pond can be located at ground level or it may be on the roof of a building, but wherever it is, the spray must be contained in the area of the pond. Spray ponds on rooftops are becoming increasingly popular as they cool the roof and reduce the solar load on the structure. If the rooftop can be cooled to 85°F, a great reduction in air-conditioning load can be realized.

The spray pond and natural-draft cooling tower use pump pressure to increase the surface area of the water by atomizing it into droplets. Spray heads are placed at strategic locations within the pond or tower through which the water is pushed. The spray nozzles impose a restriction and must be kept clean or they will not effectively atomize the water. The pumps needed to atomize the water can be very large, given the large volume of water that these applications use.

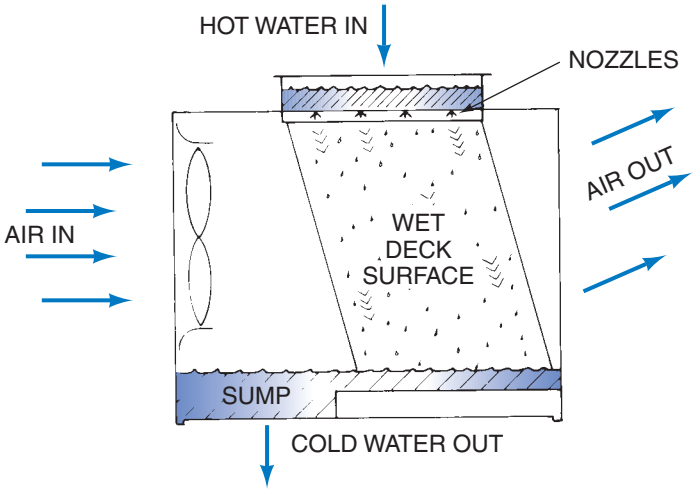
Figure 48.6 A forced-draft cooling tower.



Forced-draft and induced-draft cooling towers use fans to move the air through them, **Figure 48.5**. These are the most popular applications today because of their efficiency and reliability. Forced-draft cooling towers are so named because the fans or blowers force or push air across the water, **Figure 48.6**. Induced-draft cooling towers use fans to pull air over the wetted surfaces, **Figure 48.7.** In applications where the cooling tower is located indoors, centrifugal blowers are used to move the air through the tower, since these blowers are designed to overcome the high static pressures in the ductwork. Towers with centrifugal fans can be more compact and are therefore more desirable for some applications. These towers are available up to about 500 tons of capacity and heat rejection. The fans and blowers used on cooling towers may be either belt-driven or gear-driven. Belt-driven fans will require belt maintenance on a regular basis. Gear-driven fans have a transmission that will require only periodic lubrication.

The closed-circuit tower, **Figure 48.8**, *has a dry/wet mode, an adiabatic mode, and a dry mode. This tower has a finned coil,* **Figure 48.9**, *a prime surface coil,* **Figure 48.10**, *and a wet deck surface,* **Figure 48.11**. In the dry/wet mode the fluid to be cooled is fed to the dry finned coil and then to the prime surface coil, **Figure 48.12.** The fluid leaves the tower and is pumped back to the system, where it absorbs heat from the warmer condenser. Spray water from the cold water sump is pumped to a distribution system above the prime surface coil and allowed to fall over the coil, thus providing evaporative cooling. The spray water then falls over the wet deck

surface, where it is cooled as more evaporative heat transfer takes place. Air is drawn through the prime surface coil and the wet deck surface, leaving after passing through the finned coil, where more cooling occurs. When heat load or ambient temperatures are lower, the water usage over the evaporative cooling portion can be reduced. A valve that controls the outlet fluid temperature can modulate this water usage.

The term *adiabatic* refers to the process of cooling the circulating condenser water by evaporating the tower water. It means that there is no heat added or removed from the process by external means and that the sensible heat transferred from the condenser circulating water is equal to the latent heat transferred into the air or gained from the evaporating water in the cooling tower. In the adiabatic mode, the fluid to be cooled bypasses the prime surface coil and is pumped through the finned coil only, **Figure 48.13**. Spray water is used to help cool the air passing through the tower, providing sensible heat transfer through the finned coil.

Plume, which is the saturated discharge air from the closed-circuit tower, can be reduced (unlike conventional evaporative cooling towers)—some in the wet/dry mode and some in the adiabatic mode. Plume can be a problem in some areas when it falls on parked cars or other highly finished objects. It can also be a safety hazard when falling on areas where cars travel and at airports. *In the dry mode, the fluid to be cooled is passed through both the finned coil and the prime surface coil,* **Figure 48.14**. *No spray water is used and consequently there is no plume. The fluid is cooled by the forced air being passed over the coils.*

The closed-circuit system protects the system fluid from contamination and helps to ensure maximum efficiency over time, including reduced water usage. The closed-loop feature of this tower not only protects the circulating fluid, it also protects the heat transfer surface in the condenser. As mentioned earlier, the condenser tubes frequently get fouled, reducing the rate of heat transfer in the heat exchanger. With the closed-loop system, the potential for fouling is greatly reduced.

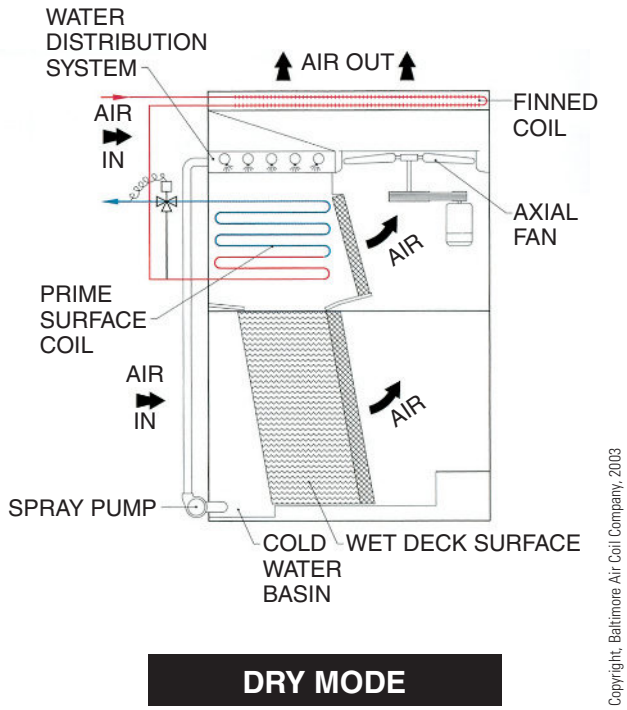

Figure 48.13 *An illustration of the closed-circuit cooling tower in the adiabatic mode.*

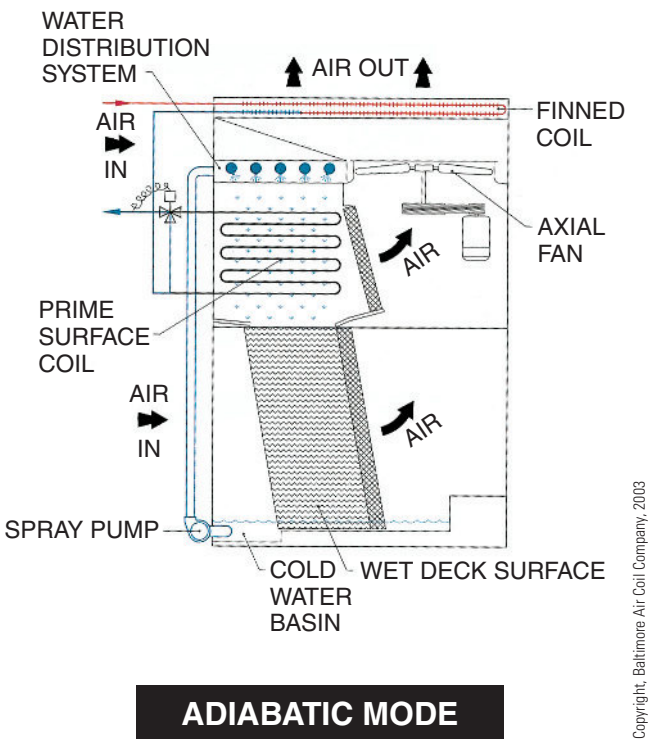

48.3 FIRE PROTECTION

An open cooling tower is a place where a fire may occur during the off-season when the tower components are dry. The tower materials may be flammable, such as wood or some plastics. Some fire codes and insurance companies may require that the tower be manufactured entirely of fireproof materials or they may require that a tower wetting system be in place, such as sprinkler heads similar to those commonly found in buildings. Some towers are controlled in such a manner that the system pump starts up on a timed cycle to wet the tower down occasionally during off-cycles. Another wetting system may be an auxiliary pumping system that keeps the tower continuously wet whenever the weather is above freezing. This type of system also may prevent expansion and contraction of any wood construction in the tower. Local codes and insurance requirements will dictate what method should be used to protect the tower from fire.

48.4 FILL MATERIAL

The cooling tower is designed to keep the water and the air in contact with each other for as long as possible. Manufacturers use various methods to slow the water as it trickles down through the tower while the air moves up. Two methods used to evaporate the water in the forced- and induced-draft tower are the splash method and the fill, or wetted-surface, method. Both use a material in the tower often called fill. This material may be layers of wood slats through which the water drips down. Other materials used in the splash method include polyvinyl chloride (PVC) plastic or fiber-reinforced polyester (FRP) plastic. These materials have slow burn rates and are desirable when the potential for fire is high. Towers with a splash system have a framework that supports the slats and is designed to keep them at the correct angle for proper water wetting of all slats with water flow from the top of the tower to the bottom.

The fill or wetted-surface type of cooling tower may also use some form of plastic or fiberglass as fill material. The water spreads out on the surface of the fill while air is passed over it, **Figure 48.15(A)**. **Figure 48.15(B)** and **Figure 48.15(C)** show a fill material with a honeycomb pattern. This type of fill may have smaller passages for the air to travel through and is not used where particles from the surroundings can contaminate the tower and restrict the passages. Both types of fill rely on water running down across it, and unless kept at the angle the manufacturer recommends, the water will not take the proper path. Water running to one side or the other will reduce the capacity of the tower. If the fill material is removed for maintenance, care should be taken to replace it in such a manner that water will move through the tower correctly.

48.5 FLOW PATTERNS

There are two distinct airflow patterns for cooling towers: **crossflow** and **counterflow**. The crossflow cooling tower, **Figure 48.16**, introduces the air from the side and usually pulls it to the top of the tower for exhaust. In smaller crossflow towers, the fan is on the side of the tower and air is exhausted out the side, **Figure 48.7**. In the crossflow tower, the water is moving downward and the air is moving at right angles to the water. Care must be taken that the moisture-laden air is not exhausted to a place where it will cause a problem, such as on a walkway or a parking lot where cars can be spotted with the water and chemicals used in treatment, which may be corrosive to car finishes. The counterflow tower, **Figure 48.17**, introduces the air at the bottom and exhausts the air out the top of the tower. The water is moving downward as the air moves up through it.

In most towers, especially those that use spray, many small particles of water are suspended in air. These particles are subject to being blown out of the tower by the prevailing winds, a loss of water called *drift*, which can be expensive

and a nuisance to any surrounding areas if the cooling tower water is treated with chemicals. The amount of drift is minimized with the aid of eliminators, **Figure 48.18.** Eliminators cause the spray to rapidly change direction and impact solid surfaces, **Figure 48.19**, where water droplets collect and run back to the tower basin. The eliminators may be louvres on the side of the tower or they may be part of the fill material in some newer towers.

Figure 48.18 Drift eliminators.

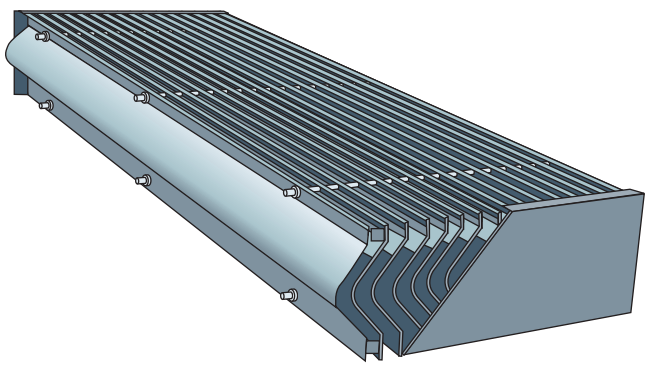

Figure 48.19 The air impacts the eliminators, separating the moisture from the air.

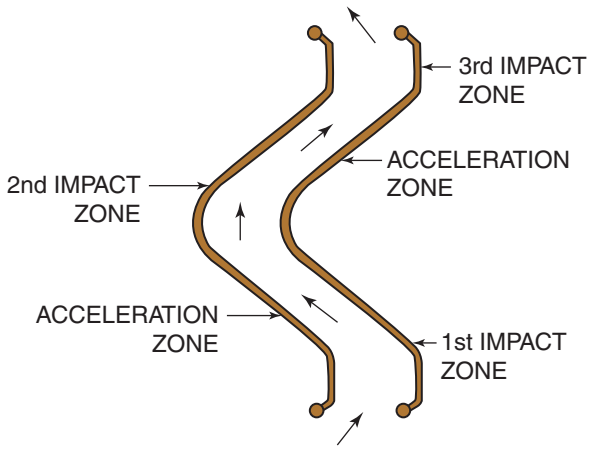

48.6 TOWER MATERIALS

The materials from which a cooling tower is constructed must be able to withstand the environment in which the tower operates. The typical tower must be able to withstand wind, the weight of tower components and the water, sun, cold, freezing weather (including any ice that may accumulate), and vibration of the fan and drive mechanisms. Towers must be carefully designed and the materials chosen according to the type and location of the tower. Typically, the smaller packaged towers are made of galvanized steel (for rust protection), fiberglass, or FRP. These towers are manufactured as a complete assembly and shipped to the job, **Figure 48.20.**

Figure 48.20 Modern cooling tower that was manufactured as a complete assembly and shipped to the job.

Larger towers may have a concrete base and sump to hold the water with sides made of other materials such as corrugated asbestos-cement panels, wood (either treated or redwood), fiberglass, or corrugated FRP. Asbestos-cement panels are no longer being used. They may be found in older towers, and technicians should handle them with care. The manufacturer should be contacted for handling instructions. In many cases, fire prevention must be considered in the selection of materials.

48.7 FAN SECTION

In all forced-draft towers the motor must have a way of turning the fan. There are two different types of drive, the belt drive and the gearbox (transmission) drive. The belt drive is normally used in the smaller towers and includes an adjustable motor mount. This mechanism will undergo the greatest wear in the tower and requires the most maintenance, so it should be located where preventive maintenance and service can be performed with as little effort as possible.

Fan motors in larger towers are mounted out to the side and have a gearbox or transmission to change the direction of the motor driveshaft by 90 degrees, **Figure 48.21**. **Figure 48.21(A)** shows a set of 90-degree bevel gears, while **Figure 48.21(B)** shows a set of 90-degree spiral bevel gears. Bevel gears are often preferred to the non-beveled variety because of the increased surface area between the mating surfaces, which reduces the wear on the gears and prolongs their useful life. These motor/fan units may also be designed to change the motor-to-fan shaft speed relationship. The typical motor will turn at 1800 or 3600 rpm and the fan shaft will turn considerably slower, depending on the gear reduction. For example, if the gear connected to the motor shaft is one-half the diameter of the gear on the fan's shaft, the fan will rotate at a speed that is one-half that of the motor. The motor is connected to the gearbox using a coupling and shaft, **Figure 48.22**. *VFDs (variable-frequency drives) are also being used for cooling tower fans. The ability to reduce the fan speed to correspond with system conditions helps control the system more closely and improves efficiency by reducing energy consumption. VFD technology is covered in detail in Unit 17, "Types of Electric Motors".* The motor, gearbox, and fan bearings must be accessible for service purposes.

The fan blade on the cooling tower is enclosed in a fan housing that improves the efficiency of the fan blades, **Figure 48.17**. The location of the fan blade is critical in

Figure 48.21 (A) Bevel gear assembly. (B) Spiral bevel gear assembly.

most towers. It must be placed at the correct distance from the top and sides for optimal performance.

In the past, all towers used a thermostat immersed in the water to cycle the cooling tower fans on or off as needed to control tower basin water temperature and maintain a minimum temperature. This system results in fairly wide temperature swings, causing the water temperature to vary considerably. As we will see later in this unit, motorized diverting valves may be used to maintain conditions closer to the condenser temperature when temperature swings occur. The VFD fan motor can be used for this function. The VFD eliminates the constant starting and stopping of the motor by modulating the motor's speed to closely match the needs of the system. *The VFDs also allow motors, some of which are quite large, to soft start and to coast down without shutting off abruptly. Both of these features improve system performance and prevent power fluctuations.*

48.8 TOWER ACCESS

All cooling towers will need service on a regular basis. There must be access doors to the fill material for cleaning and possible removal. The tower basin must also be accessible for cleaning because large amounts of sludge often accumulate there, **Figure 48.23**. The cooling tower becomes a large filter

Figure 48.23 (A) Access ports on a cooling tower. (B) Port open to gain access.

for whatever may be airborne—commonly, dirt, pollution, feathers, birds, plastic wrappers, cups, etc. These particles will gather in the sump and must be removed. There is also a strainer, **Figure 48.24**, at the water outlet port on the cooling tower that collects objects, preventing them from entering the pump and piping circuit. For the purpose of flushing the tower sump with a water hose, an adequate water supply should be available in the vicinity of the tower.

A tall tower will likely have a stairway or ladder to the top for servicing the fan and drive components, **Figure 48.25**. Provisions should be made in the vicinity of the motor and fan to lift out any component parts that may need to be removed and lowered to the ground for servicing. A service stair or ladder must meet the local codes for safety and include proper handrails and barriers to prevent stepping over the edge.

48.9 TOWER SUMP

All cooling towers must have some sort of *sump* for collecting the water. The sump on small cooling towers may consist of a metal pan that gathers the water and drains to a lower point. When the sump is located outside, it must have some means

to prevent the water from freezing, such as a thermostatically operated sump heater, **Figure 48.26.** Sump heaters are used for small installations; larger installations require more heat and may have a circulating hot water coil or a method of using low-pressure steam to heat the tower basin water in cold weather. Many cooling towers have underground sumps made of concrete. These sumps will not freeze in the southern climates but must be protected from the cold in northern climates unless the refrigeration system is operating and adding heat to the sump. Some sumps are located in the heated space of a building to prevent freezing. Antifreeze products also may be added to some systems.

48.10 MAKEUP WATER

Because the cooling tower operates on the principle of evaporation, water is continuously lost from the system. There are several methods of making up for lost water, the float valve, **Figure 48.27**, being one of the most common. When the water level drops, the float ball drops with it and opens a valve to the makeup water supply. Usually the makeup water is drawn from the normal municipal or other, similar supply. Another method of making up water is with a float switch that energizes a solenoid valve to allow water to fill the sump when the water level falls, **Figure 48.28**. When the water level reaches the proper level, the float rises and shuts off the solenoid valve. Another method to control makeup water uses sensors that determine the level of water in the sump. If the water level is high enough, both sensors are submerged in the water and the solenoid controlling the fill valve is de-energized,

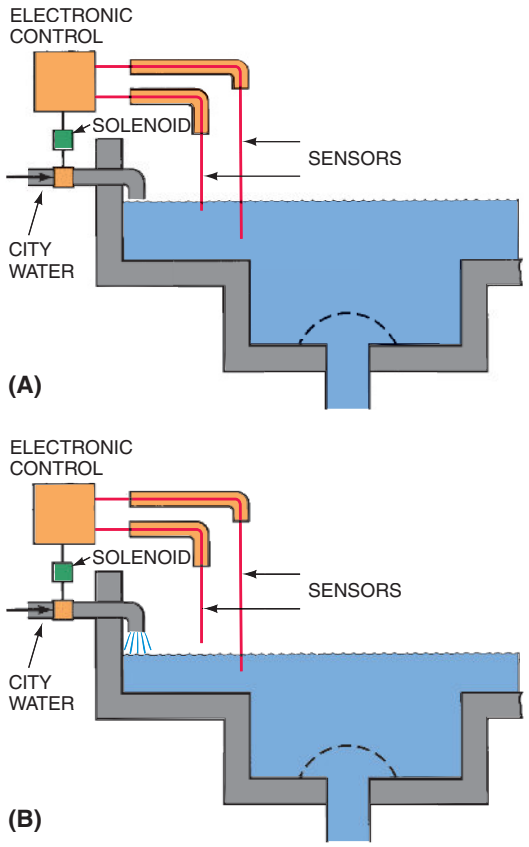

Figure 48.29(A). If the water level drops, only one of the sensors is submerged, the electric circuit between the two sensors is not complete and the solenoid on the fill valve is energized to feed more water to the sump, **Figure 48.29(B)**.

48.11 BLOWDOWN

Often, building management personnel have a difficult time grasping the purpose of blowdown, which merely means bleeding off a portion of the water in circulation. They do not understand why water is being allowed to run down the drain. **Blowdown must be managed correctly because, if not correctly implemented and monitored, the potential for losing large amounts of expensive water treatment chemicals down the drain with the water is high.**

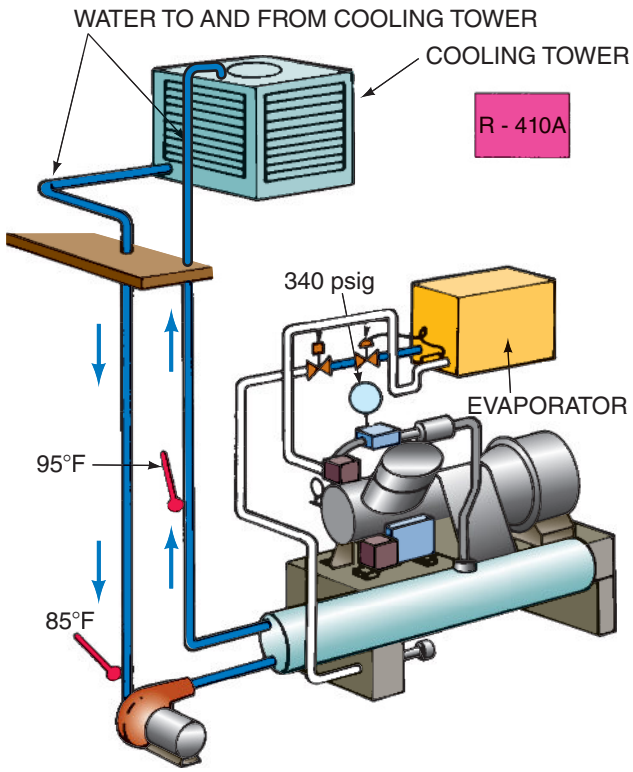
The water that evaporates from a cooling tower leaves behind any solid materials, including dust particles, minerals, and algae, a lower form of plant life. As the water evaporates, these particles become more and more concentrated in the water left behind. If this continues, the particles will drop out of the water and deposit on the surfaces of the cooling tower where they turn into a substance much like cement and become hard to remove. Even more important than what is happening in the cooling tower is what will happen to the interior surfaces of the tubes in the condenser. These mineral deposits can adhere to the piping surfaces and act like an insulator between the refrigerant and the water. This reduces the ability of the refrigerant to reject heat and will cause the head pressure as well as the condenser approach temperature to rise.

Fresh water is added to make up for water drained from the system during blowdown. When new, fresh water is added, less sediment is present, as some has gone out with the water that was bled off, and it dilutes the remaining mineral-rich water, reducing the mineral concentration. It is generally accepted that the water flowing through a water-cooled condenser used for air-conditioning experiences a 10°F temperature rise as measured between the condenser's inlet and outlet. There is also a 10°F difference between the temperature of the water leaving the condenser and the refrigerant's condenser saturation temperature. So, for a properly operating water-cooled system, the operating pressures would typically be as follows:

- Water entering the condenser: 85°F
- Water leaving the condenser: 95°F
- Condenser saturation temperature: 105°F

For an R-410A water-cooled system, the condenser saturation pressure would be about 340 psig, **Figure 48.30**. If the system is experiencing a scaling condition, as a result of

Figure 48.30 A properly operating R-410A water-cooled system. There is a 10-degree rise across the condenser and a 10-degree difference between the condenser saturation temperature and the temperature of the water leaving the condenser.



Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. improper water treatment or excessive mineral accumulation, the refrigerant in the condenser will be unable to reject heat to the water flowing through the condenser as readily. This is because the mineral deposits are preventing the refrigerant's heat from transferring to the water. This will cause the high side pressure in the system to rise and, since the water is not absorbing heat from the refrigerant, the temperature rise of the water across the condenser will not be as high. The temperatures for this system condition might be as follows:

- Water entering the condenser: 85°F
- Water leaving the condenser: 90°F
- Condenser saturation temperature: 130°F

For an R-410A water-cooled system, the condenser saturation pressure would be about 480 psig, **Figure 48.31**. Notice that the temperature difference between the condenser's inlet and outlet is only 5°F (90°F − 85°F) and the difference between the temperature of the water leaving the condenser and the refrigerant's condenser saturation temperature is an excessive 40°F (130°F − 90°F).

Blowdown can be accomplished in a number of different ways. The simplest way is to utilize a hand valve, **Figure 48.32**. With this method, there is no automation involved and the amount of water drained from the system depends on how long the operator keeps the valve open. Although this is an easy method for accomplishing blowdown, there are many downsides, which include lack of timing, uniformity, and scheduling issues. Blowdown can also be controlled by the rate at which water is introduced to the cooling tower, **Figure 48.33**. Using this method of blowdown, as the rate of makeup water added to the tower increases, the amount of water drained from the system increases. Another, more sophisticated method of controlling blowdown is to use electronic sensors, **Figure 48.34**. The electronic sensor measures the mineral content of the water and

Figure 48.31 The condenser is not removing enough heat because the tubes are fouled. There is only a 5°F temperature rise across the condenser. The condenser saturation temperature is also much higher than desired.

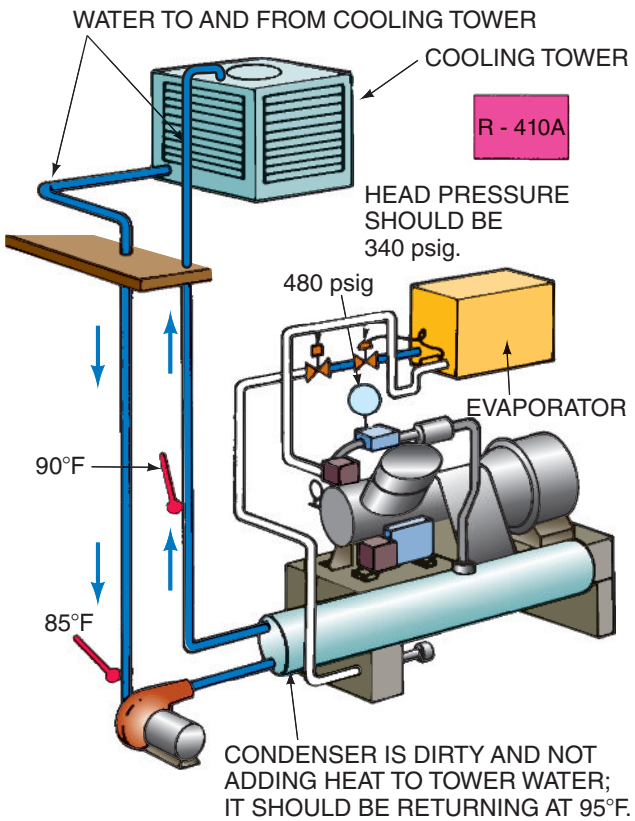

Figure 48.32 A hand valve being used for blowdown.

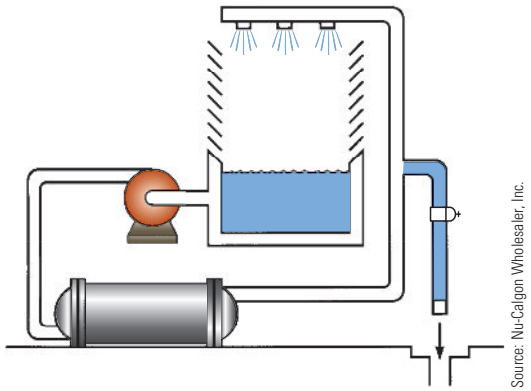

Figure 48.33 The amount of water drained from the system is proportional to the amount of water being introduced to the sump.

bleeds off water when the minerals have become too concentrated. **Figure 48.35** shows a microprocessor controller that analyzes the conductivity of the cooling tower's sump water and determines when the blowdown process is needed. Pure water is not electrically conductive; however, as dissolved minerals concentrate in the cooling tower's sump, the conductivity of the water will increase. A voltage probe located in the sump senses the conductivity of the sump water and sends a signal back to the microprocessor.

48.12 BALANCING THE WATER FLOW IN A COOLING TOWER

The water flow must be evenly distributed in a cooling tower. If a tower has two or more cells, the same amount of water must be fed to each cell or the tower will not perform as designed. Many towers use a distribution pan at the top to evenly spread the warm return water from the condenser over the fill. These pans often have a series of calibrated holes drilled into them. Water flow is controlled by one or more balancing valves set to obtain the correct flow to each side of the tower, **Figure 48.36**. The calibrated holes must be kept clean of foreign material and be of the correct size. Excessive amounts of debris or mineral deposits can block the holes in the distribution pan, **Figure 48.37**. Blocked holes, rust, or excessive mineral deposits can cause uneven flow through the cooling tower, **Figure 48.38**. In this case, water will be flowing to one side of the tower and not wetting the entire fill deck. The capacity of the cooling tower will be reduced when this happens. For example, if the tower is designed to supply water at a temperature of 85°F to the condenser and it is supplying 90°F water to the condenser, the chiller will operate with a high head pressure and the cost to run the system will increase.

48.13 WATER PUMPS

The condenser water pump is the device that moves the water through the condenser and cooling tower circuit. It normally is located where it can take water from the cooling tower sump into the pump inlet, **Figure 48.39.** The water pump is the heart of the cooling tower system because it pumps the heat-laden water. The water must be pumped at the correct rate and delivered to the cooling tower at the correct pressure.

The condenser water pump is usually a **centrifugal pump**. It uses centrifugal action to impart velocity to the water that is converted to pressure. Pressure may be expressed in pounds per square inch (psig) or feet of head. One foot of head is equal to 0.433 psig—that is, a column of water 1 ft high will cause a pressure gauge to read 0.433 psig. Similarly, a pressure of 1 psig will be able to lift a column of water

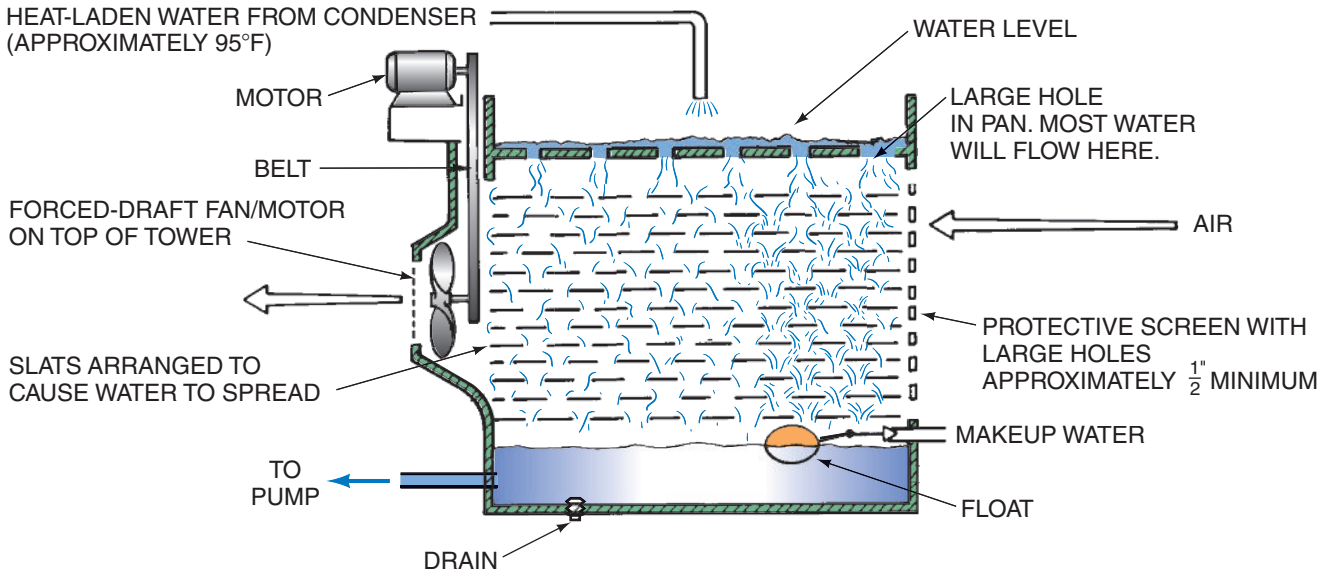

Figure 48.39 The cooling tower pump and system.

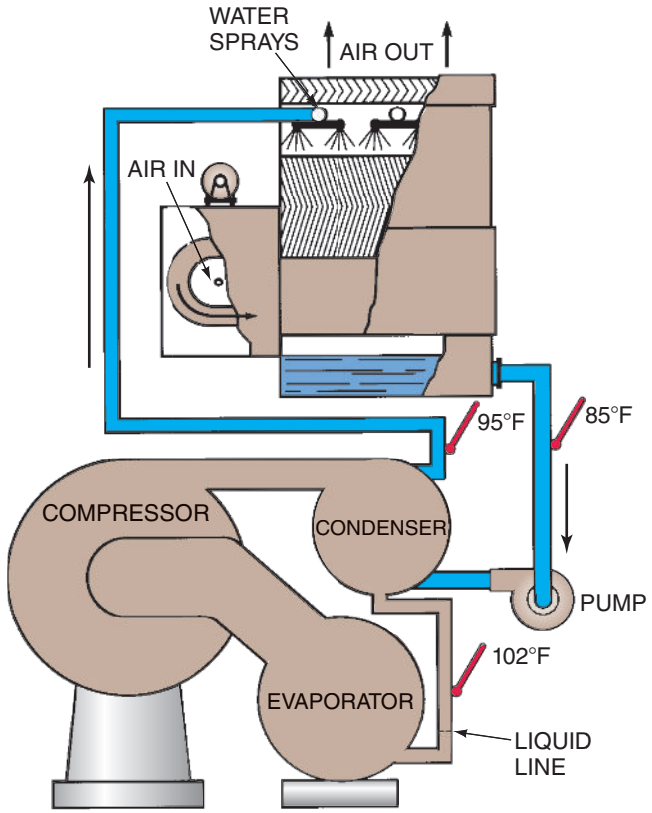

2.31 feet, or 27.7 inches. So, a pump that operates with a 10 psig pressure rise across it will be able to lift a column of water 23.1 feet. Pump capacities are expressed in feet of head. Centrifugal pump action is discussed in Unit 33, "Hydronic Heat," and a study of that unit should be helpful.

Several types of condenser water pumps are available for large systems. A *close-coupled pump* is located very close to the motor with the pump impeller actually mounted on the end of the motor shaft, **Figure 48.40**. These pumps are used for small applications. Note that all of the water enters the side of the pump housing. The pump shaft must have a seal to prevent water from leaking to the atmosphere or to prevent atmosphere from leaking in should this portion of the piping be in a vacuum.

The *base-mounted* pump is used in larger applications. It comes as an assembly with the pump mounted at the end of the pump shaft and a flexible coupling between the water and the pump, **Figure 48.41.** This pump may have a single or double-sided impeller. The base is usually made of steel or cast iron and holds the pump and motor steady during operation. It is usually fastened to the floor using cement as a filler in the open portion of the pump base. This is called "grouting the pump in," the purpose of which is to create a more firm foundation that will last for many years. The pump and motor

can still be removed from the base. One of the advantages of this pump is that the motor and pump shafts are aligned at the factory and so alignment is not required in the field.

As pumps become larger, the need for different designs becomes apparent. Some pumps have single-inlet impellers with all of the water entering the pump impeller on one side, **Figure 48.42**. The double-inlet impeller allows water to flow into both sides, **Figure 48.43**. The pump housing must be designed differently to allow water to enter both sides of the impeller. There are two styles of *double-inlet impeller pumps*: One type of pump is disassembled from the ends of the pump, as with the base-mounted pump; the other type, a split-case pump, is disassembled by removing the top of the pump, **Figure 48.44**.

These pumps must also have a shaft seal, which, as the name implies, is a seal on the shaft. The shaft seal helps reduce, or eliminate altogether, the loss of water from the pump. One type of seal is the *stuffing box* and the second is

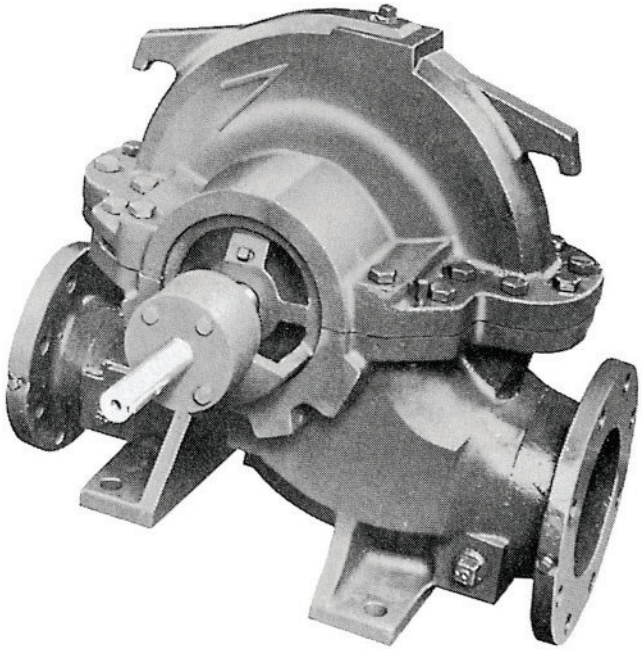
a *mechanical seal*. The stuffing-box seal has a packing gland that must be hand tightened with a wrench. When the nut on the seal is tightened, it squeezes a packing around the shaft to minimize leakage, **Figure 48.45**. Stuffing-box types of seals

Figure 48.44 A horizontal split-case pump.



Source: Bell and Gossett, ITT Industries

are typically used for pump pressures of up to about 150 psig and require some regular maintenance. The mechanical seal may be used for higher pressures, up to about 300 psig, and usually has a carbon ring mounted on the end of a bellows that turns with the shaft. The bellows is sealed to the shaft with an O-ring. The carbon ring rubs against a stationary ceramic ring while the shaft turns and seals water in the pump housing, **Figure 48.46**. Both of these seals are lubricated by the circulating water. In split-case pumps, the seals may have a special piping system that injects pump discharge water into the seal, **Figure 48.47**.

Most cooling tower pumps are manufactured of cast iron. They are heavy and may be used for pressures up to 300 psig with the correct piping flanges and arrangements.

Figure 48.46 The mechanical shaft seal.

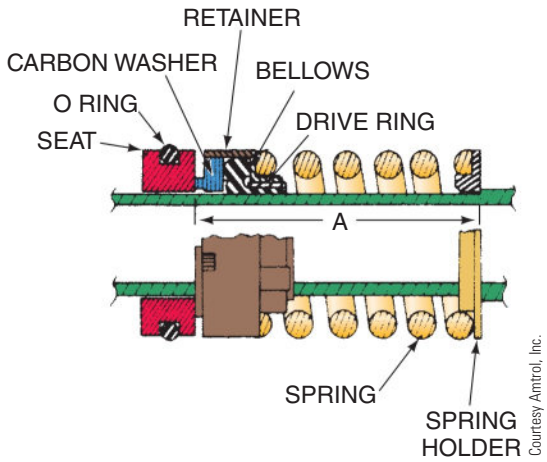

Figure 48.47 Lubricating a shaft seal.

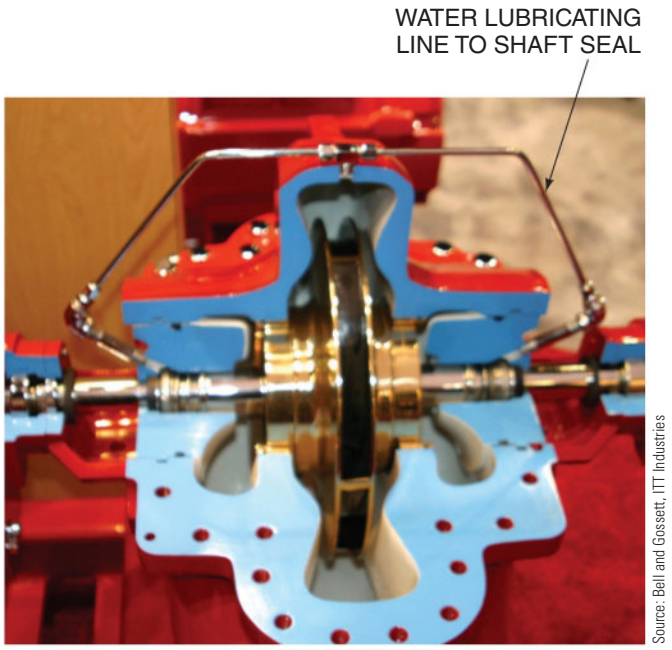

Cast iron has the capacity to last many years without deterioration from rust and corrosion. The impeller in the typical centrifugal pump is made of brass or bronze and is often mounted on a stainless-steel shaft. This can be important when the time comes to remove the impeller from the shaft because the stainless-steel shaft makes it easier to remove the impeller after many years of operation.

Impellers are furnished from the factory at a specified diameter for each pump to furnish a specific water flow against a specified pressure. It is often the case that the pump furnishes too much water flow, to the point that a smaller impeller is needed. Impellers are often trimmed in the field to meet the actual water flow and pressure requirements. Always refer to, or contact, the manufacturer for information regarding any modifications that might be needed for a specific pump.

The location of the condenser water pump is important because these pumps, which are normally centrifugal pumps, must be supplied water in a manner that keeps the eye of the impeller under water during start-up, **Figure 48.48**. Otherwise, the pump will not move any water. They *do not* have the capacity to pump air to pull water into the impeller. Pumps can be manufactured in a vertical configuration with the motor on top. These pumps are mounted on top of the sump and protrude down into the sump to pick up water, **Figure 48.49**. Otherwise, pumps should be located at a level below the tower water, and there should be nothing in the pump inlet piping that will impede flow. Allowing a free flow of water to the pump inlet is always good practice, but several things can interfere with water flow, such as vortexing in the tower, fine mesh strainers, and the cooling tower bypass.

Figure 48.50 The cooling tower sump is located below the pump.

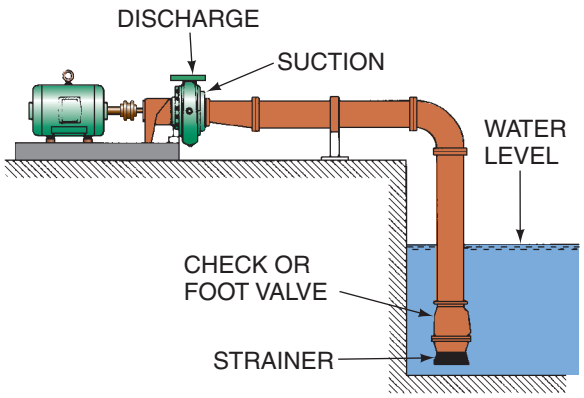

Figure 48.51 Insert used to help prevent vortexing.

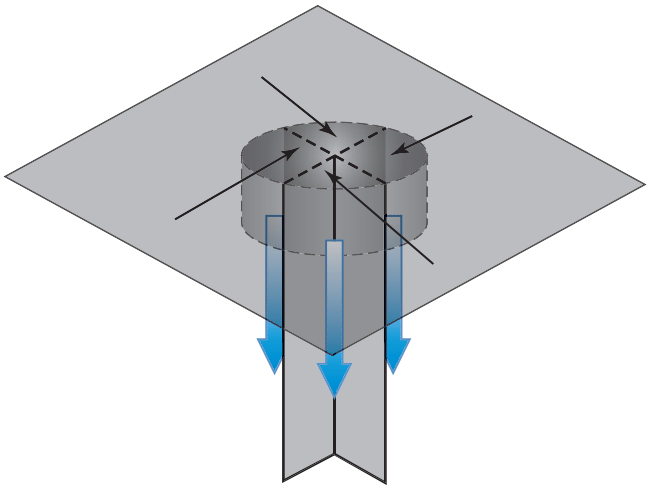

Figure 48.52 Vortex protection for a cooling tower.

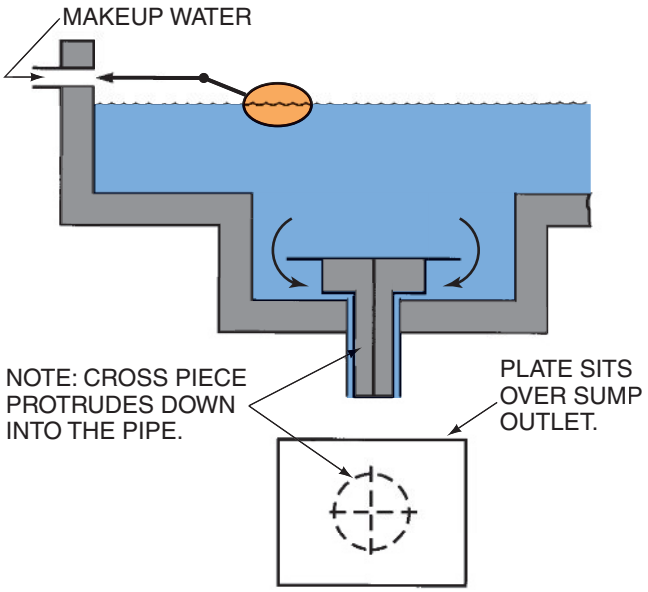

There are times when the cooling tower sump is below the level of the pump. When this is the case, special care should be taken during start-up because only air will be in the pump casing. The pump should never be started with only air inside because then the pump seal will have no water for lubrication. When the sump is below the pump, a foot or check valve must be located in the line to prevent water in the pump from flowing back into the sump during shutdown, **Figure 48.50.** Before the pump is started, water must be added to the pump inlet side until the pump casing is completely full, which can be done by connecting a water hose to the pump inlet side and filling it until water escapes the bleed port on top. If the pump inlet does not fill up, the foot or check valve is leaking and must be repaired.

Vortexing is a whirlpool action. A vortex interferes with the functioning of the tower because it introduces air to the pump inlet. The pump is designed to pump water; air will cause problems with the pump and with the condenser at the chiller. Poor piping practice is a major cause of vortexing. Vortexing can often be eliminated by a device placed in the sump outlet that breaks up the vortex. A cross-type of configuration with a plate on top can create four outlets from the sump, **Figure 48.51**. The plate causes the water to be pulled from a farther distance and from the side, **Figure 48.52**. Vortexing in multistory buildings that have the condenser water pump well below the tower has been addressed using this method.

The pump inlet must also have some sort of strainer located between it and the tower water to prevent trash from entering the pumping circuit. Typically, a coarse strainer screen is placed in the cooling tower exit to the sump, and often a fine-mesh screen is located before the pump inlet. If this screen is too fine, however, problems from pressure drop will occur as the screen becomes clogged. Pressure drop causes the pump inlet to operate in a vacuum, and the pump may pull in air if the pump seals leak. Pressure drop can also cause pump cavitation (partial vacuum)—water will turn to a vapor if the cooling tower water is warm enough and the pressure is low enough. Noise at the pump is evidence of cavitation or air at the pump inlet. It will often sound like it is pumping small rocks. If a fine screen must be used, it may often be better to install it at the pump outlet, **Figure 48.53**. It does less harm to throttle the pump discharge with a pressure drop than the pump inlet.

The tower bypass valve helps to maintain the correct tower water temperature at the condenser during start-up and during low ambient operation. The tower bypass circuit allows water from the pump outlet to be recirculated to the pump inlet so that the cold cooling tower water will not reach the condenser, **Figure 48.54**. Condenser water that is too cold in the compression cycle systems will reduce the head pressure to the point that the condenser will be so efficient that

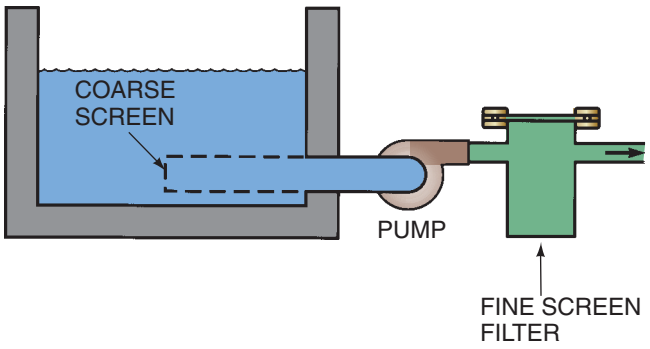
Figure 48.53 The best application for a fine-screen filter is in the pump outlet.



too much refrigerant will be held in the condenser and starve the evaporator. This will also cause the oil to migrate in some machines. Cooling tower water that is too cold for an absorption machine will often cause the salt solution to crystallize.

Two types of three-way bypass valves may be used for tower bypass: the mixing valve and the diverting valve. The mixing valve has two inlets and one outlet and needs to be located in the pump suction line between the tower and the pump inlet, **Figure 48.54(A)**. **Figure 48.54(B)** shows a direct digital controlled (DDC) butterfly valve bypass. The valve will bypass some of the warm water coming from the water-cooled condenser and mix it with cooling tower outlet water. This arrangement is used in colder climates when the building still needs cooling in its interior but the cooling tower outlet water is too cold and may shock the tubes of the water-cooled condenser, causing damage. Mixing is controlled by sensors in the condenser's inlet water that relay the message to the DDC butterfly valve to protect the condenser's tube bundles from a too cold water stream.

The diverting valve has one inlet and two outlets; it can be located in the pump discharge and piped to the cooling tower or the pump inlet, **Figure 48.55**. These valves do not come in large sizes; they are normally a maximum of 4 in., so other arrangements may have to be made if a larger size is needed. A straight-through valve can be used in the configuration shown in **Figure 48.56**. Both the diverting valve and the straight-through valve allow some cooling tower water from the basin to be introduced to the pump inlet but may cause problems at start-up until the tower water becomes the correct temperature.

All pumps must have bearings to support the turning shaft while under load. Sleeve bearings are used for small pumps, and ball or roller bearings are used for larger pumps. These bearings must be lubricated on a regular basis for satisfactory service. Notice that the bearings on the split-case pump are outside the pump, **Figure 48.57**. The pump must be fastened to the motor shaft in most of the pumps mentioned above in such a manner that they are within alignment tolerances. A flexible coupling may be installed between

Figure 48.54 (A) A mixing valve application. (B) A direct digital controlled (DDC) butterfly valve bypass. The valve will bypass some of the warm water coming from the water-cooled condenser's outlet and mix it with cooling tower outlet water.

alignment must be properly aligned. Two planes of alignment must be considered—angular and parallel. Angular alignment ensures that both shafts are at the same angle to each other, **Figure 48.59**. Parallel alignment ensures that the shafts are aligned end to end, **Figure 48.60**. Correct alignment is accomplished with a dial indicator that reads to 1/1000 of an inch. It is mounted on the shafts and the shafts are rotated through the full rotation, **Figure 48.61**. Shims (thin sheets of steel) are placed under the pump and motor as needed until both angular and parallel alignment (sometimes called radial and axial alignment) are achieved to within the manufacturer's specifications. After alignment is attained, the pump and motor are tightened down and alignment is checked once again. Then the bases of both are drilled and tapered dowel pins are driven in, **Figure 48.62**. When alignment is done correctly, the motor and pump should provide years of good service.

48.14 CHEMICAL-FREE TREATMENT OF COOLING TOWER WATER

A proprietary and patented technology has been developed by an engineering and research team dedicated to a chemical-free solution for water treatment. This proven chemical-free water purification technology eliminates scale, inhibits bacterial growth, and inhibits corrosion.

SCALE PREVENTION

Pure water is a rare commodity. Water as we know it contains many dissolved minerals. In a cooling tower, only the water evaporates. It exits the cooling tower as water vapor, but leaves the dissolved minerals behind to concentrate in the cooling tower's water system. The concentrations of these dissolved minerals gradually increase until a process called precipitation occurs. This happens when the dissolved minerals, such as calcium carbonate (limestone), reach a certain concentration, become solid, and usually cling to equipment and piping surfaces in the cooling tower. HVAC/R personnel refer to these solids as scale.

There are tiny suspended particles in large quantities in all city water or well water that is used for cooling tower or boiler makeup water. Once in the cooling tower water system, these suspended particles neither sink nor float because of their small size and are transported by the flowing water. But the particles will concentrate during the evaporation process in the cooling tower and become attracted to equipment surfaces when the concentration is so great that the water can no longer hold them. They are then forced to precipitate onto surfaces as solids, which eventually become hard, resulting in equipment-damaging scale.

When the cooling tower water holding these small, suspended particles passes through a water treatment module and is activated by a high-frequency electrical pulse field, the natural electrical static charge on the surface of the particles is removed. The suspended particles act as "seeds" for precipitation of dissolved minerals and now become the "preferred site" for precipitation instead of the equipment surfaces. Thus, hard scale is prevented from forming on the equipment and instead adheres to and coats the tiny suspended particles in the water. As more and more minerals bond to the suspended particles, they become heavier and can no longer suspend themselves in the water stream. Eventually they make their way to the cooling tower's basin as a harmless fluffy powder or tiny coated particles. The powder or coated particles can easily be removed from the cooling tower's basin by manual means, filtration, or centrifugal separation. The quantity of powder in a cooling tower is typically about 15% of the normal blown-in dirt.

The pulsed waveform of the water treatment module is shown in **Figure 48.63**. **Figure 48.64** illustrates calcium

PARTICLE SEPARATOR

The removal of particles at the bottom of the cooling tower's basin can be accomplished by using a centrifugal separator, **Figure 48.68.** Water from the cooling tower's basin is pumped to a separator and enters it tangentially. This gives the water the proper inlet velocity and a constant change of direction, which generates an initial vortexing action. Internal tangential slots located on the inner separation barrel causes the water to accelerate further and magnifies

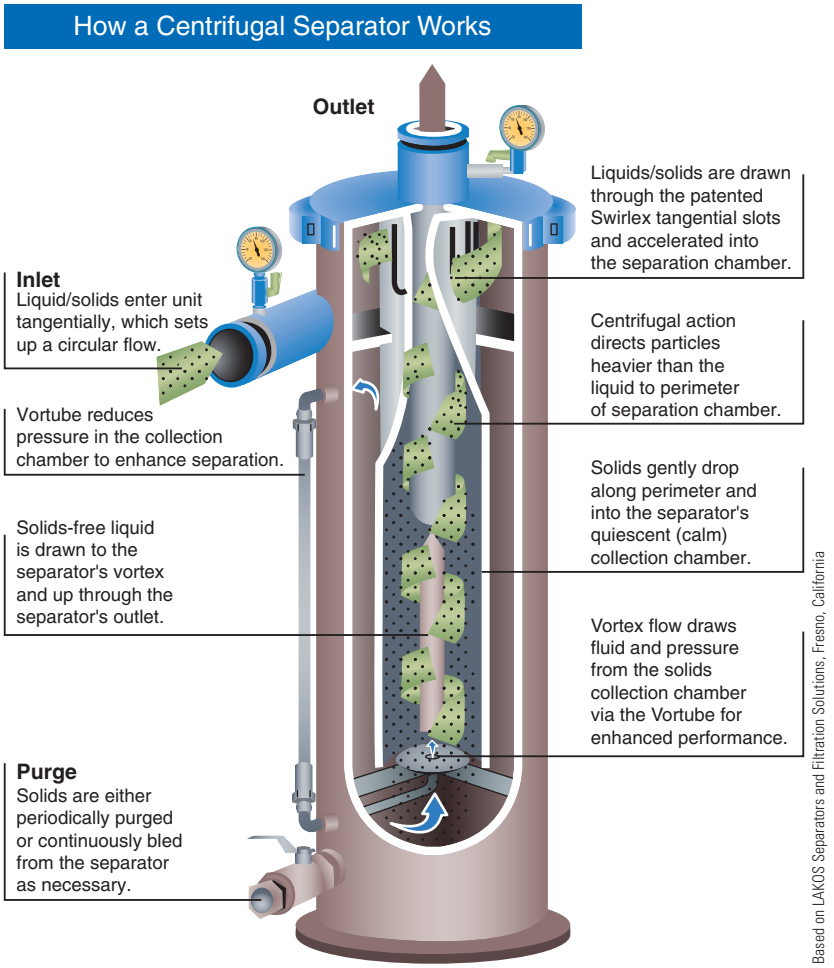
Figure 48.68 The removal of particles at the bottom of the cooling tower's basin can be accomplished using a centrifugal separator.



the strength of the vortex. Particles in the water are now separated through the centrifugal action caused by the vortex. The particles spiral downward along the perimeter of the inner separation barrel and are deposited in a collection chamber below the vortex deflector plate, where they can be automatically purged. Free of separable particles, the water spirals up the center vortex in the separation barrel and to the outlet. A vortex-driven pressure relief line draws fluid from the separator's solids collection chamber and returns it to the center of the separation barrel at the vortex deflector plate. This allows for even finer solids to be drawn into the solids collection chamber that would otherwise be re-entrained in the vortex. **Figure 48.69** shows a typical evaporative cooling tower installation incorporating a centrifugal separator and a high-frequency electrical pulse field signal generator and water treatment module.

BACTERIAL CONTROL

There are two methods of controlling bacteria or a microbial population in cooling tower systems. These methods are **encapsulation** and **electroporation**. Bacteria form a biofilm or slime layer on equipment surfaces. A biofilm is a slimy bacterial secretion that forms a canopy over the bacteria beneath it and protects them from chemical biocides. It is very slimy to the touch, four times more insulating to heat transfer than mineral scale, and is the primary cause of microbial-influenced corrosion on equipment. The bacteria that live in a biofilm and adhere to the equipment surfaces are sessile (incapable of movement) bacteria and represent 99% of the total bacteria in a system. However, this slime layer can be eliminated through a process of nutrient limitation.

Among the suspended particles in the water of a cooling tower are most of the free-floating planktonic bacteria. Normally, since like charges repel one another, these bacteria are repelled by the suspended particles in the water because nearly all tiny particles have similar negative static electrical charges on their surfaces. However, after particles are activated by the high-frequency electrical pulse field from the signal generator at the water treatment module, the natural electrical static charge on the particle surfaces is removed. The bacteria are no longer repulsed and are therefore attracted to the powder

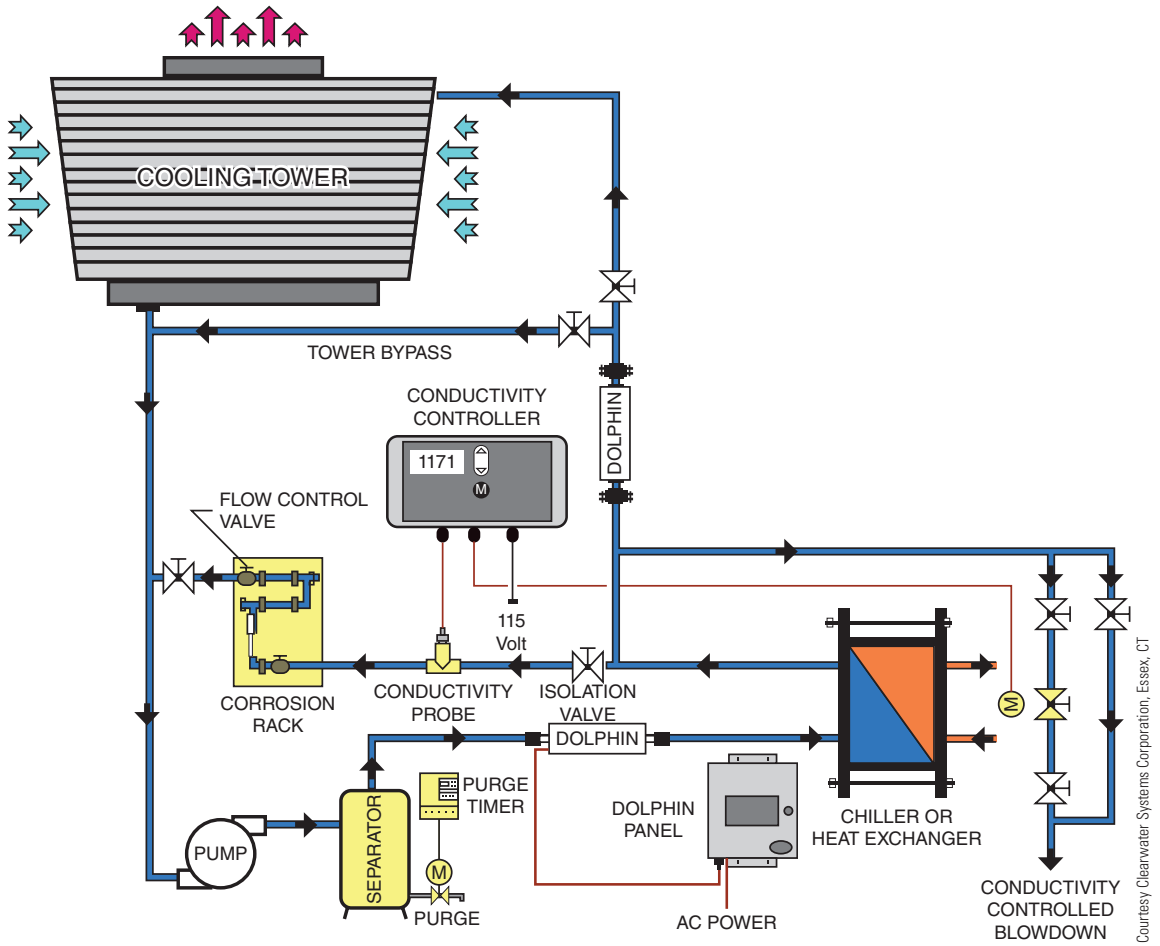

Figure 48.70 Mineral-coated bacteria (encapsulation).

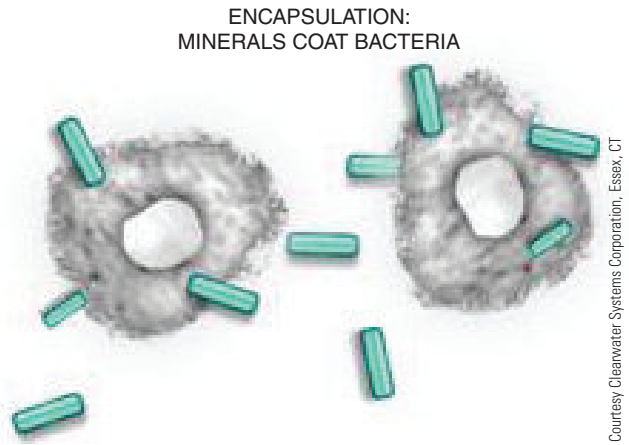

and become entrapped in the powder particles, **Figure 48.70**. The powder, in effect, sweeps the water clean of planktonic bacteria and renders them incapable of reproducing. This process is referred to as encapsulation.

The high-frequency, pulsing action of the signal generator also damages the membrane of the planktonic bacteria by creating small "pores" in their outer membrane. This weakens the bacteria and inhibits their reproductive capabilities, a process referred to as electroporation. The life span of microbial life is 24–48 hours. Any microbes not captured in the forming powder are "zapped" by the secondary pulse of the signal generator, forcing them to spend their life span repairing cell wall damage rather than reproducing, **Figure 48.71**.

All of the living organisms in a cooling tower system depend on one another for their food supply. Thus, when the nutrients from the planktonic bacteria are diluted by both encapsulation and electroporation, the biofilm cannot be sustained and will disintegrate. It will never be created in the first place if a high-frequency electrical pulse field is installed in the cooling tower system to instigate the encapsulation and electroporation processes. In summary, the combined effect of encapsulation and electroporation result in exceptionally low total bacterial counts (TBC) in cooling tower water.

CORROSION CONTROL

Most corrosion in cooling tower systems or boilers comes from

- chemical additives,
- softened water,
- biofilm, and
- mineral scale.

So, by removing chemicals, avoiding the use of softened water, and using a chemical-free water treatment module and signal generator in cooling towers and boilers, corrosion will be eliminated. The calcium carbonate that coats the particles suspended in water is in a state of saturation while it precipitates and will act as a powerful cathodic corrosion inhibitor. It will greatly slow the corrosion process by blocking the reception of electrons that are thrown off by the corrosion process. With no place for the electrons to go, the corrosion process is physically and very effectively controlled.

SUMMARY

- The cooling tower rejects heat that has been absorbed into the chilled-water system.
- Cooling towers lower the temperature of the water in a tower by means of evaporation.
- Cooling towers should be protected from fire.
- The design of a cooling tower provides for distinct airflow patterns.
- Cooling towers have a load that can be calculated using an easy formula.
- Fans for forced-draft towers may be driven by belts or gears.
- The cooling tower sump needs to be flushed periodically.
- Sumps may have heaters to protect them from freezing.
- Cooling towers must have makeup water systems.
- The water flow through the tower must follow the pattern designed by the manufacturer.
- Larger pumps may have single- or double-inlet impellers.
- Most pumps for cooling towers are manufactured of cast iron.
- Vortexing (whirlpooling) may occur in the sump, which is not good because it may introduce air into the pump.
- A tower bypass valve helps to maintain the correct tower water temperature at the condenser.
- Chemical-free cooling tower water treatment eliminates scale, inhibits bacterial growth, and inhibits corrosion.

REVIEW QUESTIONS

1. What is the purpose of the cooling tower in a water-cooled system?
2. The typical difference in temperature between the cooling tower water supplied to the condenser and the outdoor wet-bulb temperature is _____ °F.
3. Spreading the water out as it passes through the cooling tower helps the water _____ faster.
4. Two types of cooling tower are the _____ and the _____.
5. What two types of fan are used for cooling towers?
6. Why should cooling towers be constructed with fireproof materials?
7. The two types of airflow through a forced-draft cooling tower are _____ and _____.
8. As water is evaporated from a cooling tower, it is made up by
   A. the normal water supply.
   B. dripping it back into the tower.
   C. condensing it and saving it for makeup.
   D. none of the above.

UNIT 49

OPERATION, MAINTENANCE, AND TROUBLESHOOTING OF CHILLED-WATER AIR-CONDITIONING SYSTEMS

OBJECTIVES

After studying this unit, you should be able to

- discuss the general start-up procedures for a chilled-water air-conditioning system.
- describe specific chiller start-up procedures for chillers having a scroll, reciprocating, rotary screw, or centrifugal compressor.
- describe operating and monitoring procedures for scroll and reciprocating chilled-water systems.
- discuss preventive and other electrical maintenance and service that should be performed at least annually on chillers.
- list maintenance procedures that should be performed periodically on water-cooled, chilled-water systems.
- describe start-up procedures for an absorption chilled-water system.
- list preventive and routine maintenance procedures for an absorption chiller.
- state preventive and periodic maintenance procedures for the purge system on an absorption system.

SAFETYCHECKLIST

- ✔ Wear gloves and use caution when working around hot steam pipes and other heated components.
- ✔ Use caution when working around high-pressure systems. Do not attempt to tighten or loosen fittings or connections when a system is pressurized.
- ✔ Follow recommended procedures when using nitrogen.
- ✔ Follow all recommended safety procedures when working around electrical circuits.
- ✔ When working on an electrical system, lock the disconnect box or panel and tag it with your name when power is turned off. There should be only one key for this lock, and it should be in the possession of the technician.
- ✔ Never start a motor with the door to the starter components open.
- ✔ Check system operating pressures regularly as indicated by the manufacturer of the system.

The operation of chillers involves starting, running, and stopping the system's components in an orderly and precise manner. The chiller technician should be familiar with the system and its sequence of operations before operating, adjusting, or otherwise working on the system. Most chilled-water systems are designed with multiple safeties and operational backup control systems that help ensure that the equipment functions properly under most conditions, but no chances should be taken with this expensive equipment. For any major equipment installation, there should be literature at the site. The building blueprint for every major installation shows the piping diagram, an electrical diagram, a duct diagram, and a mechanical equipment layout. This information is invaluable for helping the technician to locate wiring control points and valves for controlling fluid flows. The duct diagram will help the technician find dampers and air control points. All duct and pipe sizes and routes are listed on the prints. Electrical junction boxes and control points should be on the electrical print. If a job is old and has been modified, the prints should have been kept up-to-date with the changes. Unfortunately, the updating of job site drawings is often overlooked.

Manufacturers' literature should be on-site so that the technician can become familiar with the equipment, and also reference the material in the event questions or other problems arise. This literature should not be allowed to leave the job site. If for some reason the prints are lost, copies can sometimes be obtained from the engineering firm that originally drew them up. Firms save copies for any future use. If the prints were created on a computer, there should be files from which they can be re-created.

49.1 CHILLER START-UP

The first step in starting up a chilled-water system is to establish chilled-water flow. This is true whether it is for the first time each season or the first time each day. If the system is water-cooled, the next step is to establish condenser

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. water flow. Air-cooled chillers have condenser fans and do not require nearly as much attention as water-cooled chillers. Both the chilled-water and the condenser water circuit will have some type of flow switch to establish that water is flowing before the system can start. On older chilled-water systems, the flow switch is often a paddle that protrudes into the water piping circuit. When water is flowing, the flow switch closes, allowing the chiller to operate. Newer chilled-water systems utilize controls that sense the pressure drop through a heat exchanger to confirm waterflow. These controls have pressure sensors at both the inlet and outlet of the heat exchanger. The difference between these two pressures is what confirms that water is flowing. A pressure drop of zero, for example, indicates that no water is flowing.

The technician should know how to make sure that the flow switches are functioning. Because the paddle of a mechanical flow switch is in the water stream, it is not unusual for it to break off. If it does, there may indeed be water flowing through the system, but flow might not be proven by the flow switch. The technician may verify water flow by means of the pressure gauges installed in the water piping circuit. Never bypass a chilled-water flow switch, or freeze conditions may occur. The starting point to finding out the correct water flow through a heat exchanger is to know what the pressure drop should be when the system is operating properly, and then compare this value to the actual pressure drop.

There should be a pressure test point at the inlet and outlet of any water heat exchanger, chiller, or condenser, **Figure 49.1**. The best way to ensure an accurate pressure differential measurement is to use a single gauge to read both the inlet and outlet water pressures, **Figure 49.2(A)**. To read

Figure 49.1 A condenser with inlet and leaving-water gauge ports.

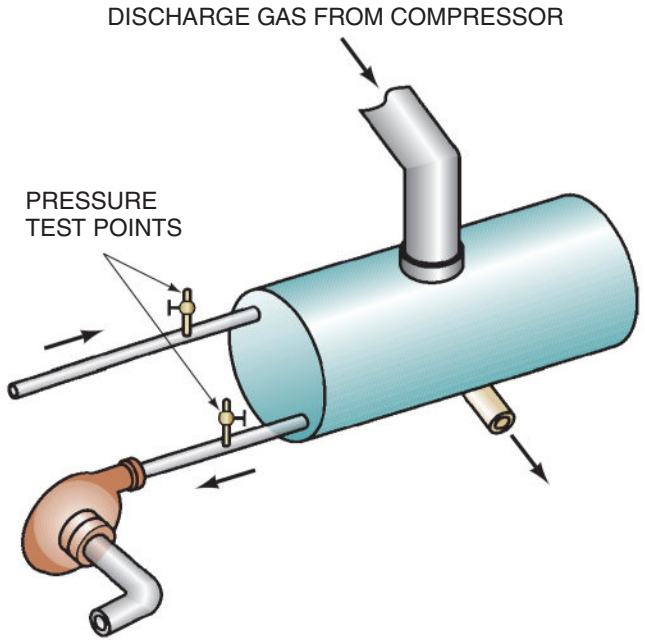

Figure 49.2 (A) One gauge being used to check both ports. (B) Inlet water pressure. (C) Outlet water pressure. The difference between (B) and (C) is the actual pressure drop through the condenser, 15 psig.

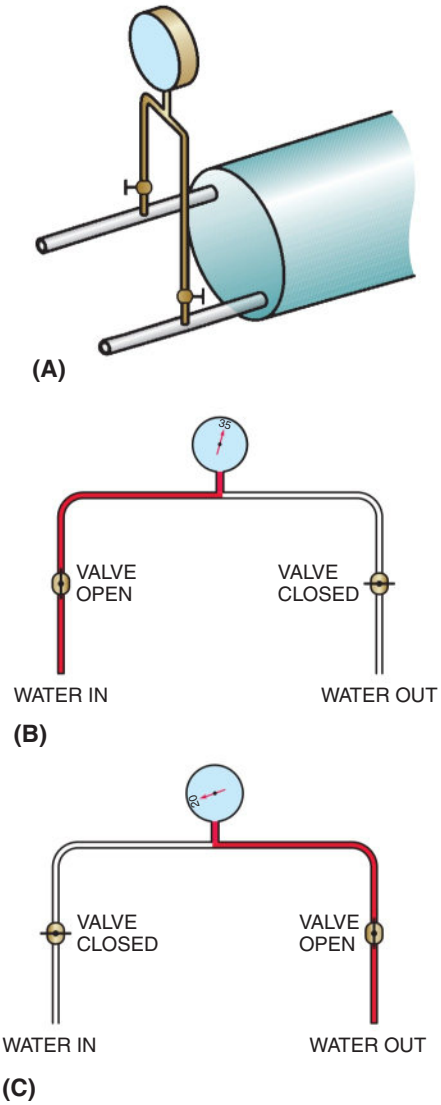

the pressure at the inlet of the heat exchanger, the valve on the pressure test port in the water inlet line will be open and the valve on the pressure test port in the water outlet line will be closed, **Figure 49.2(B)**. To measure the pressure at the outlet of the heat exchanger, the valve on the pressure test port in the water outlet line will be open and the valve on the pressure test port in the water inlet line will be closed, **Figure 49.2(C)**. If two separate gauges are used and they are not properly calibrated, they cannot be expected to give correct readings. If one gauge reads 5 psig when open to the atmosphere while the other gauge reads 0, there will be an automatic error of 5 psig in the measured pressure difference. Let's take a look at a numerical example. Consider the situation where the *actual* pressures at the inlet and outlet of a heat exchanger are 35 psig and 20 psig, respectively, **Figure 49.3(A)**. The actual

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Figure 49.3 (A) The actual pressures at the inlet and outlet of a heat exchanger provide a pressure difference of 15 psig. (B) The measured pressure difference is 20 psig with the improperly calibrated gauge "A" connected to the water *inlet* port of the heat exchanger. (C) The measured pressure difference is 10 psig with the improperly calibrated gauge "A" connected to the water *outlet* port of the heat exchanger.

pressure difference across the heat exchanger is 15 psig. Now, consider that gauge "A" reads 5 psig when open to atmosphere and gauge "B" is properly calibrated and reads 0 psig when open to atmosphere. With gauge "A" connected to the water inlet port and gauge "B" connected to the water outlet port, the pressure readings will be as follows:

- Heat exchanger inlet pressure: 40 psig
- Heat exchanger outlet pressure: 20 psig

This will give a pressure differential of 20 psig, **Figure 49.3(B)**. Now, if gauge "B" is connected to the water inlet port and gauge "A" is connected to the water outlet port, the pressure readings will be as follows:

- Heat exchanger inlet pressure: 35 psig
- Heat exchanger outlet pressure: 25 psig

This will give a pressure differential of 10 psig, **Figure 49.3(C)**. Since all that is needed is the pressure difference between the two points, and not the actual readings, using a single gauge that is not properly calibrated or 100% accurate will still yield the correct pressure difference.

The technician needs to know from the pressure readings that there is a pressure drop across the heat exchanger. As water flows through the heat exchanger, the pressure drops a specific amount from the time the water enters the heat exchanger to the time water leaves the heat exchanger. A pressure-drop chart for the heat exchanger will indicate the gallons per minute (gpm) of water flow, **Figure 49.4**. For example, if the pressure drop across heat exchanger "A" is 1.73 psig or 4 feet, the flow rate through the heat exchanger will be 20 gpm. If the pressure drop through the same heat exchanger is 4.33 psig, or 10 feet, the flow rate through the exchanger will be about 35 gpm. The original operating log sheet for the installation will show the pressure drops at start-up. This is very good information for future use. If the original log cannot be found, the manufacturer may be contacted for a copy of the log sheet or a pressure-drop chart for the chiller.

The technician should also be aware of the interlock circuit through the contactors that must be satisfied before start-up. The starting sequence for most chiller systems is to start the

Figure 49.4 A pressure-drop chart for a heat exchanger.

chilled-water pump first. A set of auxiliary contacts in the chilled-water starter then starts the condenser water pump. When the condenser water pump starts, a set of auxiliary contacts make and pass power to the cooling tower fan and the chiller circuit, **Figure 49.5**. When the signal is received at the chiller control circuit, the compressor should start. This signal is often called the field control circuit because it is the circuit that is installed by the contractor and connected to the manufacturer's control circuit. If a chiller does not start, the first thing the technician should do is check the field circuit to see if all of the conditions that are required for system start-up are met. Checking this will tell whether there is a field circuit problem (flow switches, pump interlock circuit, outdoor thermostat, and often the main controller) or a chiller problem. If there is no field control circuit power, there is no need to look at the chiller until there is power. Many chillers have a ready light that shows that the field control circuit is energized.

Different chillers have different starting sequences, usually depending on the type of lubrication the compressor has. When the chiller has a positive-displacement compressor (scroll, reciprocating, or rotary screw), the compressor will start soon after the field control circuits are satisfied. Some manufacturers may incorporate a time delay before the compressor starts after the field circuit is satisfied, but the compressor should start soon. The technician should look for a time-delay circuit in any system and note what the time delay is so that he will not be waiting and wondering what the problem is. He may think there is a problem, only to have the chiller start up unexpectedly after a planned time delay. Lubrication for the reciprocating, scroll, and rotary screw compressors comes from within, so they do not have a separate oil pump that must be started first. The reciprocating and the rotary screw compressors will start up unloaded and will begin to load when oil pressure is developed. The scroll compressor starts up under load and does not have compressor unloading capabilities.

SCROLL CHILLER START-UP

Scroll chillers are either air- or water-cooled. Regardless of the type, the water for the chilled-water circuit should be at the correct level before attempting to start the chiller. The system must be full. Then the chilled-water pump should be operated and the water flow verified using pressure drop across the chiller. All valves in the refrigerant circuit should be in the correct position, usually back-seated. The system should be visually checked for leaks. Oil on the external portion of a fitting or valve is a sure

Figure 49.5 The control circuit for a typical chiller.

sign of a leak as oil is entrained in the refrigerant. When refrigerant leaks out, small amounts of oil will be present. The compressor needs crankcase heat and it must be energized for the length of time the manufacturer requires, usually 24 hours. The compressor should not be started without adequate crankcase heat, or compressor damage may occur.

An air-cooled chiller will be located outside. The chiller barrel will have a heater to prevent it from freezing in the winter. This heater should be wired and operable. Checking this can be omitted at start-up when winter arrives because the heat strip is thermostatically controlled and will shut off when not needed. During the wintertime, if the chiller is winterized and drained, the chiller barrel heater should be shut off. Also, the condenser fans should be checked to make sure they are free to turn.

When the chiller is water-cooled, the water-cooled condenser portion must be operating. The cooling tower must be full of fresh water and the condenser water pump must be started. Water flow should be established. A look at the tower can verify this or the pressure drop across the condenser can be checked.

Once the field control circuit is calling for cooling and all of the preceding requirements are met, the chiller should be ready to start. When the chiller is started, the technician should do the following:

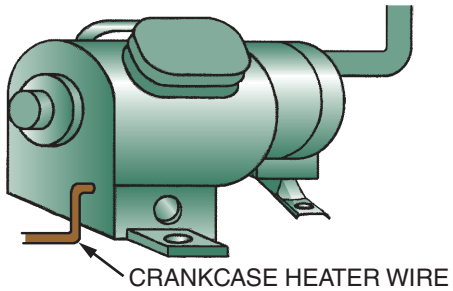
1. Observe suction pressure.
2. Observe discharge pressure.
3. Check the compressor for liquid floodback.
4. Check the entering- and leaving-water temperature on the chiller and the condenser entering- and leaving-water temperature for water-cooled units.
5. Check all refrigerant and oil sight glasses for the proper level. Refrigerant or oil may need to be added. Neither should be added until the compressor can be operated at near full load for a period of time.
6. Check the superheat at the evaporator as recommended by the manufacturer.
7. Check the subcooling at the liquid line as recommended by the manufacturer.

When the chiller is operating normally, it can usually be left unattended, except for the cooling tower in a water-cooled unit. The cooling tower should be regularly observed and maintained.

RECIPROCATING CHILLER START-UP

The reciprocating chiller may be either air- or water-cooled. When air-cooled, it may be located outside. Refer to the comments above on freeze protection for scroll chillers. Before starting a reciprocating chiller, the oil level in the sight glass should be correct, usually from 1/4 to 1/2 level at the sight glass. The manufacturer's instructions on oil level should be followed. When the level is high, refrigerant may be in the oil; the crankcase heat should be checked. Reciprocating chillers have crankcase heaters to prevent refrigerant migration to the crankcase during the off cycle. When the crankcase heat is on, the compressor will be warm to the touch, **Figure 49.6**. The crankcase heat must be energized for the prescribed length of time before start-up to prevent damage to the compressor. Refrigerant in the oil will dilute the lubrication quality of the oil and can easily cause bearing damage that does not show up immediately. The safe time for crankcase heat to be energized is 24 hours, unless the manufacturer states otherwise. It is not good practice to ever turn the crankcase heat off, even during winter shutdown, because refrigerant will migrate to the crankcase, and it is not easy to boil it out to the point where the oil is at the correct consistency for proper lubrication.

Figure 49.6 Heat from a crankcase heater.



When the compressor is started, the pressures can be observed if there are panel gauges. Typically, gauges are permanently installed by the manufacturer in chillers over 25 tons. They may be isolated by means of a service valve to prevent damage during long periods of running time, so these valves will need to be opened to read the gauges. It is not good practice to leave the gauge valves open all the time because the gauge mechanism will experience considerable wear during normal operation from reciprocating compressor gas pulsations. The gauges are intended to be read intermittently, for checking purposes, and they should be checked for accuracy from time to time because they cannot be relied on during the entire life of the chiller.

Many chillers that are manufactured today have light-emitting diode (LED) readouts that show the pressures and temperatures. These pressures are registered by transducers and converted to an electrical or electronic signal for use in the electronic control system, which may use them for troubleshooting and analysis and may store in its memory a history of operating conditions. This can be invaluable for troubleshooting, as it can show any trends, such as pressure-drop changes or suction and discharge pressure changes.

If a chiller has been secured for winter, the refrigerant may have been pumped into the receiver and the valves may need to be repositioned for start-up to the running position, which is back-seated for any valve that does not have a control operating from the back seat. **Figure 49.7** shows an example of a valve in which the low-pressure control is fastened to the gauge port on the back seat of the valve. If the valve is back-seated, the low-pressure control will not be functional because it is isolated.

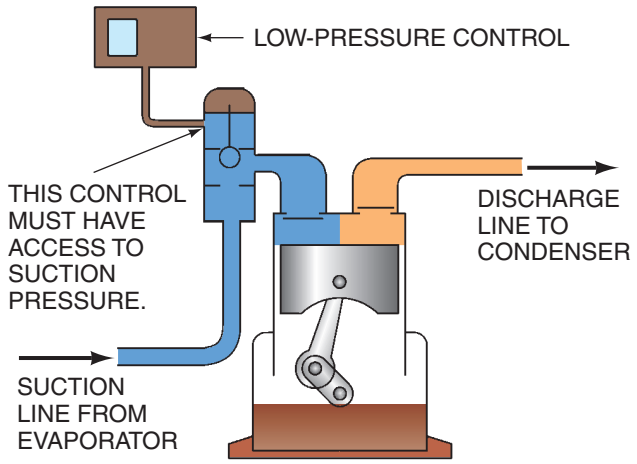
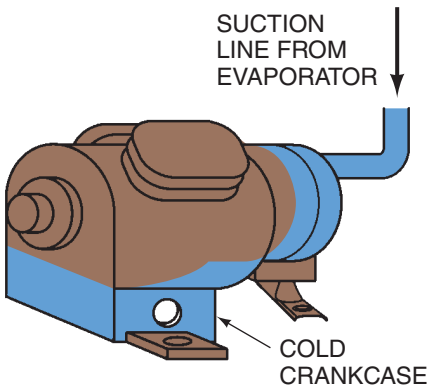
Figure 49.7 This service valve is positioned (cracked) just off the back seat so that the low-pressure control can sense the pressure.



When a winterized compressor is restarted, it will start up unloaded until the oil pressure builds up and loads the compressor. An ammeter can be applied to the motor leads to determine what the level of load is on the compressor. When it is fully loaded, the amperage should be close to full load or rated load amps. As the system temperature begins to pull down, the technician may notice that the oil level in the compressor rises and foams. This occurs in many systems, but the oil level should reach normal level after a short period of operation, usually within 15 min. The compressor is suction-cooled and the technician should ensure that liquid refrigerant is not flooding back into the compressor during the running cycle. This can be determined by feeling the compressor housing; the compressor motor should be cold where the suction line enters, then it should gradually become warm where the motor housing reaches the compressor housing. The compressor crankcase should never be cool to the touch after 30 min of running time or liquid refrigerant should be suspected to be flooding back, **Figure 49.8**.

Figure 49.8 A compressor crankcase that is cold because of liquid refrigerant returning to the compressor.



ROTARY SCREW CHILLER START-UP

The rotary screw chiller may be either air- or water-cooled. If it is air-cooled, it will be located outdoors and the availability of heat for the chiller barrel should be verified. Again, it is thermostatically controlled and will only operate when needed. The compressor must have crankcase heat before start-up. Again, most manufacturers require that this heat be energized for 24 hours before start-up. Start-up without crankcase heat can cause compressor damage.

The water flow must be verified through the chiller and the condenser if the chiller is water-cooled. The best way to do this is to use pressure gauges. All valves must be in the correct position before start-up. The manufacturer's literature should be checked for valve positions. If the chiller was pumped down for winter, the correct procedures must be followed to allow the refrigerant back into the evaporator before start-up. The field control circuit should also be checked to make sure that it is calling for cooling. When all of the preceding steps are complete, the chiller is ready to start.

The technician should start the compressor, watch for it to load up and start cooling the water, and observe the following:

1. Suction pressure
2. Discharge pressure
3. Water temperature (for both chiller and condenser when water-cooled)
4. Liquid flooding back to the compressor

When the chiller is operating normally, it can usually be left unattended, except for the cooling tower when the unit is water-cooled. The cooling tower should be observed and maintained regularly.

CENTRIFUGAL CHILLER START-UP

Centrifugal chillers often need to be started and watched for the first few minutes because of the separate oil sump system. When the compressor is a centrifugal, the oil sump should be checked before a start-up is tried. Look for the following:

1. Correct oil sump temperature, from 135°F to 165°F, depending on the machine manufacturer. **NOTE:** *Do not attempt to start a compressor unless the oil sump temperature is within the range the compressor manufacturer recommends, or serious problems may occur.* • After the machine has been operating for some time, check the bearing oil temperature to be sure that it is not overheating. If overheating occurs, check the oil cooling medium, usually water.
2. Correct level of oil in the oil sump. If the oil level is above the glass, the oil may be full of liquid refrigerant. Ensure that it is the correct temperature. The oil pump may be started in manual but observe what happens. If in doubt, call the manufacturer for recommendations. Unless the

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

technician has experience as to what to do, he should not try to start the compressor; marginal oil pressure may cause bearing damage.
3. Start the oil pump in manual and verify the oil pressure before starting the compressor; then turn it to automatic before starting the compressor.

When the chiller is started, the compressor oil pump will start and build oil pressure first. When satisfactory oil pressure is established, the compressor will start and run up to speed then change over to the run-winding configuration. This could be autotransformer, wye-delta, or electronic starter. The centrifugal compressor starts unloaded and only begins to load up after the motor is up to speed. This is accomplished with the prerotation guide vanes mentioned in Unit 47, "High-Pressure, Low-Pressure, and Absorption Chilled-Water Systems". When the chiller is up to speed, the prerotation vanes begin to open and will open to full load unless the machine demand limit control stops the vanes at a lower percentage of full load.

When the chiller compressor starts to work and pull full- or part-load current, the technician should observe the pressure gauges and look for problems such as the following:

1. The suction pressure operating too low or too high. The technician should mark on the gauge front or on a notepad the expected operating suction pressure for normal operation, which would be at design water temperature. Typically, this would be 45°F leaving water.
2. The net oil pressure should be correct. This should be noted nearby for ready reference. If the machine has been off for a long time, the oil level in the oil sump should be observed as the compressor starts to accept the load. If the oil starts to foam, the load on the compressor should be reduced. This will raise the oil sump pressure and boil the refrigerant out of the oil at a slower pace. If the load is not reduced, it is likely that the oil pressure will start to drop and the machine will shut off because of low oil pressure. If the compressor has an anti-recycle timer, it cannot be restarted until the timer completes its cycle, and that may be 30 min. It is better to avoid allowing the compressor to shut off by watching the oil pressure.
3. Discharge pressure should be correct. This should be noted nearby for ready reference or marked on the pressure gauge for typical operating conditions.
4. Compressor current should be correct and marked on the ammeter on the starter. The ammeter should be marked for all operating percentages—typically, 40%, 60%, 80%, and 100%—so the technician will be aware at all times at what load the machine is operating. The operating arm for the prerotation vanes should be marked so that the travel can be measured; this is closely correlated with the current.

Chillers manufactured in the last few years all have electronic controls, and the technician should study the particular machine's sequence of starting events. Typically, everything from default lights on the control panel to electronic readouts are used to indicate what is happening. For example, a unit may have a sequence of LED lights on the circuit board that will be lit if a particular problem occurs. The technician must use the manufacturer's trouble chart to discover what the nature of the problem is. Some manufacturers use the flash sequence of LED lights to describe a problem. Some provide an electronic readout that explains the problem in words or code numbers. These control sequences can be lengthy, and it is beyond the scope of this text to describe them. Again, nothing beats an understanding of the equipment that is based on the manufacturer's own description. One of the purposes of these electronic controls is to make troubleshooting easier for the technician.

49.2 VALVES FOR LARGE SYSTEMS

Refrigerant valves on many large systems require proper use and maintenance. Valves increase in size as the systems become larger, and they have some mechanical features that the technician must pay attention to. These valves, which are basically used in the refrigerant circuits, are diaphragm, ball, or service valves with back and front seats. They must be manufactured so that they can achieve high levels of leak-free performance, and, since they control refrigerant, they must be reliable.

Diaphragm valves are used for small lines, **Figure 49.9**. The name refers to the diaphragm made from stainless steel and located under the valve cap that is inside the valve. This valve should not be disassembled unless necessary. The valve may be fastened to the piping by a flare fitting or by solder or brazing. Some technicians will disassemble the valve for brazing purposes to prevent overheating the valve. This is not necessary if the valve body is kept cool with a wet rag or heat-sink paste material during the brazing process. When heated for brazing, the valve should not be seated—it should be backed off of the seat a few turns. Normally, the technician has no reason to take this valve apart. Once in service, it usually does not require service for the life of the system. The

Figure 49.9 This hand valve is called a diaphragm valve. The actual diaphragm is under the valve cover and can't be seen.

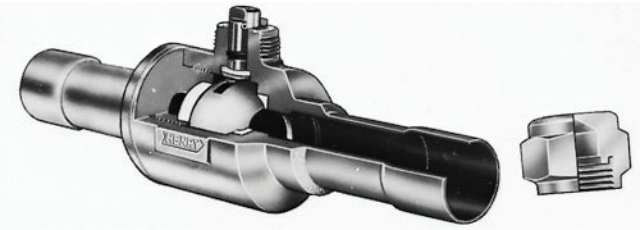
Figure 49.10 This is a ball valve, used for refrigerant. Notice that it has a protective cap to protect the valve stem and that it could also prevent a leak if the stem leaked.



Courtesy Henry Valve Company

valve is not used for everyday service, but only to valve the refrigerant off for isolation purposes. The diaphragm valve is normally used in the liquid line because it does not come in large sizes—only up to about 7/8-in. piping.

Ball valves for refrigerant piping come in sizes of up to about 2 7/8 in. and are used for larger applications, **Figure 49.10**. Ball valves usually do not have any serviceable parts inside and are not normally disassembled. Since they are used for refrigerant, they have an enclosed valve stem that has a cover which must be replaced after use. The ball valve needs to be turned only one-quarter turn to be fully open or fully closed. It is typically brazed in the line, and the manufacturer may require the valve to be wrapped in a wet rag while the valve is brazed at one end and cooled before it is wrapped again and brazed at the other end. The reason for this is to keep the valve body from getting too hot because the working parts may not be metal. The ball valve usually has a stainless steel ball and stem that will not rust or corrode.

Service valves are valves that are used on the compressor and, in some cases, in the liquid line. These valves are brazed into the line when used in the piping and when used on the compressor are bolted to the compressor and have a brazed flange for the piping, **Figure 49.11**. These valves are used on many compressors of up to about 150 tons and they have large piping connections. The valves have a front seat and a back seat and can be used in the midseated position for different purposes, **Figure 49.12**. Notice that the valve in **Figure 49.11** has a protective cap. The valve cap is also used to protect the valve stem from damage. This is particularly true with the suction-line valve, which often operates below the surrounding dew point temperature and sweats.

Often, the valve stem is made of ferrous metals (iron or steel) and the valve stem can become rusted. **If the technician turns the rusty valve stem down through the packing gland, damage to the packing gland will occur.** The packing gland is the second line of defense from refrigerant leaking. The proper practice is to use fine sand cloth (400 grit) to clean the high spots off of the valve stem, **Figure 49.13**, before turning the stem. It is also good practice to loosen the packing nut before turning the stem. This may cause refrigerant seepage,

Figure 49.11 (A) A large service valve like those used on many compressors for suction or discharge service. (B) Cutaway view of the service valve.

but the technician must preserve the packing. There are three lines of defense against refrigerant leaks:

1. The back seat
2. The packing gland
3. The protective cap

They must all be protected from damage.

The valve stem packing can often be removed and replaced by back-seating the valve. The packing portion of the valve is isolated. To determine the correct packing if it cannot be identified when removing the old packing, the compressor manufacturer should be consulted. The packing is often graphite or Teflon rope, which is available at plumbing supply houses. With large valves, it is much easier to replace the packing than to replace the valve. Another alternative is to leave the

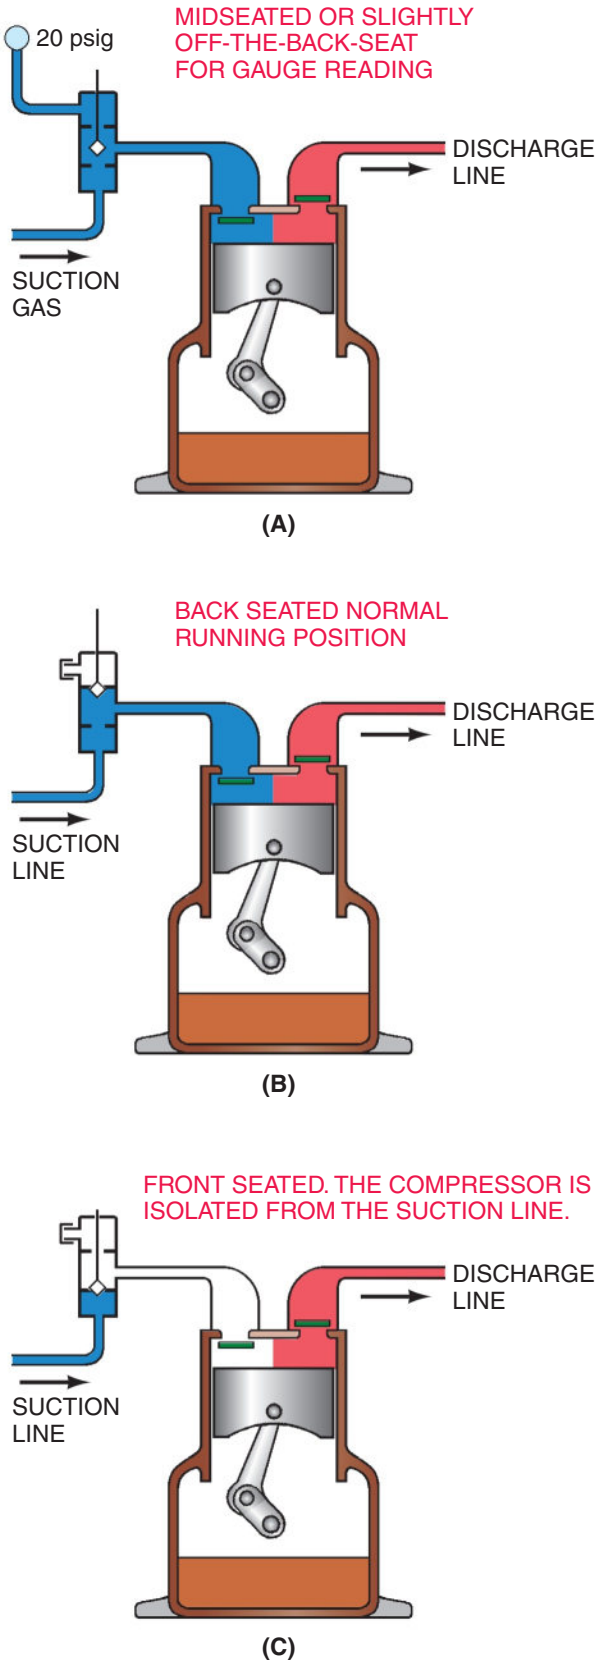

Figure 49.13 A clean stem and a rusty stem.

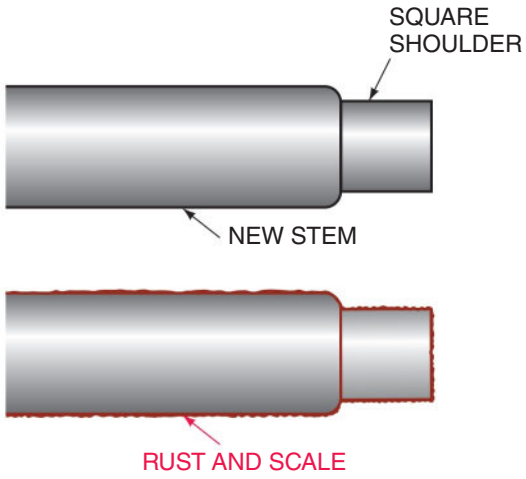

piping sleeve on the piping and just replace the valve body, when it is available. When the technician is through servicing the unit, the inside of the valve cap should be cleaned up and the stem should be wiped clear of any moisture. Many technicians then coat the valve stem with silicone spray or oil to protect it just before replacing the valve cap.

The valve cap is often hard to remove when it has been on for a long time, as rust may have accumulated on the threads. Some of these valve caps are quite large. Many technicians use a pipe wrench to take the valve cap off. Another way to remove it without leaving scars on the valve cap is to lightly tap each flat on the nut with a hammer to break the rust loose, then use a hex-jaw wrench to remove it, **Figure 49.14**. Tapping the handle of the wrench with a hammer can dislodge the valve cap.

Figure 49.12 shows ways that the compressor service valves are used. They can be back-seated to remove the gauges; this is the normal running position for the valves. Often, the low-pressure control is fastened to the service valve, and in such a case the valve should be slightly cracked (turned toward the front seat) in order for the control to

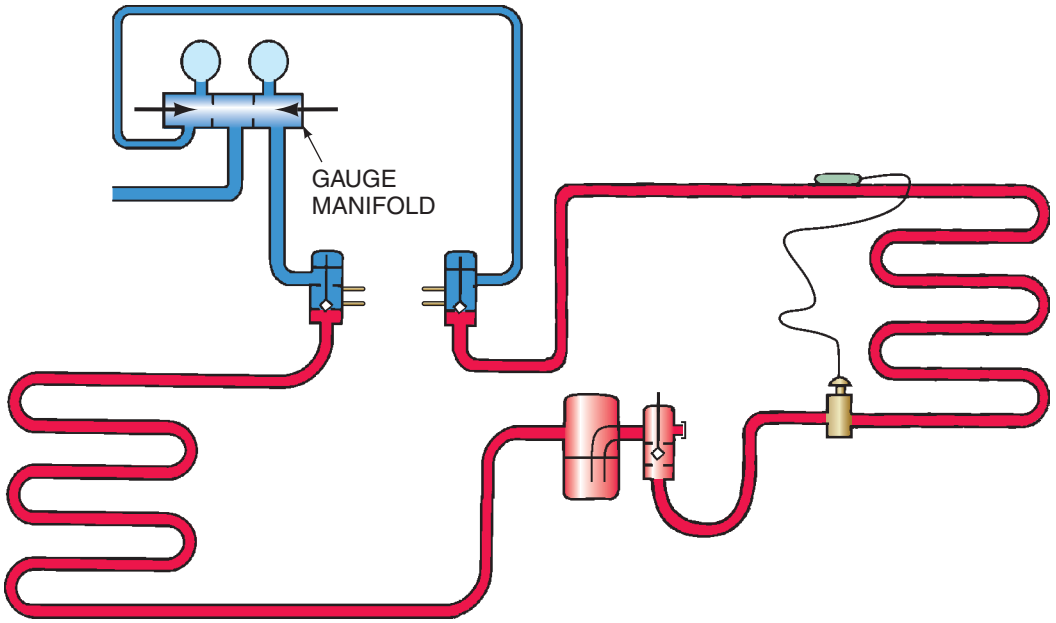
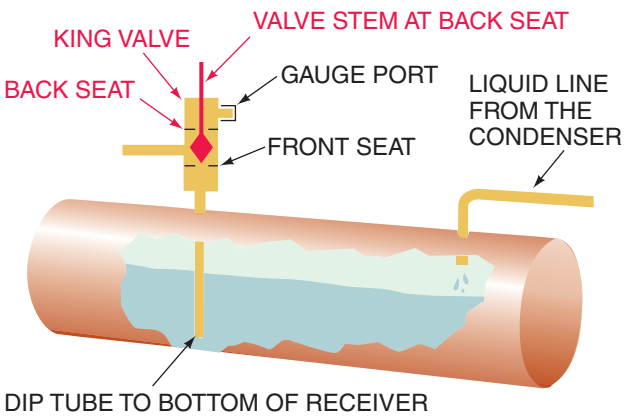
Figure 49.15 When the suction and discharge valves are front-seated, the compressor can be removed. The valves are fastened to the compressor with bolts. The compressor becomes a separate vessel.



function. The valves can be midseated or cracked off the back seat for gauge readings. The valves can be completely front-seated for compressor service. Notice that the compressor can be removed and replaced using the front seats by unbolting the compressor flange bolts, **Figure 49.15**. Only the refrigerant in the compressor must be recovered and the new compressor can be evacuated using the front-seated position.

The liquid-line king valve is a type of service valve that is usually found at the outlet of the refrigerant receiver. This valve is used to isolate the refrigerant in the condenser and receiver by pumping the refrigerant from the outlet of the receiver into the condenser and receiver, **Figure 49.16**.

Figure 49.16 The king valve in the liquid line is a little different. The back seat is open to the gauge port when the valve is front-seated. This valve has a back seat so that the gauges can be removed.



A technician can fasten a high-side gauge to the king valve, front-seat it, and start the compressor to pump the refrigerant to the condenser receiver. The gauge reading will tell the technician what the pressure is in the liquid line.

49.3 SCROLL AND RECIPROCATING CHILLER OPERATION

Once the chiller is on and operating, the operator should observe the chiller from time to time to make sure it is operating correctly. Small air-cooled chillers may be located in remote locations and not be observed on a regular basis. These chillers are usually operated unattended, but not much can go wrong if the chilled-water supply is maintained.

All water-cooled chillers require more attention because of the water circuit and cooling tower. It is good practice to check any piece of operating equipment on a periodic basis but that is expensive, so most close observation is reserved for larger systems. It is good practice to check the cooling tower water several times per day to be sure that the water level is correct. Often, a partial loss of water pressure will cause the amount of tower water to drop due to the fact that the water is evaporating faster than the water supply can make it up. With careful observation, the technician can catch this problem before it shuts the unit off and a complaint occurs. If no regular technician is on the job—for example, at a small office building—someone can be assigned to make this check with very little instruction. The chillers are often on top of buildings where

no one goes on a regular basis. Someone should be assigned to check these installations every week.

Water-cooled chillers must have water treatment to prevent minerals and algae from forming in the water circuit. It is recommended that a qualified water treatment specialist be used. This will help reduce the number of water-related problems with the system. Review the material on cooling towers in Unit 48, "Cooling Towers and Pumps," for the types of water treatment needed. All towers must also undergo blowdown, which is evacuating a percentage of the circulated water down the drain to prevent the tower water from becoming overconcentrated with minerals due to evaporation. Blowdown for a cooling tower is necessary, but often management has difficulty understanding why water that looks clean must be sent down the drain. The technician should know how to explain this to them.

49.4 LARGE POSITIVE-DISPLACEMENT CHILLER OPERATION

Large chillers that use reciprocating or rotary screw compressors may range in size to more than 1000 tons of capacity. Chillers of this size are extremely expensive and must be observed on a regular basis or problems may occur. These problems can often be expensive to correct. Large chillers are reliable but observation is very important. The technician should look for any potential problem as explained in the previous paragraphs. These chillers may also have pressure gauges that are active all the time in that they are not valved off. If so, these may be observed as much as once per hour on some critical applications. Often an operating log is maintained on a regular basis. The frequency of the recording in the operating log depends on the importance of the job. If a chiller is being used for critical manufacturing, the entries in the log may be required hourly. If it is being used in an office building, the log may be maintained on a daily or weekly basis. See **Figure 47.23** for an example of an operating log form.

49.5 CENTRIFUGAL CHILLER OPERATION

Centrifugal chillers were the largest chillers made for many years. Typically, when the requirements were greater than 100 tons, a centrifugal chiller was considered or multiple reciprocating chillers were used. Centrifugal chillers range in size from 100 tons to about 10,000 tons for a single chiller. These were the most expensive of all chillers and also the most reliable, so much attention has been given to the observation of the operation and maintenance of these chillers. For years, it has been customary for the operation of these chillers to be observed and an operating log maintained on a regular basis, usually daily. Operating logs make it possible for slowly occurring problems to be easily detected. For example, if the cooling tower water treatment system has not been working and the condenser water tubes are beginning to have a mineral buildup, the condenser water approach temperature will begin to spread. An alert operator will notice this and take corrective action, which may be to change the water treatment and certainly to clean the water tubes, because the heat exchange rate has been reduced.

49.6 AIR-COOLED CHILLER MAINTENANCE

Air-cooled chillers require little maintenance, which is one reason why they are so popular. The fan section of these chillers may require lubrication of the fan motors, or the motors may have permanently lubricated bearings. It is typical for these chillers to have multiple fans and motors. As a result, the motor horsepower can be reduced and the fans can be direct-drive. This eliminates belts and the need for routine lubrication in many cases. If one fan fails, the chiller can continue to operate.

The following electrical maintenance should be performed annually for a typical system:

1. Inspect the complete power wiring circuit because this is where the most current is drawn. Look for places where hot spots have occurred. For example, the wires on the compressor contactor should show no signs of heat. The insulation should not appear to have been hot. If so, this must be repaired. This can be done by cutting the wire back to clean copper. If the lead is not long enough, a splice of new wire may be needed or the wire may need to be replaced back to the next junction.
2. Inspect the motor terminal connections at the compressor. If these show any discoloration, a repair should be made. A hot terminal block can cause refrigerant leaks, so the wiring should be inspected carefully.
3. The contacts in all contactors should be inspected and replaced if pitting is excessive. If excess pitting begins to occur, it is likely that the contacts will weld shut in the future and they will not be able to stop the motor. This can lead to single phasing of a wye-wound motor if any two contacts weld shut. Motor burn will then occur because there is nothing to shut the motor off except the breaker, **Figure 49.17**.
4. The compressor motor should be checked for internal ground using an ohmmeter, called a megohmmeter, that can check ohm readings in the millions of ohms. **Figure 49.18** shows an example of a basic megohmmeter. This instrument uses about 50 to 500 V DC to check for leaking circuits; others may use much higher voltages and have a crank-type generator to achieve the high voltage. The motor manufacturer's recommendations should be used for the correct allowable leakage of the circuit.

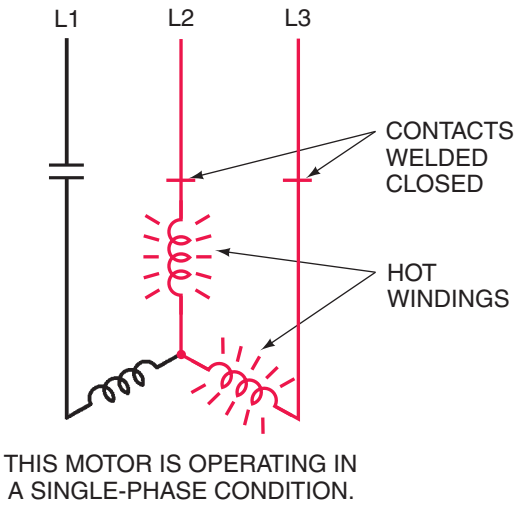
Figure 49.17 The contacts are welded shut on a wye-wound motor, which will cause the motor to try to run on L2 and L3. This is called single phasing and will burn the motor.



Typically, a motor should not have less than a 100-megohm circuit to ground or to another winding in the case of a delta-type motor or dual-voltage motor, **Figure 49.19.** The required reading depends on the motor temperature because the temperature changes the requirements. Consult the manufacturer if proper guidelines are unknown. A reliable local motor shop can also give guidelines. It is important to start a process of megging a motor when it is new and keep good records. If the motor megohm value begins to decrease, it is a sign that moisture or some other foreign matter may be getting into the system.

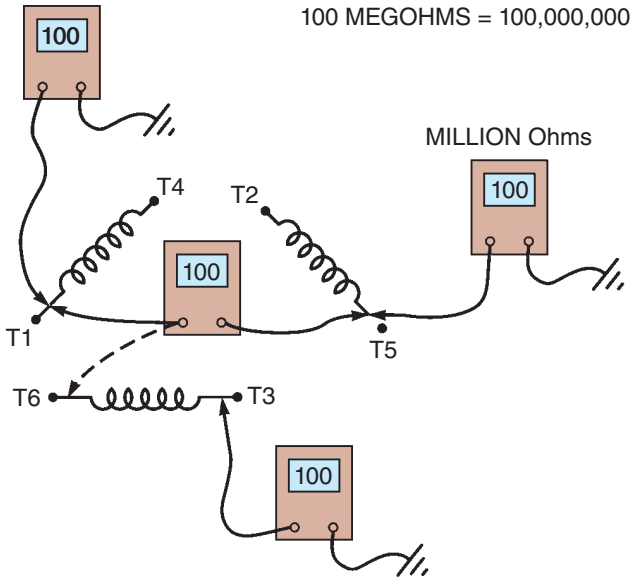
Reproduced with permission of Fluke Corporation

Figure 49.19 Using a megohmmeter to check a motor. Notice that it is checked from all windings to ground and from winding to winding.



5. An oil sample from the compressor crankcase can be sent to an oil laboratory to determine the condition of the compressor. This test, like the megohm test, should be done when the chiller is new and should be performed every year. If certain elements start appearing in greater quantities in the oil, it is evident that problems are occurring. For example, if the bearings are made of babbitt and the babbitt content increases each year, at some point it is evident that the bearings need to be inspected. If small amounts of water appear, the tubes need to be inspected for leaks. This will only occur if the water pressure is greater than the refrigerant pressure. For high-pressure chillers, this can occur if the chiller is at the bottom of a high column of water.
6. Inspect the condenser for deposits such as lint, dust, or dirt on the coil surface. These must be removed because they block airflow. It is good practice to clean all air-cooled condensers once a year or more often if needed. If the operating log shows an increase in head pressure compared with the entering-air temperature, the coil is becoming dirty. Air-cooled coils can be deceiving in that the dirt may be imbedded in the interior of the coil and cannot be seen until the coil is cleaned. A coil should be cleaned by saturating it with an approved detergent and then washing the coil backward, in reverse to the direction of the airflow; this is called backwashing. An apparently clean coil may yield a large volume of dirt from its interior.

49.7 WATER-COOLED CHILLER MAINTENANCE

Routine maintenance may involve cleaning the equipment room and keeping all pipes and pumps in good working order. The technician should ensure that the room and equipment are kept clean and in good order. It is always easier to keep a room clean than to have to clean it when the chiller breaks down and needs to be disassembled. The cooling tower should be checked to be sure the strainer is not restricted. Look at the water for signs of rust, dirt, and floating debris, and clean if necessary. The water treatment should be checked on a regular basis. Some systems call for the operating technician to perform water analysis daily to check for mineral content. When the water treatment gets out of balance, the technician should either make adjustments or call the water treatment company. Someone must be in charge of keeping the water chemicals at the correct level for best performance.

Annual maintenance should involve checking the complete system and chiller to prepare it for a season of routine maintenance. Some chillers operate year-round and are only shut down for annual maintenance. During this maintenance period, it is often wise to bring in the factory maintenance representatives. These technicians know what is happening across the nation or around the world with regard to any service or failure problems with their equipment and so will have the best technical knowledge about the equipment. Often, they will put the equipment through the complete start-up procedure just as though it is for the first time. All controls may be checked at this time to be sure they will perform up to standard. It is not uncommon for a system to operate for years without a control checkup and then fail—only to have the technician discover that a control has failed that should have saved the system but did not. A control checkup once a year can be good insurance against many failures. During annual maintenance, all electrical connections should be checked; refer to the previous section on electrical maintenance for air-cooled systems. Water-cooled equipment has the same electrical symptoms.

The water-cooled condenser should be inspected on the inside every year by draining the water from the condenser and removing the heads. The tubes should be clean. A tube is clean when a light shone inside the tube reveals copper tube with a dull copper finish. A penlight is very good for this because it can be inserted inside the tube. For proper heat exchange, any film on the inside of the tube must be removed. Many technicians believe that if the tube is open enough to allow a good water flow it is clean. This is not true; the tube must be clean down to bare copper for proper efficiency.

Several approaches may be taken to cleaning dirty tubes. The tubes may be brushed with a nylon brush that is the size of the inside of the tube. This is customarily done with a machine that turns the brush while flushing the tube with water. Some manufacturers recommend using a brush with fine brass bristles if a nylon brush will not remove the scale from the tubes. Check with the manufacturer, because some do not recommend this practice. Always keep the tubes wet until it is time to brush them or the scale will harden more. It is good practice to be prepared to brush the tubes before removing the heads so that the tubes will stay wet until they are brushed.

If brushing the tubes will not work, the tubes may be chemically cleaned using the recommended acid for the application, **Figure 49.20**. **NOTE:** *This is a very delicate process because the tubes may be damaged. Consult the chemical and chiller manufacturer for this procedure.* It may be good practice to let the chemical manufacturer clean the tubes; then if damage occurs, the manufacturer is responsible. However the process is accomplished, make sure that the chemicals are neutralized or the tubes may be damaged. The damage would be severe because the chemicals may eat the tube material, and leaks between the water and refrigerant may occur. After the tubes have been chemically treated, they may be clean or the chemicals may just soften the scale and the tubes may need brushing to remove the scale.

The water pump should be checked to make sure the coupling is in good condition. **SAFETY PRECAUTION:** *This can be done by turning off the power, locking and tagging the disconnect, and removing the cover to the pump coupling.* If materials such as filings are found inside the coupling housing, deterioration of the coupling should be suspected. Some couplings are made of rubber and some are steel. Look for the flexible material that takes up the slack to see whether it is wearing.

Figure 49.20 Chemically cleaning condenser tubes.

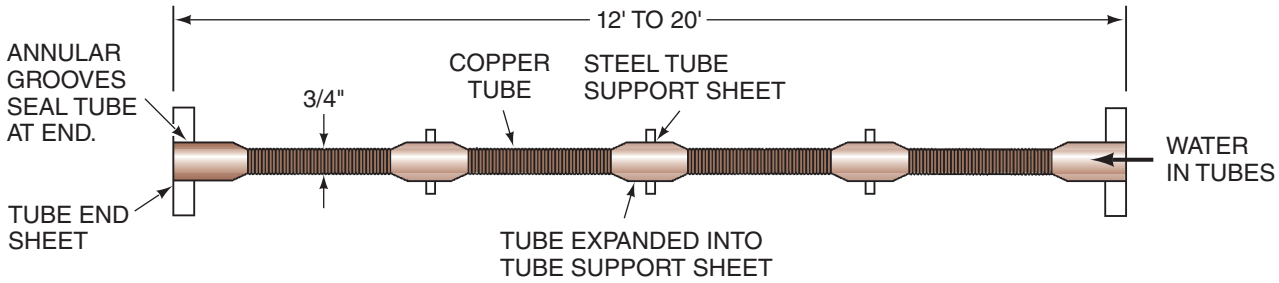
Figure 49.21 The tube assembly for a heat exchanger. Notice the tube support sheets that support the tubes.

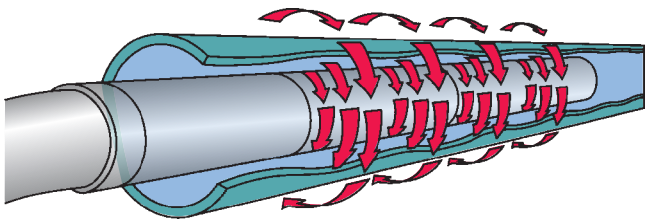


After the condenser has been cleaned, the condenser tubes may be checked for defects such as stress cracks, erosion, corrosion, and wear on the outside by means of an eddy current check. This test should be performed on the evaporator tubes as well. This check determines if there are irregularities in the tube. One common problem is wear on the tube's outer surface where it is supported by the tube support sheets. Each set of tubes has a different type of stress applied to the outside. In the condenser, the hot discharge gas is pulsating as it enters the condenser and has a tendency to shake the tubes. In the evaporator, the boiling refrigerant shakes the tubes. The tube support sheets located in the condenser and the evaporator are sheets of steel that the tubes pass through to help prevent this action and are evenly spaced between the end sheets. When the evaporator or condenser shell is tubed, the tubes are guided in place through the support sheets. When the tube is in place, a roll mechanism is inserted into the tube and expanded to hold the tube tight in the support sheet, **Figure 49.21**. The tube roller may miss a tube, and this tube can shake or vibrate until the tube sheet wears the tube. If this wear continues, the tube will rupture and a leak between the water and refrigerant circuit will occur. The worst case can flood the chiller on the refrigerant side with water. This may happen in particular with low-pressure chillers. The eddy current test can be used to find potential tube failures; these tubes may be pulled and replaced or plugged if there are not too many.

The eddy current test instrument has a probe that can be pushed through the clean tube while an operator watches a screen monitor, **Figure 49.22**. As the probe passes through the tube, it sends out a magnetic current signal that reacts with the tube and shows a profile on the screen monitor. When unusual profiles are noticed, the tube is marked for further study, which may involve comparing the profile to that of a known good tube. A decision may need to be made to pull or plug the tube. A tube failure in the middle of the cooling season can take days to repair, and it is good practice to find these problems in advance.

Water and steam valves can be maintained as leak-free as refrigerant valves but are not as intricate. The **globe valve** is the most common valve used in water and steam circuits, **Figure 49.23**. It has a packing gland like the service valves on a compressor. This valve can normally be back-seated to facilitate the removal of the existing packing and the addition of new packing. **NOTE:** *This is the only time the valve should be back-seated.* The globe valve can be disassembled and the valve seat can be replaced. The system must be drained in order to be disassembled. Notice that the valve has a directional arrow for flow. The stream to be controlled should be piped to the underside of the globe valve. If it is piped in backwards, the valve seat will often chatter or make a buzzing sound as the seat vibrates. The globe valve has a great deal of pressure drop because the fluid has to make several turns as it goes through the valve.

Figure 49.22 A probe for checking tubes that uses an eddy current tester can determine irregularities in the tubes.



The **gate valve** is another common valve used for these applications, **Figure 49.24**. The gate valve creates much less pressure drop through the valve than the globe valve and is a much better choice where excess pressure drop is a concern. Notice that the gate valve has a packing gland and a back seat for packing-gland repair. The gate valve can also be disassembled for seat repair. It does not have a replaceable seat; the gate is finely ground to fit into the finely ground seat. For large valves, this seat may be resurfaced if needed.

NOTE: *The globe valve and gate valve should not be back-seated when in operation. The reason for this is that if the valve is back-seated and then later the technician forgets the position, the valve might be damaged if technician tries to open it. It is good practice to open the valve all the way to the back seat and then turn it inward about one turn. Then, when someone tries to use the valve, its position will be known. It is not uncommon for a technician to mistake the valve for closed when it is on the back seat and do damage when trying to open it.*

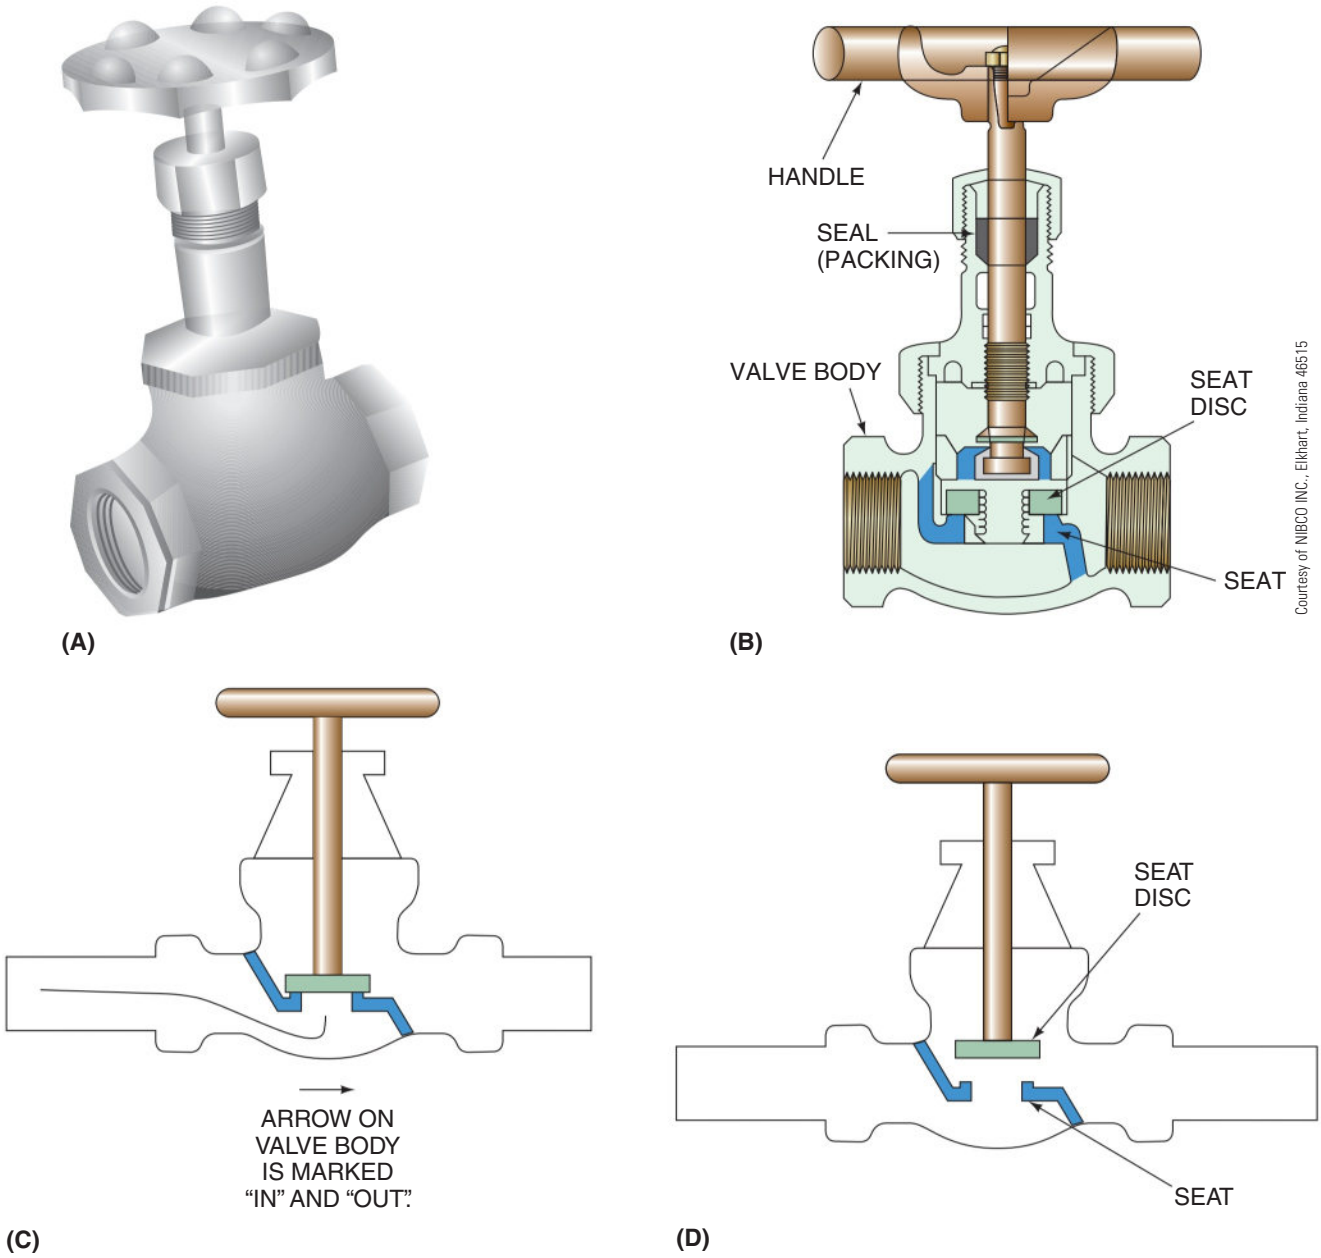
Figure 49.23 (A) A globe valve. (B) Cutaway of a globe valve. (C) Globe valve shut. (D) Globe valve open. Notice that the fluid must change directions.



To keep the valves loose, both the globe valve and gate valve should be run from all the way closed to all the way open from time to time. This must be done when it will not affect the system's operation, for example, when the system is shut off for some reason. These valves come in very large sizes—up to about 24 in. The larger valves have flanges for fastening them into the system with bolts. The **butterfly valve** is used in water circuits and is a quick-shutoff valve—as it only needs to be turned one-quarter turn from on to off, like a ball valve.

Strainers are used in water circuits to remove particles that may be in suspension and circulating. The cooling tower can be particularly dirty because it uses outside air that can have many contaminants in it. A cooling tower that has water flowing and air being forced through it is like a large filter for the air. The particles are gathered in the water and then the tower sump and onto any strainers. There are several types of strainers; consult the strainer manufacturer if there is doubt about how to clean them. **SAFETY PRECAUTION:** *When cooling towers are cleaned, the technician should be careful with the contaminants in the tower. If the tower is dry, the dust should not be breathed. Rubber gloves and boots should be worn, along with a face mask.*•

Water pumps are just as important as the chiller itself. If the water pumps will not operate, the chiller will not operate.

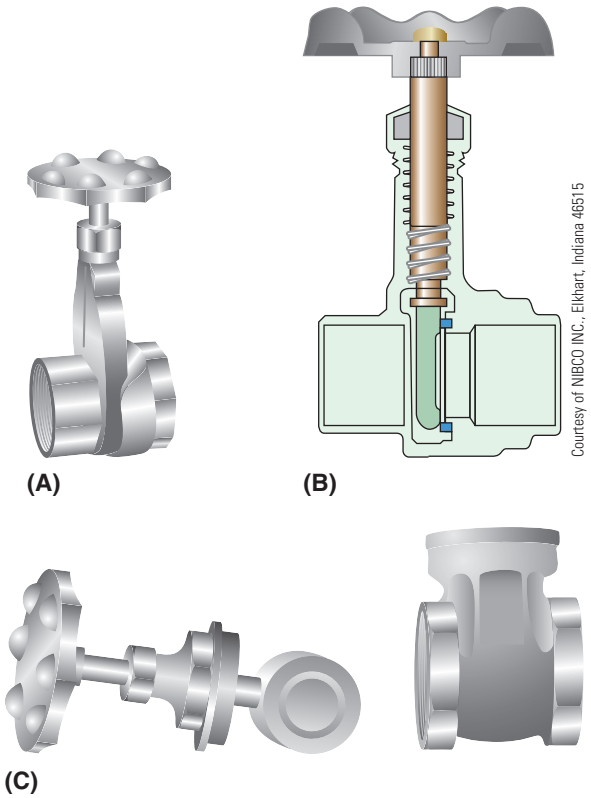
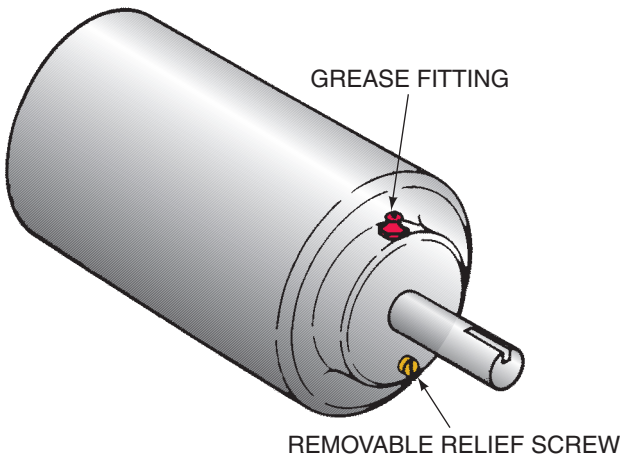
Figure 49.24 (A) A gate valve. (B) Cutaway view of a gate valve. Notice that when the gate is open, the valve goes straight through and there is very little pressure drop. (C) A gate valve disassembled.



Water pumps and their motors often require lubrication. When grease fittings are used, pay attention to the relief plug that allows excess grease to escape, **Figure 49.25**. If the relief plug is not removed, excess grease will be forced down the shaft and may harm the grease seal or enter the motor. The pump and motor will have a flexible coupling between them and it should be inspected. Turn off the power, lock it out, remove the protective cover, and visually inspect the coupling for wear.

If the chiller and water pumps are to stand idle during the winter months, all precautions should be taken to prevent freezing of any components such as piping, sumps, pumps, or the chiller, if it is located where it may freeze. Even if a chiller is in a building, it is good practice to drain it during winter because if the building loses power and the interior freezes, it would be expensive if the chiller tubes were to freeze. It is easier just to drain it and not take a chance.

Figure 49.25 A motor bearing with a grease fitting. Notice the relief plug that prevents excess pressure when grease is added. The plug must be removed while grease is applied.



49.8 ABSORPTION CHILLED-WATER SYSTEM START-UP

The absorption chiller start-up is similar to that for any chiller: Chilled-water flow and condenser water flow must be established before the chiller is started. Ensure that the cooling tower water temperature is within the range of the chiller manufacturer's recommendations. If the absorption machine is started with the cooling tower water too cold, the lithium-bromide (Li-Br) may crystallize, causing a serious problem. In addition to this, the heat source must be verified, whether it be steam, hot water, natural gas, or oil. Most absorption chillers are steam operated so the steam pressure must be available. If the chiller is operated from a boiler dedicated to it, the boiler must be started and operated until it is up to pressure.

The purge discharge may be monitored by placing the vacuum pump exhaust into a glass of water and looking for bubbles, **Figure 49.26**. Be sure to remove the purge exhaust from the water when the purge is not operating. If there are bubbles, it is a sure sign that noncondensables are in the chiller. It is pointless to start the chiller until the bubbles stop. Let the vacuum pump run even when the chiller is started (unless the manufacturer recommends not to) because often noncondensables will migrate to the purge pickup point after start-up.

Figure 49.26 The vacuum pump exhaust is placed in a glass of water to determine whether noncondensable gas is being removed; bubbles are moving out of the exhaust. **NOTE:** *Remove the glass before turning off the vacuum pump.*

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

When all systems are ready, the chiller may be started. The fluid pumps will start to circulate the Li-Br and the refrigerant and the heat source will start. The chiller will begin to cool in a very few minutes; this can be verified by the temperature drop across the chilled-water circuit. When absorption chillers are refrigerating, they make a sound like ice cracking. When this sound begins to come from the machine, the chilled-water temperature should begin to drop.

49.9 ABSORPTION CHILLER OPERATION AND MAINTENANCE

Absorption chillers must be observed for proper operation more regularly than compression cycle chillers because they can be more intricate. Chiller manufacturers use different checkpoints to measure chiller operation. The refrigerant temperature and the absorption fluid temperatures measured against the leaving chilled-water temperatures are among a few. The manufacturer's literature must be consulted for the checkpoints and procedures. Maintaining an operating log is highly recommended for absorption installations.

When the chiller is operating, it is good practice to pay close attention to the purge operation. If the chiller requires excessive purge operation, the machine may have leaks or it may be manufacturing excess hydrogen internally and need additives. The machine must be kept free of noncondensables. The heat source may also need maintenance. If it is steam, the steam valve should be checked for leaks and operating problems. A steam condensate trap will also need checking to be sure it is operating properly. The condensate trap ensures that only water (condensed steam) returns to the boiler. A typical condensate trap may contain a float. When the water level rises, the float rises and only allows water to move into the condensate return line, **Figure 49.27**. The steam or hot water valve and condensate trap should be inspected for any needed maintenance. A strainer will be located in the vicinity of the condensate trap and should be cleaned during the off season. There are several other different types of traps; the one in **Figure 49.27** is shown as an example.

When the chiller is operated using hot water, the hot water valve should be observed for proper operation and to ensure that there are no leaks. Gas- or oil-operated machines will need the typical maintenance for these fuels. Oil in particular requires maintenance of the filter systems and nozzles.

With the absorption chiller, the purge system may require the most maintenance. If the chiller has a vacuum pump, regular oil changes will help to make it last longer. Li-Br is salt and will corrode the vacuum pump on the inside. It is not recommended that a vacuum pump used for a compression cycle system be used on an absorption system because of the corrosion problem, but if one is used, extra care should be taken to change the oil immediately after use.

Any Li-Br that is spilled in the equipment room will rust any ferrous metal it contacts. It is good practice to keep the area where it is handled washed with freshwater to prevent rusting. The machine and other equipment in these areas may need to be painted periodically for additional protection. The machine room must also be kept above freezing or the refrigerant (water) inside the machine will freeze and rupture the tubes. Unlike the other chillers, water in the absorption chiller cannot be drained and must be protected.

The system solution pump or pumps may require periodic maintenance. A check with the manufacturer will detail the type and frequency of this maintenance. The water pumps need regular maintenance as with any other system.

The cooling water must be maintained by cleaning and water treatment. Do not forget blowdown water. Absorption chillers operate at higher cooling tower water temperature than compression cycle chillers and good water treatment maintenance is vital because the tubes will become fouled much quicker. Absorption chillers may need the tubes probed with an eddy current probe on a more regular basis than

Figure 49.27 The condensate float trap for a steam coil.

compression cycle chillers because of the higher temperatures in the condenser section. The tubes are stressed when the heat source is applied to these tubes, and they expand and then contract when cooled during the off-cycle. Checking with the manufacturer is a good idea.

49.10 GENERAL MAINTENANCE FOR ALL CHILLERS

Technicians who maintain chillers must be well qualified and should stay in contact with manufacturers to learn about the latest training schools and advice. Manufacturers receive feedback from all over the world on their equipment and know what is happening, such as premature failures. They should share any potential problems with the technician to prevent future problems with their equipment. Technicians should attend factory seminars and schools and make friends with the factory technicians. The technician who works on or observes work on large equipment can learn what to do during all service procedures. Because factory technicians perform much of the service on large-system chillers, the operating technician will be present to observe the service procedures and assist the factory technician. These procedures may be anything from routine checking of the controls to major overhaul of the equipment. The operating technician should be able to recognize the procedures. When the factory technician leaves, the operating technician must operate the equipment.

Refrigerant management is a big factor in any chiller application because chillers contain large amounts of refrigerant. The job site often has a supply of refrigerant on hand for emergencies because if the site is out of town it may take several days to obtain refrigerant, and this may not be satisfactory. The operating technician should be fully aware of the paperwork that must be kept current for the system. When a comfort-cooling chiller contains more than 50 lb of refrigerant, which most will, the technician must be aware that adding refrigerant to the machine just because it loses refrigerant is not satisfactory. If a machine loses more than 15% of its refrigerant in a year or leaks at a rate of 15% per year, the law requires that the leak be repaired within 30 days of discovery. The requirements are different for commercial and industrial process equipment; the allowable leak rate in those cases is 35% per year. The technician must be aware of all refrigerant purchased and where it is used and have a recordkeeping system.

49.11 LOW-PRESSURE CHILLERS

Low-pressure chillers are probably the most difficult to understand because they operate with both a positive pressure in the condenser and a vacuum in the evaporator while running. When they are shut down, both the condenser and the evaporator will be in a vacuum. The largest portion of the refrigerant is in the flooded evaporator section, and the hot gas from the condenser quickly condenses to a mass of liquid in the evaporator when shut down. Low-pressure chillers operate in a vacuum and will stay in a vacuum if the equipment room is not warm enough to keep the refrigerant warm. As mentioned earlier, a leak in a vacuum will pull air into the machine, and the purge unit will operate excessively. Unless the machine has a high-efficiency purge, it will purge too much refrigerant out with the air that was pulled in. For example, R-123 boils at about 83°F at 0 psig (atmospheric pressure). This means that in the winter when the equipment is not operating, it may sit in a vacuum. Many equipment rooms are maintained at about 60°F during winter. If the refrigerant in the R-123 chiller is below 83°F, the chiller will be in a vacuum. The owners will not want to keep the equipment room up to these temperatures, so chiller manufacturers provide ways to keep a slight positive pressure using heat in the chiller evaporator section, where the liquid refrigerant will accumulate. This heat can be thermostatically controlled with either warm water or electric heaters under the insulation of the chiller evaporator shell. It may be used to keep the chiller shell in a positive pressure to prevent air from being pulled into the shell, or it may be used to pressurize the chiller for service purposes.

Chillers may be pressurized using nitrogen pressure or heat added to the evaporator shell. Regulated nitrogen pressure can be used to quickly build pressure in the chiller shell, but it must be removed after the service call is completed. If the service involves recycling the refrigerant, nitrogen may be used to save time. If the same refrigerant is going to be put back into the chiller, heat may be the best choice so that the nitrogen will not have to be removed from the refrigerant.

Care must be used when the chiller shell is pressurized for any reason. The pressure must not exceed the stress level of the rupture disc. The rupture disc is a one-time-use device, and it is not inexpensive. The reason for the rupture disc is to keep the shell from splitting if excess pressures occur. For example, if there is a fire, it is better to lose the refrigerant than to have a shell split. If its pressure rating is exceeded, the disc will rupture (blow out), refrigerant will be lost, and the rupture disc will have to be replaced. The rupture disc rating is 15 psig, so most technicians will not pressurize a system beyond 10 psig. The head pressure on a system may operate at a condensing temperature of 105°F using cooling tower water, which would equate to about 8 psig for R-123. Since the rupture disc is located in the low-pressure part of the system, there is no chance that high head pressure will rupture the disc, **Figure 47.43**.

RECOVERING REFRIGERANT FROM A LOW-PRESSURE CHILLER

Once the chiller is pressurized to the point that the pressure inside the chiller is greater than the pressure in the recovery system, liquid is allowed to transfer to the recovery system.

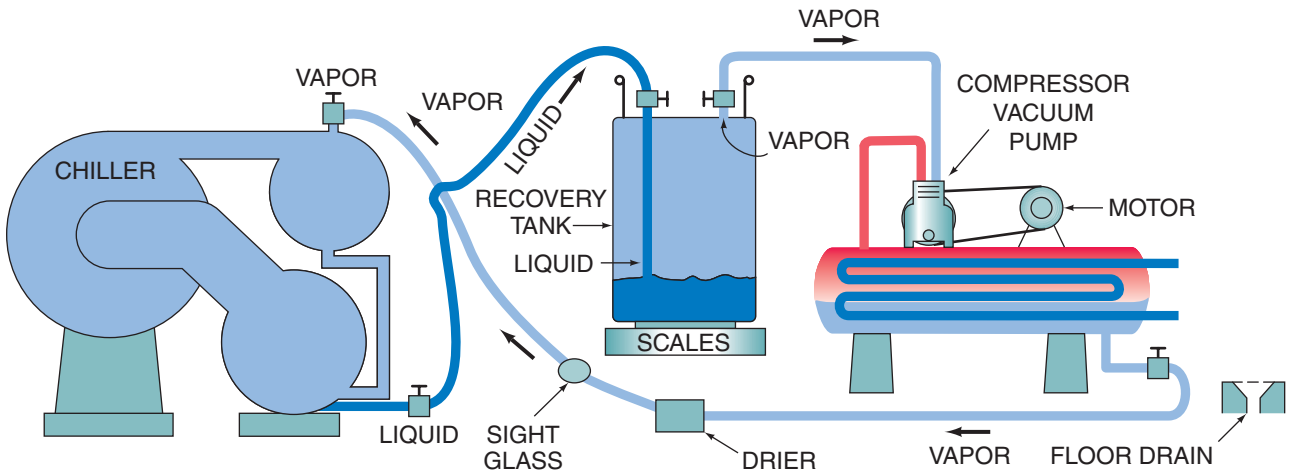
Figure 49.28 The recovery machine pulls vapor from the top of the recovery cylinder and puts it back into the chiller. This creates a low-pressure area in the recovery cylinder in relation to the chiller, and liquid moves into the recovery cylinder. Notice that there is no condensing taking place.



If the technician does not have a permanent storage cylinder on the job, a portable cylinder will need to be moved in for the recovery. A push-pull recovery machine may also be used to move the refrigerant. If the liquid is only pushed out of the machine, the vapor would still remain. When only liquid is removed from a 350-ton chiller, there is still a considerable amount, possibly over 100 pounds, of refrigerant vapor still in the system. This does not meet the EPA requirement of removing the refrigerant to the required pressure level.

Vapor from the top of the recovery cylinder is pulled out of the top and pushed into the chiller to push liquid to the recovery cylinder, **Figure 49.28**. Notice that the water is not connected to the recovery unit condenser, so no condensation takes place. When all the liquid is removed, the system is reversed, the liquid connection is shut off, and vapor is pulled out of the vapor space of the chiller, normally at the top of the condenser, **Figure 49.29**. The city water is now connected to the recovery machine condenser and condenses the liquid, and it moves to the recovery cylinder. The required evacuation level in the chiller is 25 in. Hg vacuum with recovery equipment manufactured before November 15, 1993. If the recovery equipment was manufactured after November 15, 1993, the system must be evacuated to 25 mm Hg absolute. After the service is completed, the system can be reversed and the refrigerant can be pushed back into the chiller. The push-pull equipment used is a recovery machine designed to handle large volumes of refrigerant. Some chillers can have upwards of 3000 lb of refrigerant. The recovery machines will have all the piping connections to fasten to the chiller and a

Figure 49.29 The flexible hoses are reconnected only to remove vapor from the cylinder. The vapor is condensed using water and moves to the recovery cylinder. The scales tell the technician when to stop adding refrigerant to the cylinder.

water cooling circuit to cool the condenser that is used for condensing vapor while recovering. Water from the public water supply is normally used in this condenser and permitted to be dumped down the drain. This is a procedure used only for service, so a permanent water connection is not needed.

SAFETY PRECAUTION: *When charging, vapor should be added to the system until the pressure inside the chiller is well above the pressure that corresponds to freezing. The freezing pressure is 20.3 in. Hg for R-123. The pressure in the machine must be above these two values before liquid refrigerant is introduced. It is good field practice to circulate water through the chiller during this process.*•

49.12 HIGH-PRESSURE CHILLERS

High-pressure chillers must be watched closely for leaks. A visual inspection is something that can be done anytime. Where refrigerant leaks out, oil will leak out also. Anytime a fresh oil spot appears, a leak should be suspected. An electronic leak detector or soap bubbles can be used to check the place out. The soap bubbles must be cleaned off with water or dust will collect on the spot, giving the impression that oil has leaked and dust has collected on the oil. Some systems are designed so that the refrigerant may be pumped into the condenser for repairs on the low-pressure side of the system. Otherwise, the refrigerant may have to be recovered for major repairs. A recovery system and procedures similar to the push-pull system described above is used.

The recovery of high-pressure refrigerants is much like recovering low-pressure refrigerant by means of a push-pull system that will handle high-pressure refrigerants. The same rules apply for charging refrigerant into a high-pressure machine. The pressure in the machine should be above the freezing point of the water before allowing liquid to enter the machine, or a chiller tube may be frozen and broken.

49.13 REFRIGERANT SAFETY

Large equipment rooms become places where refrigerant vapors can gather should there be a leak. These vapors are all heavier than air and will collect without being noticed. They are colorless, almost odorless, and tasteless. Not all vapors are toxic, but they will gradually displace the oxygen in the room. A technician may simply faint when there may be no one around to notice. This would be fatal. Large equipment rooms now have detectors that can detect minute concentrations of refrigerant vapor and sound an alarm. When the alarm sounds, the technician should evacuate the room and only go back in with breathing gear. **Figure 49.30** shows two of these breathing devices, in a yellow case where they can be readily noticed—one is open and the other is closed.

Courtesy Ferris State University. Photo by John Tomczyk

Figure 49.30 This breathing apparatus is mounted where a technician can easily reach it and put it on in case of a refrigerant leak alarm.

49.14 SERVICE TECHNICIAN CALLS

SERVICE CALL 1

A building manager calls and reports that the building is becoming hot. *The problem is that the cooling tower fan has a broken belt and the fan is off. The chiller is off because of high head pressure.*

The technician arrives and asks the manager for any explanation of what is happening. The manager goes with the technician to the basement where the chiller is located. It is a reciprocating water-cooled chiller. The chiller is off, and the technician looks around for the problem. He opens the control panel and notices that the reset button on the high-pressure control is out, signaling that the control needs resetting. The pressure drop across the condenser is normal, and the water temperature is normal (because the chiller has been off, the tower is able to lower the temperature without the fan). The technician resets the button, and the compressor starts. As the technician watches, the compressor starts to load up. Everything runs normally for about 10 min, and then the compressor sounds as though it is straining. The technician feels the water line entering the condenser. It is warmer than hand temperature. The cooling tower water is too hot. The technician shuts the compressor off rather than letting it be shut off by the high-pressure control.

The technician goes to the roof to look at the cooling tower, fully expecting to see it full of algae because the management does not conduct regular maintenance. When on the roof, he notices that the fan belt for the cooling tower fan is broken. He shuts off the disconnect to

the fan, locks it out, and tags it for safety. Writing down the numbers from the old belt, the technician goes to the truck for a new one. While at the truck, he picks up a grease gun for greasing the fan and motor bearings at the cooling tower. The belt is replaced, and the tower fan is turned on. It starts to turn, and the technician can see from the moist air leaving the tower that the water is loaded with heat.

The technician goes back to the basement and touches the water line leading from the tower to the condenser and notices that the water has cooled back to below hand temperature. He restarts the compressor and stays with it for about 30 min to make sure that it will stay on, and it does. He uses this to lubricate the pump and fan motors and, in general, to look for any other potential problems. The technician explains to the manager what happened and what was done to correct the problem. He also explains that he greased the motors, pumps, and fans while observing the system.

The manager thanks the technician for doing a good and efficient job.

SERVICE CALL 2

A building owner reports that the building is hot and the chiller is off. The chiller is a low-pressure R-123 chiller and has an air leak. *The building maintenance personnel have been operating the purge for several days to remove air that is leaking into the chiller and are waiting for the weekend to leak test the machine. The purge water has been valved off and the purge condenser is not operable, causing high purge pressure and releasing refrigerant. This chilled-water system has a total refrigerant charge of 600 pounds.*

The technician arrives at the equipment room where the chiller is located. The building maintenance man is there and explains what has been done. The signal light indicates that the chiller is off because of freeze protection. The technician looks around and notices the purge pressure is very high, as the purge is still running on manual. On inspection, he notices that the purge relief valve is seeping refrigerant. The technician then checks the water circuit to the purge and discovers that there is no water cooling the condenser in the purge. The valve is opened to the purge water condenser. This system uses chilled water, which is now warmed up to 80°F, but will still condense the refrigerant in the purge.

The technician then starts the compressor in the 40% mode and watches the suction pressure; it is not too low, so the load is advanced to 60%. The suction pressure begins to drop. The technician looks in the sight glass at the evaporator for the refrigerant level, and it is low. There is some refrigerant at the sight glass, so the technician gets set up to add refrigerant. The refrigerant drum is piped to the charging valve and the valve is opened. Meanwhile, the technician places a thermometer in the well in the evaporator to check the refrigerant temperature. The chilled-water temperature leaving the chiller is down to 55°F, and the thermometer in the refrigerant reads 43°F. This is a 12°F approach, and it should be 7°F according to the log sheet that was left at start-up. Two hundred pounds of refrigerant is added before the compressor is operated at full load, and the refrigerant approach is lowered to 7°F. The technician is satisfied with the system charge. The chilled-water temperature pulls down to 45°F and the compressor begins to unload in about 30 min. The purge pressure is running normally and not relieving continuously as it had been.

The technician talks to the maintenance man and sets up an appointment to perform the leak check at a later time. The leak in this system must be repaired, as the technician has added 200 pounds of refrigerant to the system, which normally operates with a 600-pound charge. One-third, or 33%, of the charge has leaked from the system and the acceptable annual leak rate for comfort cooling equipment that contains more than 50 pounds of refrigerant is 15%. For this particular system, the maximum allowable annual leak rate is 15% of 600 pounds, or 90 pounds.

SERVICE CALL 3

A building manager reports that the chiller is off and the building is hot. *The problem is that the flow switch in the condenser water circuit has a broken paddle, and the field control circuit is not passing power to the chiller and telling it to start.*

The technician arrives and goes straight to the chiller. The manager is in the chiller room, pacing the floor. He explains that the chiller really needs to be running and there are a lot of complaints of no cooling. The technician gets the manager calmed down with an explanation that it shouldn't take long. This chiller has a ready light on the control panel that indicates when the field circuit is calling for cooling. The light is off. The technician first looks to see what the chilled-water temperature is. It is 80°F; the controller is calling for cooling. The technician then checks the water gauges that register the pressure drop across the chiller and the condenser. The correct pressure drop registers across both, so there is water flow. The technician then goes to the wiring diagram for the system and looks to see

what other controls are in this circuit. The flow switches and the pump interlocks are all in the circuit. It is a matter of tracing the wiring to see what has caused the chiller to shut down.

The technician realizes that the flow switches are likely to be a problem because these devices move a lot since they are located in a moving water stream. The compressor switch is turned off so that the compressor will not try to start during the control testing. The technician removes the cover from the chilled-water flow switch and checks voltage across it. There is no voltage.

NOTE: *If the switch were open, there would be voltage. The cover is replaced and the same test is performed on the condenser-water flow switch and there is voltage. This flow switch is open. The technician jumps the switch with a jumper and the light on the chiller panel lights up. This is the problem.*•

The technician leaves the jumper on the flow switch and starts the chiller. Flow in the condenser-water circuit is not as critical as it would be in a chilled-water circuit. If the water flow were to stop in the condenser circuit, the compressor would shut down because of high pressure. **NOTE:** *The chilled-water flow switch should not be jumped with the compressor running because that could freeze the chiller.*•

The technician explains to the building manager that the flow switch paddle must be replaced. The manager requests this be done after hours, so the technician leaves and will return at 5:00 PM with the parts to repair the switch.

The technician returns to the equipment room to make the repair. The chiller is off for the day because of the energy management time clock. The condenser water pump is turned off and locked. The valves on either side of the condenser system are valved off and the water is drained from the condenser. The flow switch is removed, repaired, and reinstalled. The water valves are turned on, and the condenser system is allowed to fill. Air is vented out of the water system at the high places in the piping. The technician then turns the water pump on in the manual mode and verifies that the flow switch is passing power. By leaving the meter leads on the flow switch and shutting off the water, it can be verified that the flow switch will also shut the system off if the water flow is stopped. The system is made ready to run the next morning when the time clock calls for cooling, and the technician leaves.

The technician calls the building manager the next morning and the manager says, "That was a great job you did for us yesterday. Sorry if I was grouchy, I really was under a lot of pressure." The technician explained that it is all in a day's work—most people are unhappy when their system is not working.

SERVICE CALL 4

A building manager telephones to report that the centrifugal chiller in the basement of the building is making a screaming noise. When he went to the door, he was scared to go in. *The problem is that the cooling tower strainer is stopped up and restricting the water flow to the condenser. The centrifugal has high head pressure causing a surge, which produces a loud screaming sound but is normally otherwise harmless.*

The technician can hear the compressor screaming from the parking lot. When he enters the room, he turns the machine capacity control down to 40% to reduce the load. The machine has high head pressure. The manager shows up and explains his fear of the loud machine. The technician explains, "There is nothing to be afraid of, there are safety controls that prevent damage, but you did the right thing calling for service."

A look at the pressure gauges across the condenser shows that there is reduced water flow, so the technician proceeds to the cooling tower on the roof.

A look at the cooling tower basin shows what has happened—there are tree leaves in the basin. The technician takes off the cover from the cooling tower and removes the leaves from the strainer. Immediately, the water flows faster. The technician replaces the cover to the tower basin, goes to the basement, and turns the capacity control up to 100%.

The technician then talks to the manager about cleaning the cooling tower after hours when the building air-conditioning is off and gets permission to do this.

When the technician returns that afternoon, the system is off because of the time clock in the energy management system. He cleans and washes out the tower, which contains many small leaves. The technician then goes to the basement and prepares to check the condenser for leaves. He valves off and drains the condenser circuit. Then he removes the marine water-box cover on the piping inlet end of the condenser where any trash would accumulate. There are small leaves in the condenser that have passed through the cooling tower strainer. These are cleaned out. While the water-box cover is removed, the technician uses a small penlight and examines the tubes. There is no scale or fouling of the tubes, which is good news.

The water-box cover is replaced, and the valves are opened to the condenser. The technician waits a few minutes for the tower to refill with water after the condenser has been filled and then starts the condenser water pump in the manual mode and verifies there is water flow. This is a necessary step if the condenser is large enough to drain most of the water from the tower; the tower must have time to refill before starting the pump. Now the technician knows that when the machine starts in the morning, there should be no cooling tower water problems.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The technician calls the manager in the morning and verifies that the cooling is working. The technician explains what the problem was and what was done to make the repair. He explains that the condenser water-box cover was removed and the tubes were checked and look good. The manager thanks the technician and says, "Thanks for the explanation, I was really afraid of that machine yesterday." The technician says, "They make a really frightening sound, but it is really only a whistle of the gases in the machine."

SERVICE CALL 5

A building maintenance person calls and says that the chiller is off. A light that says "freeze control" is lit. He wants to know if it should be reset. It is a mild day without much need for air-conditioning. The dispatcher tells him no; a technician will be over within 30 min. *The problem is that the main controller is not calibrated and is drifting, causing the water temperature to fall too low.*

When the technician arrives, the maintenance person leads the way to the chiller, which is on the roof in a penthouse. The technician checks the water flow through the chiller by comparing the pressure in and out to the log sheet, and it is correct. The freeze control is reset, and the chiller compressor starts. When it starts to lower the water temperature, the technician watches the controller. It is a pneumatic controller and as the water temperature drops, the air pressure should drop from the 15 psig furnished. When the water temperature reaches 43°F, the pneumatic air pressure should be 7 psig. When the water temperature reaches 41°F, the air pressure should be 3 psig and the chiller should shut off. This does not happen; the chiller continues to run and the water temperature reaches 39°F without shutting off. The technician then adjusts the controller to the correct calibration. The chiller shuts off.

The technician waits for the chiller to restart when the building water warms up; this takes about 30 min. When it is established that the chiller is operating correctly, the technician explains to the maintenance person what was happening and said that the right thing to do was to call for service. He explained that one should never jump out a freeze control and what the results might be. The technician then leaves.

SERVICE CALL 6

A building manager reports that the chiller is off and the building is getting hot. The chiller is a centrifugal chiller. *The problem is that the building technician has been adjusting the controls and has adjusted the load-limiting control, trying to get the motor to operate at more capacity to reduce the building temperature faster. The compressor was pulling too much current, which tripped the overload device.*

The technician goes to the equipment room with the building technician. The building technician does not reveal that the load-limiting control has been adjusted. The technician checks the field control circuit and discovers that all field controls are calling for cooling. A further check shows that an overload device has tripped. The technician knows that something has happened and that he should use caution.

The technician shuts off the power to the compressor starter and checks the motor windings for a ground or a short circuit from winding to winding. The motor seems fine, so power is restored. There is not much else to do except to start the motor and observe.

The technician starts the compressor in the 40% mode. When the compressor starts to load up, the current is observed. Start-up data show that the compressor should draw 600 A at full load and 240 A at 40%. The compressor is pulling 264 A; this is too much, so the technician turns the load limiter back to 240 A and then turns the selector up to 100%. The compressor begins to load up and reaches 600 A and throttles to hold this current. The technician then turns to the building maintenance technician and asks whether anyone has adjusted the demand limiter. The building technician admits that this has been done and is told that these controls should not be adjusted, because they are reliable. The technician then uses nail polish to mark the setting on the control so that it will be obvious if it is adjusted again.

The technician realizes that the controls belong to the building owner, but they should be adjusted only by a qualified technician. He explains to the building technician that the chiller will only pull the system down so fast, that the limiting factor is the maximum amperage for the compressor. If the system is not getting cool on time, the chiller should be started up earlier, not made to work harder in a short period of time. The technician shows the maintenance technician the ammeter on the starter door where 600 A is marked as full load.

SERVICE CALL 7

A customer calls to say the building is becoming warm and that water is still flowing over the cooling tower, but there is no cooling. The unit is a 300-ton centrifugal with a hermetic compressor. *The problem is the compressor motor is burned and will need to be replaced or rewound.*

The technician goes straight to the equipment room on the 10th floor of an office building. He notices that the building is hot, so there is a problem with the chiller.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The technician checks the field control circuit and discovers that all signals are correct; it is calling for cooling. The technician then goes to the starter and discovers that there is no line voltage to the starter. He then goes to the main power supply and discovers the breaker is tripped. There must be something very wrong.

The technician locks out and tags the breaker and uses a Megger (megohmmeter) to check the motor leads in the starter to ground and discovers a circuit to ground. There is always a possibility that the problem may be in the wiring between the starter and the motor terminals on the motor, so the technician removes the leads from the motor terminals. The motor is checked at the terminals without the wiring and it shows a circuit to ground.

The technician goes to the building management for advice as to the next step. He explains that the motor will have to be removed from the equipment room for replacement or rebuild. 4R *Because the motor is a hermetically sealed motor, the refrigerant will have to be recovered.* 4R The technician explains that there are two possibilities for making the repair. The motor can be replaced with a factory motor, which may take several days for delivery, or the motor may be rebuilt at a local rebuild shop that is approved for work with hermetic motors. Building management gives permission to proceed with the rebuild job to save time because the building must have air-conditioning. Like many modern buildings, no windows open and the computers rely on the air-conditioning.

The technician calls the home office and requests backup help and the tools recommended for the job. These would include a hoist to lift the motor and a dolly to transport it onto the elevator and out to the truck, which is equipped with a lift gate.

While the helper is getting the tools together, the technician prepares to pull the motor. 4R *The refrigerant is recovered from the machine using the recovery system brought by the helper. Water in the chilled-water circuit and condenser water are circulated through the machine during recovery to prevent the tubes from freezing and to aid in boiling the refrigerant out of the machine. The system refrigerant is stored in DOT-approved recovery cylinders. The machine uses R-123 and the refrigerant will be checked for acid content and recycled for reuse in the machine, if needed. Once the refrigerant has been recovered from the system, the technician breaks the vacuum with dry nitrogen that has been brought by the helper.* 4R Breaking the vacuum with dry nitrogen will minimize oxidation inside the machine when it is opened to the atmosphere. The machine is made of steel inside and it will quickly rust.

The technician then removes the wires from the motor terminal box and starts to disconnect the compressor from the motor. When the motor is free to move, the hoist is set up and the motor is set on a rolling dolly to transport it to the truck. The motor is then rolled onto the lift gate, lifted to the back of the truck, and secured. The helper takes the motor to the motor shop for rebuild. This will take about 48 hours. It is now 2:30 on Tuesday.

The technician goes back to the equipment room and prepares the equipment for when the motor is returned. A sample of the refrigerant and a sample of the refrigerant oil from the compressor sump are pulled and shipped by next-day carrier to a chemical analysis firm. The report can be called in by Wednesday afternoon to determine what must be done about the refrigerant. The refrigerant and oil sample do not smell as though they have very much acid, but the analysis will reveal the facts.

The technician checks the contacts in the starter. There must have been quite a surge of current when the motor grounded. The contacts are good and do not require replacement.

The oil heater is turned off, locked, and tagged, and the oil is removed. The technician then cleans all gasket sealant from all compressor flanges and is now ready for the motor to be returned. Time has been saved by doing all of this before the motor is brought back.

Thursday morning, the technician checks with the rebuild shop and is told the motor will be ready by 11:30 AM. He arranges for the helper to pick up the motor and a compressor gasket kit. They meet at the building at 1:00 PM and proceed to install the motor. The motor is moved to the equipment room and lifted back into place. All gaskets are installed and everything is tightened. This system has a history of being very tight, so the only leak checking that needs to be performed is on the fittings, including the gasketed flanges that were removed and in the area where the work was done.

When all is ready, the machine is pressured with nitrogen to 10 psig for a leak test. The machine is leak checked and found to be good. The nitrogen and refrigerant are exhausted, and it is time to pull the vacuum. The motor leads are connected to the motor terminals.

The vacuum pump is installed and started. It will take about 5 hours to pull the vacuum down to 1000 microns on the micron gauge and it is 5:30 PM. The technician leaves the job and decides to come back at 10:30 PM to check the vacuum. If the vacuum can be verified this evening and the vacuum pump shut off for 8 hours, the machine can be started in the morning if all is well. The technician checks the vacuum at about 11:00 PM, and the micron gauge reads 700 microns. The vacuum pump is valved off, and the technician leaves to return in the morning.

When the technician arrives at 7:30 AM, the micron gauge reads 900 microns, so the machine is leak-free and it is time to charge the system. The refrigerant and oil report came back "OK," so no extra precautions need to be taken

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

with the refrigerant. The technician starts the chilled-water pump and the condenser water pump in preparation for start-up. A drum of refrigerant is connected to the machine at the drum vapor valve. The valve is slowly opened to the machine and vapor is allowed to enter until the pressure is above that corresponding to freezing. This is important because if liquid refrigerant is allowed to enter the machine at such a low pressure, the tubes may freeze. The chilled water is circulating, but if there is one tube that does not have circulation, this tube may freeze. The pressure in the machine must be above 19 in. Hg vacuum to prevent freezing while charging liquid.

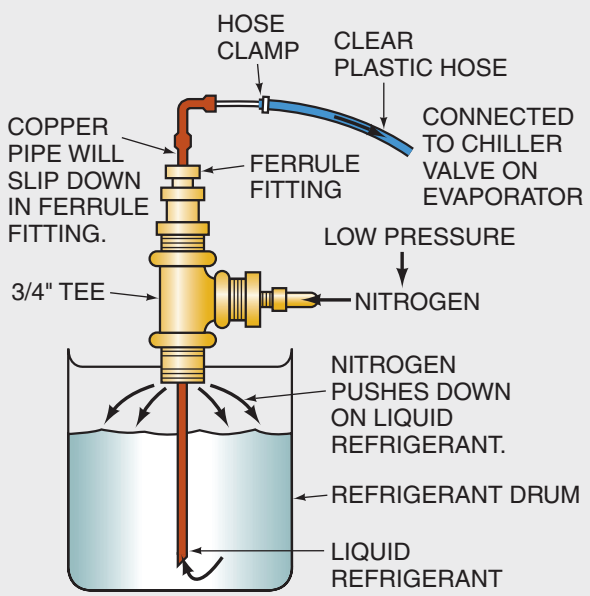
When the machine pressure reaches 19 in. Hg vacuum, the technician starts charging liquid refrigerant. While he is charging refrigerant, the helper pulls the oil in the oil sump using the machine vacuum. When the oil is charged, the oil heater is turned on to bring the oil up to temperature.

The technician is not able to charge all of the refrigerant into the machine using the vacuum because the chilled-water circuit warms the refrigerant and pressure is soon raised. The technician then changes over and pushes the remainder of the refrigerant into the machine by pressuring the drum with nitrogen on top of the liquid and drawing liquid from the bottom of the drum, **Figure 49.31**.

The technician starts the purge pump to remove any nitrogen that may have entered the system while charging, even though he was careful and could see no nitrogen in the clear charging hose while charging. The purge pressure does not rise, so the machine should be free of nitrogen. The technician has closed the main breaker and is ready to start the machine. The machine is started and quickly turned up to 100% to reduce the building temperature as quickly as possible. There is no apparent reason that the motor developed a circuit to ground; the motor rebuild shop could not find any problem, so the motor failure is accounted for as random failure.

The chiller is quickly pulling the building water down to 45°F leaving-water temperature. The technician calls the building manager and explains that the chiller is on and operating normally. It will take several hours for the building temperature and humidity to return to normal. The building manager thanks the technician for doing a fast, professional job. The technician stays with the chiller for 2 hours and completes entries (including the motor current) in an operating log. When it is determined that the system is functioning properly, the technician leaves.

Figure 49.31 Using nitrogen to charge refrigerant into a low-pressure chiller. The clear plastic tube will tell the technician when any nitrogen is passing into the system.



SERVICE CALL 8

The technician is called to do routine maintenance on a reciprocating chiller. *This chiller has not had maintenance in several years. The last technician did not take proper care of the service valves and the suction service cap is rusted tight to the valve body.*

When the technician arrives and talks to the building manager about what should be done, the manager says, "Give the system a good check up." It is determined that the suction and discharge pressure should be measured to determine whether the chiller, an air-cooled chiller using R-134a, is operating correctly. The technician removes the protective cap from the discharge service line and installs a high-pressure gauge. The head pressure is 146 psig and the outside temperature is 80°F, so the head pressure is good (80 + 30 = 110°F condensing temperature).

The technician then attempts to remove the cap from the suction service valve and discovers the cap is rusted tight. He uses a soft-face hammer and taps hard on all of the flats on the cap, then uses a hex-jaw wrench, **Figure 49.14**, to loosen the cap. It still will not turn. He uses a heavier steel hammer to tap the flat surfaces on the valve, and it still will not loosen. The technician then uses the hammer to tap the handle of the wrench and sees the cap begin to turn. It is not good practice to hit a wrench handle with a hammer, but sometimes this is necessary. If the valve cap is struck too hard, it may split because

it is cast iron. Cast iron can be brittle and breaks easily. Spraying a penetrating oil would help, but doing that will gather dust and lead the next technician to believe there is a leak.

When the valve cap is removed, the technician sees there has been moisture inside the cap for a long time. The valve stem is really rusty with scale buildup on it.

He cleans the valve stem with a fine sand tape until there are no more high spots on the stem. He then slightly loosens the packing gland and turns the valve stem forward until a gauge reading is obtained. The suction pressure reads 39 psig. The chilled water in is 50°F, and out, 45°F. The chiller would normally have a 10°F difference and the suction pressure would normally be 36 psig. The chiller has the correct water temperature, so it is running at half capacity to fit the building's load. All is well.

The technician shuts the system off for about 30 min to give the chilled-water temperature a chance to warm up—at which point the technician will start the system up and run it at full load. Meanwhile, he greases the pump motor and examines the inlet to the condenser to see if it needs cleaning. The fan motors are examined, and they are permanently lubricated motors.

When the chiller is started back up, the suction pressure reduces to 36 psig, the compressor is now pulling full-load amperage, and the sight glass to the expansion valve is full. The chiller is running as it should. The technician then places a thermometer lead to the refrigerant liquid line, just before the expansion valve, and determines that the unit is operating with 15°F of subcooling. This tells the technician that the refrigerant charge is correct for the chiller.

The technician back seats both service valves and tightens the packing gland nut and cleans the inside of the valve cap of the suction service valve to remove the rust. He then takes a small wire brush and cleans the threads on the valve body. The technician wipes the valve stem, sprays oil-free silicone spray on it and on the inside of the valve cap, and turns the cap onto the valve body. It is tightened with the square jaw wrench.

The technician then uses an electronic leak detector and leak checks all around the service valves where service has been performed. He then reports the results to the building manager. The system is good to go for another season.

SUMMARY

- The operation of chilled-water air-conditioning systems involves starting, running, and stopping the chiller systems in an orderly manner.
- When starting a chilled-water system, first check for sufficient chilled-water flow. If the system is water-cooled, check for condenser water flow. The interlock circuit through the contactors must be satisfied—the cooling tower pump followed by the compressor. There may be a time delay before the compressor starts.
- The reciprocating, scroll, and rotary screw compressors may be either air- or water-cooled.
- The centrifugal chiller will have a separate oil lubrication system. That the lubrication system is functioning satisfactorily should be verified before starting the compressor.
- After the chiller is on and operating, the technician should observe the operation for a period of time to ensure that it is all operating correctly.
- Water-cooled chillers must have water treatment to prevent minerals and algae from collecting and forming.
- Inspecting and cleaning the water tower should be done on a regular basis.
- Water-cooled condenser tubes should be checked at least annually. If they are found to be not clean or to have a scale buildup, they must be cleaned either with a brush or chemically.
- Condenser and evaporator tubes may be checked for defects with an eddy current test instrument.
- Absorption chilled-water system and compression cycle system start-up are similar in many respects. Condenser and chilled-water flow must be established before the chiller is started. The cooling tower water must not be too cold or the Li-Br may crystallize.
- Absorption chillers must be observed for proper operation on a more regular basis than compression cycle chillers because they can be more intricate.
- On the absorption chiller, the purge system may require more maintenance than on other systems. The vacuum pump oil should be changed regularly.
- Technicians who maintain chillers should stay in contact with the manufacturers of the equipment for the latest information, advice, and schedule for service schools.

REVIEW QUESTIONS

1. How does the compressor lubrication system differ for reciprocating and centrifugal compressors?
2. True or False: Most reciprocating compressors have crankcase heaters.
3. True or False: All reciprocating compressors start up fully loaded.
4. Describe how a centrifugal compressor starts up at part load and then goes to full load.
5. What system component must be started before the compressor in a chilled-water system?
6. When condenser tubes become fouled, they may be cleaned by
   A. using a steel brush.
   B. using a brass brush.
   C. using a chisel and hammer.
   D. running a mixture of sand and water through them.
7. Describe what happens when an absorption chiller is operated when the cooling tower water is too cold.

UNIT 50

COMMERCIAL, PACKAGED ROOFTOP, VARIABLE REFRIGERANT FLOW, AND VARIABLE AIR VOLUME SYSTEMS

OBJECTIVES

After studying this unit, you should be able to

- list various types and configurations of rooftop units.
- list the five air-conditioning processes that are often performed by rooftop units.
- describe the various blowers and fans commonly found on rooftop units.
- list the steps required to properly install a rooftop unit.
- explain how rooftop units are typically brought up to the roof.
- describe various parts of a crane used to rig air-conditioning equipment onto a roof.
- demonstrate the hand and body signals used to communicate with the crane operator.
- explain how rooftop units are positioned on the roof.
- explain the function and installation of a roof curb.
- explain the purpose of an economizer.
- explain the function of an enthalpy control and a dual enthalpy sensor.
- list and describe the four basic modes of economizer operation.
- explain the importance of ASHRAE Standard 62 as it pertains to the proper design of ventilation systems.
- describe the concept of demand control ventilation (DCV).
- explain how carbon dioxide (CO_2) sensors can be used to help control the ventilation process.
- explain the concept of variable air volume (VAV).
- explain the differences between constant air volume (CAV) and variable air volume (VAV) systems.
- list and explain the four common configurations of VAV boxes or terminal units.
- explain the function of a reheat coil.
- name and describe the two types of valves used to control the flow of hot water through a reheat coil.
- explain the operation of a chilled-water variable air volume (VAV) system.
- explain the concept of variable refrigerant flow (VRF).
- explain the difference between a two-pipe VRF installation and a three-pipe VRF installation.
- explain the operation of a dry cooler.
- describe various applications for which dry coolers are best suited.
- explain how dry coolers can be used to effectively provide space cooling year round.

SAFETYCHECKLIST

- ☑ Quite often, access to a commercial roof is gained by using an extension ladder. Be sure the ladder's feet are positioned level on solid ground, the top of the ladder extends at least two rungs above the roof line, and the ladder is properly tied and secured to prevent it from falling over.
- ☑ Always inspect extension ladders prior to use to ensure that all rungs and locking mechanisms are operational and not damaged.
- ☑ Roof penetrations must be made for the installation of rooftop equipment. Be sure to take every precaution to prevent anyone from falling through the roof.
- ☑ Make certain that the roof is designed to handle the weight of the equipment. In some instances, roof reinforcement may be necessary. Failure to do this may result in equipment damage, severe personal injury, or death.
- ☑ When making roof penetrations, be sure to seal off any areas under the penetration location so that injury does not result from falling debris.
- ☑ When working on rooftop equipment, make every effort to stay as far away from the edge of the roof as possible to reduce the possibility of injury.
- ☑ When equipment is being lifted onto or from a roof, do not stand under the unit.
- ☑ Use all pertinent pieces of personal protection equipment (PPE), such as hard hats, eye protection, gloves, work boots, back support, and safety harnesses.
- ☑ Roofs can be slippery. Make certain that conditions are safe before accessing the roof.
- ☑ Tools and equipment should be lifted to the roof by rope or other means. Individuals should not carry tools, parts, or supplies up a ladder. At least one hand must be holding onto the ladder at all times.
- ☑ The surface of a roof can be much hotter than the ambient air temperature, so be sure to take proper precautions to prevent heat-related injuries.
- ☑ Silver-colored roofs reflect sunlight and can cause sunburn. Be sure to wear protective clothing and use appropriate sunscreen.
- ☑ Before installing or servicing equipment, make certain to read all literature and observe all guidelines and recommendations.
- ☑ Know the type of refrigerant that is contained in a system to avoid injury and possible equipment damage.
- ☑ Always protect yourself from excessive heat and excessive cold by wearing proper articles of personal protection equipment.
- ☑ Do not ingest glycol or other antifreeze products. Although sweet to the taste, ingested ethylene glycol can form oxalic acid, which is toxic.

50.1 ROOFTOP PACKAGE UNITS

Package units are factory-assembled, factory-charged, self-contained systems that contain all of the major system components in a single housing, **Figure 50.1**. Since the compressors, condensers, metering devices, and evaporators are all in the same cabinet, installing package equipment does not require the installation crew to install refrigerant lines, leak check or evacuate the system, or adjust the refrigerant charge of the unit. Information regarding the amount and type of refrigerant in the unit is provided on the unit's nameplate. The amount of refrigerant indicated on the unit's nameplate is the total refrigerant charge for the unit, not simply a holding charge as in the case of a split-type system. This is useful information because, in the event of a total refrigerant loss, the service technician can, after repairing the system, weigh in the exact amount of refrigerant needed.

The refrigerant piping on a rooftop unit can be configured either as a single circuit or a multiple circuit. A single-circuit system typically has one compressor, one condenser circuit, one metering device, and one evaporator circuit. When the compressor is energized, refrigerant will flow through the entire refrigerant circuit. Varying the capacity of a piece of cooling equipment with single-circuit piping is more complicated than with a multicircuit piping arrangement. In a multiple-circuit configuration, there is more than one active refrigerant circuit. For example, a 10-ton, two-circuit setup might have two separate circuits with separate 5-ton compressors. When the heat load on the system is low, one compressor will be operating, allowing the system to operate as a 5-ton system. As the load on the structure increases, the second stage or circuit will be energized, allowing the system to operate as a 10-ton system.

A more sophisticated arrangement might utilize circuits of different capacities, such as a 4-ton circuit and a 6-ton circuit, **Figure 50.2**. When the load on the structure is low, the 4-ton circuit might be energized. As the load on the system increases, the 4-ton circuit can cycle off as the 6-ton circuit comes on line. If the load on the system continues to increase, the 4-ton circuit will then cycle on to bring the system capacity to 10 tons. When configured in this manner, the system can operate at 4, 6, or 10 tons as opposed to the 5 or 10 tons if the circuits are similarly sized. Of course, using inverter-controlled compressors will allow the system to closely match the heat load on the space.

Although not required, packaged units are typically located on the roof of the building, and when so located, the acronym RTU (rooftop unit) is commonly used. Depending on the building, several rooftop package units may be needed, **Figure 50.3**. When multiple rooftop units are used to condition the air in a building, it is common practice to label them and their corresponding thermostats, **Figure 50.4**. This makes it easier for the service technician to identify the piece of equipment that is being controlled by a particular thermostat.

Rooftop packaged units are often configured with a number of features that allow for total air treatment. These features include cooling, heating, exhausting, ventilating, and filtering. In general, a rooftop packaged unit operates as follows. Air from the conditioned space is brought up to the unit. Depending on the requirements of the structure, some of this air may be exhausted from the system to the outside of the building. The air that is not exhausted is mixed with air from the outside. The amount of outside air that is mixed

with the return air varies with the needs of the building. This mixed air is filtered and either heated or cooled before being returned to the occupied space by the blowers within the unit, **Figure 50.5**.

ROOFTOP BLOWERS AND FANS

The rooftop unit houses the fans and blowers that move air through the heating and cooling portions of the unit as well as through the air-cooled condenser. The blower that is responsible for moving air through the heating and cooling coils is a forward-curved centrifugal blower and has the ability to overcome the pressures that are present in the air distribution system. Depending on the system, the blower may be a constant-volume blower or a blower that can modulate the volume of air circulated. Refer to the section on variable air volume (VAV) in this unit for more on variable-volume supply blowers.

The fans that move air through the air-cooled condensers are of the propeller type, which are desirable when large static pressures are not present. They have the ability to move large volumes of air at low pressure differentials. Many rooftop package units are equipped with multiple condenser fans, **Figure 50.6**. These fans often have control configurations that allow them to cycle on and off to maintain the desired head pressure in the system. Typically, some of the fans will operate whenever the system is in the cooling mode while the remaining fans will cycle on and off as needed to raise or lower the head pressure. *Some condenser fans have the ability to modulate airflow by changing motor speed instead of cycling on and off. By ramping motor speeds up and down as opposed to starting and stopping the motor, wear and tear on the motor is reduced and significant energy savings are achieved.* Refer to Unit 17, "Types of Electric Motors," for more information on these motors. Some rooftop package units contain relief fans. Relief fans are located in the exhaust air path of the RTU. Their purpose is to help raise the pressure of the air being exhausted from the return airstream to the outside. Since the exhaust dampers offer some resistance to flow, the relief fan helps the air overcome it.

50.2 INSTALLATION OF PACKAGED ROOFTOP UNITS

Although packaged air-conditioning equipment comes precharged with refrigerant and require no field piping, installing a rooftop unit involves many steps and can be very

dangerous. Roof penetrations must be made and the dangers associated with falling from substantial heights are very real. In addition, cranes or helicopters are often used to rig the equipment to the roof, creating additional potential for personal injury. Elements of a rooftop unit installation include:

- Selection of unit location
- Roof penetration
- Installation of the curb and roof sealing
- Rigging of the unit to the roof
- Installation of required electric circuits, both power and control
- Installation of fuel lines for heating mode of operation, if needed
- Installation of return and supply ductwork

SELECTION OF UNIT LOCATION

Rooftop units are often positioned directly above the space that is to be served by the equipment. Although this is the ideal situation, it is not always possible or the best alternative. The unit's location should be carefully selected so that its operation is not adversely affected by air being able to circulate back through the condenser coil or by air not being able to flow freely through the coil, **Figure 50.7**. Improper condenser airflow could be caused by a low overhang above the unit or by positioning the unit too close to a wall or interior corner, **Figure 50.8**. Always refer to the installation and service data provided with the equipment and adhere to all clearance guidelines. Insufficient clearances can affect system operation. In addition, the future servicing of the equipment should be taken into account when locating the unit. It is important that the service technician have access to all portions of the system and be able to remove, service, or replace parts as needed. Improper clearances can have a negative effect on the ability of service personnel to perform their jobs adequately. In areas that have snowfall, it is important that potential snow accumulation be accounted for. The unit should be mounted on a support structure that will keep the unit above the snow level, **Figure 50.9**.

The limits of the crane must be considered as well when selecting the roof location. Specific cranes will be able to lift only so much weight and extend booms only so far without tipping over. If the crane cannot successfully deposit the unit at its proper location, it will have to be moved manually across the roof. Foresight with respect to this is important, and potential obstacles need to be addressed early on in the installation process.

ROOF PENETRATION

Roof penetration is done only after determining the location of the unit. It is good field practice to double-check and possibly triple-check the location, since the cost of repairing an improperly cut roof can be very high. Some roofs are bonded, which means that there is a written warranty or insurance policy that protects the building owner in the event of damage from leaks. Any penetrations of a bonded roof must be made by the company that provided the bond or one that is recommended by the bond-issuing company. Ignoring these guidelines can result in severe financial obligations in the event of roof failure. If you are not certain whether a roof is bonded, it is best to check first and cut later.

When penetrating a roof, it is important to keep the following in mind:

- Measure twice, cut once. Roof repairs can be very expensive, so be sure to check the accuracy of all measurements.
- Do not assume that the size of the cut should be the same as the interior measurements of the roof curb. The penetrations should only be large enough to accommodate the ducts and pipes that must pass through.
- Maintain integrity of the roof. Be sure that you do not remove any load-bearing or structural elements.
- Reinforce as needed. Be sure to reinforce any roof sections that may have improper support due to the penetration.
- Properly vacate areas under penetration locations. Do not perform any penetrations until the areas underneath have been roped off and vacated. Falling debris can damage property and people.
- Properly isolate rooftop areas where cuts are made. Roof penetration should never be done at the same time the roof curb and units are being installed. Improper lighting and distractions can result in an individual falling through the hole. Be sure to take all precautions to alert people and prevent falls.
- Wear proper articles of personal protection equipment (PPE). The penetration process is dangerous and can result in flying debris. Be sure to properly protect yourself and those working around you.
- Avoid coming in contact with sharp edges. Roofing materials can be very sharp, so be careful when handling them.
- Avoid positioning yourself under the roof as the penetration is made. Whenever possible, be over the penetration area, not under it, to avoid being hit by roofing materials.
- When in doubt, ask for help. If you are unsure about the process, do not be afraid to ask for assistance. At the end of the day, it is much better to be safe than sorry.

ROOF CURB INSTALLATION AND ROOF SEALING

The rooftop unit is often set on a curb, **Figure 50.10**, which is a frame used to mount HVAC/R equipment. Curbs can be prefabricated, but many larger curbs are shipped unassembled. Assemble the curb according to the manufacturer's guidelines, making certain to properly caulk and seal all joints and seams. Be sure to read the entire installation booklet prior to beginning installation.

Gasketing materials and foam panels that are shipped with the curb are part of the curb and should not be discarded. Gaskets help ensure a leak-tight seal between the unit and curb. The foam panels are intended to help deaden the noise that is produced in the compressor/condenser section of the unit.

If the curb is mounted as part of new construction, it can be assembled and installed as soon as the roof support system is in place. Whenever possible, the curb should be positioned directly on the roof supports and fastened to them using tack welding or other acceptable methods. If the curb is mounted directly on the roof, nailing plates must be provided below the curb flanges to secure it. Properly supporting and securing

Figure 50.11 The curb must be properly sealed to prevent water leaks.

Photo by Eugene Silberstein

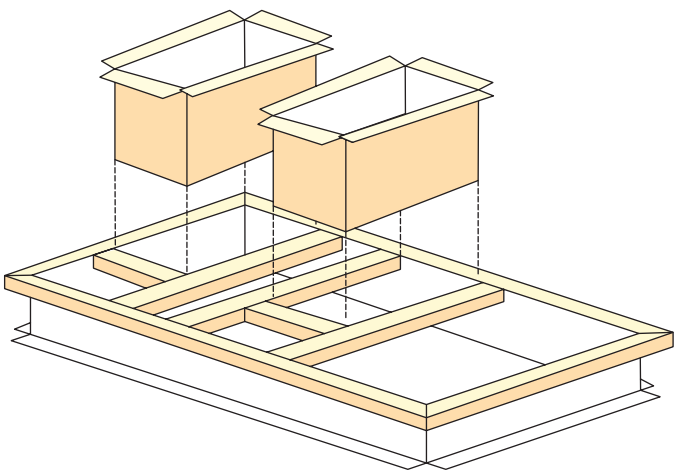
the curb will help minimize the potential for leaks and noise transmission from the system to the occupied space below. Once the curb has been installed, make certain that the roof is properly sealed. Improperly sealed penetrations can lead to leaks, which can cause major property damage, **Figure 50.11**.

INSTALLATION OF RETURN AND SUPPLY DUCTWORK

It should be noted that, in most cases, the supply and return ductwork must be attached to the curb before the unit is set in place, **Figure 50.12**. All ductwork must be properly fabricated, insulated, lined, and installed. To make sure of this, follow all of the industry-accepted processes and procedures.

SAFETY PRECAUTION: *The curb's cross braces are intended to support the duct connections to the unit, not the entire air distribution system. Be sure to provide proper and adequate support for the duct system according to local building codes.*•

Figure 50.12 Supply and return ducts must be connected to the curb before the unit is set in place.



RIGGING OF THE UNIT TO THE ROOF

The process of rigging involves placing the new unit on the roof as well as removing the old unit from the roof when a system changeout is being done. The rigging process is performed by a rigging contractor that often gets paid by the hour, not the job. Since rigging costs can be substantial, it is best to have everything ready to go when the crane arrives at the job site. Before the rigger arrives, the following tasks should have been completed:

- The old equipment to be removed from the roof should be completely disconnected. This includes all electrical, piping, gas, and any other connections between the equipment and the building.
- Measurements pertaining to the location of the curb on the roof should be taken so that the crane operator has a good idea of where the unit will be placed before starting.
- A crew consisting of at least three members should be on hand. One crew member will be in charge of giving the appropriate hand signals to the crane operator, **Figure 50.13**, while the other two crew members will guide the unit to the proper location on the roof, **Figure 50.14**. Some hand signals that are commonly used to give instructions to the crane operator are provided later in this unit.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

SAFETY PRECAUTION: *When working with cranes, the use of proper hand signals is required by the Occupational Safety and Health Administration (OSHA), the American National Standards Institute (ANSI), and the American Society of Mechanical Engineers (ASME).*•

- The curb should have been installed on the roof. This includes the mounting of the curb, making the necessary roof penetrations, and sealing the curb to the roof.
- Equipment gaskets and insulation materials that are positioned between the curb and the unit must be in place.
- On units that have their duct connections on the bottom, the supply and return ductwork must be attached to the curb.
- All necessary permits pertaining to the rigging, such as street closures, must be obtained long before the rigger arrives.
- Arrangements for the removal of the old equipment, where applicable, must be made. Quite often, the rigging company will remove and dispose of the old equipment.

CRANE INFORMATION

The crane itself is a massive piece of equipment, and it requires a highly skilled individual to safely operate one, **Figure 50.15**. A well-trained crane operator can make easy work of setting or replacing a piece of rooftop equipment. It is beneficial for technicians who will be working with cranes to have at least a basic understanding of the crane and its components. Some common crane-related terms include:

Main hoist
Auxiliary hoist (whip line)
Cable or line
Outriggers
Boom
Boom extension markings

Some cranes are equipped with two hoists; others have only one. When there are two hoists, one is the main hoist and the other is the auxiliary hoist, **Figure 50.16**. The line is the cable that is attached to the hook on the crane. Outriggers extend from the sides of the crane and increase the base on which it rests. This makes the crane more stable and less likely to topple, **Figure 50.17**. The boom is the largest and most visible part of the crane. It is the telescopic, steel arm of the crane that is responsible for lifting and/or lowering the load, **Figure 50.18**. The markings on the boom tell the crane operator how far the boom has been extended, **Figure 50.19**.

Figure 50.15 A typical crane.

Figure 50.16 Main and auxiliary hoists on a crane.

Photo by Eugene Silberstein

Figure 50.17 Outriggers on the side of the crane.

Photo by Eugene Silberstein

COMMUNICATING WITH THE CRANE OPERATOR

Since the crane is often located at ground level and the HVAC/R installation crew is on the roof to accept delivery of the equipment, communication between the roof crew and the ground crew can be difficult. In addition to the physical distances between the crane operator and the installers, cranes and job sites in general can be noisy, making the communication process even harder. For this reason, a set of industry-accepted hand and body signals is used by the installation crew to give nonverbal instructions to the crane operator.

Since many cranes have a main hoist and an auxiliary hoist, known as a whip line, there are hand signals that tell the crane operator which hoist to use. By tapping his fist on his head, the crew member is telling the crane operator to use the main hoist, **Figure 50.20(A)**. By tapping his elbow with one

Figure 50.18 The boom on a crane.

Photo by Eugene Silberstein

hand, the crew member is telling the crane operator to use the whip line, or auxiliary hoist, **Figure 50.20(B)**. The boom can either be extended or retracted depending on the hand signal given. With both fists in front of the body, pointing the thumbs outward tells the crane operator to extend the boom; pointing the thumbs inward tells the operator to retract the boom, **Figure 50.21**. The boom can also be raised or lowered depending on the hand signal given. With an extended arm and closed fist, an upward-pointing thumb tells the operator to raise the boom; a downward-pointing thumb tells the operator to lower the boom, **Figure 50.22**. The boom may also need to be rotated. If such is the case, an extended arm with an extended, pointing index finger tells the crane operator which way to rotate the crane, **Figure 50.23**. During the rigging process, the load will have to be raised and lowered. By raising the forearm in the air, index finger pointing upward, and rotating the hand in small circles, the operator will know to raise the cable on the crane, **Figure 50.24**. By extending the arm downward, index finger pointing downward, and rotating the hand in small circles, the operator will know to lower the cable on the crane, **Figure 50.25**. An extended, palm-down hand tells the crane operator to stop. In an emergency, a rapidly shaking (from side to side) extended palm-down hand tells the operator to stop immediately, **Figure 50.26**. Some cranes are mobile

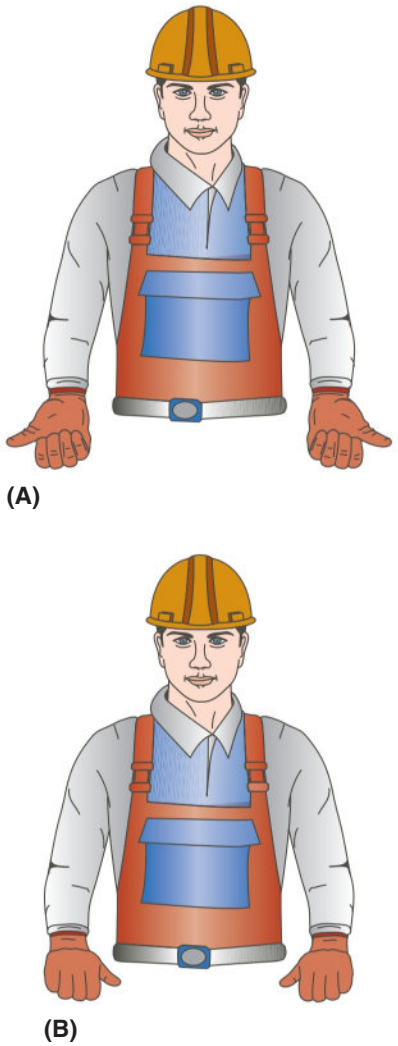
and have the ability to roll or travel during operation. In such cases, an extended and slightly raised arm with an open hand gives a pushing signal to tell the crane operator which way to roll the crane, **Figure 50.27**.

INSTALLATION OF REQUIRED ELECTRIC CIRCUITS AND FUEL LINES

In addition to making provisions for the supply- and return-air ductwork connections between the rooftop unit and the space below, electrical and fuel connections must also be made.

Figure 50.21 (A) Signal to extend the boom. (B) Signal to retract the boom.



Depending on the equipment and installation, these lines may be brought into the unit within the space occupied by the curb. If such is the case, the sealing of the roof curb, by default, also provides adequate sealing of the electrical and piping runs. If the piping and electrical penetrations are made outside of the curb area, a pitch pocket or pitch pan is often used. A pitch pocket is a flanged piece of roof flashing positioned around irregularly shaped roof penetrations. The pitch pocket must then be properly sealed to prevent leaks. It is good field practice to avoid using pitch pockets whenever possible, as they increase the chances of roof leaks, **Figure 50.28**.

50.3 ECONOMIZERS

Most rooftop packaged units are equipped with economizers, **Figure 50.29**. Economizers are intended to perform two main functions. One function is to help provide the correct amount of ventilation air to the structure as required under ASHRAE

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Figure 50.23 By an extended arm and a pointed finger, the crane operator knows which way to rotate the boom.

Standard 62, which will be discussed later in this unit. The second function is to help reduce cooling costs by allowing outside air into the air conditioning equipment when the outside air conditions are favorable and able to meet at least part of the cooling needs of the structure. By using outside air to help cool the structure, the vapor-compression refrigeration system will not need to operate as frequently, thereby saving energy. This is referred to as economizing. But, how is it determined if the outside air conditions are favorable or not to help cool the structure?

Figure 50.24 Hand signal for raising the cable.

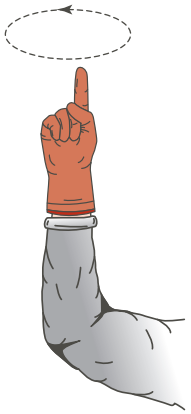

Figure 50.25 Hand signal for lowering the cable.

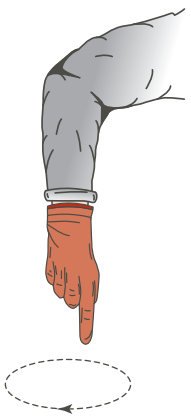

Two common control types are used to help determine if the outside air can be used to provide some system relief: dry-bulb and enthalpy-sensing devices. Dry-bulb and enthalpy sensors can each be used in conjunction with two common control strategies to establish if the outside air is capable of reducing the load on the cooling equipment. One method is to measure the dry-bulb temperature of the outside air and/or the return air, while the other is to measure the enthalpy, or heat content, of the outside air and/or the return air, **Figure 50.30**. One of the important functions of these controls is to set the high limit, or cut-out point, for economizer operation. The high limit for an economizer is the point at which economizing will end if the sensed conditions are above the desired levels. The strategies for controlling the economizer's high limit are:

- Fixed dry-bulb
- Differential dry-bulb
- Fixed enthalpy
- Differential enthalpy

FIXED DRY-BULB

The fixed dry-bulb type of control is the least expensive and is commonly found on older economizer systems. This type of control utilizes a fixed set point for the outside air. If the outside air is warmer than the set point, no economizing will take place. This means that the amount of outside air being brought into the structure will be in line with the ventilation requirements for the space. For example, if the set point on the control is 68°F and the outside ambient temperature is 70°F, the economizer mode will not be utilized. However,

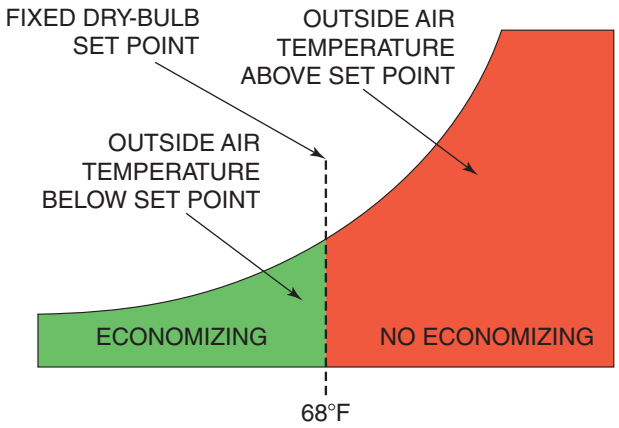
Figure 50.31 The set point of the fixed dry-bulb control sets the boundary between the economizing and the non-economizing modes.



if the outside ambient temperature is 65°F, the economizer mode will be utilized, **Figure 50.31**.

Newer systems do not measure only the dry-bulb temperature of outside air, because the air's actual heat content cannot be determined and the operation of the economizer will not be as accurate. Enthalpy controls are the norm on new equipment. The term enthalpy refers to the total heat content in the air, which accounts for both the temperature (sensible heat portion) and the moisture content (latent heat portion) of the air. Consider the psychrometric chart in **Figure 50.32**. If a dry-bulb thermometer indicates that the outside-air temperature is 90°F, the enthalpy of the outside air could be 45.3 Btu/lb if the relative humidity is 70%, or 35.2 Btu/lb if the relative humidity is 40%. However, if an enthalpy control is used, the exact heat content of the air will be known and the economizer can adjust accordingly. Enthalpy controls are discussed a little later in this section.

DIFFERENTIAL DRY-BULB

Unlike the fixed dry-bulb control, the differential dry-bulb control uses a *variable* set point for the outside air. This type of control uses a return air temperature (RAT) sensor as well as an outside air temperature (OAT) sensor. The differential dry-bulb control compares the difference between the return air temperature and the outside air temperature. If the outside air temperature is higher than the return air temperature, the economizer is disabled. If the outside air temperature is lower than the return air temperature, the economizer is enabled. Mathematically, the operation of the device looks like this:

$$\text{If OAT} - \text{RAT} > 0 \text{ ECONOMIZER DISABLED}$$

$$\text{If OAT} - \text{RAT} < 0 \text{ ECONOMIZER ENABLED}$$

For example, if the outside air temperature is 90°F and the return air temperature is 70°F, we get:

$$\text{OAT} - \text{RAT} = 90°\text{F} - 70°\text{F} = 20°\text{F}$$

Since 20 is greater than zero, the economizer is disabled. On the other hand, if the outside air temperature is 60°F and the return air temperature is 70°F, we get:

$$\text{OAT} - \text{RAT} = 60°\text{F} - 70°\text{F} = -10°\text{F}$$

Since −10 is less than zero, the economizer is enabled.

FIXED ENTHALPY

The fixed enthalpy high limit is more sophisticated than the dry-bulb high limit controls. Enthalpy sensors include both solid-state temperature and humidity sensors. The enthalpy control measures the *total heat content* of the outside airstream. The total heat content measurement is then compared to a preset set point in the control, which is often close to 28 Btu/lb, but can be changed depending on the particular climate in which the system is installed. If the heat content of the outside air is greater than the set point, the economizer is disabled. If the heat content of the outside air is lower than the set point, the economizer is enabled, **Figure 50.33**.

DIFFERENTIAL ENTHALPY

The differential enthalpy high limit is a very expensive high limit strategy. This control measures the enthalpy, or *total heat content* (h), of the outside airstream as well as the *total heat content* of the return airstream. These two values are then compared to each other. If the heat content of the outside air, h_{OA}, is greater than the heat content of the return air, h_{RA}, the economizer is disabled. If the heat content of the outside air is lower than the heat content of the return air, the economizer is enabled. The calculations are similar to those used for the differential dry-bulb control, but enthalpy is used instead of temperature as shown here:

$$\text{If } h_{OA} - h_{RA} > 0 \text{ ECONOMIZER DISABLED}$$

$$\text{If } h_{OA} - h_{RA} < 0 \text{ ECONOMIZER ENABLED}$$

For example, if the enthalpy of the outside air is 28.2 Btu/lb and the enthalpy of the return air is 23.2 Btu/lb, we get:

$$h_{OA} - h_{RA} = 28.2 \text{ Btu/lb} - 23.2 \text{ Btu/lb} = 5 \text{ Btu/lb}$$

Since 5 is greater than zero, the economizer is disabled. On the other hand, if the enthalpy of the outside air is 23.2 Btu/lb and the enthalpy of the return air is 28.2 Btu/lb, we get:

$$h_{OA} - h_{RA} = 23.2 \text{ Btu/lb} - 28.2 \text{ Btu/lb} = -5 \text{ Btu/lb}$$

Since −5 is less than zero, the economizer is enabled, **Figure 50.34**.

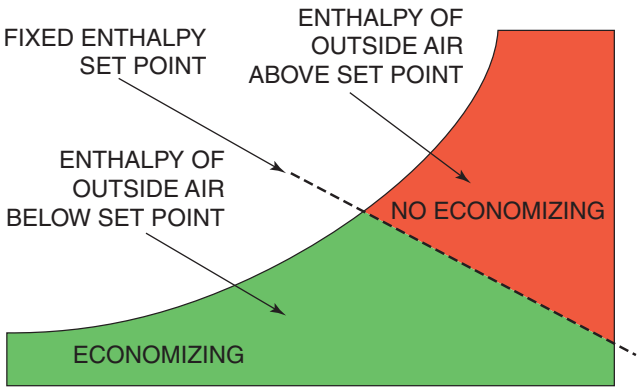
Figure 50.33 Diagram showing the economizing and non-economizing regions for a fixed enthalpy control.



If the heat content of the outside air is lower than the heat content of the indoor air and the system thermostat is calling for cooling, the economizer can bring outside air into the system instead of operating the compressor. The term often used to describe this is **free-cooling**, even though the evaporator blower motor is operating to move the air. So, in reality, we are not getting free-cooling, but the cooling costs are greatly reduced.

50.4 ECONOMIZER MODES OF OPERATION

The economizer is able to increase or decrease the amount of outside air that is brought into the structure with two dampers. One damper is located in the return-airstream and the other is located in the outside-airstream, **Figure 50.35**. These dampers are referred to as opposing dampers, meaning that if one closes, the other opens and vice-versa. If the outside-air conditions do not warrant free-cooling, then the outside-air damper will close to its minimum position, delivering approximately 10% outside air, and the return air damper will be completely open, **Figure 50.36**. If the heat content of the outside air is low enough, the outside-air damper will be completely open and the return-air damper will be completely closed, **Figure 50.37**. In almost all cases, both dampers will be open at least partially to allow for an outside-air/return-air mixture. All across the country, building codes require that a certain amount of outside air be brought into a structure, regardless of the outside-air conditions. So, even if the heat content of the outside air is very high, the outside-air damper will move to its minimum setting, which is often in the 10% range. It should be noted that when outside air is brought in, the structure could become pressurized. To prevent this, some type of exhaust mechanism must be in place. Refer back to **Figure 50.5** for a diagram of a sample rooftop system that incorporates the process of exhausting air.

NOTE: *In order to operate properly, the economizer must be set up to meet the requirements of the system and local building codes. Improperly installed, configured, or maintained economizers can result in poor indoor air quality and increased system operating costs.*

There are four modes of operation for systems that are equipped with economizers. These modes are:

- Heating mode
- Modulating mode
- Integrated mode
- Mechanical mode

HEATING MODE

Heating mode refers to the mode of operation during which there is no call for cooling, and the heating portion of the system is energized. In this mode of operation, the outside air is typically below 30°F. Since the outside air is very cold and the system is operating in the heating mode, only the minimum amount of outside air is brought into the space. If the minimum amount of outside air is 10%, the dampers will close to allow only 10% outside air into the system; the remaining 90% of the airstream will be from the return airstream from the occupied space, **Figure 50.36**.

MODULATING MODE

Modulated economizer mode, or just modulating mode, refers to the mode of operation during which there is a call for cooling, but the outside ambient temperature is low; typically between 30°F and 50°F. Since the outside air is cold and the system is calling for cooling, the outside airstream can be used to meet the cooling needs of the structure. In this mode the system compressors do not operate. The outside and return air dampers open and close to provide the needed cooling for the space. When the cooling load is relatively low, there is more return air than outside air in the mixed airstream, **Figure 50.36**. As the cooling load in the space increases, the amount of outside air being brought in increases, and the amount of return air in the mixed airstream is reduced, **Figure 50.35**. Maximum "free-cooling" occurs when the outside air dampers are 100% open and the return air is reduced to 0%, **Figure 50.37**. Modulating mode is often referred to as "free-cooling," but the system blowers are still operating, so there are still energy costs associated with this mode of operation.

INTEGRATED MODE

Integrated mode refers to the mode of operation during which there is a call for cooling, but the outside ambient temperature is relatively mild, typically between 55°F and 75°F.

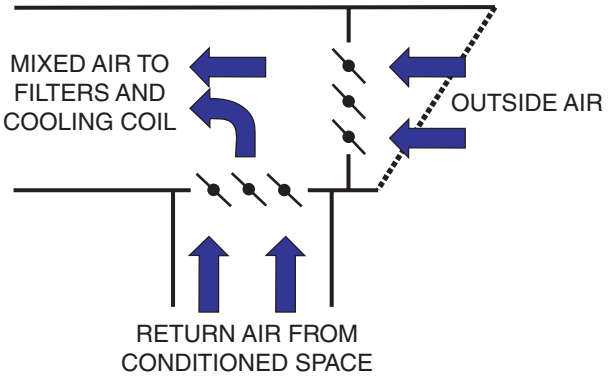
Figure 50.35 Return-air and outside-air dampers.

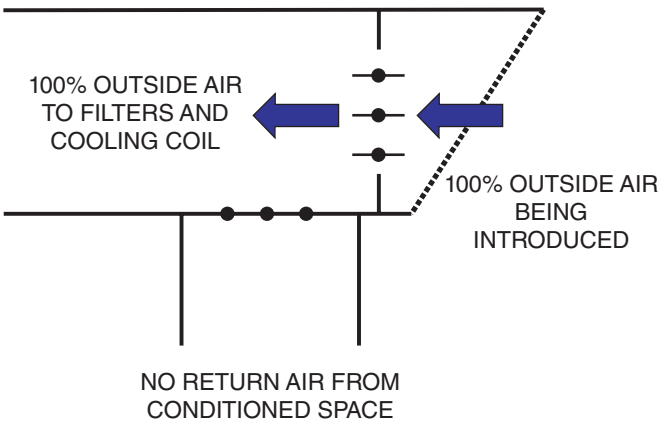


Since the outside air is cool, but not cold, the outside airstream can be used to meet *some of* the cooling needs of the structure. In this mode of operation, the system compressors are operating to provide the remainder of the needed cooling capacity. During integrated mode, the outside air dampers are open 100% and the return air dampers are fully closed, **Figure 50.37**. As the load on the system increases, the mechanical cooling system must contribute more to meet the cooling needs of the occupied space.

MECHANICAL MODE

Mechanical cooling mode, or mechanical mode, refers to the mode of operation during which there is a call for cooling, but the outside ambient temperature is too warm (usually above 75°F) to provide any assistance in satisfying the cooling requirements for the conditioned space. At this point the economizer is disabled and the outside air damper returns to its minimum position, **Figure 50.36**. The mixed airstream is cooled by the mechanical cooling system only. As the load on the system increases, the mechanical cooling system must ramp up its capacity to meet the cooling needs of the occupied space.

Figure 50.37 The outside air damper will open fully when the outside air can meet the cooling requirements of the space.

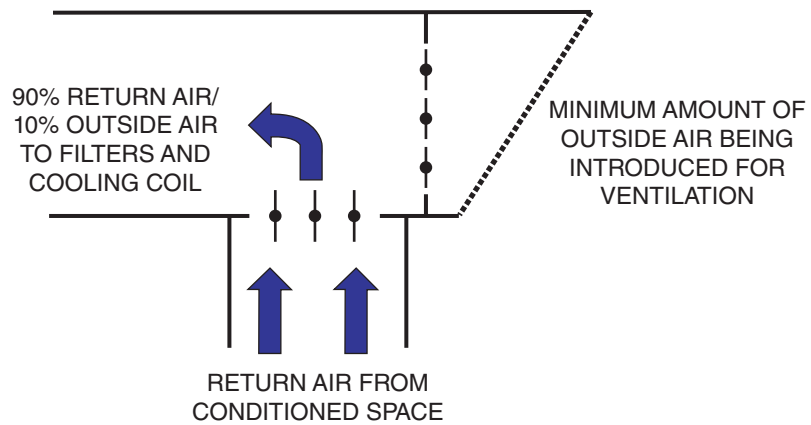


50.5 ASHRAE STANDARD 62

ASHRAE Standard 62, a document that is constantly updated and revised, establishes the standard for the design of ventilation systems to provide acceptable indoor air quality levels that are intended to minimize the potential for adverse health effects. Standard 62 was first created in 1973 and has undergone many changes since then. Most local building codes across the country reference Standard 62 as the guideline for establishing ventilation levels in commercial, industrial, and residential structures.

Although indoor air quality (IAQ) is the major issue addressed in Standard 62, acceptable IAQ levels cannot be maintained by tackling a single air-related element. Instead,

Figure 50.36 The outside-air damper will close when the outside air conditions do not warrant free-cooling.



Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

acceptable indoor air quality can best be attained when air contamination sources, ventilation, air cleanliness, air movement, air filtration, and relative humidity are all maintained within acceptable ranges, levels, and limits. Indoor air quality issues can be greatly reduced when emphasis is placed on these items by the building's maintenance staff. Indoor air quality issues are discussed in more detail in Unit 34, "Indoor Air Quality."

One important aspect of ASHRAE Standard 62 addresses the quality of ventilation air and how air contaminants can enter a building through the system's economizer. Standard 62 states that make-up air inlets are to be located so that they help minimize contamination of the system air. This alerts the system designer and installer to be aware of any exhaust vents, flue pipes, automobile exhaust sources, cooling towers, garbage dumpsters, or other similar contaminant sources when selecting the location for make-up air ducts.

50.6 DEMAND CONTROL VENTILATION (DCV)

In traditional "outside-air" air-conditioning systems, the amount of outside air that is introduced to the system can never be lower than the amount permitted by the minimum allowable setting on the economizer. This minimum economizer setting is established by the system designer to ensure that the guidelines of ASHRAE Standard 62 are adhered to. The system designer chooses this minimum setting based on what the *expected* occupancy of the building will be, not what the *actual* occupancy is at any given time. If an office building is nearly empty at 6:00 PM, the amount of outside air being introduced to the space at that time will be the same as the amount of air introduced when it is near full capacity at 10:00 in the morning. It is easy to see that the amount of outside air needed for adequate ventilation is much lower at 6:00 PM than at 10:00 AM. By utilizing a strategy called demand control ventilation, DCV, the amount of outside air being brought in can be varied based on the actual occupancy level in the structure. In applications where there are numerous, separate conditioned areas, such as in the case of a multiplex movie theater, the amount of outside air can be adjusted depending on the actual number of people in each individual theater. Carbon dioxide-sensing controls, **Figure 50.38**, are often used in conjunction with DCV modules to adjust the amount of outside air being brought into a particular area, based on the ventilation needs at that particular point in time.

HOW DEMAND CONTROL VENTILATION (DCV) WORKS

The demand control ventilation system controls the amount of outside air that needs to be brought to the occupied space for ventilation by estimating the occupancy level in a particular occupied area. The control system does this by measuring the levels of carbon dioxide, CO_2, in the space. Since we produce carbon dioxide when we breathe, as the number of people in a space increases, the level of carbon dioxide in the space will increase as well. Similarly, as the occupancy level in an area drops, so does the CO_2 level. If the occupancy level in a particular area greatly decreases, the amount of outside air required drops as well. In many instances, the required amount of outside air will be less than if the outside air damper were to be positioned at its minimum setting.

A number of existing information streams can be used in conjunction with the DCV system to help it operate more efficiently. In the case of the movie theater, the box office has computerized data on how many tickets are sold for each individual theater at each specific showtime. The DCV system, if properly configured and equipped, can adjust the amount of ventilation air provided to each theater based on the number of people who will be occupying the theater. The ventilation rates can therefore be different for each theater in the multiplex and for each showing of a particular film. In many instances, office buildings are equipped with sensors that turn the lighting off in a particular area if the room has been vacant for a period of time. These sensors can be linked to the DCV control system to reduce the amount of ventilation air when an area is no longer occupied.

Figure 50.38 A carbon dioxide sensor.

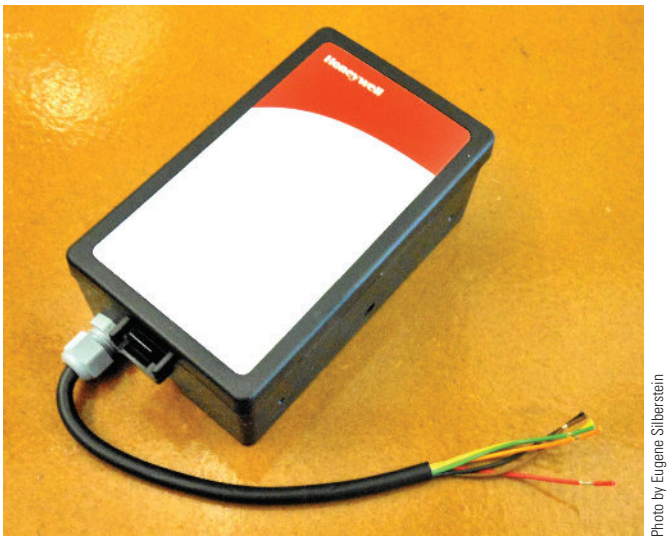


Photo by Eugene Silberstein

THE CARBON DIOXIDE (CO_2) SENSORS

As mentioned, the DCV control strategy estimates the actual occupancy level in a space based on the level of carbon dioxide sensed. In order for the carbon dioxide reading to be

accurate, sensor placement is extremely important. Improperly positioned sensors may or may not provide an accurate representation of the entire space. Sensors should not be placed in or near an entryway or in the corner of an area. Poorly chosen sensor locations may result in CO_2 readings that are either too high or too low.

Control strategies might employ a single CO_2 sensor or multiple sensors located throughout the structure. A single sensor would typically be positioned in the return airstream and would sense the average of all returning airstreams. In this case, it would not be possible to vary the amount of ventilation air to individual areas. When used in conjunction with a variable air volume (VAV) system, carbon dioxide sensors can be positioned in each zoned area. When configured like this, the amount of ventilation air can be tailored to the needs of each conditioned area.

As with any control strategy, proper installation, start-up, and maintenance will help ensure successful system operation down the road. The economizer and its controls must be properly programmed to work correctly with the input from the carbon dioxide sensors. Improper installation, programming, or maintenance can negate any of the benefits systems of this type are intended to provide. Improper economizer damper settings may under- or overventilate an area, resulting in increased cooling costs.

50.7 TRADITIONAL CONSTANT-VOLUME AIR DISTRIBUTION METHODS

Most older-generation air-conditioning systems were de-signed to circulate constant volumes of air to each location served whenever the system called for blower operation. When the blower was off, no air at all was circulated through the duct system. When the blower cycled on, it delivered its design air volume through the main trunk line on the air distribution system. This air was then delivered to the occupied space through the supply registers and grilles. The next generation of air-conditioning systems allowed for the zoning of occupied spaces.

The process of zoning involves the separation of the occupied areas by similar heating or cooling needs. For example, areas located on the west side of a single-story office building may have similar heating and cooling patterns, just as the areas located on the east side of the same building might have similar air-conditioning requirements. In this simple case, the east side of the building can be treated as one zone, and the west side can be treated as a second zone. The duct system is designed with a set of dampers that open or close to either allow airflow to a particular zone or prevent air from reaching a zone. When neither zone is calling for airflow, the blower will cycle off. When only one zone is calling for blower operation, the other zone damper will be closed and the blower motor will operate at a lower speed to deliver the required amount of airflow to the zone that is calling. When both zones are calling for blower operation, both zone dampers will open and the motor will operate at high speed to deliver the amount of air desired. In any case, the amount of air being delivered to a particular zone is either zero or the design air volume. With the introduction of variable air volume, VAV, systems, the air-conditioning equipment can modulate the airflow to the occupied spaces, allowing for more even space conditioning, increased energy efficiency, and a longer expected life cycle for the equipment.

50.8 VARIABLE AIR VOLUME (VAV) SYSTEMS

As the name implies, variable air volume systems are designed to vary the amount of air that is introduced to an area. Some air distribution systems are designed as all-or-nothing delivery systems, but the VAV system can modulate and regulate the amount of air that actually reaches each location in the conditioned space. The airflow requirements of a particular area depend on a number of factors that include, but are not limited to, the cooling requirements of the space, the heating requirements, the ventilation requirements, and the occupancy levels in the space.

Just like conventional rooftop packaged equipment, the typical VAV system is equipped with an economizer, air filters, a mixing box for the return and outside air, a heat source for the heating mode operation, and the four main system components that make up the vapor-compression refrigeration cycle. The main difference between a VAV rooftop packaged unit and a conventional rooftop packaged unit is the supply blower. The supply blower on the VAV system has the ability to deliver varying amounts of air based on the needs of the conditioned space. In addition to the variable volume blower, the VAV system also relies on individual terminal units that are located in each zone. These terminal units are typically equipped with a damper, an air pressure sensor, a reheat coil, and the devices needed to properly control damper position and the rate of hot water flow through the reheat coil in response to the temperature and ventilation requirements of the space. Some VAV boxes or terminal units are equipped with separate blowers or fans.

50.9 BLOWERS ON VAV SYSTEMS

In order to deliver different volumes of air to various areas in an occupied space, the blowers used on VAV systems must be able to modulate their speeds to accommodate the changing needs of the system. Motor speed modulation involves more than simply changing back and forth between a motor's high-speed winding and its low-speed winding, as in the case of a conventional heating and cooling system.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

As the system needs change, dampers open and close to supply more or less air to the individually controlled zoned areas. As these dampers open and close, the pressures in the air distribution system change as well. Strategically placed sensors measure the pressures in the duct system and determine the speed at which the blower should operate. This information is then sent along to the motor's control circuitry and the delivered air volume is adjusted accordingly. A method commonly used to alter the motor's speed is a variable frequency drive, or VFD. The VFD modulates the frequency of the supply power's sine wave to reduce the effective speed of the motor. These drives and other variable motor speed strategies are discussed in more detail in Unit 17, "Types of Electric Motors."

When the demand for cooling in a structure is reduced, the dampers that control the airflow to the various locations begin to close. This creates a restriction in the air distribution system and the pressure in the system increases. Less air is being introduced to the occupied space because of the closing dampers and the pressure in the duct system continues to rise. Sensors in the ducts register this increase in static pressure and send a signal to the control system to slow the motor down. By slowing the motor down, the pressure in the duct system is reduced to an acceptable level as determined by the parameters of the control system.

50.10 VAV BOXES AND TERMINAL UNITS

The VAV boxes or terminal units can be configured in a number of different ways, depending on the needs of the structure. There are four common types of VAV boxes; quite often, a particular installation may use multiple types to meet the heating/cooling/ventilation needs of the conditioned space. The four common types of VAV boxes are cooling and heating, cooling only, parallel blower-assisted, and series blower-assisted.

The cooling and heating VAV box is made up of the damper, air pressure sensor, reheat coil, and the required control devices, **Figure 50.39**. A reheat coil is typically a hot water coil but, in some applications, can be an electric coil. The reheat coil can be used to temper air that is flowing into the occupied space in the cooling or ventilation modes, or to heat the air in the heating mode.

The cooling-only VAV box is made up of the damper, air pressure sensor, and the controls needed to properly position the damper for the desired airflow rate. There is no reheat coil on the cooling-only VAV box.

The blower-assisted VAV boxes include additional blowers that introduce air from the space above the occupied areas into the VAV box cabinet. This allows air from the ceiling to mix with the conditioned air being supplied to the room. In the parallel blower-assisted VAV configuration, a small blower is energized when it is desired that ceiling air be

mixed with the main airstream prior to entering the conditioned space, **Figure 50.40**.

In the cooling mode, the damper opens and closes as long as the need for cooling remains. As the space temperature nears the set point for the space, the damper begins to close. When the space temperature reaches the set point, the damper in the VAV box for that particular area will be at its minimum position, **Figure 50.41**. This minimum position allows for proper ventilation as required under ASHRAE Standard 62. (More information on this standard can be found elsewhere in this unit.) If, at the minimum damper setting, the air being supplied continues to cool the space below the desired temperature, the blower cycles on to mix ceiling cavity air with the cooler supply air. This tempers the air just enough to reduce the cooling effect on the occupied space, **Figure 50.42**. Reheat coils can be added to the parallel blower-assisted VAV box for additional tempering and for heating the air in the cooler winter months.

A larger blower is used in the series blower-assisted VAV configuration. This blower is energized all the time, as long as the area is occupied, even if there is no call for heating or cooling, **Figure 50.43**. If the zone is calling for cooling, the damper on the VAV will be open and the blower will deliver cooled air to the conditioned space. If there is no call for cooling, the damper on the VAV will be closed and the blower will deliver air from the ceiling cavity to the occupied space, **Figure 50.44**.

Figure 50.40 A parallel blower-assisted VAV box.

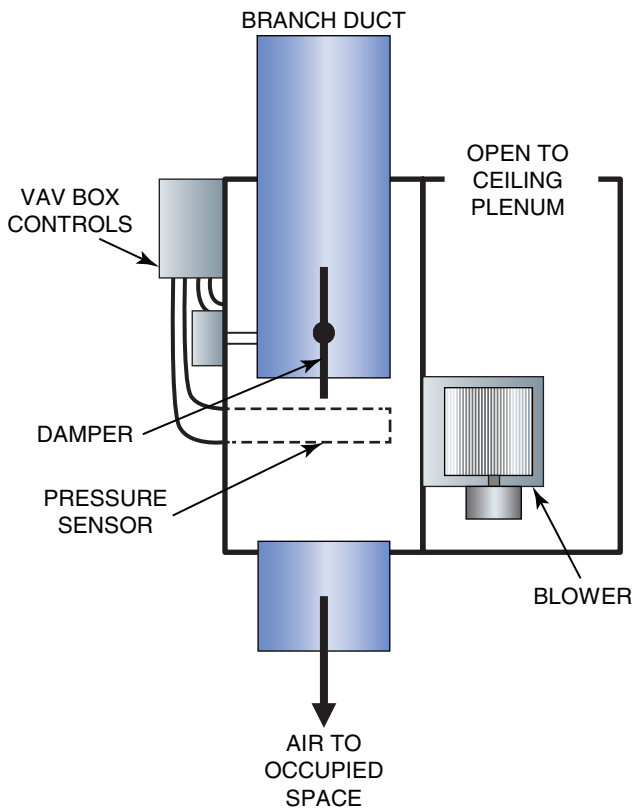

Figure 50.41 As the cooling load on the system is reduced, the damper closes to send less air to the occupied space.

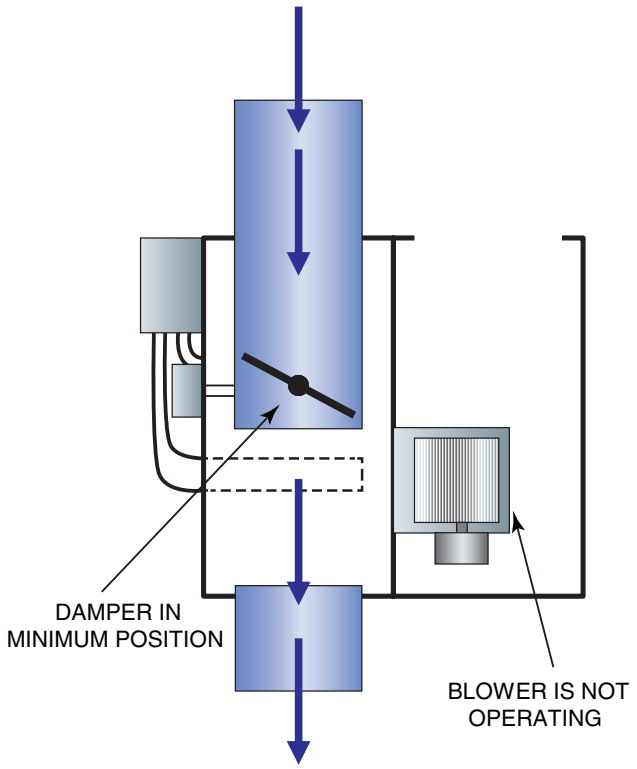

Figure 50.42 If the temperature of the space continues to drop, even at the minimum damper position, the VAV blower cycles on to mix warmer ceiling air with the colder supply air.

50.11 HOT WATER IN THE REHEAT COILS

Some VAV boxes or terminal units are equipped with reheat coils. These coils are intended to temper air as needed when cooling or ventilation is called for or to heat the air when an area is calling for heating. Reheat coils are typically either of the electric resistive type or of the hydronic, hot water, type. Electric resistive reheat coils are similar to the electric heaters discussed in Unit 30, "Electric Heat"; refer to that unit for more information.

As with any hot water coil, precautions should be taken to prevent it from freezing. The possibility of freezing is greater when the water flow has been stopped completely. There are two common piping configurations that are used on hot water reheat coils and utilize either a two-way or a three-way modulating valve.

TWO-WAY MODULATING VALVES

When a two-way modulating valve is used to control the flow of hot water through a reheat coil, the rate of flow varies with the needs of the particular zone. The valve is typically installed at the outlet of the reheat coil, **Figure 50.45**. Since the valve modulates the flow of hot water, precautions must be taken to avoid dead-heading the circulating pump. To prevent this, pumps that can vary flow rates must be used. As the need for hot water declines, the pump will slow down as needed. Since two-way modulating valves can, under some circumstances, be completely closed off, the possibility of coil freezing exists, so precautionary actions must be taken.

Figure 50.45 Reheat coil with a two-way modulating valve.

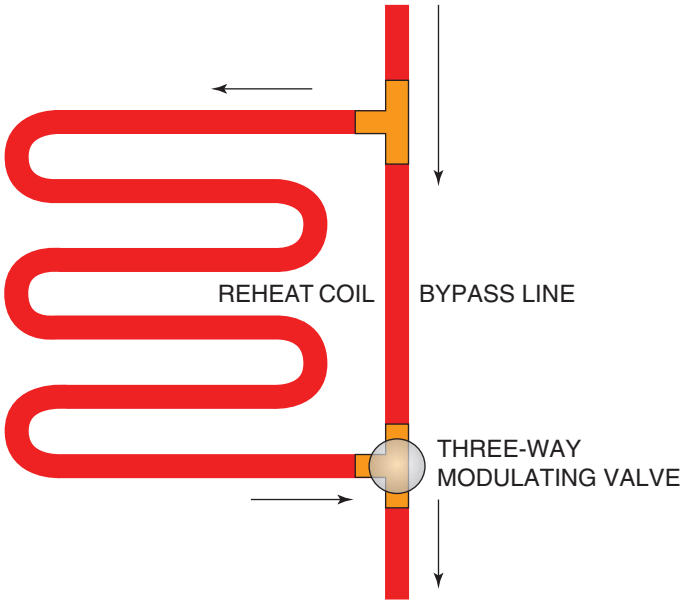
Figure 50.46 Reheat coil with a three-way modulating valve.



THREE-WAY MODULATING VALVES

When a three-way modulating valve is used to control the flow of hot water through a reheat coil, the rate of flow circulated by the pump remains constant. Even though the amount of water needed for reheat might vary, the unwanted volume of hot water flows through a bypass pipe that is connected across the coil, **Figure 50.46**. The valve is typically installed at the outlet of the reheat coil. Constant volume pumps can be used in conjunction with three-way modulating valve systems because they deliver a constant flow of water. The two extreme settings on the three-way valve allow for all of the hot water to be directed through the reheat coil or all of the water to bypass the reheat coil. In most cases, the actual position of the valve will allow at least some flow through both the reheat coil and the bypass line, **Figure 50.47**. Systems with three-way modulating valves are less likely to freeze, but precautions should be taken, as freezing could result in the event of pump failure.

50.12 CHILLED-WATER VAV SYSTEMS

Variable air volume systems can be used in conjunction with conventional, vapor-compression refrigeration systems or with chilled-water systems. When variable air volume technology is incorporated into an air-cooled, conventional system, the system is commonly packaged equipment. When the VAV technology is incorporated into a chilled-water system, the system is most often configured as a split system, where the chiller is positioned in a remote location compared to that of the air handler. Chilled-water VAV systems can be configured in a number of ways, depending on the equipment used. Some common chilled-water VAV system setups include:

- Water-cooled chilled-water system in the basement of the building with rooftop VAV air handlers, **Figure 50.48**.
- Water-cooled chilled-water system in the basement of building with VAV air handlers located on each floor of the building, **Figure 50.49**.
- Air-cooled chilled-water system in the basement of the building with an outdoor air-cooled condenser and VAV air handlers, **Figure 50.50**.
- Air-cooled chilled-water system in the basement of the building with an outdoor air-cooled condenser and VAV air handlers located on each floor of the building, **Figure 50.51**.

Just as with a rooftop packaged VAV system, a chilled-water VAV system typically incorporates a means of exhausting air from the system, bringing outside air into the system;

filtering, cooling, heating , and tempering the air; and delivering the treated air back to the occupied space. The main difference between the configurations is that a rooftop packaged unit also contains all components of the refrigerant-carrying circuit while the chilled-water system does not. In the case of the packaged unit, all refrigeration-related repair work is done at the unit. In the case of the chilled-water system, the air handler consists of two water coils: one for chilled water and one for hot water. Refrigerant-related repairs in the chiller are performed at the chiller location.

PROTECTING THE CHILLED-WATER VAV FROM FREEZING

Since the air handlers on a chilled-water VAV system contain water, precautions must be taken to protect the coils from freezing. It is important to remember that the outside air brought into the system for ventilation can be cold enough to freeze the water in the coils. Even if the return air from the occupied space is well above the freezing point, outside airstreams and return airstreams do not always mix well. Since colder air is more dense than warmer air, the colder outside air may fall to the lower portion of the mixing box, while the warmer return air from the space may occupy the upper portion. This condition has the potential to allow very cold air to pass through the coils, resulting in a freeze-up. A number of precautions can be taken to prevent coil freeze-up. These include heating the outside air as it enters the system, adding antifreeze to the water in the chilled-water piping circuit, or draining the chilled-water coils in the colder months.

HEATING THE OUTSIDE AIR AS IT ENTERS THE SYSTEM. In geographic areas where subfreezing temperatures occur, a thermostat can be positioned in the outside ventilation airstream to detect when the outside air is cold enough to

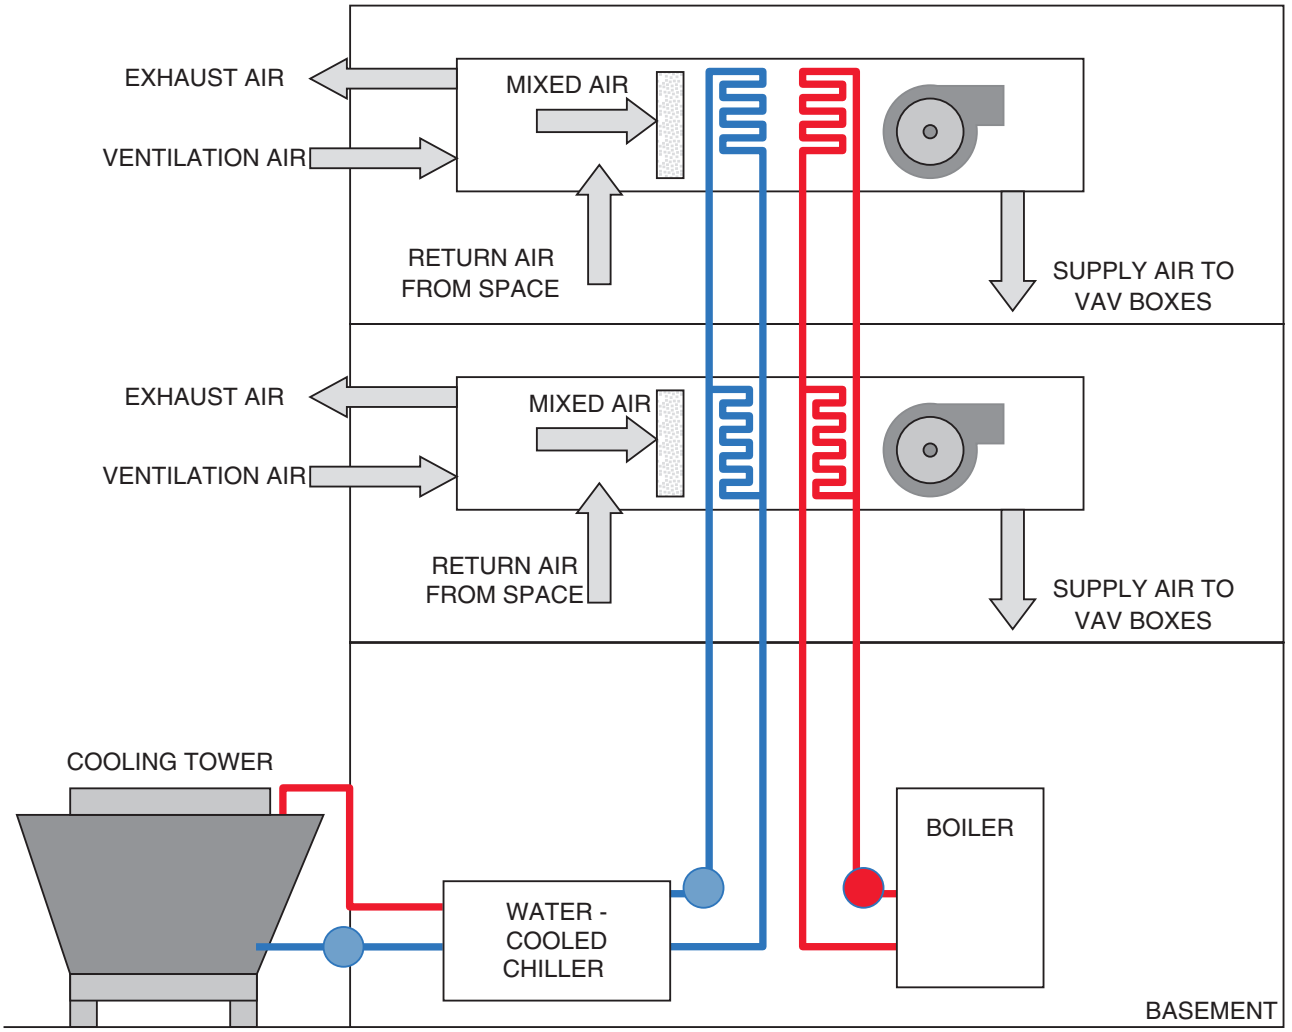
Figure 50.49 Water-cooled chilled-water system with VAV air handlers on each floor of the building.



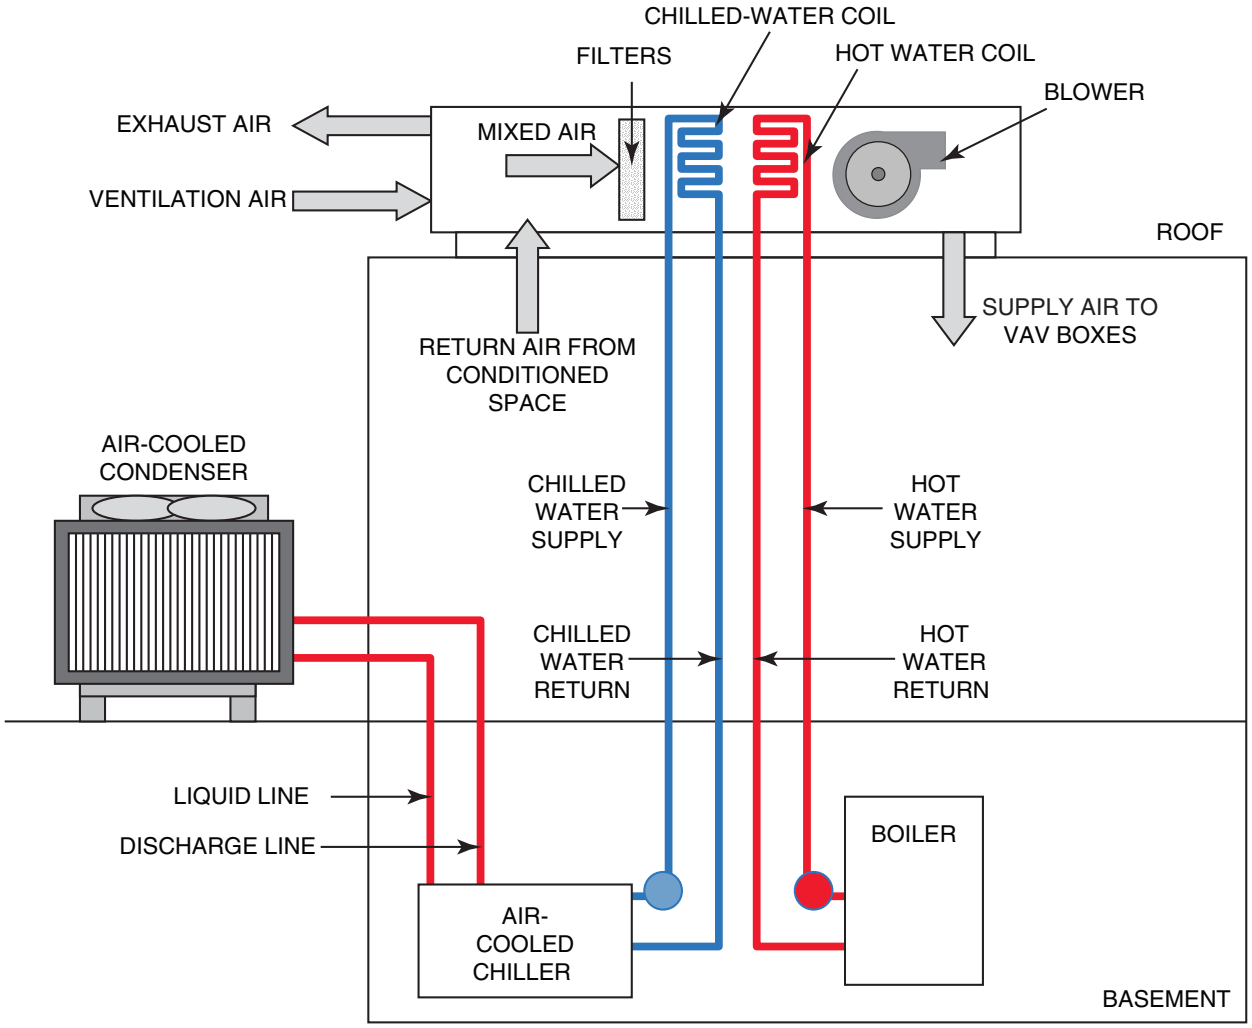
cause coil freezing. This temperature sensor, typically called a **freezestat**, is intended to energize a heater circuit that will heat the ventilation air prior to mixing and passing through the water coils. When the temperature of the ventilation air is above the freezing point, the heaters are not activated. The heaters are typically electric resistive-type heaters. If other methods, such as hot water or steam, are used to heat the air, these coils must also be protected from freezing. In this case, the solution to the problem results in duplicating the initial problem.

ADDING ANTIFREEZE TO THE WATER IN THE CHILLED-WATER PIPING CIRCUIT. Another method of preventing freezing is to mix the water with an antifreeze, such as ethylene glycol. Adding antifreeze to the water lowers the freezing temperature of the coil. As the amount of antifreeze in the mixture increases, the freezing point of the coil drops further. Different formulations of glycol also affect the freezing point. The following table provides information regarding the approximate range of freezing temperatures for various concentrations of ethylene glycol mixed with water.

Percentage of Ethylene Glycol	Freezing Temperature in Degrees Fahrenheit	Freezing Temperature in Degrees Celsius
0%	32°F	0°C
10%	23°F to 26°F	−5°C to −3°C
20%	14°F to 20°F	−10°C to −7°C
30%	2°F to 8°F	−17°C to −13°C
40%	−13°F to −10°F	−25°C to −23°C
50%	−36°F to −30°F	−38°C to −34°C

Upon initial inspection, it might seem obvious that it is definitely better to add more ethylene glycol to the mixture, as this will greatly lower the freezing temperature of the water/antifreeze mixture. But there are some drawbacks to adding more antifreeze than needed. It reduces the heat-transfer rate

Figure 50.50 Air-cooled chilled-water system with rooftop VAV air handlers.



of the solution and requires larger pumps to circulate the solution through the piping.

The concept of specific heat was discussed back in Unit 1, "Heat, Temperature, and Pressure". The discussion established that the specific heat of water is 1.0 Btu/lb°F. As impurities are mixed with the water, the specific heat capacity of the water changes. At 40°F, a mixture of 30% glycol and 70% water will have a specific heat capacity of about 0.89 Btu/lb°F. This is about a 10% reduction in the ability of the solution to transfer heat. If the percentages of glycol and water are changed to create a 50%/50% mixture, the specific heat capacity drops to about 0.795 Btu/lb°F. This equates to a 20% reduction in heat-transfer capability. The decision about whether to add ethylene glycol to the system must be made early in the design process, as this will have a major effect on the amount of fluid that needs to be circulated through the system.

Another major concern in using ethylene glycol as an additive for freeze protection is the issue of viscosity. The viscosity, or thickness, of glycol is much greater than that of water. This increase in viscosity means that it is harder to pump and the head loss in the system will be increased. In Unit 33, "Hydronic Heat," we discussed the concept of "feet of head" and established that a pressure of 1 psig could raise a column of water 2.31 feet, **Figure 50.52**. In the case of a glycol/water mix, this conversion is no longer accurate, since we are not dealing with pure water. If the addition of ethylene glycol resulted in a 50% increase in head loss, then we would need a pump that was 50% larger to effectively circulate the antifreeze/water mixture. Once again, the decision about whether or not to add ethylene glycol to the system must be made early in the design process, as this will have a major effect on the size and capacity of the pump that is selected for the particular application.

SAFETY PRECAUTION: *Ethylene glycol should not be ingested. Although it has a sweet taste, once ingested it can form glycolic and oxalic acid, which can have a negative effect on the central nervous system, the heart, and the kidneys. If treatment for ingestion is not received, death can result.*•

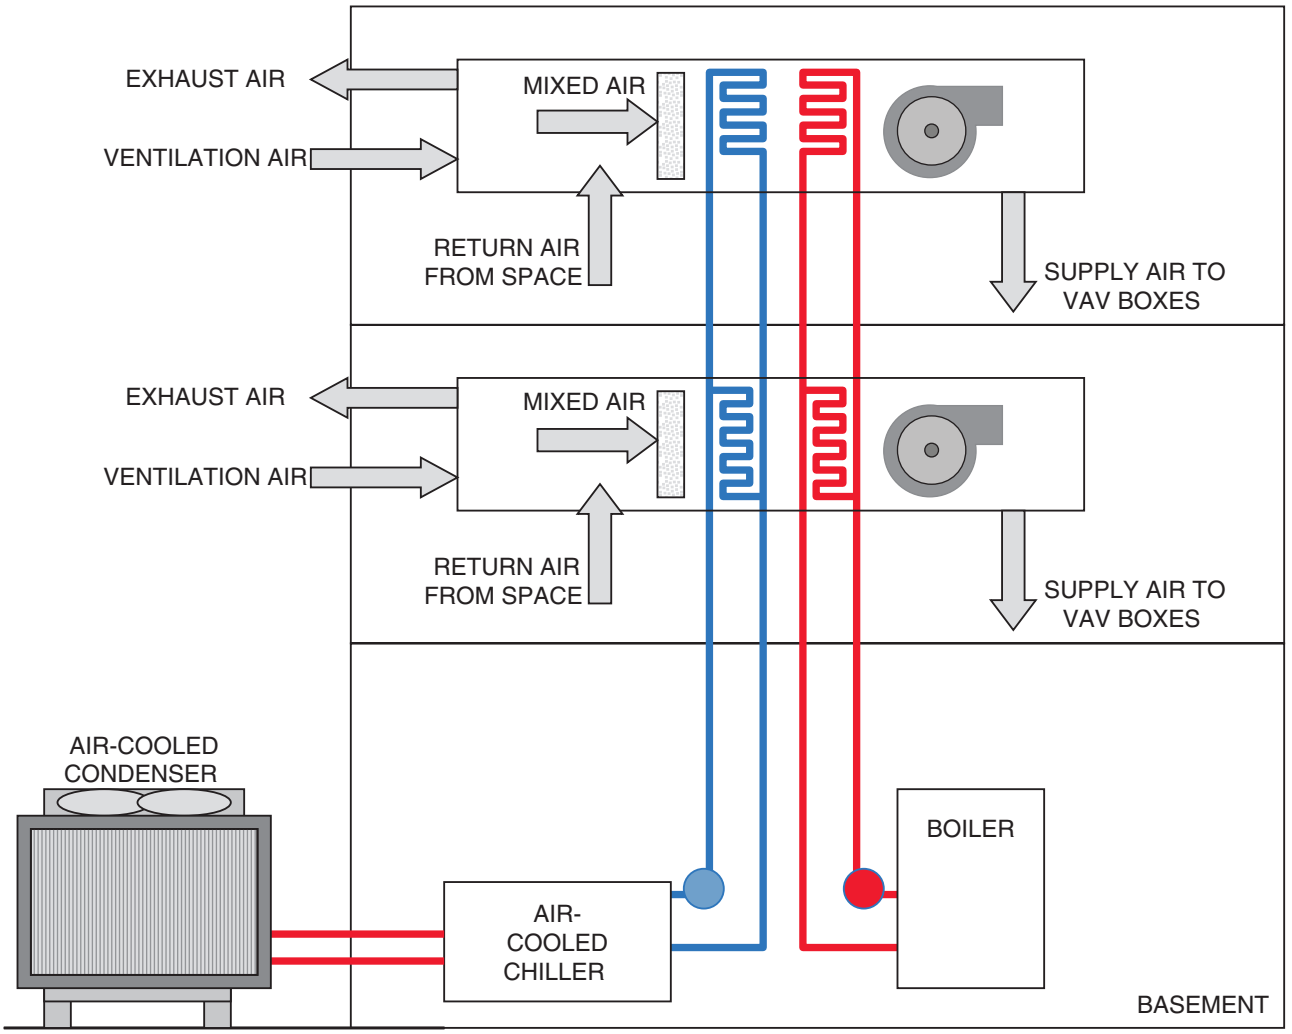

Figure 50.52 One psig of pressure can lift a column of water 2.309 feet.

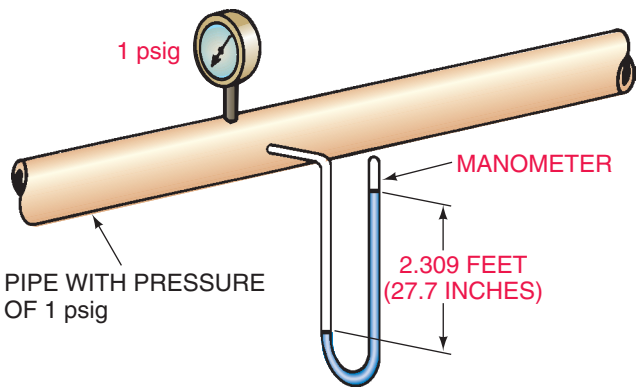

DRAINING THE CHILLED-WATER COILS IN THE COLDER MONTHS. One way to avoid the negative effects of adding antifreeze to the system or employing heaters to prevent freezing is to remove the water from the chilled-water coils altogether. This is the most labor-intensive option but eliminates all possibility of coil freezing, provided that the draining process is performed properly. In order to effectively drain the chilled-water coil, there must be a drain port at the coil, along with a vent port and a means to valve off the coil from the rest of the chilled-water piping arrangement, **Figure 50.53**.

To properly drain the coil, it must first be isolated from the rest of the chilled-water piping circuit by closing the supply and return water valves, **Figure 50.54**. The vent port should then be opened. This will allow air to flow into the coil as the water is drained from the bottom. A hose should be connected to the drain port on the coil and be directed outside, to a floor drain, or to another location where the draining water will not pose a problem. The drain port can then be opened to drain the coil, **Figure 50.55**. Once the coil has been drained, it is a good idea to push pressurized air through the vent port to push any remaining water out of the coil. Once this has been done, the drain valve should be closed and some glycol should be pumped into the coil, **Figure 50.56**. This will help prevent any remaining

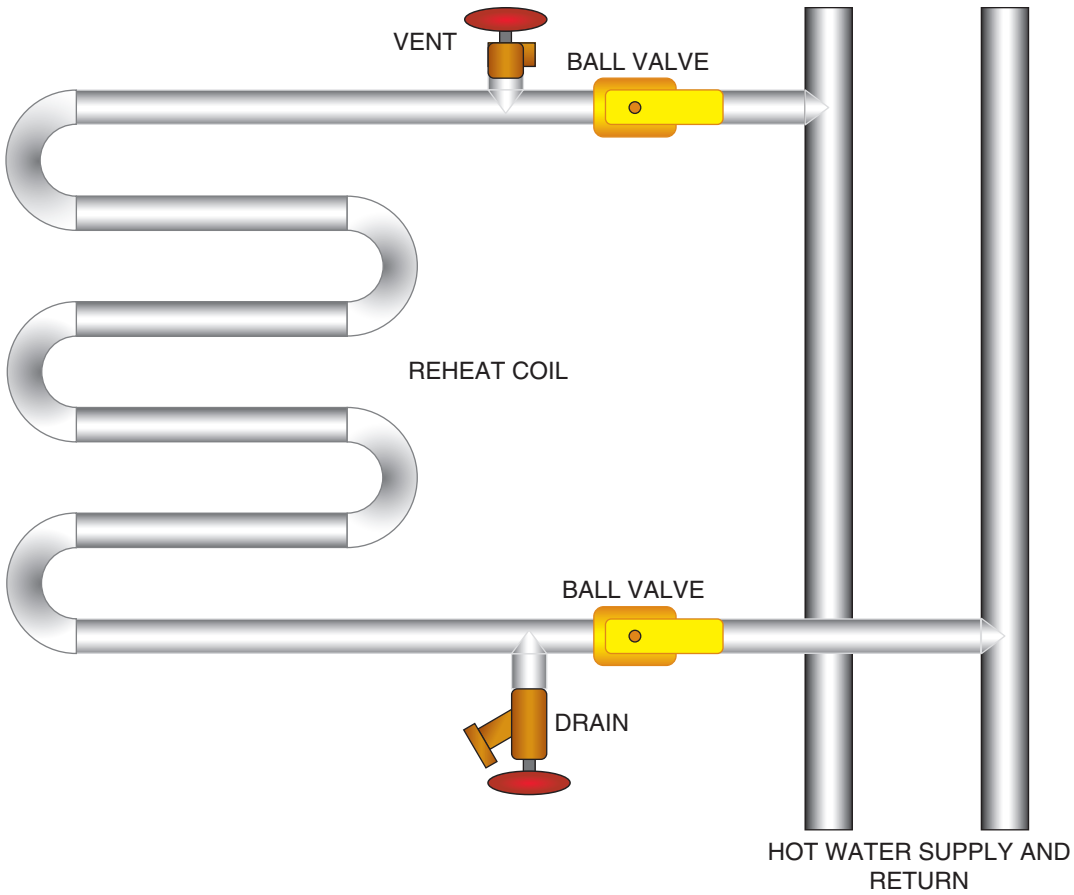
Figure 50.53 Piping arrangement for effective reheat coil draining.



water from freezing. The vent port can be left open for the winter, but proper signage should be posted alerting other technicians that the valve is open. Should they open the isolation valves without first checking the position of the vent port, a flood could result. However, if the draining process is properly performed, closing the vent port will not pose a problem.

To put the coil back into operation, the glycol should first be drained. This is accomplished by opening the vent port and then opening the drain port. The glycol should be captured in a container and stored for the next time the coil needs to be drained, **Figure 50.57**. Blowing pressurized air through the vent port helps ensure that all of the antifreeze has been removed from the coil.

Once the antifreeze has been removed, the vent and drain ports should be closed. Then the lower isolation valve on the main chilled-water circuit can be opened slightly. This will allow water to flow into the coil. Once water begins to flow into the coil, the vent port can be opened slightly. This will purge the air from the chilled-water coil, **Figure 50.58**. Water is allowed to enter the coil until it flows from the vent port. Once that happens, the vent port is closed and the upper isolation valve is opened.

50.13 VARIABLE REFRIGERANT FLOW (VRF) SYSTEMS

Unlike the VAV systems described in the previous section of this unit, variable refrigerant flow (VRF) systems modulate the volume of refrigerant that is pumped through the system. Variable refrigerant flow systems are able to operate effectively and efficiently within a wide range of capacities by changing the speed at which the system compressor or compressors operate by means of inverter-controlled compressor motors. Inverters change the frequency of the power supplied to a motor to alter the speed. (Inverters are discussed in more detail in Unit 17, "Types of Electric Motors," and in Unit 26, "Applications of Refrigeration Systems.") The control system for the inverter-controlled compressor motors sense, among other things, the saturation temperatures and pressures of the refrigerant to modulate the volume of refrigerant that is pumped by the system compressors. In addition to the inverter-controlled compressors, variable airflow systems can also use inverter-controlled fan motors to modulate the rate of airflow through the outdoor coils.

Variable refrigerant flow systems can be configured as cooling-only, as heat pumps, or as heat pump systems with heat recovery. Cooling-only systems are capable of providing comfort cooling to the occupied space and are typically used in conjunction with a variety of heating methods, such as baseboard heat around the perimeter of a structure and hydronic fan coil units throughout the interior spaces. When configured as heat pumps, VRF systems can provide either heating or cooling to the occupied space, depending on the needs of the structure. The heat-recovery heat pump system is the most complicated of the three common configurations but provides the most versatility. The heat-recovery heat pump VRF system allows different areas in the structure to operate in different modes at the same time. Some areas can call for heating while other areas can call for cooling; the system will be able to satisfy both requests simultaneously.

VRF SYSTEM COMPRESSOR CONFIGURATIONS

The compressors in VRF systems can be configured in a number of different ways, depending on the capacity and design of the system. Some systems might have a single inverter compressor; others might have multiple inverter compressors. Some systems utilize a combination of inverter and standard, single-speed compressors, **Figure 50.59**.

Some equipment manufacturers utilize a modular approach by which multiple outdoor units can be piped together to increase the capacity of the system. The outdoor units can be manifolded together to meet the air-conditioning and heating needs of the structure, **Figure 50.60**. In some applications, the VRF system can service over 50 separate indoor locations.

VRF SYSTEM CONTROL

Electronic control circuits are used in order to ensure that the proper amount of refrigerant is being circulated through the system. A number of control strategies can be employed, but each is designed using three basic control-based building blocks. These building blocks are proportional, integral, or derivative controls.

Proportional controls are designed to react to present errors that exist between the desired state of operation and what is actually taking place. The larger the error, the more

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Figure 50.59 Outdoor units on VRF systems can be a combination of standard and inverter compressors.

adjusting the proportional control will do. Integral controls react to the sum of all of the previous errors that existed and attempt to bring that total to zero. In simple terms, integral controls sum up all the positive errors (values above the desired set point) and the negative errors (values below the desired set point) and adjust the output signal to help create a net zero error value. Derivative controls attempt to predict the future needs of the system based on the rate of change of measured parameters.

Controls that utilize all three of these building blocks are referred to as PID controls. An example of a system component that utilizes PID controls is the step-motor expansion valve that was discussed in Unit 24, "Expansion Devices." The control strategy that seems to be prevalent in VRF systems is the proportional integral (PI) strategy, which does not utilize the derivative or predictive element.

PROPORTIONAL INTEGRAL (PI) CONTROL SYSTEM RESPONSE

The VRF system reacts to changes in system saturation temperatures and pressures and controls the operation of the system compressors accordingly. In the cooling mode of operation, the evaporator saturation temperature and pressure are monitored; the condenser saturation temperature and pressure are monitored when operating in the heating mode.

While operating in the cooling mode, low evaporator saturation temperature and pressure indicate that the cooling load on the system is low. If the space is cool and close to the thermostat's set point, less heat will be added to the system. This will result in lower evaporator temperatures and pressures. If the cooling load on the system is high, the evaporator saturation temperature and pressure will be higher than desired. In either case, the control system can increase or decrease the speed of compressor motors based on this sensed information. The speed of the compressor is varied in steps, with each step representing a different frequency or speed of the compressor motor.

Let us assume that we have a VRF unit that is equipped with a single inverter compressor and that the control system can vary the frequency of the compressor from 60 Hz (60 cycles per second) to 200 Hz. When the system is initially energized, the compressor motor will start at its lowest speed, which, in this example, is 60 Hz. As the need for refrigerant flow increases, the controller will continue to move up steps in the control sequence. If the control sequence has 15 steps, each step might increase the frequency of the compressor by 10 Hz. The following table represents this. As the cooling load on the system increases, the speed of the compressor will also increase from step 1 until it reaches its maximum speed, if needed, at step 15. As the load on the system drops, the control module will drop from higher to lower steps, slowing the compressor down.

Step	Frequency	Step	Frequency	Step	Frequency
1	60 Hz	6	110 Hz	11	160 Hz
2	70 Hz	7	120 Hz	12	170 Hz
3	80 Hz	8	130 Hz	13	180 Hz
4	90 Hz	9	140 Hz	14	190 Hz
5	100 Hz	10	150 Hz	15	200 Hz

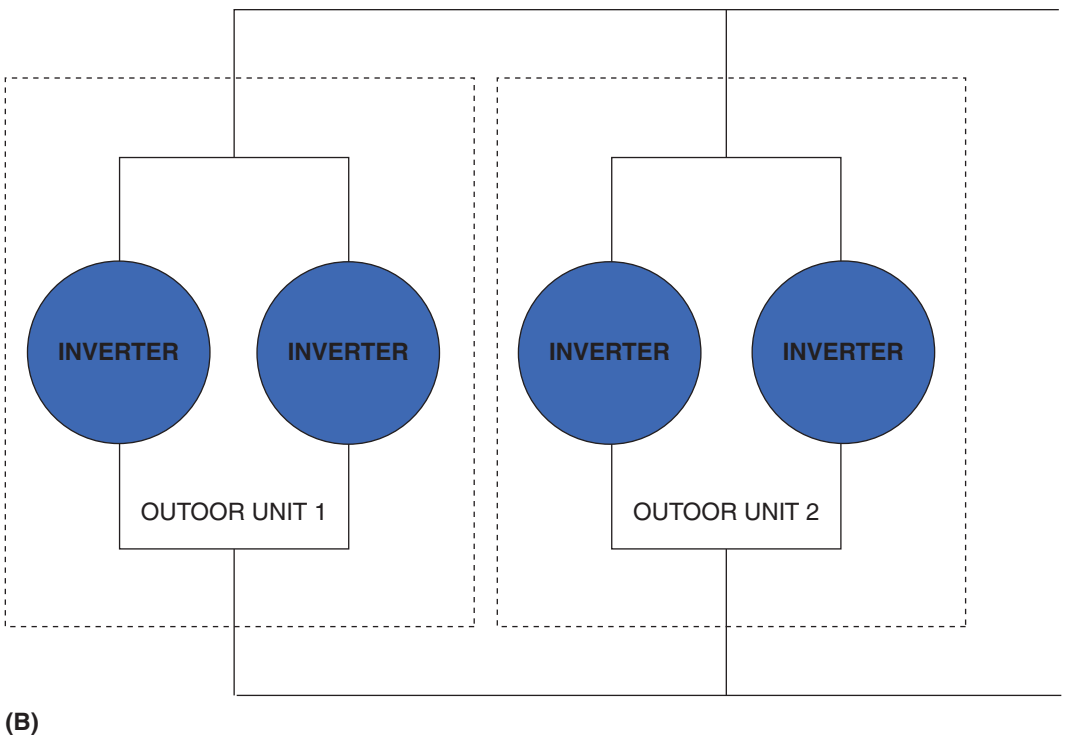
(A)



(B)

In the case of a VRF system that utilizes one inverter compressor and one standard compressor, the control strategy is similar, in the sense that moving from one step to another will increase or decrease the volume of refrigerant circulated. However, the standard compressor will cycle on only when the inverter compressor is not able to handle the cooling load by itself. The following table provides a sample control strategy for the inverter compressor (INV) and the

standard compressor (STD). When the system is operating at any of the control steps 1 through 15, the standard compressor is not in operation. As it moves from step 15 to step 16, the inverter compressor drops to its slowest speed and the standard compressor cycles on. As the cooling load on the system increases from this point, the standard compressor remains in operation and the inverter compressor ramps up its speed to satisfy the cooling needs of the space.

VRF PIPING CONFIGURATIONS

Two typical piping configurations are found on VRF systems. One is the piping circuit used in heat pump systems and the other is the piping circuit used in conjunction with a heat pump system that has a heat-recovery feature. The heat pump VRF configuration utilizes two refrigerant lines that are connected to the outdoor unit. One line is the liquid line and the other line is the gas line. The heat pump system that is equipped with heat recovery can have either two or three field-installed lines connected between the outdoor units and the indoor units, depending on the equipment manufacturer. Be sure to check the model number of the system being worked on to determine if the system has the heat recovery feature or not.

TWO-PIPE VRF PIPING CONFIGURATION. A simplified piping diagram of the two-pipe arrangement with one outdoor unit and two indoor units is shown in **Figure 50.61**. This outdoor unit has one inverter compressor, INV, and one standard compressor, STD, that are connected in parallel with each other. There are two four-way valves, RV1 and RV2, to aid in the changeover between the heating and cooling modes. In addition, there are two capillary tubes, S1 and S2, that are intended to allow pressure from the high side of the system to bypass to the low side to prevent refrigerant accumulation in the lines.

When only one indoor coil is calling for cooling, the refrigerant path can be traced out as shown in **Figure 50.62**. The sequence is as follows:

- The high-pressure, high-temperature vapor is discharged from the compressors INV and STD and flows to reversing valve RV1.
- The refrigerant is directed to the outdoor coil, which is functioning as the condenser. It is here that system heat is rejected.
- At the outlet of the outdoor coil, the refrigerant bypasses the outdoor metering device as it flows though the check valve piped in parallel with the metering device.
- The high-pressure, high-temperature liquid then flows to the indoor coil.
- Solenoids at the indoor unit open to allow refrigerant to flow through the metering device and onto the evaporator coil.
- The low-pressure, low-temperature vapor leaves the evaporator and flows through reversing valve RV2.
- From RV2 the suction gas returns to the compressors, INV and STD.

NOTE: *A small amount of refrigerant is able to pass from the compressor discharge back to the compressor inlet through RV2 and S2. This is to prevent refrigerant accumulation in the refrigerant lines.* •

When both of the indoor units are calling for cooling, the flow path is similar to the one just discussed, with two exceptions. First, the liquid refrigerant flow from the outdoor coil splits to feed both indoor units to provide cooling for both areas. Second, when the suction gas leaves the two evaporator coils, the two paths join and the refrigerant flows back through RV2 and on to the compressors, **Figure 50.63**.

When only one indoor coil is calling for heating, the refrigerant path can be traced out as shown in **Figure 50.64**. The sequence is as follows:

- The high-pressure, high-temperature vapor is discharged from the compressors INV and STD and flows to reversing valve RV2.
- The refrigerant is directed to the indoor coil, which is functioning as the condenser. It is here that system heat is rejected into the occupied space for heating purposes.
- Solenoid valves at the indoor coil allow the hot gas to flow through the indoor coil.
- At the outlet of the indoor coil, the refrigerant bypasses the indoor metering device as it flows though the check valve piped in parallel with the metering device.
- The high-pressure, high-temperature liquid then flows to the outdoor coil.
- At the outdoor unit, refrigerant flows through the metering device and into the outdoor coil, which is functioning as the evaporator coil.
- The low-pressure, low-temperature vapor leaves the evaporator and flows through reversing valve RV1.
- From RV1 the suction gas returns to the compressors, INV and STD.

NOTE: *A small amount of refrigerant is able to pass from the compressor discharge back to the compressor inlet through RV1 and S1. This is to prevent refrigerant accumulation in the refrigerant lines.* •

When both of the indoor units are calling for heating, the flow path is similar to the one just discussed, with two exceptions. First, the hot discharge gas from the compressor splits to feed both indoor units to provide heating for both areas. Second, when the high-pressure, high-temperature liquid leaves the indoor coils, the two paths join and the refrigerant flows on to the outdoor metering device and evaporator coil, **Figure 50.65**.

THREE-PIPE VRF PIPING CONFIGURATION. The three-pipe configuration allows for some indoor units to provide heating while others are providing cooling. This is referred to as heat recovery. This piping arrangement is somewhat more complicated and requires the use of a branch selector box, **Figure 50.66**. The branch selector box has three pipes that connect back to the outdoor units and two pipes that are connected to the indoor unit. Inside the branch selector, there can be as many as five electronic expansion valves that function to modulate refrigerant flow based on the mode of system operation desired as well as the conditions of the system external to the individual indoor unit, **Figure 50.67**. For example, if needed, the SC valve can be put into operation to provide additional subcooling when some areas are calling for cooling and others are calling for heating. The EEVC1 and EEVC2 electronic expansion valves operate during the cooling mode, and the EEVH1 and EEVH2 electronic expansion valves operate during the heating mode. If two or more indoor units will always be functioning in the same mode, either heating or cooling, a single branch selector can be used in conjunction with them, **Figure 50.68**.

Figure 50.66 A branch selector box.

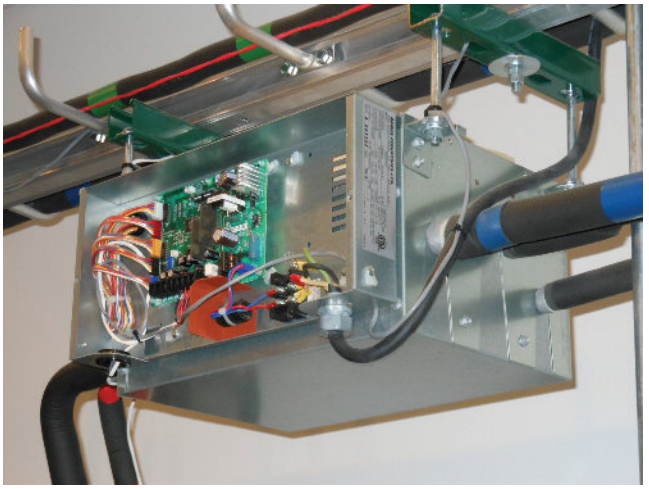

Photo by Eugene Silberstein

A simplified three-pipe VRF piping arrangement is shown in **Figure 50.69**. In this setup, there are two compressors and two outdoor coils. The compressors can be a combination of standard and inverter. There are three pipes connecting the outdoor units to the branch selector boxes. These lines are the suction line, the liquid line, and a dual-pressure gas line.

Figure 50.65 Two-pipe VRF configuration with both units calling for heating.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

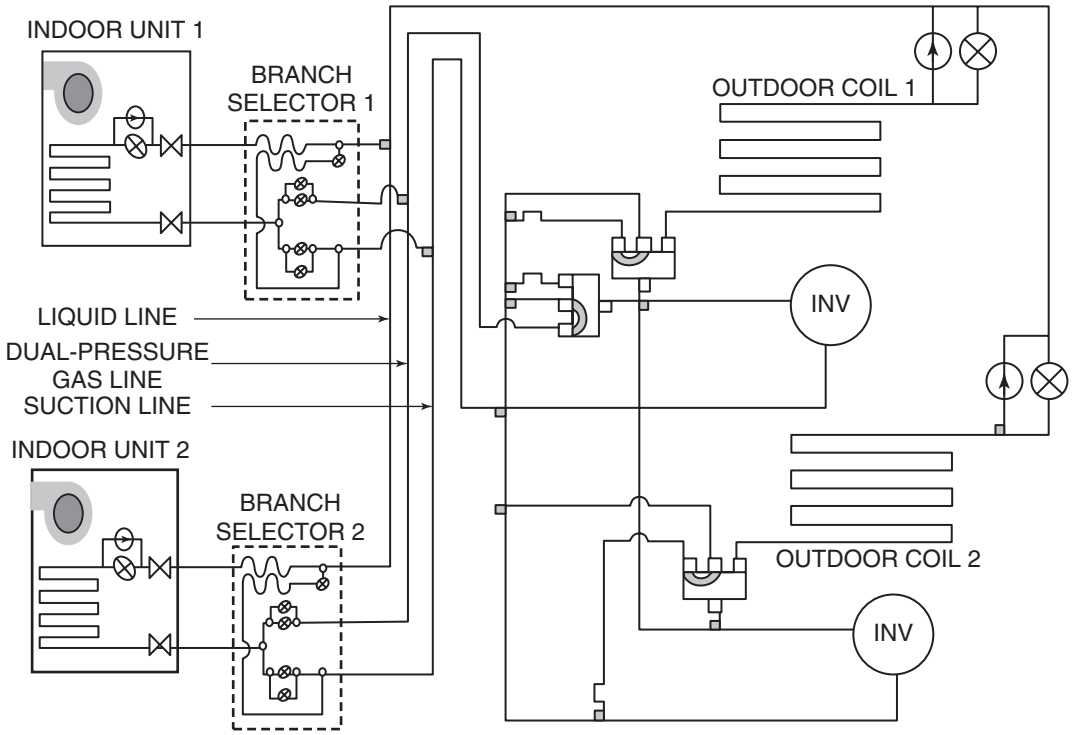
Figure 50.69 Simplified three-pipe VRF piping arrangement.



The dual-pressure gas line can carry either high- or low-pressure gas, depending on the mode of system operation. There are also two pipes that connect the branch selector box to the indoor units. These lines are the liquid line and the gas line. In the cooling mode, the liquid line will carry high-pressure, high-temperature subcooled liquid into the EEV at the indoor unit, and in the heating mode, it will carry high-pressure, high-temperature subcooled liquid from the indoor coil.

Indoors, there are multiple indoor units and multiple branch selectors. The three conditioning modes of operation are:

- all indoor units operating in the cooling mode,
- all indoor units operating in the heating mode, or
- some indoor units operating in the cooling mode and some indoor units operating in the heating mode.

When all indoor units are calling for cooling, both of the outdoor coils will function as condensers. The refrigerant lines at the outlet of the outdoor coils join and form a common liquid line that carries the refrigerant to the branch selector boxes. From the branch selector boxes, the refrigerant flows through the EEVs at the indoor units. This is represented by the red arrowed lines in **Figure 50.70**.

At the indoor units, the coils function as evaporator coils to provide comfort cooling to the occupied space. From the evaporator coils, the low-pressure, low-temperature superheated vapor returns to the compressors by flowing through the dual-pressure gas line and the suction line. This is represented by the blue arrowed lines in **Figure 50.70**.

When all indoor units are calling for heating, both of the outdoor coils will function as evaporators, while the indoor coils function as condensers. The refrigerant at the discharge of the compressors join at an equalizer line where the hot gas is directed through a four-way valve. This valve directs the high-pressure, high-temperature discharge gas to the branch selector boxes via the dual-pressure gas line. The branch selector boxes pass the hot gas to the indoor coils to heat the space. After passing through the indoor condenser coil, the high-pressure liquid bypasses the indoor EEVs by means of check valves. The liquid lines at the outlets of the branch selector boxes form a common liquid line that carries the refrigerant to the outdoor coils. The refrigerant passes through the outdoor EEVs and passes low-temperature saturated liquid into the outdoor evaporator coils. The high-pressure side of the system is represented by the red arrowed lines in **Figure 50.71**. At the outdoor coils, the refrigerant vaporizes and then returns to the compressors. This is represented by the blue arrowed lines in **Figure 50.71**.

When one indoor unit is calling for cooling while the other is calling for heating, one outdoor coil functions as the condenser, while the other functions as the evaporator. The piping arrangement is shown in **Figure 50.72**. The hot discharge gas from the compressors is directed to both Outdoor Coil 1 and Indoor Coil 2. The hot gas is supplied to the indoor coil through the dual-pressure gas line.

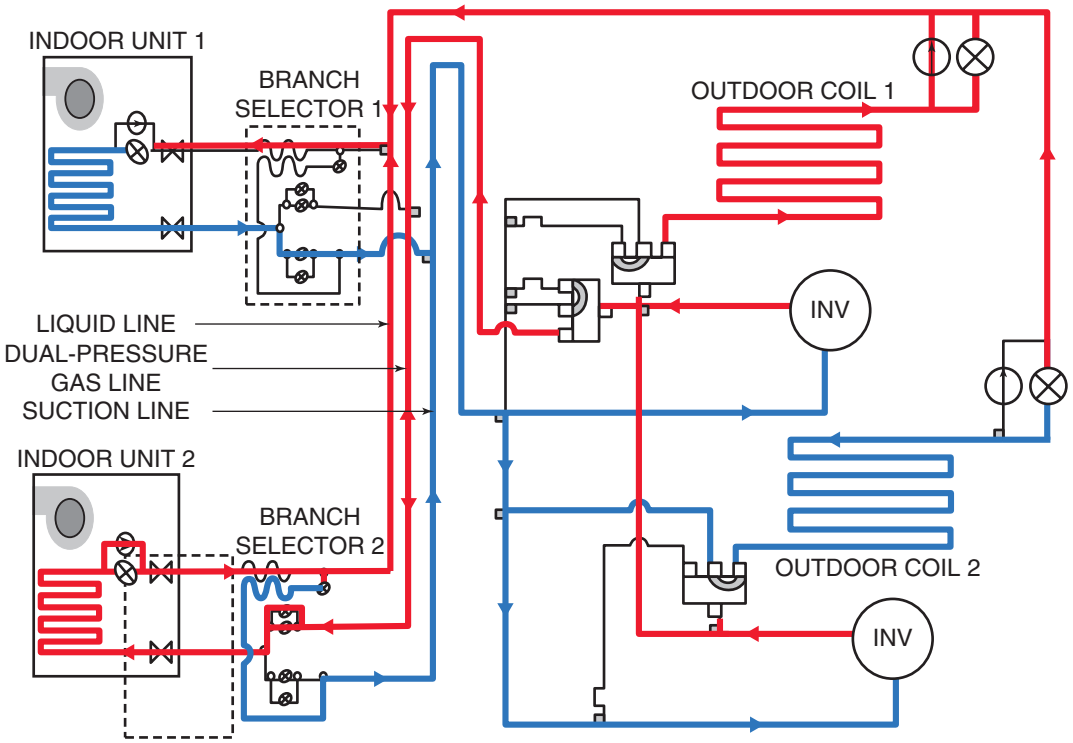
Figure 50.72 Three-pipe VRF system with one unit calling for cooling and one unit calling for heating.



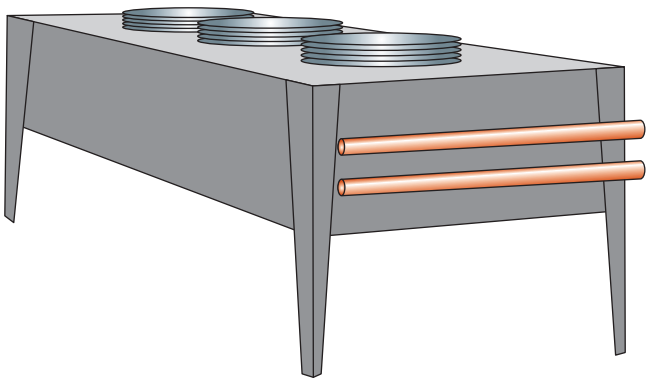
Outdoor Coil 1 and Indoor Coil 2 are both functioning as condensers. The outlets of Outdoor Coil 1 and Indoor Coil 2 are joined and supply high-temperature, high-pressure subcooled liquid refrigerant to the EEVs at Indoor Coil 1 and Outdoor Coil 2, which are both operating as evaporators. From the evaporators, the suction gas returns to the compressors. It should also be noted that the EEV (labeled SC in **Figure 50.67**) at Indoor Unit 2 is in operation to provide additional subcooling to the liquid refrigerant leaving Indoor Unit 2.

50.14 DRY COOLERS

Dry coolers, **Figure 50.73**, are unique commercial systems that incorporate a number of different technologies to create an efficient method of cooling spaces that require year-round conditioning. Dry coolers are especially desirable for use in geographic regions with four distinct seasons and for applications such as data storage facilities and medical equipment cooling. Upon initial inspection, dry coolers look very similar to air-cooled condensers. However, instead of having refrigerant coils in them, dry coolers have water coils, **Figure 50.74**. The water coil can contain 100% water or can be a glycol/water mix, depending on the climate in which the system is installed. In areas in which freezing is a problem, an antifreeze/water solution is used. Dry coolers can be described as a combination of the following concepts and processes:

- Closed-loop cooling tower
- Water-cooled equipment
- Chilled water cooling
- Economizing

Figure 50.73 A dry cooler looks like an air-cooled condenser.



DRY COOLER CONCEPTS

Closed-loop cooling towers are desirable because the water circuits of the system are not exposed to the elements and the water treatment requirements are much easier to meet than those for open-loop cooling towers. The closed-loop cooling tower, **Figure 50.75**, has a water circuit that is open to the atmosphere, but this water is only present in the tower and does not circulate through the cooling equipment. The piping circuit that carries water between the indoor and outdoor portions of the system is completely isolated from environmental contamination. The closed-loop cooling tower has a bank of fans to move air across the water piping circuit. Dry coolers

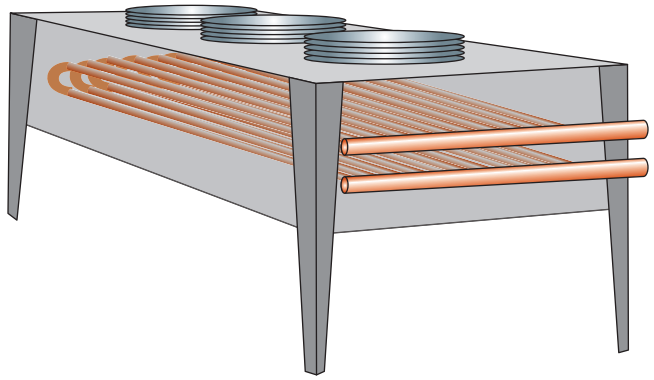
Figure 50.74 Water coils inside the dry cooler.



are similar to the closed-loop tower in the sense that they also have completely sealed water circuits and banks of fans to move air across them. This is where the similarities end. Dry coolers, as implied by their name, do not have water cascading over the piping circuits, as the closed-loop cooling tower does.

When the system's compressor is operating, the hot discharge gas from the compressor is directed to the condenser coil, which is commonly configured as a tube-in-tube heat exchanger, **Figure 50.76**. The heat that the vapor-compression refrigeration system is rejecting is absorbed by the water in the dry cooler's piping circuit. This heat is then transferred to the outside ambient air by means of water circulating through the dry cooler's piping circuit and fans moving outside air over the surface of the coils.

During periods of low ambient temperature, space cooling is achieved by circulating the cool water in the dry cooler's piping circuit through a water coil located in the airstream of the cooling equipment. This is similar in operation to a chilled water system in the sense that the cooling effect is achieved from some type of secondary refrigerant, such as water, instead of from a primary refrigerant, as in the case of direct-expansion (DX) cooling coils.

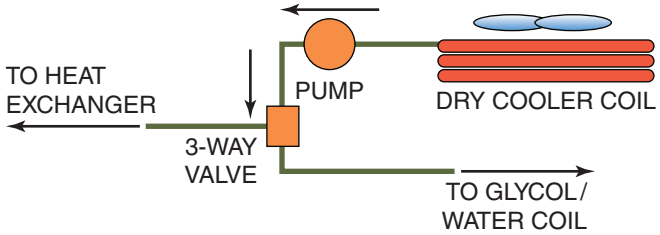
Source: Noranda Metal Industries, Inc.

Economizing is a major benefit of dry coolers. Economizing is any process by which a cooling effect is achieved that reduces, or eliminates completely, the need to operate system compressors. When the outside ambient temperature is low, the cold water in the dry cooler's piping circuit is used to provide the cooling effect without having to operate the system compressors.

DRY COOLER PIPING BASICS

The piping of a basic dry cooler is provided in **Figure 50.77**. The red and blue lines represent the high-pressure and low-pressure refrigerant lines that connect the compressor, condenser, metering device, and evaporator coil. The heat exchanger is a tube-in-tube condenser, and the direct-expansion evaporator coil is located in either the air distribution system or the dry cooler itself. The green lines represent the water piping circuit. Water is pumped from the dry cooler coil to a three-way valve. The three-way valve directs the water flow to either the tube-in-tube heat exchanger or the glycol/water coil that is located in the duct system or the dry cooler itself, **Figure 50.78**.

Figure 50.78 Three-way valve piping on a dry cooler.



DRY COOLER: WARM AMBIENT OPERATION

During periods of warm ambient temperatures, the compressor is operating and the water in the glycol/water circuit is directed to the tube-in-tube heat exchanger, **Figure 50.79**. The heat from the vapor-compression refrigeration system is rejected to the condenser. The glycol/water mix in the water piping circuit absorbs the heat from the refrigerant in the condenser and rejects this heat to the outside. When operating in this mode, the direct-expansion evaporator coil is providing the required cooling for the space.

DRY COOLER: COOL AMBIENT OPERATION

During periods of cool ambient temperatures, the compressor does not operate and the cool water in the glycol/water circuit is directed to the glycol coil, which is located in the

Figure 50.77 Basic piping circuit of a dry cooler.

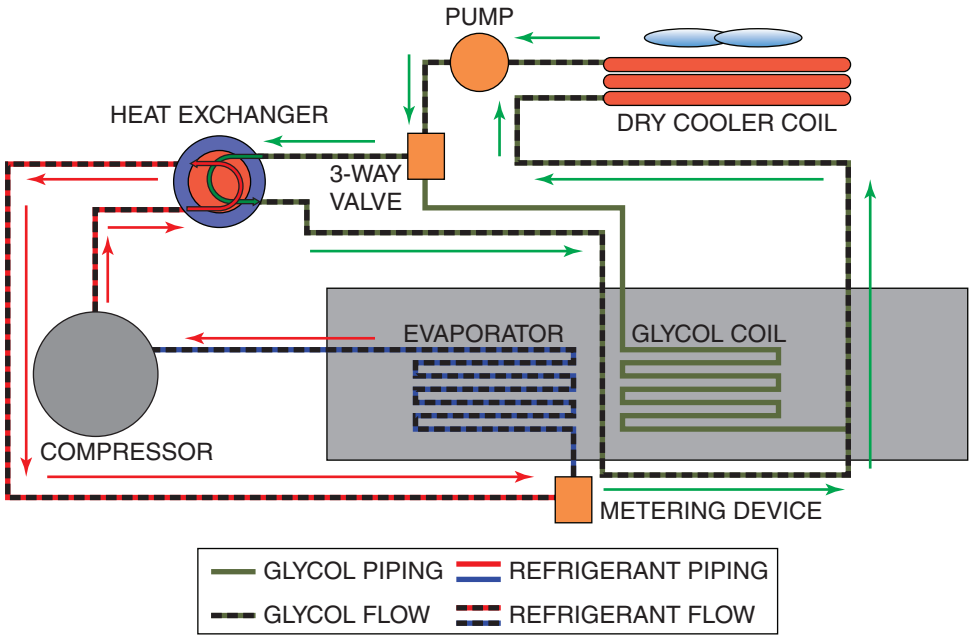
Figure 50.79 Fluid flow diagram of a dry cooler operating during warm ambient conditions.



air distribution system, **Figure 50.80**. Since the compressor is not operating, there is no need to send water to the tube-in-tube heat exchanger. The cold glycol/water mix in the water piping circuit absorbs the heat from the conditioned space providing the required cooling. After flowing through the glycol coil, the glycol/water mix is warm and then returns to the outdoor coil where it is cooled by the outside ambient air.

NOTE: *The changeover point between economizing and mechanical cooling can be determined by a number of different control strategies that include dry-bulb or enthalpy differential-type controls. If the dry-bulb or enthalpy measurement of the outside air is above the control's set point, mechanical cooling will be used. If it is determined that the temperature of the glycol/water solution can effectively cool the space, then the solution will be used instead of operating the system compressor.*

SUMMARY

- Package units are self-contained, have all major system components in one case, and require no field-installed refrigerant piping.
- Rooftop units can be manufactured with single-circuit or multicircuit refrigeration systems.
- Many package units have the ability to exhaust, ventilate, cool, heat, and filter air.
- Installation of rooftop equipment often requires the rigging of equipment onto the roof, which can be dangerous.
- Rooftop units are typically positioned directly above the conditioned space.
- Rooftop unit location should allow for proper air circulation and proper service access.
- Roof penetrations are only to be made once the unit location has been selected and all structural and safety issues have been addressed.
- Rooftop units are commonly mounted on curbs or raised steel frameworks.
- The installation crew must be in contact with the crane operator; hand signals are used to facilitate this communication.
- Economizers provide mechanical ventilation and, when conditions are desirable, can provide free-cooling to the conditioned space.
- The four modes of economizer operation are heating, modulating, integrated, and mechanical.
- Return-air conditions and outside-air conditions are compared to determine the best position for the economizer dampers.
- Air conditions can be measured using dry-bulb thermometers or enthalpy sensors.
- ASHRAE Standard 62 addresses the quality and quantity of ventilation air in commercial structures.
- Demand control ventilation, DCV, controls the amount of ventilation air in response to carbon dioxide sensor readings and estimated occupancy levels
- Carbon dioxide levels rise as occupancy rises and drop as occupancy levels drop
- Traditional air-conditioning systems deliver constant volumes of air to the occupied space.
- Variable air volume, VAV, systems modulate the flow of air to the occupied space depending on the heating, ventilating, or cooling requirements of the area.
- VAV boxes can be configured as cooling only, cooling and heating, parallel blower-assisted, or series blower-assisted.
- VAV systems can be used in conjunction with direct expansion systems or chilled-water systems.
- Valves on hot water reheat coils are typically two-way or three-way modulating valves.
- Variable refrigerant flow, VRF, systems vary the flow of refrigerant to match the needs of the system.
- VRF systems sense the saturation temperatures of the system to determine if the system load is increasing or decreasing and adjust the refrigerant flow accordingly.
- Outdoor units on VRF systems can contain a combination of standard and inverter compressors.
- Multiple outdoor units can be manifolded together to increase the capacity of the system.
- VRF systems are typically controlled by proportional integral, PI, controls.
- VRF systems can be configured as a two-pipe or three-pipe system.
- VRF systems can be configured as heat pump systems or heat pump systems with a heat recovery feature.
- The heat recovery feature allows for simultaneous heating and cooling of different areas.
- Dry coolers are a good choice for cold climate applications that require year-round cooling.
- Dry coolers can provide space cooling when the outside ambient temperature is low without operating the system compressors.

REVIEW QUESTIONS

1. Which of the following is true regarding the refrigerant piping on a rooftop package unit?
   A. The discharge and liquid lines must be field installed.
   B. The suction and liquid lines must be field installed.
   C. The discharge and suction lines must be field installed.
   D. No refrigerant lines are field installed.
2. Which process would best represent the opposite of exhausting air from a system?
   A. Cooling
   B. Ventilating
   C. Heating
   D. Filtering
3. Mixed air is best described as the combination of
   A. exhaust air and return air.
   B. return air and outside air.
   C. supply air and return air.
   D. exhaust air and outside air.
4. Which of the following should be taken into account when selecting the location and position of a rooftop package unit?
   A. Possible snow accumulation
   B. Condenser air circulation
   C. Serviceability
   D. All of the above

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

5. A bonded roof is one that has
   A. reinforced steel structural members.
   B. a written warranty or insurance policy.
   C. a leak-free rubber membrane.
   D. a slope of no more than 30 degrees.
6. Properly installed roof curbs will reduce the chances of
   A. leaks.
   B. noise transmission.
   C. Both A and B are correct.
   D. Neither A nor B is correct.
7. When rigging a unit to the roof, what minimum number of installation crew members should be on hand, not including the crane operator?
   A. 1
   B. 2
   C. 3
   D. 4
8. What is the acceptable method for communicating with the crane operator while rigging a unit to the roof?
   A. Cell phones
   B. Walkie-talkies
   C. Hand signals
   D. Verbal communications
9. Economizers are intended to
   A. provide mechanical ventilation.
   B. help reduce cooling costs.
   C. Both A and B are correct.
   D. Neither A nor B is correct.
10. Economizers have a return-air damper that
    A. opens when the outside air damper opens.
    B. opens when the outside air damper closes.
    C. closes when the outside air damper closes.
    D. Both A and C are correct.
11. The most efficient way to establish the best possible economizer position is to measure
    A. the dry-bulb temperature of the return and outside airstreams.
    B. the dry-bulb temperature of the return air and the enthalpy of the outside air.
    C. the enthalpy of the return air and the dry-bulb temperature of the outside air.
    D. the enthalpy of both the return air and the outside air.
12. Free-cooling can be accomplished if the
    A. enthalpy of the return air is lower than the enthalpy of the outside air.
    B. enthalpy of the outside air is lower than the enthalpy of the return air.
    C. enthalpy of the return air is lower than the enthalpy of the supply air.
    D. enthalpy of the return air is the same as the enthalpy of the outside air.
13. The economizer mode of operation that uses the system compressor(s) and has the outside air dampers fully open is called
    A. heating mode.
    B. modulating mode.
    C. integrated mode.
    D. mechanical mode.
14. The economizer mode of operation that uses the system compressor(s) and has the outside air dampers at their minimum position is called the
    A. heating mode.
    B. modulating mode.
    C. integrated mode.
    D. mechanical mode.
15. Explain why the outside air damper is typically never completely closed, even when the outside air conditions are not adequate to provide free-cooling.
16. Briefly explain the purpose of ASHRAE Standard 62.
17. Explain the concept of demand control ventilation.
18. Explain how carbon dioxide levels can be used to estimate the occupancy level in a particular area in a structure.
19. Describe the blowers used on VAV systems.
20. A cooling-only VAV box has all of the following except a(n)
    A. damper.
    B. control module.
    C. reheat coil.
    D. air pressure sensor.
21. Which of the following is true regarding a reheat water circuit that utilizes two-way modulating valves?
    A. The water is always circulating and is not prone to coil freeze-up.
    B. The flow rate is always constant through the reheat water circuit.
    C. The pump must be able to vary its flow.
    D. The reheat coil is equipped with a bypass pipe.
22. Variable refrigerant flow systems sense the _____ _____ and _____ of the refrigerant to determine the optimal volume of refrigerant to circulate.
23. The acronym PID stands for _____, _____, and _____.
24. Explain the main benefit of a heat-recovery VRF system.
25. The pump on a dry cooler can direct water to either the tube-in-tube heat exchanger or the cooling coil with the aid of a
    A. two-way valve.
    B. three-way valve.
    C. four-way valve.
    D. five-way valve.
26. During low ambient conditions, the dry cooler provides space cooling by
    A. operating the system compressors.
    B. pumping water to the tube-in-tube heat exchanger.
    C. pumping water to a cooling coil located in the airstream.
    D. de-energizing the blower in the air distribution system.

APPENDIX A

ALTERNATIVE HEATING (STOVES AND FIREPLACE INSERTS)

OBJECTIVES

After studying this unit, you should be able to

- list reasons for the formation of creosote.
- describe methods to help prevent the formation of creosote.
- explain how stovepipe should be assembled and installed.
- list safety hazards that may be encountered with wood stoves.
- describe the three types of venting for gas stoves.
- explain how a fireplace insert can improve on the heating efficiency of a fireplace.

SAFETYCHECKLIST

☑ Many safety practices must be adhered to when installing or using a wood-burning appliance. Many of these safety practices are stated within this unit, printed in red. Many other safety practices must be adhered to, including those provided by manufacturers and local, regional, and state codes. It is also necessary to use good judgment and common sense at all times.

Codes, regulations, and laws regarding wood-burning and gas heating appliances and components change frequently. It is essential that you become familiar with the appropriate current National Fire Protection Association (NFPA) information and other codes, regulations, and laws.

A.1 WOOD-BURNING STOVES

Both wood- and gas-burning stoves are used as an alternative heating appliance in many homes. In some homes, stoves are a primary heat source; in others they are used to supplement primary heat sources. Wood must be readily available to make wood-burning stoves practical. However, pellet stoves, which burn small compressed wood by-products, may be used in many locations where pellets are available.

A.2 ORGANIC MAKEUP AND CHARACTERISTICS OF WOOD

Wood plants manufacture glucose. Some of this glucose, or sugar, turns into cellulose. Approximately 88% of wood is composed of cellulose and lignin in equal parts. Cellulose is an inert substance and forms the solid part of wood plants. It forms the main or supporting structure of each cell in a tree. Lignin is a fibrous material, a polymer, which binds to cellulose fibers and hardens and strengthens the cell walls of trees. The remaining 12% of the wood is composed of resins, gums, and a small quantity of other organic material. Water in green or freshly cut wood constitutes from one-third to two-thirds of its weight. Thoroughly air-dried wood may have as little as 15% moisture content by weight.

Wood is classified as hardwood or softwood. Hickory, oak, maple, and ash are examples of hardwood. Pine and cedar are examples of softwood. **Figure A.1** lists some common types of wood and the heat value in each type in millions of Btus/cord. A cord of wood can be split, unsplit, or mixed. It is important to know whether the wood is split, because there is more wood in a stack that is split. Wood is sold by the cord, which is a stack 4 ft × 4 ft × 8 ft, or 128 ft^3. Because wood is sold by volume and not by weight, wood that is split has less air space between the individual pieces. This will give the cord of wood a higher density, meaning more wood per cord.

Wood should be dry before burning. Approximately 20% more heat is available in dry wood than in green wood. Wood should be stacked off the ground on runners and should be

Figure A.1 The table indicates the weight per cord, the Btus per cord of air-dried wood, and the equivalent value of No. 2 fuel oil in gallons.

TYPE	WEIGHT CORD	BTU PER CORD AIR DRIED WOOD	EQUIVALENT VALUE #2 FUEL OIL, GALS.
White Pine	1800#	17,000,000	120
Aspen	1900	17,500,000	125
Spruce	2100	18,000,000	130
Ash	2900	22,500,000	160
Tamarack	2500	24,000,000	170
Soft Maple	2500	24,000,000	170
Yellow Birch	3000	26,000,000	185
Red Oak	3250	27,000,000	195
Hard Maple	3000	29,000,000	200
Hickory	3600	30,500,000	215

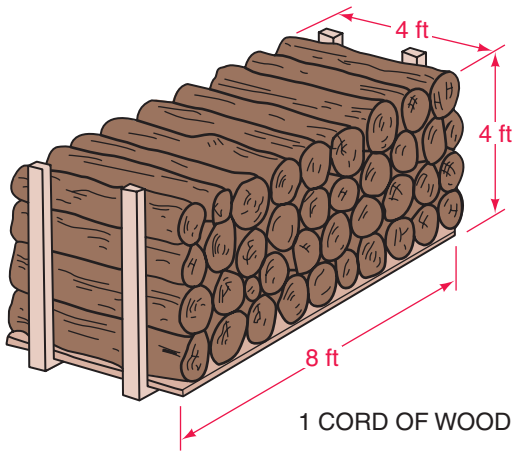
Figure A.2 Wood should be stacked on runners so that air can circulate through and around it.



well ventilated, **Figure A.2**. When possible, the wood should be covered, but air should be allowed to circulate through it. Wood splits more easily when it is green or freshly cut and dries better when it has been split. When green wood is burned, combustion will be incomplete, resulting in unburned carbon, oils, and resins, which leave the fire as smoke.

During oxidation, or burning, oxygen is added to the chemical process. This actually turns wood back into products that helped it grow as a plant: primarily carbon dioxide (CO_2), water (H_2O), and other miscellaneous materials. Heat also is produced. Some woods produce more heat than others per cord, **Figure A.1**. Generally, dry hardwoods are the most efficient.

A.3 ENVIRONMENTAL PROTECTION AGENCY (EPA) REGULATIONS

On July 1, 1988, the Environmental Protection Agency's first national woodstove emissions standards went into effect. Emissions from wood-burning appliances were adding to the pollutants in the air along with all the other sources of air pollution. Wood smoke contains both polycyclic organic matter (POM) and nonpolycyclic organic matter, which are considered to be health hazards and are of concern to many people. All wood-burning stoves manufactured after July 1, 1989 must be EPA certified. Two EPA standards exist—one for **catalytic combustor stoves** and one for **noncatalytic stoves**. Catalytic stoves contain a catalytic combustor and may not emit more than 5.5 g/h of particulates for those stoves manufactured between July 1, 1989, and June 30, 1990. The noncatalytic stoves manufactured between these dates may not emit more than 8.5 g/h. These limits are reduced further for stoves manufactured after July 1, 1990, to 4.1 g/h for the catalytic models and 7.5 for the noncatalytics. As new stoves are purchased and installed, replacing older stoves, the air pollutants from wood-burning stoves will be drastically reduced because the particulate emission of the catalytic stove is approximately 10% of the emissions of the older stoves. Some individual states have implemented what are called *No-Burn Days*. On a no-burn day, it is illegal to use a wood-burning fireplace or stove. The intent is to limit pollution on days when pollutants are at high levels. On February 3, 2015, the EPA made some significant changes to its New Source Performance Standards (NSPS) for residential wood-burning appliances. At the time of this writing, the changes have not been finalized, but are intended to update the emission levels that reflect improved technologies in wood-burning appliances. The changes would apply only to newly manufactured appliances, not those already in use. More information can be found at the EPA website, *www.epa.gov/burnwise*.

A.4 CREOSOTE

Creosote is a mixture of unburned organic material. When it is hot, it is a thick, dark-brown liquid. When it cools, it forms into a tar-like residue. It then often turns into a black, flaky substance that adheres to the inside of the chimney or stovepipe. The formation of creosote is particularly a problem with the uncertified stoves manufactured before July 1, 1989. Some of the primary causes of excessive creosote are:

- smoldering low-heat fires.
- smoke in contact with cool surfaces in the stovepipe or chimney.
- burning green wood.
- burning softwood.

SAFETY PRECAUTION: *Creosote buildup in the stovepipe and chimney is dangerous. It can ignite and burn with enough force to cause a fire in the building, blow stovepipes apart, and cause chimney fires.*

To help prevent the formation of creosote, dry hardwood should be burned with some intensity. When the stovepipe or chimney flue temperature drops below 250°F, creosote will condense onto the interior surfaces of the chimney. The run of stovepipe should be as short as possible. The minimum rise should be 1/4 in. per foot of horizontal run. A rise of 30° is recommended, **Figure A.3**. Anything that slows the movement of the gases allows them to cool more quickly, which will cause more creosote condensation. The stovepipe should be assembled with the crimped end down, **Figure A.4**; this will keep the creosote inside the pipe. Stovepipes and chimneys should also be cleaned regularly.

A.5 DESIGN CHARACTERISTICS OF WOOD-BURNING STOVES

As mentioned, all wood-burning stoves manufactured since July 1, 1989, must be EPA certified, as either noncatalytic or catalytic combustor stoves.

Figure A.3 The stovepipe should be pitched upward from the stove to the chimney.

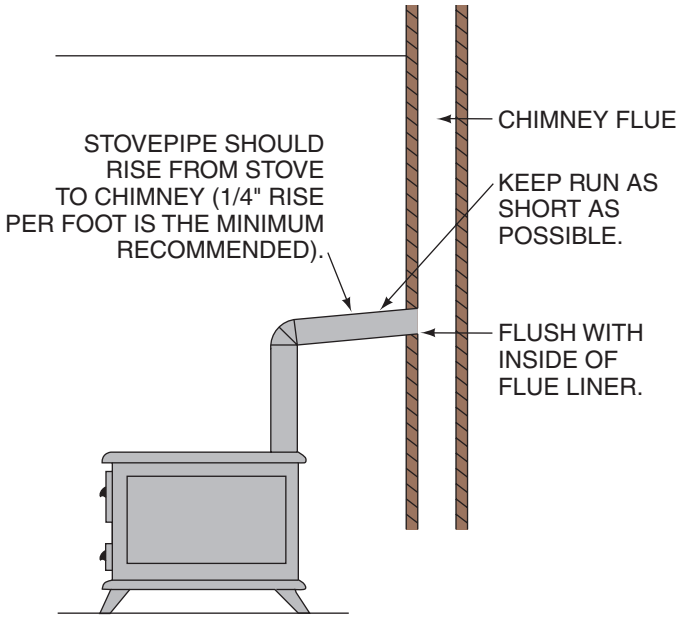

Figure A.4 The stovepipe sections should be assembled with the crimped ends of the stovepipe pointing down to prevent the creosote from leaking out of the joint.

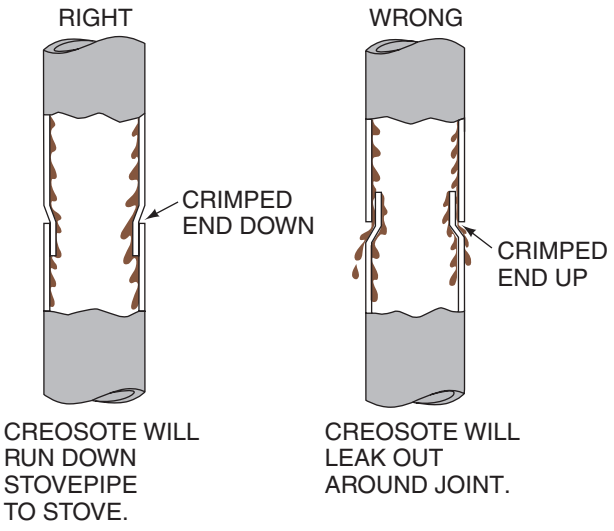
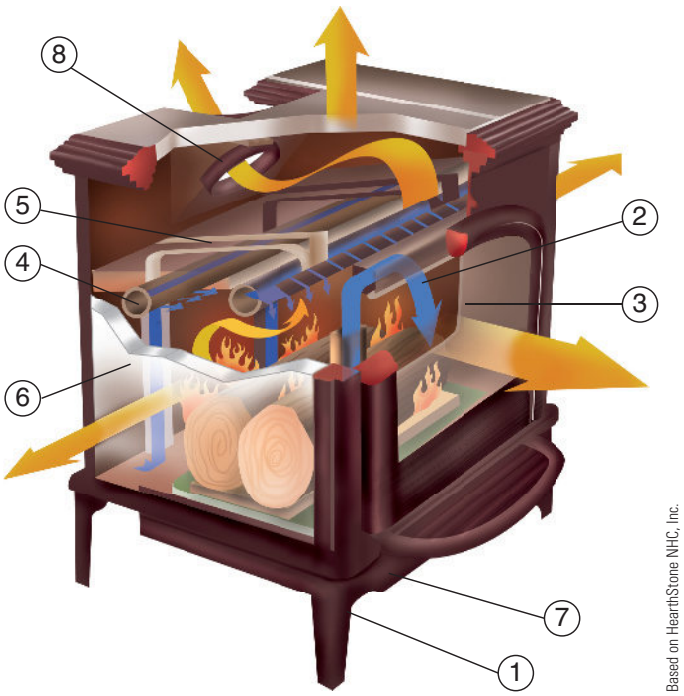


NONCATALYTIC CERTIFIED STOVES

Noncatalytic stoves force the unburned gases to pass through a secondary combustion chamber. Temperatures higher than 1000°F are maintained in this chamber, which burns the gases and therefore the pollutants, including most of the creosote, and produces more heat, providing a better operating efficiency. **Figure A.5** is an example of one design of this type of stove.

Figure A.5 A noncatalytic wood-burning stove.



CATALYTIC COMBUSTOR CERTIFIED STOVES

A catalytic combustor is a form of afterburner that increases the burning of wood by-products. These combustors use a catalyst to cause combustion by producing a chemical reaction, which burns the flue gases at about 500°F rather than the 1000°F otherwise required.

Most combustors have a cell-like structure, **Figure A.6**, and consist of a substrate, washcoat, and catalyst. The *substrate* is a ceramic material formed into a honeycomb shape. Ceramic material is used because of its stability in extremely cold and hot conditions. The *washcoat,* usually made of an aluminum-based substance called alumina, covers the

ceramic material and helps disperse the catalyst across the combustor surface. The *catalyst* is made of a noble metal, usually platinum, palladium, or rhodium, which is chemically stable in extreme temperatures. **Figure A.7** is an illustration of a woodstove with a catalytic combustor. A disadvantage of this combustor is that it must be replaced every few years.

RADIATION AND CONVECTION CHARACTERISTICS

Wood-burning stoves heat by both radiation and convection. Radiation is heat that comes from the stove in waves and heats objects in its path, such as the walls, floor, and furniture. The stove also heats the air around it. This is called convective heat. As the air is heated, it rises, and cooler air comes in to take its place and is heated. This cycle of convection currents is continuous. Some stoves are designed to utilize convective heating to a greater extent than others. They may have a blower system to spread the heat out further and to make the convection process more efficient.

PELLET STOVES

Pellet stoves are a more recent design, are energy efficient, and use a renewable energy source, **Figure A.8**. The fuel consists of small, compressed pellets made from waste wood, primarily sawdust from lumber sawmills, **Figure A.9.** The pellets may also be made from waste cardboard or even agricultural wastes such as sunflower and cherry seed hulls. Stove owners should make sure that they use only the type of pellets recommended by the manufacturer. Pellets are normally packaged in 40- or 50-lb bags.

Figure A.8 A pellet stove.

Photo by Eugene Silberstein

Figure A.9 Wood pellets.

Photo by Eugene Silberstein

Most pellet stoves are designed with a hopper at the back or top. The pellets are fed to the combustion chamber with an auger powered by an electric motor, which is often controlled by a thermostat. The room air is generally circulated through the heat exchanger and into the conditioned space by a multispeed blower.

Very little air pollution is produced and as little as 1% of the pellet material remains as ash. Most stoves do not require a chimney because exhaust gases are forced outside through a vent pipe by a combustion fan. Combustion air may be drawn in from outdoors so that heated room air is not used for combustion. This provides additional efficiency by not

Figure A.10 A horizontal vent pipe must have an end cap to prevent air or exhaust gases from being blown into the stove. A vent pipe may be extended vertically above the eaves.

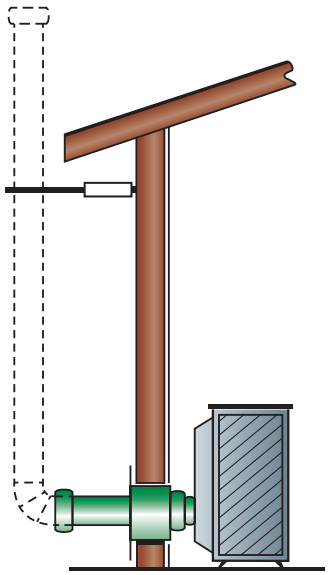

Figure A.11 Pellet stoves may operate more efficiently if masonry chimneys are relined with a stainless steel liner.

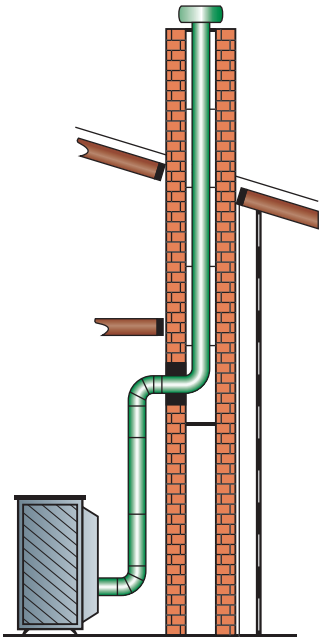

creating a negative pressure in the room and thus decreasing the cold air that will infiltrate through cracks in doors and windows. The exhaust gases may be vented through a horizontally positioned vent pipe with an end cap to prevent wind from blowing air and the exhaust gases into the stove, **Figure A.10.** The vent pipe must be constructed of PL vent pipe tested to UL 641 standards, which is a double-walled pipe with an air space between the walls. All joints must be sealed with an approved sealer. This is important because the venting system has an electrically operated exhaust combustion fan; if there should be a power failure, the combustion fumes could enter the conditioned space.

A lined masonry chimney that meets all appropriate codes may be used with pellet stoves. However, many masonry chimneys will be large enough to affect the operation of the stoves adversely. These chimneys may be relined with a stainless steel liner, **Figure A.11**. The stove manufacturer's literature should be consulted for the recommended diameter of the liners.

STOVE CONSTRUCTION

Stoves may be constructed of steel, cast iron, soapstone, or a combination of these materials. Stoves made of steel are normally the least expensive. They are made of sheet steel welded together and normally have a firebox of refractory bricks. These stoves give off heat almost immediately after the fire is started. With a large, hot fire, they will quickly give off a considerable amount of heat. However, when the fire dies, the heat from the stove will also quickly cool.

Many stoves are manufactured of cast iron. These can be much more decorative, because the casting process provides an opportunity for intricate detail, particularly on the sides and legs. Cast iron is more durable than steel, and the heat is more even and less intense than that of a sheet-steel stove. These stoves also cool down more slowly after the fire extinguishes.

Soapstone may be used, particularly in combination with cast iron, as a material in the manufacture of wood-burning stoves. Soapstone can withstand the changes in temperature, such as from room temperature to very intense heat. It may be used not only on the exterior of stoves but also for the firebox because it can withstand exposure to direct flames. This material provides a gentle heat and can hold and radiate heat for longer periods than the other materials.

MAKEUP AIR

Air used in combustion must be made up or resupplied from the outside with, for example, an inlet from the outside directly to the stove, **Figure A.12.** Often, an older home has many air leaks. The hot air may leak out near the ceiling or through the attic. Cool air can leak in through cracks around windows, under doors, and elsewhere. Although this may disturb the normal heating cycle, it does help to make up for air leaving through the chimney as a result of the combustion and venting.

SAFETY PRECAUTION: *In modern homes that are sealed and insulated well, some provision may have to be made to supply the makeup air. A door may have to be opened a crack to provide a proper draft. A stove could actually burn enough oxygen in a small home to make it difficult to get enough oxygen to breathe. Always make sure that there is enough makeup air.*

SAFETY HAZARDS

SAFETY PRECAUTION: *Live coals in the stove in the living area of a house, along with creosote in stovepipes and chimneys, make it absolutely necessary to install, maintain, and operate stoves safely. This cannot be emphasized enough.*

Following are some of the safety hazards that may be encountered:

- A hot fire can ignite a buildup of creosote, resulting in a stovepipe or chimney fire.
- Radiation from the stove or stovepipe may overheat walls, ceilings, or other combustible materials in the house and start a fire.
- Sparks may get out of the stove, land on combustible materials, and ignite them. This could happen through a defect in the stove, while the door is left ajar, while the firebox is being filled, or while ashes are removed.
- Flames could leak out through faulty chimneys, or heat could be conducted through cracks to a combustible material.

Burning materials coming out of the top of the chimney can also start a fire on the outside of the house. These sparks or glowing materials can ignite roofing materials, leaves, brush, or other matter outside the house.

A.6 INSTALLATION PROCEDURES

A national testing laboratory should approve a wood-burning stove or appliance. Before installing a stove, stovepipe, or prefabricated chimney, all building and fire marshal's codes must be followed, as well as the instructions of the testing laboratory and manufacturer. If one code or set of instructions is more restrictive than another, the most restrictive instructions should be followed.

Instructions should include the distance the stove is to be located from any combustible material, such as a wall or the floor. They should also indicate the minimum required protective material between the stove and the wall and between the stove and the floor. Excessive heat from the stove can heat the walls or floor to the point where a fire can be started.

The stove must be connected to the chimney with an approved stovepipe, often called a connector. Codes and instructions must be followed. A stove collar adapter, often supplied by the manufacturer, should be used to connect the stovepipe to the stove, **Figure A.13**. The manufacturer may make special provision for this.

Figure A.14 shows three different types of installations. The stovepipe must not run through any combustible material, such as a ceiling or wall. Approved chimney sections with necessary fittings should be used. **Figure A.15** illustrates details for adapting the stovepipe to the "through-the-wall" chimney fittings. As mentioned earlier, horizontal stovepipe runs should be kept to a minimum. A rise of 1/4 in. per ft should be considered a minimum, **Figure A.3**. Local codes or manufacturers may require a greater rise. Approved thimbles, joist shields, insulation shields, and other necessary fittings must be used where required, all materials should be approved by a recognized national testing laboratory, and all codes should be met.

Only one stove can be connected to a chimney. For masonry chimneys with more than one flue, no more than one stove can be connected to each flue. A factory-built chimney used for woodstoves should be rated as a residential and building heating appliance chimney. Check all codes.

SAFETY PRECAUTION: *Many stoves are vented through masonry chimneys. If a new chimney is being used, it should have been constructed according to applicable building codes and carefully inspected. If an old chimney is being used, an experienced person should inspect it to ensure that it is safe.*

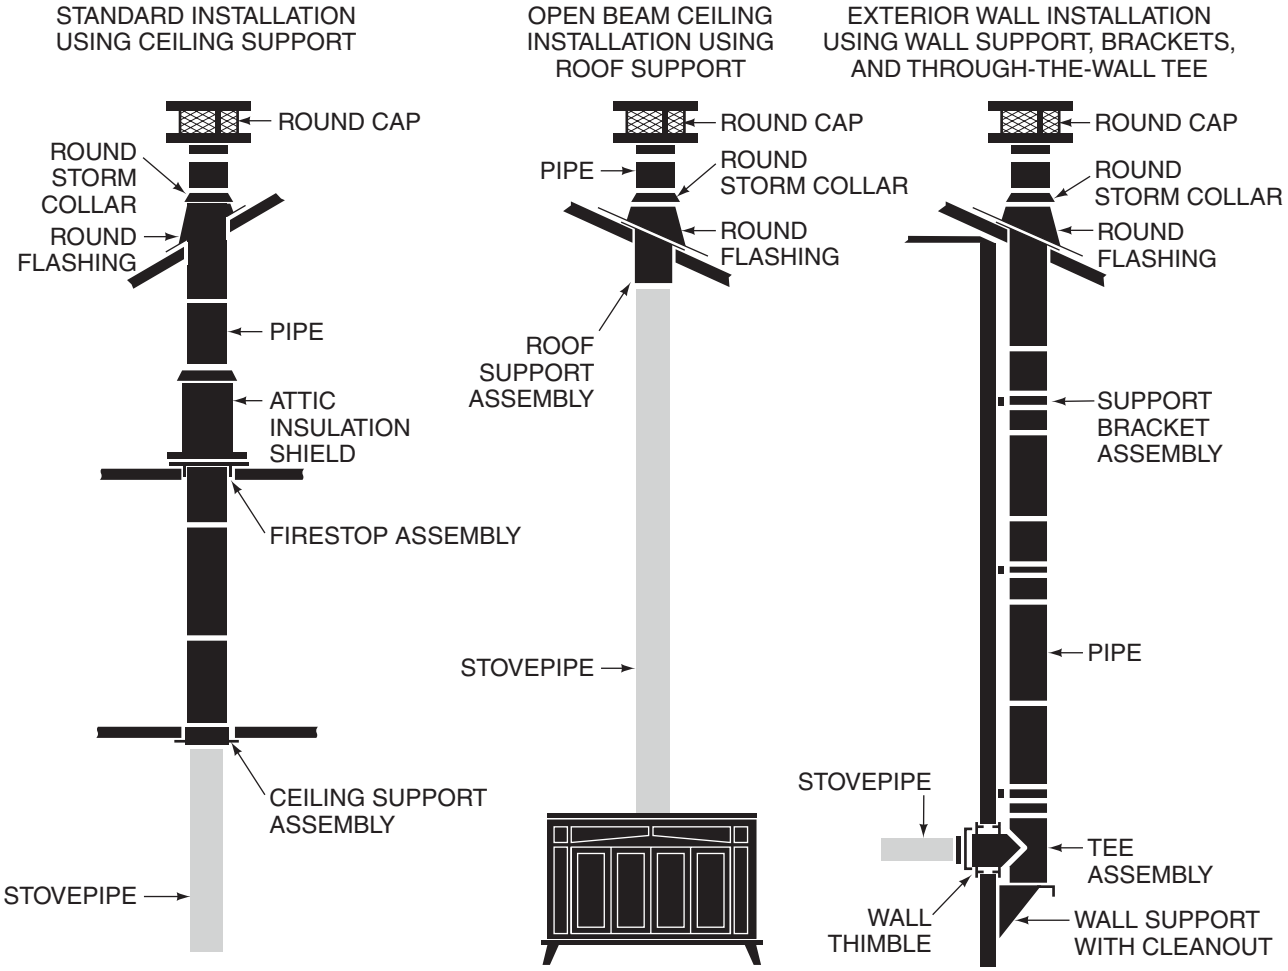
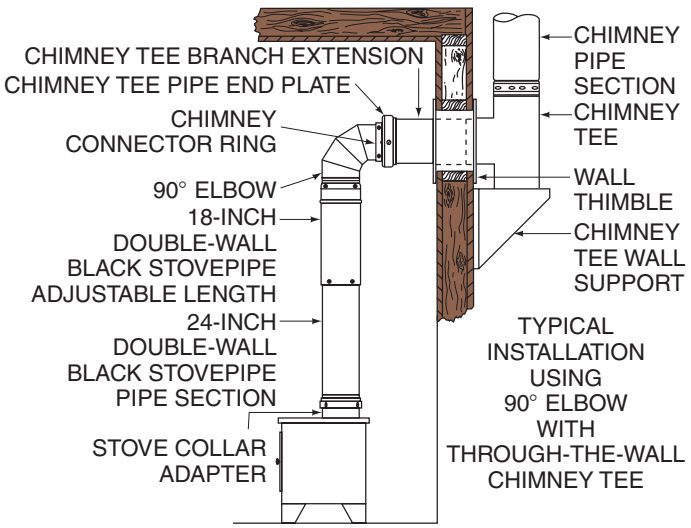
Figure A.14 Three different types of stove installations.



CHIMNEY MUST BE ENCLOSED WHERE IT PASSES THROUGH OCCUPIED SPACES TO MAINTAIN REQUIRED CLEARANCES TO COMBUSTIBLES AND TO PROTECT A GAINST DAMAGE.

NOTE: OUTSIDE CHIMNEYS ARE NOT AS DESIRABLE, SINCE THEY ARE MORE SUBJECT TO DOWNDRAFTS AND CREOSOTE BUILDUP.

Figure A.15 Details of a through-the-wall installation.



The mortar in the joints may be deteriorated and loose, or a serious chimney fire may have cracked the chimney. All necessary repairs should be made to the chimney by a competent mason before connecting the stove to it. Manufacturers or their suppliers may recommend that chimneys be lined, Figure A.10, for a better draft and/or safety.

A.7 SMOKE DETECTORS

SAFETY PRECAUTION: *Smoke detectors should be used in all homes regardless of the type of heating appliance. It is even more important to install smoke detectors when burning wood fuel. Many types of detectors are available. They may be AC-powered photoelectric detectors or an AC-or battery-powered ionization chamber detector.*

If the smoke detectors are battery-powered, be sure to change the batteries regularly to ensure continued satisfactory operation.

A.8 GAS STOVES

Gas stoves are becoming popular as a heating appliance. The American National Standards Institute (ANSI) may certify these as a "decorative appliance" or as a "room heater." Decorative appliances are attractive but not designed for larger space heating. Room heaters are, as the name implies, heating appliances and will have efficiency ratings. They may be manufactured of materials similar to woodstoves and are available in many attractive colors, **Figure A.16**. Gas appliances should be installed by certified personnel or by those approved to do so.

Gas stoves may be designed to burn either natural or propane gas. Many are designed so the orifice can be adjusted or changed to switch from burning one type of gas to the other. Most utilize a standing pilot for ignition and have controls to shut off the gas should the pilot go out. Many gas stoves operate without electricity and can be used for heating during a power outage. Some have variable-speed convection blowers to help circulate the heated air.

VENTING

Gas stoves may be designed as **B-vent**, **direct-vent**, or **vent-free** stoves.

B-VENT. Stoves requiring a B-vent must be vented through the roof or into an existing chimney. A flue liner may be suggested or required if venting into an existing chimney. The liner will reduce the size of the flue so that the stove will draft properly.

Figure A.16 A gas stove.

Courtesy Hearth & Home Technologies®

DIRECT-VENT. Stoves utilizing a direct-vent system make use of a double-wall pipe to pull outside air in for combustion and to vent flue gases to the outside. Direct-vent options may include:

- venting straight back from the stove and through the wall.
- venting up from the stove and then through the wall.
- venting up through the roof.
- in some cases, venting into a lined fireplace flue.

VENT-FREE. Vent-free stoves, as the name implies, require no venting. Some people are concerned about gas combustion in the living area and not venting the flue gases. These stoves do have a good safety record but are not approved at this writing in all states. They have an oxygen depletion sensor (ODS), which turns off the pilot light and gas supply when the oxygen level in the area of the stove is depleted to a certain level.

A.9 FIREPLACE INSERTS

Fireplace inserts can convert a fireplace from a very inefficient heat source to one that is more efficient. Very little heat can be obtained from a fireplace without some device to help contain the heat and move it from the fireplace into the room. The fireplace insert provides a way to retain the heat and blow it into the room. **Figure A.17** is a photo of a fireplace insert.

WOOD-BURNING INSERTS

Fireplace inserts can be either wood- or gas-burning. A wood-burning insert is basically a woodstove that is designed to be placed into an existing fireplace. New wood-burning inserts must be certified by the EPA just as woodstoves are. The regulations ensure that they will burn more cleanly

Figure A.17 A wood-burning fireplace insert.

and efficiently. A wood-burning insert generally requires a fireplace and chimney to be of masonry construction. Local building codes and the manufacturer's specifications for the particular insert should be consulted to ensure that the size and construction of the fireplace can accommodate the insert. All installations should meet the NFPA and other appropriate codes. Many factory-built or prefabricated fireplaces are not approved for inserts.

Inserts are usually made from plate steel, cast iron, or a combination of these materials. They may fit into the fireplace opening so that they are basically flush with the front, or they may protrude to some degree onto the hearth. Those that protrude are usually more efficient, as this part of the insert will provide more radiant heat. Inserts normally have blowers that may be controlled manually or with a thermostat and that improve efficiency.

In many areas, codes for new insert installations now require that the insert be installed with a positive connection to the chimney flue, which prevents creosote from running down into the fireplace and becoming a fire hazard. Smoke and gases will then exit the fireplace more directly into and out of the chimney.

Inserts should never be used in a chimney flue that is used for another purpose. Before an insert is installed, a professional should inspect the chimney. If there is creosote buildup, the chimney must be cleaned. Professional chimney sweeps should be employed to clean chimneys.The chimney and fireplace should also be checked for cracks or flaws that could be a fire hazard. Many inserts make it more difficult to clean the chimney, as they must be removed from the fireplace. Some inserts have a special collar and direct flue liner to the top of the chimney, and these may be left in place for cleaning.

GAS FIREPLACE INSERTS

Gas inserts may be used to convert an existing wood-burning fireplace to a gas appliance. Many of these may be installed in prefabricated fireplaces where wood-burning units may not. They may be designed to burn either natural gas or propane but usually need to be adjusted for one or the other. Before any insert is installed, the existing fireplace and chimney should be of the type approved for the insert chosen.

Many gas units and/or installations require that the chimney flue be lined with a metal liner and connected to the insert. This produces a better draft and more efficiency. The inserts are usually sealed with glass doors and have blowers that help to make them more efficient. The doors prevent excess indoor air from being used for combustion. Just the right amount of combustion air is usually introduced through adjustable air shutters. Blowers simply make the convective heat transfer more efficiently. NFPA and other codes should be consulted regarding these liners. Some newer gas inserts are designed so that a chimney liner is not required. However, they are less efficient and allow more heat to go up the chimney, which heats the existing chimney flue liner and increases the draft.

All gas appliances, stoves, or inserts must be connected to the gas source. Piping needs to be routed and installed. This usually means cutting, threading, and sealing pipe and should be done by a professional trained and approved to do this work.

GLOSSARY/GLOSARIO

NOTE: English term appears **boldface** followed by Spanish term set in ***italic***.

A

Absolute pressure Gauge pressure plus the pressure of the atmosphere, normally 14.696 at sea level at 70°F.

Presión absoluta La presión del manómetro más la presión de la atmósfera, que generalmente es 14696 al nivel del mar a 70°F (21.11°C).

Absolute zero temperature The lowest obtainable temperature where molecular motion stops, −460°F and −273°C.

Temperatura del cero absoluto La temperatura más baja obtenible donde se detiene el movimiento molecular, –460°F y −273°C.

Absorbent (attractant) The salt solution used to attract water in an absorption chiller.

Hidrófilo Solución salina utilizada para atraer el agua en un enfriador por absorción.

Absorber That part of an absorption chiller where the water is absorbed by the salt solution.

Absorbedor El lugar en el enfriador por absorción donde la solución salina absorbe el agua.

Absorption The process by which one substance is absorbed by another.

Absorción Proceso mediante el cual una sustancia es absorbida por otra.

Absorption air-conditioning chiller A system using a salt substance, water, and heat to provide cooling for an air-conditioning system.

Enfriador por absorción para acondicionamiento de aire Sistema que utiliza una sustancia salina, agua y calor para proveer enfriamiento en un sistema de acondicionamiento de aire.

ABS pipe Acrylonitrile-butadiene-styrene plastic pipe used for water, drains, waste, and venting.

Tubo de acronitrilo-butadieno-estireno Tubo plástico de acronitrilo-butadieno-estireno utilizado para el agua, los drenajes, los desperdicios y la ventilación.

ACCA Manual J The Air Conditioning Contractors of America Manual that facilitates the calculations of heat gains and heat losses in residential structures.

Manual J de la ACCA Manual de los contratistas de acondicionamiento de aire de los Estados Unidos, que facilita el cálculo de las pérdidas y ganancias de calor en estructuras residenciales.

Accumulator A storage tank located in the suction line. It allows small amounts of liquid refrigerant to boil away before entering the compressor. Sometimes used to store excess refrigerant in heat pump systems during the winter cycle.

Acumulador Tanque de almacenaje ubicado en el conducto de aspiración. Permite que pequeñas cantidades de refrigerante líquido se evaporen antes de entrar al compresor. Algunas veces se utiliza para almacenar exceso de refrigerante en sistemas de bombas de calor durante el ciclo de invierno.

Acetylene A gas often used with air or oxygen for welding, brazing, or soldering applications.

Acetileno Gas usado con frecuencia, junto con aire u oxígeno, en trabajos de soldadura y soldaduras de cobre.

ACH An acronym for (air changes per hour).

ACH Acrónimo de intercambios de aire por hora.

ACH_{50} An acronym for air changes per hour of air leakage while the blower door is connected and pulling 50 Pascal of vacuum on the house.

ACH_{50} Acrónimo de intercambios de aire por hora de pérdida de aire cuando se conecta un extractor de aire potente en una de las entradas, el cual genera un vacío de 50 Pascales en el interior de la vivienda.

Acid-contaminated system A refrigeration system that contains acid due to contamination.

Sistema contaminado de ácido Sistema de refrigeración que, debido a la contaminación, contiene ácido.

"A" coil An evaporator coil that can be used for upflow, downflow, and horizontal-flow applications. It actually consists of two coils shaped like a letter "A."

Serpentín en forma de "A" Serpentín de evaporación que puede utilizarse para aplicaciones de flujo ascendente, descendente y horizontal. En realidad, consiste en dos serpentines en forma de "A."

ACR tubing Air-conditioning and refrigeration tubing that is very clean, dry, and normally charged with dry nitrogen. The tubing is sealed at the ends to contain the nitrogen.

Tubería ACR Tubería para el acondicionamiento de aire y la refrigeración que es muy limpia y seca, y que por lo general está cargada de nitrógeno seco. La tubería se sella en ambos extremos para contener el nitrógeno.

Activated alumina A chemical desiccant used in refrigerant driers.

Alúmina activada Disecante químico utilizado en secadores de refrigerantes.

Activated charcoal A substance manufactured from coal or coconut shells into pellets. It is often used to adsorb solvents, other organic materials, and odors.

Carbón activado Sustancia fabricada utilizando carbón o cáscaras de coco, en forma de gránulos. Se emplea para adsorber disolventes, así como otros materiales orgánicos y olores.

Active recovery Recovering refrigerant with the use of a recovery machine that has its own built-in compressor.

Recuperación activa El hecho de recuperar refrigerante utilizando un recuperador que dispone de su propio compresor.

Active sensor Sensors that send information back to the controller in terms of milliamps (mA) or volts.

Sensor activo Sensores que devuelven información al controlador en miliamperios (mA) o voltios.

Active solar system A system that uses electrical and/or mechanical devices to help collect, store, and distribute the sun's energy.

Sistema solar activo Sistema que utiliza dispositivos eléctricos y/o mecánicos para ayudar a acumular, almacenar y distribuir la energía del sol.

Adsorption The process by which a thin film of a liquid or gas adheres to the surface of a solid substance.

Adsorción Proceso mediante el cual una fina capa de líquido o gas se adhiere a la superficie de una sustancia sólida.

Air, standard Dry air at 70°F and 14.696 psi, at which it has a mass density of 0.075 lb/ft^3 and a specific volume of 13.33 ft^3/lb, ASHRAE.

Aire, estándar Aire seco a 70°F (21.11°C) y 14696 psi (libra por pulgada cuadrada); a dicha temperatura tiene una densidad de masa de 0075 $libra/pies^3$ y un volumen específico de 1333 $pies^3/libra$, ASHRAE.

Air-acetylene A mixture of air and acetylene gas that when ignited is used for soldering, brazing, and other applications.

Aire-acetilénico Mezcla de aire y de gas acetileno que se utiliza en la soldadura, la broncesoldadura y otras aplicaciones al ser encendida.

Air-acetylene unit A torch kit that uses acetylene as its fuel.

Unidades de aire-acetileno un juego de antorcha que utiliza acetileno como su combustible

Air Changes per Hour (ACH_{50}) The number of times the air is replaced in an interior space each hour.

Cambios de aire por hora (ACH_{50}) El número de veces que el aire se reemplaza en un espacio interior cada hora.

Air conditioner Equipment that conditions air by cleaning, cooling, heating, humidifying, or dehumidifying it. A term often applied to comfort cooling equipment.

Acondicionador de aire Equipo que acondiciona el aire limpiándolo, enfriándolo, calentándolo, humidificándolo o deshumidificándolo. Término comúnmente aplicado al equípo de enfriamiento para comodidad.

Air conditioning A process that maintains comfort conditions in a defined area.

Acondicionamiento de aire Proceso que mantiene condiciones agradables en un área definida.

Air Conditioning, Heating and Refrigeration Institute (AHRI) A nonprofit association that regulates equipment manufacturers and rates the capacity of equipment.

Instituto del acondicionamiento de aire, calefacción y refrigeración (ARHI en inglés) Una asociación sin fines lucrativos que regula los fabricantes del equipo y que establece la capacidad de dicho equipo.

Air-cooled condenser One of the four main components of an air-cooled refrigeration system. It receives hot gas from the compressor and rejects heat to a place where it makes no difference.

Condensador enfriado por aire Uno de los cuatro componentes principales de un sistema de refrigeración enfriado por aire. Recibe el gas caliente del compresor y dirige el calor a un lugar donde no afecte la temperatura.

Air friction chart A chart used to determine proper round duct sizes.

Gráfica de fricción del aire Gráfica utilizada para determinar los tamaños correctos de conductos redondos.

Air gap The clearance between the rotating rotor and the stationary winding on an open motor. Known as a vapor gap in a hermetically sealed compressor motor.

Espacio de aire Espacio libre entre el rotor giratorio y el devandado fijo en un motor abierto. Conocido como espacio de vapor en un motor de compresor sellado herméticamente.

Air handler The device that moves the air across the heat exchanger in a forced air system—normally considered to be the fan and its housing.

Tratante de aire Dispositivo que dirige el aire a través del intercambiador de calor en un sistema de aire forzado—considerado generalmente como el ventilador y su alojamiento.

Air heat exchanger A device used to exchange heat between air and another medium at different temperature levels, such as air-to-air, air-to-water, or air-to-refrigerant.

Intercambiador de aire y calor Dispositivo utilizado para intercambiar el calor entre el aire y otro medio, como por ejemplo aire y aire, aire y agua or aire y refrigerante, a diferentes niveles de temperatura.

Air loop The heat pump's heating and cooling ducted air system, which exchanges heat with the refrigerant loop.

Circuito de aire Sistema de tubería del aire de calentamiento y de refrigeración de la bomba de calor, que sirve para intercambiar el calor con el circuito de refrigeración.

Air pressure control (switch) Used to detect air pressure drop across the coil in a heat pump outdoor unit due to ice buildup.

Regulador de la presión de aire (conmutador) Utilizado para detectar una caída en la presión del aire a través de la bobina en una unidad de bomba de calor para exteriores debido a la acumulación de hielo.

Air sensor A device that registers changes in air conditions such as pressure, velocity, temperature, or moisture content.

Sensor de aire Dispositivo que registra los cambios en las condiciones del aire, como por ejemplo cambios en presión, velocidad, temperatura o contenido de humedad.

Air shutters Devices that are placed in an airstream for the purpose of controlling airflow.

Contraventanas del aire Aparatos que se ponen en un corriente de aire con el propósito de regular el fluir del aire.

Air vent A fitting used to vent air manually or automatically from a system.

Válvula de aire Accesorio utilizado para darle al aire salida manual o automática de un sistema.

Alcohol Antifreeze solution used in the water loop of geothermal heat pumps.

Alcohol Líquido anticongelante que se utiliza en el circuito de agua en bombas de calor geotérmicas.

Algae A form of green or black, slimy plant life that grows in water systems.

Alga Tipo de planta legamosa de color verde o negro que crece en sistemas acuáticos.

Algorithm A computer code or set of instructions to make specific calculations.

Algoritmo Un código o juego de instrucciones computadora para hacer cálculos específicos.

Alkylbenzene A popular synthetic lubricant that works best with HCFC-based refrigerant blends. This lubricant can be used with CFC and HCFC refrigerants.

Alquilbenceno Lubricante sintético muy compatible con mezclas de refrigerantes basados en HCFC. También puede utilizarse con refrigerantes que usan CFC y HCFC.

Allen head A recessed hex head in a fastener.

Cabeza allen Cabeza de concavidad hexagonal en un asegurador.

All-weather system System providing year-round conditioning of the air.

Sistema para todo el año Sistema que proporciona una aclimatación ambiental todo el año.

Alternating current An electric current that reverses its direction at regular intervals.

Corriente alterna Corriente eléctrica que invierte su dirección a intervalos regulares.

Alternative refrigerants Newer refrigerants that are replacing the traditional CFC and HCFC refrigerants that have been used for many years. Many of these refrigerants have very low ozone depletion and global-warming indices. Some are completely chlorine-free.

Refrigerantes alternativos Nuevos productos que sirve para sustituir a los refrigerantes basados en CFC y HCFC que han sido utilizados durante muchos años. Muchos de estos nuevos refrigerantes tienen un índice muy bajo de desgaste de la capa de ozono y de calentamiento de la superficie terrestre. Algunos no utilizan cloro.

Altitude adjustment An adjustment to a refrigerator thermostat to account for a lower-than-normal atmospheric pressure such as may be found at a high altitude.

Ajuste para elevación Ajuste al termostato de un refrigerador para regular una presión atmosférica más baja que la normal, como la que se encuentra en elevaciones altas.

Ambient temperature The surrounding air temperature.

Temperatura ambiente Temperatura del aire circundante.

American standard pipe thread Standard thread used on pipe to prevent leaks.

Rosca estándar estadounidense para tubos Rosca estándar utilizada en tubos para evitar fugas.

Ammeter A meter used to measure current flow in an electrical circuit.

Amperímetro Instrumento utilizado para medir el flujo de corriente en un circuito eléctrico.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Ampacity The maximum amount of current that a conductor or electrical device can safely carry without damage.

Ampacidad La cantidad máxima de corriente que un conductor o dispositivo eléctrico puede transportar sin daños.

Amperage Amount (quantity) of electron or current flow (the number of electrons passing a point in a given time) in an electrical circuit.

Amperaje Cantidad de flujo de electrones o de corriente (el número de electrones que sobrepasa un punto específico en un tiempo fijo) en un circuito eléctrico.

Ampere Unit of current flow.

Amperio Unidad de flujo de corriente.

Analog electronic devices Devices that generate continuous or modulating signals within a certain control range.

Aparatos electrónicos analógicos Aparatos que generan señales continuas o modulares adentro de cierto registro de control.

Analog signal A continuous signal with an infinite number of steps.

Señal analógico Un señal continuo con un número infinitésimo de pasos.

Analog VOM A volt-ohm-milliammeter constructed so that the meter indicator is a needle over a printed surface.

VOM analógico Medidor de voltios-ohmios-miliamperímetros construido de forma que el indicador consiste en una aguja que se mueve encima de una superficie impresa.

Anemometer An instrument used to measure the velocity of air.

Anemómetro Instrumento utilizado para medir la velocidad del aire.

Aneroid barometer An instrument used to measure atmospheric pressure. This barometer uses a closed bellows linked to a needle and can be easily carried from place to place.

Barómetro aneroide Instrumento utilizado para medir la presión atmosférica. Este tipo de barómetro utiliza un fuelle cerrado unido a una aguja. Es muy fácil de trasladar de un lugar a otro.

Angle valve Valve with one opening at a 90° angle from the other opening.

Válvua en ángulo Válvula con una abertura a un ángulo de 90° con respecto a la otra abertura.

Annealing The process of heating and slowly cooling a metal in order to strengthen it.

Recocido El proceso de calentar y enfriar lentamente un metal con el fin de fortalecerlo.

Annual Fuel Utilization Efficiency (AFUE) The U.S. Federal Trade Commission requires furnace manufacturers to provide this rating so consumers may compare furnace performances before purchasing. This value is derived in a laboratory and used for heating appliances in which it accounts for cycling losses, chimney losses, and furnace jacket losses.

Eficiencia anual de uso de combustible (AFUE por sus siglas en inglés) La Comisión de comercio federal de los EE.UU. exige que los fabricantes de estufas informen este valor de manera de que los consumidores puedan comparar los rendimientos de las estufas antes de adquirirlas. Este valor se investiga en laboratorios y se utiliza para calefactores, cuantificando las pérdidas cíclicas, pérdidas por chimeneas y pérdidas a través de camisas de enfriamiento.

Annual Fuel Utilization Index (AFUI) The AFUI compares the amount of (seasonal) energy used in BTUs to the (seasonal) output of BTUs and expresses the ratio as a percentage. AFUI is calculated by the manufacturer of fuel burning combustion equipment.

Índice anual de uso de combustible (AFUI por sus siglas en inglés) El AFUI compara la cantidad de energía (estacional) utilizada, en BTU, con la emisión de energía calórica en BTU y expresa la relación como un porcentaje. El fabricante del equipo de combustión es quien calcula el valor del AFUI.

Anode A terminal or connection point on a semiconductor.

Ánodo Punto de conexión o terminal en un semiconductor.

ANSI Abbreviation for the American National Standards Institute.

ANSI Acrónimo de American National Standards Institute (Instituto Nacional Americano de Normas).

Anticipator Resistance heaters in thermostats that lessen the effects of system lag and overshoot.

Anticipador Calentador de resistencia en un termostato que reduce los efectos de subida y bajada del sistema.

Antifreeze solution A solution that will mix with water that has a freezing point much lower than water. Different solutions are mixed with water to lower the freezing point to the desired level.

Solución anticongelante Una solución que puede mezclarse con agua que tiene un punto de congelar mucho más bajo de lo del agua. Soluciones diferentes están mezcladas con agua para bajar el punto de congelar al nivel deseado.

Approach The temperature difference between the water leaving the cooling tower and the wet-bulb temperature of the tower's entering air.

Acercamiento La diferencia de temperatura entre el agua que sale de la torre de enfriar y la temperatura del bulbo mojado del aire que entra en la torre.

Approach temperature The difference in temperature between the refrigerant and the leaving water in a chilled-water system.

Temperatura de acercamiento Diferencia en temperatura entre el refrigerante y el agua de salida en un sistema de agua enfriada.

Aromatic oil A refrigeration mineral oil in which the alkylbenzene lubricant group originates.

Aceite aromático Aceite mineral de refrigeración del cual se deriva el grupo de lubricantes basados en alquilbenceno.

ASA Abbreviation for the American Standards Association [now known as American National Standards Institute (ANSI)].

ASA Abreviatura de Asociación Estadounidense de Normas [conocida ahora como Instituto Nacional Estadounidense de Normas (ANSI)].

ASHRAE Abbreviation for the American Society of Heating, Refrigerating, and Air-Conditioning Engineers.

ASHRAE Abreviatura de Sociedad Estadounidense de Ingenieros de Calefacción, Refrigeración y Acondicionamiento de Aire.

ASME Abbreviation for the American Society of Mechanical Engineers.

ASME Abreviatura de Sociedad Estadounidense de Ingenieros Mecánicos.

Aspect ratio The ratio of the length to width of a component.

Coeficiente de alargamiento Relación del largo al ancho de un componente.

Atmospheric draft heaters Combustion heating appliances which rely solely on the buoyancy of their combustion gasses for their draft.

Calentadores atmosféricos por corriente de aire Calefactores en los cuales la corriente de aire caliente se produce únicamente debido a la presión ejercida por los gases de combustión.

Atmospheric pressure The weight of the atmosphere's gases pressing down on the earth. Equal to 14.696 psi at sea level and 70°F.

Presión atmosférica El peso de la presión ejercida por los gases de la atmósfera sobre la tierra, equivalente a 14696 psi al nivel del mar a 70°F.

Atom The smallest particle of an element.

átomo Partícula más pequeña de un elemento.

Atomization The process of using pressure to change liquid to small particles of vapor.

Pulverización El proceso de utilizar la presión para cambiar un líquido a partículas pequeñas de vapor.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Atomizing humidifier A type of humidifier that discharges tiny water droplets into the air, which evaporate very rapidly into the duct airstream or directly into the conditioned space.

Humidificador por pulverización Dispositivo que descarga al aire pequeñas gotas de agua que se evaporan rápidamente en el conducto de aire o en ambiente acondicionado.

Attractant A type of salt solution, usually lithium bromide, used as an absorbent in absorption refrigeration.

Atrayente Tipo de solución salina, normalmente bromuro de litio, utilizado como absorbente en la refrigeración por absorción.

Automatic changeover thermostat A thermostat that changes from cool to heat automatically by room temperature.

Termostato de cambio automático Un termostato que cambia de enfriar a calentar automáticamente con la temperatura del cuarto.

Automatic combination gas valve A gas valve for gas furnaces that incorporates a manual control, gas supply for the pilot, adjustment and safety features for the pilot, pressure regulator, and the controls for and the main gas valve.

Válvula de gas de combinación automática Válvula de gas para hornos de gas que incorpora un regulador manual, sumi-nistro de gas para la llama piloto, ajuste y dispositivos de seguridad, regulador de presión, la válvula de gas principal y los reguladores de la válvula.

Automatic control Controls that react to a change in conditions to cause the condition to stabilize.

Regulador automático Reguladores que reaccionan a un cambio en las condiciones para provocar la estabilidad de dicha condición.

Automatic defrost Using automatic means to remove ice from a refrigeration coil at timed intervals.

Desempañador automático La utilización de medios automáticos para remover el hielo de una bobina de refrigeración a intervalos programados.

Automatic expansion valve (AXV) A refrigerant control valve that maintains a constant pressure in an evaporator. Sometimes abbreviated AEV.

Válvula de expansión automática Válvula de regulación del refrigerante que mantiene una presión constante en un evaporador. Puede también designarse con la abreviatura "AEV".

Automatic pumpdown system A control scheme in refrigeration consisting of a thermostat and liquid-line solenoid valve that clears refrigerant from the compressor's crankcase, evaporator, and suction line just before the compressor off cycle.

Sistema de bombeo hacia abajo automático Un sistema de control en refrigeración que consiste de un termostato y una válvula de línea de líquido solenoide que vacía el refrigerante del cárter del cigüeñal del compresor, evaporador y línea de succión justo antes del ciclo de apagar del compresor.

Auxiliary drain pan A separate drain pan that is placed under an air-conditioner evaporator to catch condensate in the event that the primary drain pan runs over.

Plato de drenaje auxiliar Un plato separado de drenaje debajo del evaporador de un aire acondicionado para recoger la condensación en caso de que el plato principal se derrame.

Auxiliary line See whipline.

Línea auxiliar Ver Línea auxiliar.

Azeotropic blend Two or more refrigerants mixed together that will have only one boiling and/or condensing point for each system pressure. Negligible fractionation or temperature glide will occur.

Mezcla azeotrópica Mezcla de dos o más refrigerantes y que tiene un solo punto de ebullición y/o condensación para cada presión del sistema. Puede producirse un fraccionamiento o una variación térmica insignificantes.

B

Backdrafting A continuous spillage of combustion by-products usually caused from a pressure difference that causes a reversal of the vent or chimney's normal flow upward.

Retroceso de la corriente de aire La pérdida continua de los productos de la combustión causada por una diferencia de presión, la cual produce la inversión del flujo normal, hacia arriba, de la ventilación o de una chimenea.

Back electromotive force (BEMF) This is the voltage-generating effect of an electric motor's rotor turning within the motor.

Fuerza contraelectromotriz (BEMF en inglés) El efecto de generar tensión provocado por el rotor de un motor eléctrico al girar dentro del motor.

Back pressure The pressure on the low-pressure side of a refrigeration system (also known as ***suction pressure***).

Contrapresión La presión en el lado de baja presión de un sistema de refrigeración (conocido también como ***presión de aspiración***).

Back seat The position of a refrigeration service valve when the stem is turned away from the valve body and seated, shutting off the service port.

Asiento trasero Posición de una válvula de servicio de refrigeración cuando el vástago está orientado fuera del cuerpo de la válvula y aplicado sobre su asiento, cerrando así la apertura de servicio.

Baffle A plate used to keep fluids from moving back and forth at will in a container.

Deflector Placa utilizada para evitar el libre movimiento de líquidos en un recipiente.

Balanced-port TXV A valve that will meter refrigerant at the same rate when the condenser head pressure is low.

Válvula electrónica de expansión con conducto equilibrado Válvula que medirá el refrigerante a la misma proporción cuando la presión en la cabeza del condensador sea baja.

Balance point The temperature in a structure where the heat pump will run full-time and maintain the temperature in the structure. Auxiliary heat must be used to accompany the heat pump when the temperature is below the balance point.

Punto de balance La temperatura en una estructura donde la bomba de calor corre todo el tiempo y mantiene la temperatura en la estructura. Calor auxiliar debe usarse para acompañar la bomba de calor cuando la temperatura está por debajo del punto de balance.

Ball check valve A valve with a ball-shaped internal assembly that only allows fluid flow in one direction.

Válvula de retención de bolas Válvula con un conjunto interior en forma de bola que permite el flujo de fluido en una sola dirección.

Ball valve Valve that uses a round ball in the flow chamber in the valve. The round ball is bored to the approximate inside diameter of the pipe and also offers very little resistance or pressure drop to the flow of water or fluid flow. The handle only has to be turned 90° to fully open or close the valve.

Válvula de bola Válvula que utiliza una bola redonda en la cámara de flujo en la válvula. La bola redonda está calibrada aproximadamente al diámetro interior de la tubería y también presenta muy poca resistencia o caída de la presión al flujo del agua o fluido. El mango solamente se gira 90° para abrir o cerrar la válvula completamente.

Barometer A device used to measure atmospheric pressure that is commonly calibrated in inches or millimeters of mercury. There are two types: mercury column and aneroid.

Barómetro Dispositivo comúnmente calibrado en pulgadas o en milímetros de mercurio que se utiliza para medir la presión

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

atmosférica. Existen dos tipos: columna de mercuro y aneroide.

Barometric damper A place for drawing indoor air (dilution air) into a chimney after the combustion process for open combustion type oil fired furnaces and boilers.

Regulador barométrico Espacio a través del cual se regula la entrada de aire (aire de dilución) hacia una chimenea luego del proceso de combustión, en estufas o calderas de combustión abierta que utilizan combustibles líquidos.

Base A terminal on a semiconductor.

Base Punto terminal en un semiconductor.

Baseboard heating Convection heaters providing whole-house, spot, or individual room heating. The heat is normally provided by electrical resistance or hot water.

Calefacción de zócalo Calentadores por convección que proporcionan calefacción a toda la casa, en un punto específico o en una sola habitación. Normalmente, el calor se obtiene mediante una resistencia eléctrica o agua caliente.

Base loads Base loads are consistent, everyday consumers of energy in residential structures which include freezers, refrigerators, lights, water heaters, clothes dryers, copiers, cell phone chargers, computers, and printers.

Consumidores básicos Artefactos que consumen energía diariamente y de manera continua en estructuras residenciales, como congeladores, heladeras, luces, calentadores de agua, secarropas, copiadoras, cargadores de teléfonos celulares, computadoras eimpresoras.

Batt The term used to describe precut panels of insulation that fit in between wall studs or ceiling joists.

Paneles de aislación Término que se utiliza para describir los paneles precortados de aislación que se colocan entre los perfiles de paredes o las viguetas de los techos.

Battery A device that produces electricity (DC power) from the interaction of metals and acid.

Pila Dispositivo que genera electricidad (corriente continua) por la interacción entre metales y el ácido.

Bearing A device that surrounds a rotating shaft and provides a low-friction contact surface to reduce wear from the rotating shaft.

Cojinete Dispositivo que rodea un árbol giratorio y provee una superficie de contacto de baja fricción para disminuir el desgaste de dicho árbol.

Bearing washout A cleaning of the compressor's bearing surfaces, which causes lack of lubrication. It is usually caused by liquid refrigerant mixing with the compressor's crankcase oil due to liquid floodback or migration.

Derrubio del cojinete Una limpieza de las superficies del cojinete del compresor, lo que lleva a falta de lubricación. Generalmente causado por refrigerante líquido mezclado con aceite del cárter del cigüeñal del compresor debido a inundación o migración del líquido.

Bellows An accordion-like device that expands and contracts when internal pressure changes.

Fuelles Dispositivo en forma de acordeón con pliegues que se expanden y contraen cuando la presión interna sufre cambios.

Bellows seal A method of sealing a rotating shaft or valve stem that allows rotary movement of the shaft or stem without leaking.

Cierre hermético de fuelles Método de sellar un árbol giratorio o el vástago de una válvula que permite el movimiento giratorio del árbol o del vástago sin producir fugas.

Belly-band-mount motor An electric motor mounted with a strap around the motor secured with brackets on the strap.

Motor con barriguera Motor eléctrico que se monta colocando una cincha a su alrededor y fijándola con abrazaderas.

Bending spring A coil spring that can be fitted inside or outside a piece of tubing to prevent its walls from collapsing when being formed.

Muelle de flexión Muelle helicoidal que puede acomodarse dentro o fuera de una pieza de tubería para evitar que sus paredes se doblen al ser formadas.

Bimetal Two dissimilar metals fastened together to create a distortion of the assembly with temperature changes.

Bimetal Dos metales distintos fijados entre sí para producir una distorción del conjunto al ocurrir cambios de temperatura.

Bimetal strip Two dissimilar metal strips fastened back-to-back.

Banda bimetálica Dos bandas de metales distintos fijadas entre sí en su parte posterior.

Binary Consisting of 1s and 0s. The 1s and 0s represent numbers, words, or signals that can be stored in the computer's memory for future use. Calculators and computers are digital systems.

Binario Consiste de 1s y 0s. Los 1s y 0s representan números, palabras o señales que pueden almacenarse en la memoria de la computadora para uso futuro. Las calculadoras y computadoras son sistemas digitales.

Biofilm Consists of a slimy bacterial secretion or film that forms a protective canopy to protect the bacteria beneath it from chemical biocides in cooling tower and boiler water systems.

Biofilm Consiste en una secreción bacteriana con aspecto de película suave, que forma una cubierta protectora que resguarda a la bacteria en su interior de sustancias químicas biocidas en sistemas de enfriamiento en torre y calentadores de agua.

Bleeding Allowing pressure to move from one pressure level to another very slowly.

Sangradura Proceso a través del cual se permite el movimiento de presión de un nivel a otro de manera muy lenta.

Bleed valve A valve with a small port usually used to bleed pressure from a vessel to the atmosphere.

Válvula de descarga Válvula con un conducto pequeño utilizado normalmente para purgar la presión de un depósito a la atmósfera.

Blocked suction A method of cylinder unloading. The suction line passage to a cylinder in a reciprocating compressor is blocked, thus causing that cylinder to stop pumping.

Aspiración obturada Método de descarga de un cilindro. El paso del conducto de aspiración a un cilindro en un compresor alternativo se obtura, provocando así que el cilindro deje de bombear.

Blowdown A system in a cooling tower whereby some of the circulating water is bled off and replaced with fresh water to dilute the sediment in the sump.

Vaciado Sistema en una torre de refrigeración por medio del cual se purga parte del agua circulante y se reemplaza con agua fresca para diluir el sedimento en el sumidero.

Boiler A container in which a liquid may be heated using any heat source. When the liquid is heated to the point that vapor forms and is used as the circulating medium, it is called a steam boiler.

Cardera Recipiente en el que se puede calentar un líquido utilizando cualquier fuente de calor. Cuando se calienta el líquido al punto en que se produce vapor y se utiliza éste como el medio para la circulación, se llama caldera de vapor.

Boiling point The temperature level of a liquid at which it begins to change to a vapor. The boiling temperature is controlled by the vapor pressure above the liquid.

Punto de ebullición El nivel de temperatura de un líquido al que el líquido empieza a convertirse en vapor. La temperatura de ebullición se regula por medio de la presión del vapor sobre líquido.

Boiling temperature The boiling temperature of the liquid can be controlled by

controlling the pressure. The standard boiling pressure for water is an atmospheric pressure of 29.92 in. Hg (mercury) where water boils at 212°F.

Temperatura de ebullición La temperatura de ebullición de un líquido puede controlarse controlando la presión. La presión de ebullición estándar para agua es una presión atmosférica de 29.92 pulgadas de mercurio donde el agua hierve a 212°F.

Bonded roof A roof that is insured against damage resulting from leaks.

Techo impermeabilizado Techo que está protegido contra daños resultantes de pérdidas.

Booster compressor The compressor on a parallel compressor system that is dedicated to the coldest evaporators.

Compresor elevador Compresor montado en un sistema de compresión en paralelo, destinado a los evaporadores más fríos.

Booster pump An additional pump that is used to build the pressure above what the primary pump can accomplish.

Bomba promotora Una bomba adicional que se usa para aumentar la presión por encima de lo que la bomba primaria puede.

Boot The connection between the branch line duct and the floor or ceiling register. It transitions the branch duct to the register size. It may be from rectangular to another size of rectangle or from round to rectangular.

Manguito La conexión entre el conducto de la línea ramal y el contador en el piso o en el techo. Él hace la transición de la línea ramal al tamaño del contador. Puede conectar un rectángulo a otro rectángulo de tamaño diferente o círculo a un rectángulo.

Bore The inside diameter of a cylinder.

Calibre Diámetro interior de un cilindro.

Bourdon tube C-shaped tube manufactured of thin metal and closed on one end. When pressure is increased inside, it tends to straighten. It is used in a gauge to indicate pressure.

Tubo Bourdon Tubo en forma de C fabricado de metal delgado y cerrado en uno de los extremos. Al aumentarse la presión en su interior, el tubo tiende a enderezarse. Se utiliza dentro de un manómetro para indicar la presión.

Boyle's Law Gas law that that states an inverse relationship between pressure and volume at a constant temperature.

Ley de Boyle Ley del Gas, que establece una relación inversa entre la presión y el volumen a una temperatura constante.

Brazing High-temperature (above 800°F) melting of a filler metal for the joining of two metals.

Broncesoldadura El derretir de un metal de relleno para fusionar dos metales a temperaturas altas (sobre los 800°F o 430°C).

Breaker A heat-activated electrical device used to open an electrical circuit to protect it from excessive current flow.

Interruptor Dispositivo eléctrico activado por el calor que se utiliza para abrir en circuito eléctrico a fin de protegerlo de un flujo excesivo de corriente.

British thermal unit (Btu) The amount (quantity) of heat required to raise the temperature of 1 lb of water 1°F.

Unidad térmica británica Cantidad de calor necesario para elevar en 1°F (−17.56°C) la temperatura de una libra inglesa de agua.

Btu Abbreviation for British thermal unit.

BTU Abreviatura de unidad térmica británica.

Bubble point The refrigerant temperature at which bubbles begin to appear in a saturated liquid. Bubble point values are used to calcuate subcooling on systems that operate with blended refrigerants.

Punto de burbujear La temperatura refrigerada en que burbujas empiezan a aparecer en un liquído saturado. Los valores del punto de burbujeo se utilizan para calcular el subenfriamiento en sistemas que utilizan refrigerantes mixtos.

Building Performance Institute (BPI) A nationally recognized energy certification for home energy auditors and contractors. A non-profit organization that accredits auditors, contractors, and other building professionals that specialize in evaluating building systems and potential energy savings in homes.

Instituto del rendimiento de la construcción (BPI, por sus siglas en inglés) Organización nacional de certificación de energía para auditores y contratistas de energía para viviendas residenciales. Organización sin fines de lucro que acredita a auditores, contratistas y otros profesionales de la construcción que se especializan en la evaluación de los sistemas de construcción y el ahorro potencial de energía en viviendas residenciales.

Bulb, sensor The part of a sealed automatic control used to sense temperature.

Bombilla sensora Pieza de un regulador automático sellado que se utiliza para advertir la temperatura.

Burner A device used to prepare and burn fuel.

Quemador Dispositivo utilizado para la preparación y la quema de combustible.

Burr Excess material squeezed into the end of tubing or pipe after a cut has been made. This burr must be removed.

Rebaba Exceso de material introducido por fuerza en el extremo de una tubería después de hacerse un corte. Esta rebaba debe removerse.

Butane gas A liquefied petroleum gas burned for heat.

Gas butano Gas licuado derivado del petróleo que se quema para producir calor.

Butterfly valve Valve constructed with a disk in the valve chamber that can be adjusted across the water or fluid stream. Imagine a coin that has a handle that can be turned crossways of the water or fluid flow to adjust or stop the flow. The valve handle only travels 90°, similar to the ball valve.

Válvula en forma de mariposa Válvula construída con un disco en la cámara de la válvula que se puede ajustar a través del corriente del agua o fluido. Imagina una moneda con un mango que se puede girar transversal al flujo del agua o fluido para ajustar o parar el flujo. El mango de la válvula solamente pasa 90°, tal como la válvula de bola.

B-vent A double-walled venting system for gas stoves or other gas appliances using approved piping through the roof or into a chimney.

Evacuación tipo B Sistema de evacuación de doble pared para estufas u otros dispositivos que funcionan con gas, utilizando conductos apropiados a través del techo o que se desembocan en una chimenea.

C

Cad cell A device containing cadmium sulfide used to prove the flame in an oil-burning furnace or boiler.

Celda de cadmio Dispositivo que contiene sulfuro de cadmio utilizado para probar la llama en un horno o caldera de aceite pesado.

Calibration The adjustment of instruments or gauges to the correct setting for known conditions.

Calibración El ajuste de instrumentos o manómetros en posición correcta para su operación en condiciones conocidas.

Calorimeter An instrument of laboratory-grade quality used to measure heat absorbed into a substance.

Calorímetro Instrumento de calidad laboratorio que sirve para medir el calor absorbido por una sustancia.

Capacitance The term used to describe the electrical storage ability of a capacitor.

Capacitancia Término utilizado para describir la capacidad de almacenamiento eléctrico de un capacitador.

Capacitive circuit Electrical circuit that contains capacitors. In this type of circuit, the current leads the voltage.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Circuito capacitivo Un circuito electrico que tiene capacitadores. En esta clase de circuito, la corriente mueve el voltaje.

Capacitive reactance Term used to describe a capacitor's resistance to electric current flow.

Reactancia capacitiva un término usado para describer la resistancia de un condensador al flujo de corriente eléctrica.

Capacitor An electrical storage device used to start motors (start capacitor) and to improve the running efficiency of motors (run capacitor).

Capacitador Dispositivo de almacenamiento eléctrico utilizado para arrancar motores (capacitador de arranque) y para mejorar el rendimiento de motores (capacitador de funcionamiento).

Capacitor-start–capacitor-run motor A single-phase motor that has a start capacitor in series with the start winding that is disconnected after start-up and a run capacitor that is also in parallel with the start windings that stays in the circuit while running. This run capacitor is built for full-time duty and is used to increase the running efficiency of the motor.

Motor de arranque capacitivo–marcha capacitiva Motor de fase sencilla que tiene un condensador de arranque en serie con la bobina de arranque que se desconecta después del encendido, y un condensador de marcha que está en paralelo con las bobinas de arranque y que permanece en el circuito mientras está en marcha. Este condensador está hecho para servicio a tiempo completo y se utiliza para mejorar la eficiencia de marcha del motor.

Capacitor-start motor A single-phase motor with a start and run winding that has a capacitor in series with the start winding, which remains in the circuit until the motor gets up to about 75% of the motor's rated speed.

Motor de arranque capacitivo Motor de fase sencilla con una bobina de arranque y marcha que tiene un condensador en serie con la bobina de arranque, el cual permanece en el circuito hasta que el motor alcanza alrededor de 75% de la velocidad calificada del motor.

Capacity The rating system of equipment used to heat or cool substances.

Capacidad Sistema de clasificación de equipo utilizado para calentar o enfriar sustancias.

Capillary attraction The attraction of a liquid material between two pieces of material such as two pieces of copper or copper and brass. For instance, in a joint made up of copper tubing and a brass fitting, the solder filler material has a greater attraction to the copper and brass than to itself and is drawn into the space between them.

Atracción capilar Atracción de un material líquido entre dos piezas de material, como por ejemplo dos piezas de cobre o cobre y latón. Por ejemplo, en una junta fabricada de tubería de cobre y un accesorio de latón, el material de relleno de la soldadura tiene mayor atracción al cobre y al latón que a sí mismo y es arrastrado hacia el espacio entre éstos.

Capillary tube A fixed-bore metering device. This is a small-diameter tube that can vary in length from a few inches to several feet. The amount of refrigerant flow needed is predetermined and the length and diameter of the capillary tube is sized accordingly.

Tubo capilar Dispositivo de medición de calibre fijo. Éste es un tubo de diámetro pequeño cuyo largo puede oscilar entre unas cuantas pulgadas y varios pies. La cantidad de flujo de refrigerante requerida es predeterminada y, de acuerdo a esto, se fijan el largo y el diámetro del tubo capilar.

Carbon dioxide A by-product of natural gas combustion that is not harmful, but does contribute to global warming.

Bióxido de carbono Subproducto de la combustión del gas natural que no es nocivo.

Carbon monoxide A poisonous, colorless, odorless, tasteless gas generated by incomplete combustion.

Monóxido de carbono Gas mortífero, inodoro, incoloro e insí pido que se desprende en la combustión incompleta del carbono.

Carrier frequency The speed at which the variable frequency drive's power device switches the waveform's positive and negative halves on and off. Also referred to as the switch frequency.

Frecuencia de onda portadora La velocidad a la que el dispositivo de alimentación de frecuencia variable intercambia las mitades positiva y negativa de una onda se denomina frecuencia de intercambio o frecuencia de onda portadora. Diseño sustentable: se adecua a las necesidades actuales sin perjuicio de que las generaciones futuras tengan la posibilidad de cubrir sus propias necesidades.

Catalytic combustor stove A stove that contains a cell-like structure consisting of a substrate, washcoat, and catalyst that produces a chemical reaction causing pollutants to be burned at much lower temperatures.

Estufa de combustor catalítico Estufa con una estructura en forma de celda compuesta de una subestructura, una capa brochada y un catalizador que produce una reacción química. Esta reacción provoca la quema de contaminantes a temperaturas muchas más bajas.

Cathode A terminal or connection point on a semiconductor.

Cátodo Punto de conexión o terminal en un semiconductor.

Cavitation A vapor formed due to a drop in pressure in a pumping system. Vapor at a pump inlet may be caused at a cooling tower if the pressure is low and water is turned to vapor.

Cavitación Vapor producido como consecuencia de una caída de presión en un sistema de bombeo. El vapor a la entrada de una bomba puede ser producido en una torre de refrigeración si la presión es baja y el agua se convierte en vapor.

Cellulose A substance formed in wood plants from glucose or sugar.

Celulosa Sustancia presente en plantas de madera y que se forma a partir de glucosa y azúcar.

Celsius scale A temperature scale with 100- degree graduations between water freezing (0°C) and water boiling (100°C).

Escala Celsio Escala dividida en cien grados, con el cero marcado a la temperatura de fusión del hielo (0°C) y el cien a la de ebullición del agua (100°C).

Centigrade scale See Celsius scale.

Centígrado Véase escala Celsio.

Centrifugal compressor A compressor used for large refrigeration systems that uses centrifugal force to accomplish compression. It is not positive displacement, but it is similar to a blower.

Compresor centrífugo Compresor utilizado en sistemas grandes de refrigeración que usa forza centrifuga para lograr compresión. No es desplazamiento positivo, pero es similar a un soplador.

Centrifugal pump A pump that uses centrifugal force to move a fluid. An impeller is rotated rapidly within the pump, causing the fluid to fly away from the center, which forces the fluid through a piping system.

Bomba centrífuga Bomba que utiliza la fuerza centrífuga para desplazar un fluido. Un propulsor dentro de la bomba gira a alta velocidad alejando el líquido del centro e impulsándolo a través de una tubería.

Centrifugal switch A switch that uses a centrifugal action to disconnect the start windings from the circuit.

Conmutador centrífugo Conmutador que utiliza una acción centrífuga para desconectar los devanados de arranque del circuito.

CFM cubic feet per minute.

CFM Pies cúbicos por minuto.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

CFM_{50} The air flow measured in cubic feet per minute (CFM) through a blower door while maintaining a constant vacuum of 50 Pascals inside a home is referred to as CFM_{50}.

CFM_{50} El flujo de aire, medido en pies cúbicos por minuto (CFM), que pasa a través de una abertura en la que se coloca un extractor potente que mantiene un vacío constante de 50 Pascales dentro de una vivienda se denomina CFM_{50}.

Change of state The condition that occurs when a substance changes from one physical state to another, such as ice to water and water to steam.

Cambio de estado Condición que ocurre cuando una sustancia cambia de un estado físico a otro, como por ejemplo el hielo a agua y el agua a vapor.

Charge of refrigerant The quantity of refrigerant in a system.

Carga de refrigerante Cantidad de refrigerante en un sistema.

Charging curve A graphical method of assisting a service technician with charging an air-conditioning or heat pump system.

Curva de recarga Un método gráfico para asistir al técnico de servicio con el recargar de un sistema de aire acondicionado o de bomba de calor.

Charging cylinder A device that allows the technician to accurately charge a refrigeration system with refrigerant.

Cilindro cargador Dispositivo que le permite al mecánico cargar correctamente un sistema de refrigeración con refrigerante.

Charging scale A scale used to weigh refrigerant when charging a refrigeration or air-conditioning system.

Báscula de plancha Báscula que se utiliza para pesar el refrigerante durante la carga de un sistema de refrigeración o de aire acondicionado.

Charles' law Gas law that that states a direct relationship between temperature and volume at a constant pressure.

Ley de Charles la ley de gas que establece una relación directa entre la temperatura y el volumen con una presión constante.

Check valve A device that permits fluid flow in one direction only.

Válvula de retención Dispositivo que permite el flujo de fluido en una sola dirección.

Chilled-water system An air-conditioning system that circulates refrigerated water to the area to be cooled. The refrigerated water picks up heat from the area, thus cooling the area.

Sistema de agua enfriada Sistema de acondicionamiento de aire que hace circular agua refrigerada al área que será enfriada. El agua refrigerada atrapa el calor del área y la enfria.

Chiller purge unit A system that removes air or noncondensables from a low-pressure chiller.

Unidad enfriadora de purga Sistema que remueve el aire o sustancias no condensables de un enfriador de baja presión.

Chill factor A factor or number that is a combination of temperature, humidity, and wind velocity that is used to compare a relative condition to a known condition.

Factor de frío Factor o número que es una combinación de la temperatura, la humedad y la velocidad del viento utilizado para comparar una condición relativa a una condición conocida.

Chimney A vertical shaft used to convey flue gases above the rooftop.

Chimenea Cañón vertical utilizado para conducir los gases de combustión por encima del techo.

Chimney draft Another name for stack draft.

Corriente de chimenea Denominación alternativa para "corriente de ventilación".

Chimney effect A term used to describe air or gas when it expands and rises when heated.

Efecto de chimenea Término utilizado para describir el aire o el gas cuando se expande y sube al calentarse.

Chlorofluorocarbons (CFCs) Those refrigerants thought to contribute to the depletion of the ozone layer.

Clorofluorocarburos (CFCs en inglés) Líquidos refrigerantes que, según algunos, han contribuido a la reducción de la capa de ozono.

Circuit An electron or fluid-flow path that makes a complete loop.

Circuito Electrón o trayectoria del flujo de fluido que hace un ciclo completo.

Circuit breaker A device that opens an electric circuit when an overload occurs.

Interruptor para circuitos Dispositivo que abre un circuito eléctrico cuando ocurre una sobrecarga.

Clamp-on ammeter An instrument that can be clamped around one conductor in an electrical circuit and measure the current.

Amperímetro fijado con abrazadera Instrumento que puede fijarse con una abrazadera a un conductor en un circuito eléctrico y medir la corriente.

Clearance volume The volume at the top of the stroke in a reciprocating compressor cylinder between the top of the piston and the valve plate.

Volumen de holgura Volumen en la parte superior de una ca rrera en el cilindro de un compresor recíproco entre la parte superior del pistón y la placa de una válvula.

Closed circuit A complete path for electrons to flow on.

Circuito cerrado Circuito de trayectoria ininterrumpida que permite un flujo continuo de electrones.

Closed-circuit cooling tower May have a wet/dry mode, an adiabatic mode, and a dry mode.

Torre de enfriamiento de circuito cerrado Puede tener un modo seco/mojado, un modo adiabático y un modo seco.

Closed loop Piping circuit that is complete and not open to the atmosphere.

Ciclo cerrado Circuito de tubería completo y no abierto a la atmósfera.

Closed-loop control configuration A closed-loop control configuration can maintain the controlled variable, like the air in a duct, at its set point because the sensor is now located in the air being heated or cooled (controlled medium).

Configuración de control de circuito cerrado Una configuración de control de circuito cerrado puede mantener el variable controlado, por ejemplo el aire en un conducto, en su punto de ajuste porque el sensor ya está ubicado en el aire que se calienta o se enfría (el medio controlado).

Closed-loop heat pump Heat pump system that reuses the same heat transfer fluid, which is buried in plastic pipes within the earth or within a lake or pond for the heat source.

Bomba de calor de circuito cerrado Sistema de bomba de calor que reutiliza el mismo líquido de transferencia térmica que se encuentra en tubos de plástico enterrados o sumergidos en un lago o estanque de los que obtiene el calor.

CO_2 indicator An instrument used to detect the quantity of carbon dioxide in flue gas for efficiency purposes.

Indicador del CO_2 Instrumento utilizado para detectar la cantidad de bióxido de carbono en el gas de combustión a fin de lograr un mejor rendimiento.

Coaxial heat exchanger A tube-within-a-tube liquid heat exchanger. Typically it is used for water-source heat pumps and small water-cooled air conditioners.

Intercambiador de calor coaxial Intercambiador de calor líquido con un tubo dentro de un tubo. Típicamente se usa para bombas de calor en fuentes de agua y acondicionadoras de aire pequeñas enfriadas por agua.

Code The local, state, or national rules that govern safe installation and service of systems and equipment for the purpose of safety of the public and trade personnel.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Código Reglamentos locales, estatales o federales que rigen la instalación segura y el servicio de sistemas y equipo con el propósito de garantizar la seguridad del personal público y profesional.

Coefficient of performance (COP) The ratio of usable output energy divided by input energy.

Coeficiente de rendimiento (COP en inglés) Relación de la de energía de salida utilizable dividida por la energía de entrada.

Cold The word used to describe heat at lower levels of intensity.

Frío Término utilizado para describir el calor a niveles de intensidad más bajos.

Cold anticipator A fixed resistor in a thermostat that is wired in parallel with the cooling contacts. This starts the cooling system before the thermostat calls for cooling, which allows the system to get up to capacity before the cooling is actually needed.

Anticipador de frío Resistor fijo en un termostato, conectado en paralelo con los contactos de enfriamiento. Dicho resistor pone en marcha el sistema de enfriamiento antes de que lo haga el termostato, permitiendo así que el sistema alcance su plena capacidad antes de que realmente se necesite el enfriamiento.

Cold junction The opposite junction to the hot junction in a thermocouple.

Empalme frío El empalme opuesto al empalme caliente en un termopar.

Cold trap A device to help trap moisture during the evacuation of a refrigeration system.

Trampa del frío Dispositivo utilizado para ayudar a atrapar la humedad durante la evacuación de un sistema de refrigeración.

Cold wall The term used in comfort heating to describe a cold outside wall and its effect on human comfort.

Pared fría Término utilizado en la calefacción para comodidad que describe una pared exterior fría y sus efectos en la comodidad de una persona.

Collector A terminal on a semiconductor.

Colector Punto terminal en un semiconductor.

Combustion A reaction called rapid oxidation or burning produced with the right combination of a fuel, oxygen, and heat.

Combustión Reacción conocida como oxidación rápida o quema producida con la combinación correcta de combustible, oxígeno y calor.

Combustion air Primary and/or secondary air. Primary air enters the furnace before the combustion process takes place. Secondary air is air introduced into a furnace after combustion and supports combustion.

Aire de combustión Aire primario y/o secundario. El aire primario entra a la estufa antes de que se produzca el proceso de combustión. El aire secundario se introduce en la estufa luego de la combustión, para que ésta se mantenga.

Combustion analyzer An instrument used to measure oxygen concentrations within flue gases. This analyzer can test smoke and test for carbon monoxide and other gases.

Analizador de combustión Instrumento que se utiliza para medir la concentración del oxígeno en los gases de escape. Este tipo de analizador permite medir el contenido de monóxido de carbono y otros gases en los humos.

Combustion appliance Any heating appliance that incorporates the combustion process which may include; gas and oil furnaces and boilers, water heaters, stoves, fireplaces and space heaters.

Dispositivo de combustión Cualquier dispositivo de calefacción que utiliza el proceso de combustión, entre los que se encuentran: estufas y calderas a gas o combustible líquido, calentadores de agua, estufas portátiles, chimeneas y calentadores para espacios confinados.

Combustion appliance zone (CAZ) An area or zone within a residence or building where combustion appliances reside and operate.

Zona de dispositivos de combustión (CAZ, por sus siglas en inglés) El área o zona dentro de una vivienda o construcción donde se encuentran y funcionan los dispositivos de combustión.

Combustion blower motor A motor mounted either before or after the heat exchanger of a furnace or boiler which turns a fan to either push or pull combustion gasses through the heat exchanger.

Motor de ventilación de combustión Motor montado antes o después del intercambiador de calor de una estufa o caldera, que enciende un ventilador que expele o succiona los gases de combustión a través del intercambiador de calor.

Comfort People are said to be comfortable when they are not aware of the ambient air surrounding them. They do not feel cool or warm or sweaty.

Comodidad Se dice que unas personas están cómodas cuandos no están conscientes del aire ambiental que les rodea. No sienten frío i calor, ni están sudadas.

Comfort chart A chart used to compare the relative comfort of one temperature and humidity condition to another condition.

Esquema de comodidad Esquema utilizado para comparar la comodidad relativa de un a condición de temperatura y humedad a otra condición.

Compound gauge A gauge used to measure the pressure above and below the atmosphere's standard pressure. It is a Bourdon tube sensing device and can be found on all gauge manifolds used for air-conditioning and refrigeration service work.

Manómetro compuesto Manómetro utilizado para medir la presión mayor y menor que la presión estándar de la atmósfera. Es un dispositivo sensor de tubo Bourdon que puede encontrarse en todos los manómetros de línea utilizados para el servicio de sistemas de acondicionamiento de aire y de refrigeración.

Compounds Substances that form when different elements combine chemically.

Compuestos sustancias que se forman cuando los diferentes elementos se combinan químicamente.

Compression A term used to describe a vapor when pressure is applied and the molecules are compacted closer together.

Compresión Término utilizado para describir un vapor cuando se aplica presión y se compactan las moléculas.

Compression ratio A term used with compressors to describe the ratio between the high- and low-pressure sides of the compression cycle. It is calculated by dividing the absolute discharge pressure by the absolute suction pressure.

Relación de compresión Término utilizado con compresores para describir la relación entre los lados de baja y alta presión del ciclo de compresión. Se calcula dividiendo la presión absoluta de descarga por la presión absoluta de aspiración.

Compressor A vapor pump that pumps vapor (refrigerant or air) from one pressure level to a higher pressure level.

Compresor Bomba de vapor que bombea el vapor (refrigerante o aire) de un nivel de presión a un nivel de presión más alto.

Compressor crankcase The internal part of the compressor that houses the crankshaft and lubricating oil.

Cárter del compresor Parte interna del compresor donde se aloja el cigüeñal y el aceite de lubricación.

Compressor displacement The internal volume of a compressor's cylinders, used to calculate the pumping capacity of the compressor.

Desplazamiento del compresor Volumen interno de los cilindros de un compresor, utilizado para calcular la capacidad de bombeo del mismo.

Compressor head The component that sits on top of the compressor cylinder and holds the components together.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Cabeza del compresor El componente que está en la parte superior del cilindro y que mantiene a los componentes unidos.

Compressor oil cooler One or more piping systems used for cooling the crankcase oil.

Enfriador del aceite del compresor Uno o varios sistemas de tubería que sirven para enfriar el aceite del cárter.

Compressor shaft seal The seal that prevents refrigerant inside the compressor from leaking around the rotating shaft.

Junta de estanqueidad del árbol del compresor La junta de estanqueidad que evita la fuga, alrededor del árbol giratorio, del refrigerante en el interior del compresor.

Concentrator That part of an absorption chiller where the dilute salt solution is boiled to release the water and concentrate the solution.

Concentrador El lugar en el enfriador por absorción donde se hierve la solución salina diluida para liberar el agua y concentrar la solución.

Condensate The moisture that forms on an evaporator coil.

Condensado Humedad que se forma sobre la bobina de un evaporador.

Condensate pump A small pump used to pump condensate to a higher level.

Bomba para condensado Bomba pequeña utilizada para bombear el condensado a un nivel más alto.

Condensation Liquid formed when a vapor condenses.

Condensación El líquido formado cuando se condensa un vapor.

Condense Changing a vapor to a liquid.

Condensar Convertir un vapor en líquido.

Condenser The component in a refrigeration system that transfers heat from the system by condensing refrigerant.

Condensador Componente en un sistema de refrigeración que transmite el calor del sistema al condensar el refrigerante.

Condenser flooding An automatic method of maintaining the correct head pressure in mild weather by using refrigerant from an auxiliary receiver.

Inundación del condensador Método automático de mantener una presión correcta en la cabeza en un tiempo utilizando refrigerante de un receptor auxiliar.

Condenser splitting Split the condenser into two separate and identical condenser circuits to reduce the amount of extra refrigerant charge needed for changing outdoor ambient conditions.

División del condensador División del condensador en dos circuitos de condensación idénticos pero separados, para reducir la carga extra de refrigerante necesaria para cambiar las condiciones ambientales del exterior.

Condensing boiler High-efficiency boiler designed to operate with low flue-gas temperatures. These boilers allow for the condensing of flue gas.

Caldera para condensación de gas Una caldera muy eficiente diseñada para operar cuando la temperatura del gas de combustión está baja. Estas calderas permiten la condensación de los gases de combustión.

Condensing gas furnace A furnace with a condensing heat exchanger that condenses moisture from the flue gases, resulting in greater efficiency.

Horno para condensación de gas Horno con un intercambiador de calor para condensación que condensa la humedad de los gases de combustión. El resultado será un mayor rendimiento.

Condensing oil furnace An oil furnace with a coil that causes moisture to condense from the flue gases, producing latent heat. This increases the efficiency of the furnace.

Horno de petróleo con serpentín de condensación Horno de petróleo, con un serpentín que provoca la condensación de la humedad presente en los gases de combustión, produciendo un calor latente. Permite aumentar la eficacia del horno.

Condensing pressure The pressure that corresponds to the condensing temperature in a refrigeration system.

Presión para condensación La presión que corresponde a la temperatura de condensación en un sistema de refrigeración.

Condensing temperature The temperature at which a vapor changes to a liquid.

Temperatura de condensación Temperatura a la que un vapor se convierte en líquido.

Condensing unit A complete unit that includes the compressor and the condensing coil.

Conjunto del condensador Unidad completa que incluye el compresor y la bobina condensadora.

Conditioned space Areas of a structure or residence that are heated or cooled.

Espacio acondicionado Áreas de una estructura o residencia cuyo ambiente se acondiciona mediante frío o calor.

Conduction Heat transfer from one molecule to another within a substance or from one substance to another.

Conducción Transmisión de calor de una molécula a otra dentro de una sustancia o de una sustancia a otra.

Conductivity The ability of a substance to conduct electricity or heat.

Conductividad Capacidad de una sustancia de conducir electricidad o calor.

Conductor A path for electrical energy to flow on.

Conductor Trayectoria que permite un flujo continuo de energía eléctrica.

Connecting rod A rod that connects the piston to the crankshaft.

Barra conectiva Barra que conecta al pistón con el cigüeñal.

Contactor A larger version of the relay. It can be repaired or rebuilt and has movable and stationary contacts.

Contactador Versión más grande del relé. Puede ser reparado o reconstruido. Tiene contactos móviles y fijos.

Contaminant Any substance in a refrigeration system that is foreign to the system, particularly if it causes damage.

Contaminante Cualquier sustancia en un sistema de refrigeración extraña a éste, principalmente si causa averías.

Continuous coil voltage This is the maximum back electromotive force (BEMF) that the relay's coil can tolerate "continuously" without overheating and opening circuit.

Voltaje continuo de serpentín Es la fuerza contra electromotriz máxima (BEMF, por sus siglas en inglés) que puede soportar el serpentín del relé de manera continua sin que se produzca sobrecalentamiento y apertura del circuito.

Control A device for stopping, starting, or modulating the flow of electricity or fluid to maintain a preset condition.

Regulador Dispositivo para detener, poner en marcha o modular el flujo de electricidad o de fluido a fin de mantener una condición establecida con anticipación.

Control agent The control agent is the fluid that transfers energy or mass to the controlled medium. It is the control agent (such as hot or cold water) that will flow through a final control device (water valves).

Agente de control El agente de control es el fluido que transfiere energía o masa al medio controlado. Es el agente (como agua caliente o fría) que fluye por un dispositivo de regulación (válvulas de agua).

Controlled device May be any control that stops, starts, or modulates fuel, fluid flow, or air to provide expected conditions in the conditioned space.

Aparato controlado Un aparato que puede ser cualquier control que detiene, enciende o modula el combustible, flujo de fluido o aire para proveer las condiciones esperadas en un espacio acondicionado.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Controlled environment The conditioned space the HVACR system is trying to maintain.

Medio ambiente controlado El espacio acondicionado que el sistema HVACR trata de conservar.

Controlled medium The controlled medium is what absorbs or releases the energy or mass transferred to or from the HVACR process. Controlled mediums can be air in a duct or water in a pipe.

Medio controlado El medio controlado absorbe o libera la energía o la masa transferidas al proceso HVACR o del mismo proceso. Un medio controlado puede ser el aire en un conducto o el agua en un tubo.

Controlled output device Any device of an array of dampers, fans, variable-frequency drives (VFDs), cooling coil valves, heating coil valves, relays, and motors—all of which control the controlled environment.

Aparato de salida controlada Una serie de desviadores, abanicos, propulsiones de frecuencia variable (VFDs en inglés), válvulas del serpentín de enfriamiento, válvulas del serpentín de calefacción, relés y motores—que controlan el medio ambiente controlado.

Controller A device that provides the output to the controlled device.

Controlador Aparato que provee la salida para el aparato controlado.

Control loop A sensor, a controller, and a controlled device.

Circuito de control Un sensor, un controlador y un aparato controlado.

Control point The actual value of the controlled variable at a particular point in time.

Punto de control El valor verdadero del variable controlado en un tiempo específico.

Control system A network of controls to maintain desired conditions in a system or space.

Sistema de regulación Red de reguladores que mantienen las condiciones deseadas en un sistema o un espacio.

Convection Heat transfer from one place to another using a fluid.

Convección Transmisión de calor de un lugar a otro por medio de un fluido.

Conventional boilers Boilers that are classified as non-condensing and have flue gas temperatures above 130

Calderas convencionales las calderas que son clasificados como no-condensación y tienen temperaturas de gases de combustión mas alto de 130

Conversion factor A number used to convert from one equivalent value to another.

Factor de conversión Número utilizado en la conversión de un valor equivalente a otro.

Cooler A walk-in or reach-in refrigerated box.

Nevera Caja refrigerada donde se puede entrar o introducir la mano.

Cooling tower The final device in many water-cooled systems, which rejects heat from the system into the atmosphere by evaporation of water.

Torre de refrigeración Dispositivo final en muchos sistemas enfriados por agua, que dirige el calor del sistema a la atmósfera por medio de la evaporación de agua.

Copper plating Small amounts of copper are removed by electrolysis and deposited on the ferrous metal parts in a compressor.

Encobrado Remoción de pequeñas cantidades de cobre por medio de electrólisis que luego se colocan en las piezas de metal férreo en un compresor.

Corrosion A chemical action that eats into or wears away material from a substance.

Corrosión Acción química que carcoma o desgasta el material de una sustancia.

Cotter pin Used to secure a pin. The cotter pin is inserted through a hole in the pin, and the ends spread to retain it.

Pasador de chaveta Se usa para asegurar una clavija. El pasador se inserta a través de un roto en la clavija y sus extremos se abren para asegurarla.

Counter EMF Voltage generated or induced above the applied voltage in a single-phase motor.

Contra EMF Tensión generada o inducida sobre la tensión aplicada en un motor unifásico.

Counterflow Two fluids flowing in opposite directions.

Contraflujo Dos fluidos que fluyen en direcciones opuestas.

Coupling A device for joining two fluid-flow lines. Also the device connecting a motor driveshaft to the driven shaft in a direct-drive system.

Acoplamiento Dispositivo utilizado para la conexión de dos conductos de flujo de fluido. Es también el dispositivo que conecta un árbol de mando del motor al árbol accionado en un sistema de mando directo.

CPVC (Chlorinated polyvinyl chloride) Plastic pipe similar to PVC except that it can be used with temperatures up to 180°F at 100 psig.

CPVC (Cloruro de polivinilo clorado) Tubo plástico similar al PVC, pero que puede utilizarse a temperaturas de hasta 180°F (82°C) a 100 psig [indicador de libras por pulgada cuadrada].

Crackage Small spaces in a structure that allow air to infiltrate the structure.

Formación de grietas Espacios pequeños en una estructura que permiten la infiltración del aire dentro de la misma.

Cradle-mount motor A motor with a mounting cradle that fits the motor end housing on each end and is held down with a bracket.

Motor montado con cuña Motor equipado de una cuña adaptada a la caja en los dos extremos y sujetado por fijaciones.

Crankcase heat Heat provided to the compressor crankcase.

Calor para el cárter del cigüeñal Calor suministrado al cárter del cigüeñal del compresor.

Crankcase pressure-regulating valve (CPR valve) A valve installed in the suction line, usually close to the compressor. It is used to keep a low-temperature compressor from overloading on a hot pulldown by limiting the pressure to the compressor.

Válvula reguladora de la presión del cárter del cigüeñal (CPR en inglés) Válvula instalada en el conducto de aspiración, normalmente cerca del compresor. Se utiliza para evitar la sobrecarga en un compresor de temperatura baja durante un arrastre caliente hacia abajo limitando la presión al compresor.

Crankshaft In a reciprocating compressor, the crankshaft changes the round-and-round motion into the reciprocating back-and-forth motion of the pistons using off-center devices called throws.

Cigüeñal En un compresor alternativo, el cigüeñal cambia el movimiento circular en un movimiento alternativo hacia delante y hacia atrás de los pistones usando aparatos descentrados llamados cigüeñas.

Crankshaft seal Same as the compressor shaft seal.

Junta de estanqueidad del árbol del cigüeñal Exactamente igual que la junta de estanqueidad del árbol del compresor.

Crankshaft throw The off-center portion of a crankshaft that changes rotating motion to reciprocating motion.

Excentricidad del cigüeñal Porción descentrada de un cigüeñal que cambia el movimiento giratorio a un movimiento alternativo.

Creosote A mixture of unburned organic material found in the smoke from a wood-burning fire.

Creosota Mezcla del material orgánico no quemado que se encuentra en el humo proveniente de un incendio de madera.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Crisper A refrigerated compartment that maintains a high humidity and a low temperature.

Encrespador Compartimiento refrigerado que mantiene una humedad alta y una temperatura baja.

Critical point A point on the pressure/enthalpy diagram where the critical temperature and critical pressure exist. No liquid refrigerant can be produced above a refrigerant's critical point.

Punto crítico Punto en el diagrama presión/entalpía en el que coinciden la temperatura crítica con la presión crítica. Ningún refrigerante líquido puede obtenerse por licuado de un gas a una temperatura por encima del punto crítico del mismo.

Critical pressure The lowest pressure at which refrigerant vapor cannot condense.

Presión crítica La presión baja a la que el vapor de refrigerante no puede condensarse.

Critical seals Refers to components that are difficult to isolate or service and, as a result, require that the system refrigerant be recovered for service.

Junta elastomérica se refiere a componentes que son difíciles de aislar o servicio y, como consecuencia, requieren que el refrigerante del sistema pueden recuperarse para el servicio.

Critical temperature The critical temperature of a gas is the highest temperature the gas can have and still be condensable by the application of pressure.

Temperatura crítica La temperatura crítica de un gas es la máxima temperatura a la cual el mismo puede condensarse mediante la aplicación de presión (licuado).

Cross charge A control with a sealed bulb that contains two different fluids that work together for a common specific condition.

Carga transversal Regulador con una bombilla sellada compuesta de dos fluidos diferentes que pueden funcionar juntos para una condición común específica.

Crossflow Term used to indicate that two fluids are flowing in different directional paths with respect to each other, usually at a 90-degree angle.

Flujo Cruzado término utilizado para indicar que dos fluidos fluyen en diferentes rutas direccionales con respecto a cada uno de otros, generalmente en un ángulo de 90 grados.

Cross liquid charge bulb A type of charge in the sensing bulb of the TXV that has different characteristics from the system refrigerant. This is designed to help prevent liquid refrigerant from flooding to the compressor at start-up.

Bombilla de carga del líquido transversal Tipo de carga en la bombilla sensora de la válvula electrónica de expansión que tiene características diferentes a las del refrigerante del sistema. La carga está diseñada para ayudar a evitar que el refrigerante líquido se derrame dentro del compresor durante la puesta en marcha.

Cross vapor charge bulb Similar to the vapor charge bulb but contains a fluid different from the system refrigerant. This is a special-type charge and produces a different temperature/pressure relationship under different conditions.

Bombilla de carga del vapor transversal Similar a la bombilla de carga del vapor pero contiene un fluido diferente al del refrigerante del sistema. Ésta es una carga de tipo especial y produce una relación diferente entre la temperatura y la presión bajo condiciones diferentes.

Crystallization When a salt solution becomes too concentrated and part of the solution turns to salt.

Cristalización Condición que ocurre cuando una solución salina se concentra demasiado y una parte de la solución se convierte en sal.

Cupronickel A material used in heat exchangers. This material is made with an alloy of copper for a higher corrosion resistance for acid cleaning.

Cuproníquel Material utilizado en intercambiadores térmicos. Se trata de una aleación de cobre y níquel con una elevada resistencia a la corrosión en procesos de limpieza con ácido.

Curb Frame that is used to mount and support HVAC equipment.

Marco Perfil que se utiliza para montar y sostener equipos de calefacción, ventilación y acondicionamiento de aire.

Current, electrical Electrons flowing along a conductor.

Corriente eléctrica Electrones que fluyen a través de un conductor.

Current relay An electrical device activated by a change in current flow.

Relé para corriente Dispositivo eléctrico accionado por un cambio en el flujo de corriente.

Current sensing relay An inductive relay coil usually located around a wire used to sense current flowing through the wire. Its action usually opens or closes a set of contacts.

Relé detector de corriente Una bobina de relé inductiva que generalmente está ubicada cerca de un cable y se usa para detectar el flujo de corriente a través del cable. Su acción generalmente abre o cierra una serie de contactos.

Cut-in and cut-out The two points at which a control opens or closes its contacts based on the condition it is supposed to maintain.

Puntos de conexión y desconexión Los dos puntos en los que un regulador abre o cierra sus contactos según las condiciones que debe mantener.

Cycle A complete sequence of events (from start to finish) in a system.

Ciclo Secuencia completa de eventos, de comienzo a fin, que ocurre en un sistema.

Cylinder A circular container with straight sides used to contain fluids or to contain the compression process (the piston movement) in a compressor.

Cilindro Recipiente circular con lados rectos, utilizado para contener fluidos o el proceso de compresión (movimiento del pistón) en un compresor.

Cylinder, compressor The part of the compressor that contains the piston and its travel.

Cilindro del compresor Pieza del compresor que contiene el pistón y su movimiento.

Cylinder, refrigerant The container that holds refrigerant.

Cilindro del refrigerante El recipiente que contiene el refrigerante.

Cylinder head, compressor The top to the cylinder on the high-pressure side of the compressor.

Culata del cilindro del compresor Tapa del cilindro en el lado de alta presión del compresor.

Cylinder unloading A method of providing capacity control by causing a cylinder in a reciprocating compressor to stop pumping.

Descarga del cilindro Método de suministrar regulación de capacidad provocando que el cilindro en un compresor alternativo deje de bombear.

D

Dalton's Law Gas law that states that the total pressure exerted by a gas mixture is the sum of the pressures of the individual gases. Also called the law of partial pressures.

La Ley de Dalton Ley del gas, que establece que la presión total ejercida por una mezcla de gases es la suma de las presiones de los gases distintos. También, llamada la ley de las presiones parciales.

Damper A component in an air-distribution system that restricts airflow for the purpose of air balance.

Desviador Componente en un sistema de distribución de aire que limita el flujo de aire para mantener un equilibrio de aire.

Database A collection of data or information stored in the memory of the

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

controller to be used by the digital controller at a later point in time.

Base de datos Una colección de datos o información almacenados en la memoria del controlador, para el uso del controlador digital más adelante.

DC converter A type of rectifier that changes alternating current (AC) to direct current (DC).

Convertidor CD Tipo de rectificador que cambia la corriente alterna (CA) a corriente directa (CD).

DC motor A motor that operates on direct current (DC).

Motor CD Un motor que opera con corriente directa (CD).

DCV See Demand Control Ventilation.

DCV Ver Control de demanda de ventilación.

Declination angle The angle of the tilt of the earth on its axis.

Ángulo de declinación Ángulo de inclinación de la Tierra en su eje.

Decorative appliance A term used by ANSI to indicate a gas appliance that is not designed for larger space-heating applications.

Aparato decorativo Término usado por ANSI para indicar un aparato de gas que no está diseñado para calentar espacios grandes.

Deep vacuum An attained vacuum that is below 250 microns.

Vacío profundo Un vacío que se obtiene lo cual es menor de 250 micrones.

Defrost Melting of ice.

Descongelar Convertir hielo en líquido.

Defrost condensate The condensate or water from a defrost application of a refrigeration system.

Condensado de descongelación Condensado o agua causada por el dispositivo de descongelación en un sistema de refrigeración.

Defrost cycle The portion of the refrigeration cycle that melts the ice off the evaporator.

Ciclo de descongelación Parte del ciclo de refrigeración que derrite el hielo del evaporador.

Defrost termination switch A temperature-activated switch that stops the defrost cycle and returns the equipment to the refrigeration cycle.

Interruptor de terminación de descongelación Un interruptor activado por temperatura que detiene el ciclo de descongelación y regresa al equipo al ciclo de refrigeración.

Defrost timer A timer used to start and stop the defrost cycle.

Temporizador de descongelación Temporizador utilizado para poner en marcha y detener el ciclo de descongelación.

Degassing Removing air and other noncondensable gasses from a system using a vacuum pump.

Desgasificación Eliminación de aire y otros gases no condensables de un sistema utilizando una bomba de vacío.

Degreaser A cleaning solution used to remove grease from parts and coils.

Desengrasador Solución limpiadora utilizada para remover la grasa de piezas y bobinas.

Dehumidify To remove moisture from air.

Deshumidificar Remover la humedad del aire.

Dehydration Removing moisture from a sealed system or a product.

Deshidratación Removiendo la humedad de un sistema sellado o un producto.

Delta-T The temperature difference at two different points, such as the inlet and outlet temperature difference across a water chiller.

Delta-T La diferencia en temperatura en dos puntos diferentes, tales como la diferencia de temperatura entre la entrada y la sa lida de un enfriador de agua.

Delta transformer connection A transformer connection that results in a voltage output of 115 V and 230 V.

Conexión de transformador delta Una conexión de transformador que resulta en una salida de voltaje de 115 voltios y 230 voltios.

Demand Control Ventilation, DCV Ventilation strategy that calculates required ventilation based on actual, not expected, occupancy levels.

Control de demanda de ventilación, DCV por sus siglas en inglés Estrategia de ventilación que calcula la ventilación necesaria basándose en niveles de ocupación reales, no teóricos.

Demand metering In this system, the power company charges the customer based on the highest usage for a prescribed period of time during the billing period. The prescribed time for demand metering may be any 15- or 30-min period within the billing period.

Medición por demanda Un sistema utilizado por la compañía de electricidad en el cual cobran al consumidor por el período de facturación basado en el uso más alto durante un período de tiempo prescrito durante el período de facturación. El tiempo prescrito para la medición por demanda puede ser cualquier período de 15 ó 30 minutos durante el período de facturación.

Density The weight per unit of volume of a substance.

Densidad Relación entre el peso de una sustancia y su volumen.

Department of Transportation (DOT) The governing body of the U.S. government that makes the rules for transporting items, such as volatile liquids.

Departamento de Transportación (DOT en inglés) El cuerpo regente del gobierno de los Estados Unidos que crea las reglas para transportar artículos tales como líquidos volátiles.

Derivative (differential) controller A control mode where the controller will change its output signal according to the rate of change of the error or offset.

Controlador derivativo (diferencial) Un modo de control en el cual el controlador cambiará su salida de acuerdo a la razón de cambio del error o de la compensación.

Desiccant Substance in a refrigeration system drier that collects moisture.

Disecante Sustancia en el secador de un sistema de refrigeración que acumula la humedad.

Desiccant drier A device that dehumidifies compressed air for use in controls or processing.

Secador desecante Un aparato que se usa para deshumedecer el aire comprimido que se usa en los controles o procesos.

Design pressure The pressure at which the system is designed to operate under normal conditions.

Presión de diseño Presión a la que el sistema ha sido diseñado para funcionar bajo condiciones normales.

Desuperheating Removing heat from the superheated hot refrigerant gas down to the condensing temperature.

Des-sobrecalentamiento Reducir el calor del gas caliente del refrigerante sobrecalentado hasta alcanzar la temperatura de condensación.

Detector A device used to search for and find, as in a leak detector.

Detector Dispositivo de búsqueda y detección.

Detent or snap action The quick opening and closing of an electrical switch.

Acción de detén o de encaje El abrir y cerrar rápido de un interruptor eléctrico.

Dew Moisture droplets that form on a cool surface.

Rocío Gotitas de humedad que se forman en una superficie fría.

Dew point temperature The exact temperature at which moisture begins to form.

Temperatura del punto de rocío Temperatura exacta a la que la humedad comienza a formarse.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Diac A semiconductor often used as a voltage-sensitive switching device.

Diac Semiconductor utilizado frecuentemente como dispositivo de conmutación sensible a la tensión.

Diagnostic thermostat A thermostat that can receive information from various sensors and determine when a system is having a problem. It may give a fault signal in the form of a code indicating the problem.

Termostato diagnóstico Un termostato que puede recibir información de varios sensores y determinar cuándo un sistema tiene problemas. Puede indicar una señal de fallo en forma de un código que indica el problema.

Diaphragm A thin flexible material (metal, rubber, or plastic) that separates two pressure differences.

Diafragma Material delgado y flexible, como por ejemplo el metal, el caucho o el plástico, que separa dos presiones diferentes.

Diaphragm valve A valve that has a thin sheet of metal between the valve and the fluid flow. This thin sheet is called the diaphragm and contains the pressure in the system from the action of the valve.

Válvula de diafragma Una válvula que tiene una lámina fina de metal entre la válvula y el flujo de fluido. La lámina fina se llama diafragma y separa la presión del sistema de la acción de la válvula.

Die A tool used to make an external thread such as on the end of a piece of pipe.

Troquel Herramienta utilizada para formar un filete externo, como por ejemplo en el extremo de un tubo.

Differential The difference between the cut-in and cut-out points of a control, pressure, time, temperature, or level.

Diferencial Diferencia entre los puntos de conexión y des conexión de un regulador, una presión, un intervalo de tiempo, una temperatura o un nivel.

Diffuser The terminal or end device in an air-distribution system that directs air in a specific direction using louvres.

Placa difusora Punto o dispositivo terminal en un sistema de distribución de aire que dirige el aire a una dirección específica, utilizando aberturas tipo celosía.

Diffuse radiation Radiation from the sun that reaches the earth after it is reflected from other substances, such as moisture or other particles in space.

Radiación difusa Radiación solar que alcanza la Tierra después de haber sido reflejada por otras sustancias como gotas de agua u otras partículas presentes en el aire.

Digital electronic devices Devices that generate strings of data or groups of logic consisting of 1s and 0s.

Aparatos electrónicos digitales Aparatos que generan cadenas de data o grupos de lógica que consisten de unos y ceros.

Digital electronic signal An electrical signal, usually 0 to 10 V DC or 0 to 20 milliamps DC, that is used to control system conditions.

Señal electrónica digital Una señal eléctrica, generalmente de 0 a 10 voltios CD o de 0 a 20 miliamperes CD, que se usa para controlar las condiciones del sistema.

Digital VOM A volt-ohm-milliammeter that displays the reading in digits or numbers.

VOM digital Medidor de voltios-ohmios-miliamperímetros que indica la lectura en dígitos o números.

Dilution air Excess air introduced after combustion and usually enters at the end of the heat exchanger. It is brought in by the draft hood of the natural draft furnace.

Aire de dilución Aire en exceso que se introduce luego de la combustión y generalmente entra por la salida del intercambiador de calor. Se introduce a través de la campana de la estufa de corriente natural.

Diode A solid-state device composed of both P-type and N-type material. When connected in a circuit one way, current will flow. When the diode is reversed, current will not flow.

Diodo Dispositivo de estado sólido compuesto de material P y de material N. Cuando se conecta a un circuito de una manera, la corriente fluye. Cuando la dirección del diodo cambia, la corriente deja de fluir.

DIP (dual inline pair) switch A very small low-amperage, single -pole, double-throw switch used in electronic circuits to set up the program in the circuit.

Interruptor de doble paquete en línea (DIP en inglés) Un interruptor muy pequeño, de bajo amperaje, unipolar de doble tiro que se usa en los circuitos electrónicos para preparar el programa en un circuito.

Direct current Electricity in which all electron flow goes continuously in one direction.

Corriente continua Electricidad en la que todos los electrones fluyen continuamente en una sola dirección.

Direct digital control (DDC) Very low-voltage control signal, usually 0 to 10 V DC or 0 to 20 milliamps DC.

Control digital directo (DDC en inglés) Señal control de voltaje bien bajo generalmente 0 a 20 voltios CD o de 0 a 20 miliamperes CD.

Direct-drive compressor A compressor that is connected directly to the end of the motor shaft. No pulleys are involved.

Compresor de conducción directa Un compresor que está conectado directamente a un extremo del eje de un motor, sin usar poleas.

Direct-drive motor A motor that is connected directly to the load, such as an oil burner motor or a furnace fan motor.

Motor de conducción directa Un motor que está conectado directamente a la carga, tal como un motor de un quemador de aceite o el motor de un ventilador en un calefactor.

Direct expansion The term used to describe an evaporator with an expansion device other than a low-side float type.

Expansión directa Término utilizado para describir un evaporador con un dispositivo de expansión diferente al tipo de dispositivo flotador de lado bajo.

Direct-fired absorption system An absorption refrigeration system that uses gas or oil as the heat source.

Sistema de absorción de inyección directa. Sistema de refrigeración por absorción que emplea gas o petróleo como fuente de calor.

Direct GeoExchange system A geothermal system where a primary, phase-changing refrigerant is circulated in copper tubing directly in contact with the earth.

Sistema de geo-intercambio Sistema geotérmico en el que un refrigerante primario de cambio de fase se hace circular por una tubería de cobre en contacto con la tierra.

Direct radiation The energy from the sun that reaches the earth directly.

Radiación directa Energía solar que alcanza la Tierra directamente.

Direct-spark ignition (DSI) A system that provides direct ignition to the main burner.

Encendido de chispa directa (DSI en inglés). Sistema que le provee un encendido directo al quemador principal.

Direct-vent A venting system for a gas furnace, which pulls the outside air in for combustion and vents the flue gases to the outside.

Escape directo Sistema de escape en un horno, con un conducto de doble pared. El conducto hace entrar el aire del exterior para la combustión, y evacúa los gases de combustión hacia afuera.

Discharge line The refrigerant line that connects the discharge port of the compressor to the inlet of the condenser.

Línea de descarga La tubería de refrigerante que conecta el puerto de descarga del compresor a la entrada del condensador.

Discharge pressure The pressure on the high-pressure side of a compressor.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Presión de descarga La presión en el extremo de alta presión de un compresor.

Discharge valve The valve at the top of a compressor cylinder that shuts on the downstroke to prevent high-pressure gas from reentering the compressor cylinder, allowing low- pressure gas to enter.

Válvula de descarga La válvula que está en la parte superior del cilindro de un compresor que se cierra en el recorrido hacia abajo del pistón para evitar que el gas a alta presión regrese al cilindro del compresor y permitir que el gas a baja presión entre.

Discus compressor A reciprocating compressor distinguished by its disc-type valve system.

Compresor de disco Compresor alternativo caracterizado por su sistema de válvulas de tipo disco.

Discus valve A reciprocating compressor valve design with a low clearance volume and larger bore.

Válvula de disco Diseño de válvula de compresor alternativo con un volumen de holgura bajo y un calibre más grande.

Distributor A component installed at the outlet of the expansion valve that distributes the refrigerant to each evaporator circuit.

Distribuidor Componente instalado a la salida de la válvula de expansión que distribuye el refrigerante a cada circuito del evaporador.

Diverter tee Special tee fitting used on one-pipe hydronic systems to facilitate water flow through remote terminal units.

Desviadores en forma de T Un accesorio especial en forma de T usado en sistemas hidrónicos para facilitar la fluya de agua por las unidades de terminal remoto.

Domestic hot water loop Domestic hot water heated by the refrigerant loop of the heat pump.

Circuito de agua caliente doméstica Agua caliente doméstica calentada por el circuito de refrigeración de la bomba de calor.

Doping Adding an impurity to a semiconductor to produce a desired charge.

Impurificación La adición de una impureza para producir una carga deseada.

Double flare A connection used on copper, aluminum, or steel tubing that folds tubing wall to a double thickness.

Abocinado doble Conexión utilizada en tuberías de cobre, aluminio o acera que pliega la pared de la tubería y crea un espesor doble.

Dowel pin A pin, which may or may not be tapered, used to align and fasten two parts.

Pasador de espiga Pasador, que puede o no ser cónico, utilizado para alinear y fijar dos piezas.

Downflow furnace This furnace sometimes is called a counterflow furnace. The air intake is at the top, and the discharge air is at the bottom.

Horno de corriente descendente También conocido como horno de contracorriente. La entrada del aire está en la parte superior y la salida en la parte inferior.

Draft Draft is the force that allows air to travel into the combustion chamber and to force the combustion gasses out through a vent or chimney.

Corriente La corriente es la fuerza que permite que el aire entre en la cámara de combustión y empuje los gases de combustión hacia afuera, a través de una ventilación o chimenea.

Draft diverter A place for drawing indoor air (dilution air) into a vent or chimney after the combustion process for open combustion type gas furnaces and boilers. Part of its function is to prevent down drafts from affecting burner performance.

Deflector de corriente Área a través de la cual el aire del interior (aire de dilución) se hace pasar hacia una ventilación o chimenea luego del proceso de combustión en estufas o calderas a gas de combustión abierta. Parte de su función es prevenir que el rendimiento del quemador se vea afectado por las corrientes inversas.

Draft gauge A gauge used to measure very small pressures (above and below atmospheric) and compare them with the atmosphere's pressure. Used to determine the flow of flue gas in a chimney or vent.

Manómetro de tiro Manómetro utilizado para medir presiones sumamente pequeñas (mayores o menores que la atmosférica) y compararas con la presión de la atmósfera. Utilizado para determinar el flujo de gas de combustión en una chimenea o válvula.

Draft hood A place for drawing indoor air (dilution air) into a vent or chimney after the combustion process for open combustion type gas furnaces and boilers. Part of its function is to prevent down drafts from affecting burner performance.

Campana de corriente Área a través de la cual el aire del interior (aire de dilución) se hace pasar hacia una ventilación o chimenea luego del proceso de combustión en estufas o calderas a gas de combustión abierta. Parte de su función es prevenir que el rendimiento del quemador se vea afectado por las corrientes inversas.

Drier A device used in a refrigerant line to remove moisture.

Secador Dispositivo utilizado en un conducto de refrigerante para remover la humedad.

Drilled well A well with a well casing, electric pump, and electric lines that is drilled into the ground into a water source.

Pozo perforado Un pozo con recubrimiento, bomba eléctrica y cables de alimentación eléctrica perforado en el suelo para extraer agua.

Drip pan A pan shaped to collect moisture condensing on an evaporator coil in an air-conditioning or refrigeration system.

Colector de goteo Un colector formado para acumular la humedad que se condensa en la bobina de un evaporador en un sistema de acondicionamiento de aire o de refrigeración.

Drip-proof motor A motor that can stand water dripping on it, such as a condenser fan motor in an outdoor condensing unit.

Motor a prueba de goteo Un motor que puede tolerar el goteo de agua sobre él, tal como el motor del condensador en una unidad externa de condensación.

Drip time Once the defrost cycle is terminated; the fans must remain off for a period of time to prevent moisture from being blown off the coil and on to the product. This fan-off time after defrost is referred to as "drip time".

Tiempo de goteo Una vez que finaliza el ciclo de descongelado, los ventiladores deben detenerse durante un tiempo para evitar que el agua que permanece depositada sobre el serpentín caiga sobre el producto. Este tiempo de parada de los ventiladores luego del descongelado se denomina "tiempo de goteo".

Drive clip One of the fasteners that holds square or rectangular steel ducts together.

Grapa de conducto Uno de los sujetadores que une los conductos cuadrados o rectangulares de acero.

Drop-out voltage The minimum back electromotive force (BEMF) that the potential relay coil must experience or its armature will drop out and the contacts between terminals 1 and 2 will close.

Voltaje de desconexión Fuerza contraelectromotriz (BEMF, por sus siglas en inglés) mínima que puede soportar la bobina del relé de potencial sin desmontarse y sin que se cierren los contactos entre las terminales 1 y 2.

Dry-base Term used to describe boilers that are configured so that all of the water in the appliance is above the combustion chamber.

Base seca término utilizado para describir a las calderas que están configuradas

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. de manera que toda el agua en el aparato está por encima de la cámara de combustión.

Dry-bulb temperature The temperature measured using a plain thermometer.

Temperatura de bombilla seca Temperatura que se mide con un termómetro sencillo.

Dry well A well used for the discharged water in an open-loop geothermal heat pump.

Pozo seco Pozo que se utiliza para depositar agua de descarga en una bomba de calor geotérmica de circuito abierto.

Dual pressure control Two controls that are mounted in the same housing, typically low-and high-pressure controls together.

Control de presión doble Dos controles que se colocan en el mismo cárter, típicamente controles para alta y baja presión juntos.

Duct A sealed channel used to convey air from the system to and from the point of utilization.

Conducto Canal sellado que se emplea para dirigir el aire del sistema hacia y desde el punto de utilización.

Duct blower An instrument used to pressurize and test ductwork systems and air handler cabinets for air leakage.

Ventilador de conducto Instrumento utilizado para presurizar y analizar los sistemas de conducto y cabinas de manejo de aire para verificar pérdidas de aire.

Dust mites Microscopic spiderlike insects. Dust mites and their remains are thought to be a primary irritant to some people.

Ácaros del polvo Insectos microscópicos parecidos a arañas. Los ácaros del polvo y sus restos se consideran irritantes principales para algunas personas.

Duty cycling The process by which non essential equipment is intentionally shut down during high peak loads to lower power consumption and energy costs.

Ciclo de trabajo El proceso por el cual el equipo no-esencial es apagado intencionalmente durante periodos de carga elevada para reducir el consumo de energía y los costos de energía.

E

Earth-coupled heat pump Another name for a closed-loop heat pump.

Bomba de calor conectada a tierra Otro nombre para una bomba de calor de circuito cerrado.

Eccentric An off-center device that rotates in a circle around a shaft.

Excéntrico Dispositivo descentrado que gira en un círculo alrededor de un árbol.

ECM An electronically commutated motor. This DC motor uses electronics to commutate the rotor instead of brushes. It is typically built for under 1 hp.

CEM (ECM en inglés) Un motor conmutado electrónicamente. Este motor CD usa electrónica para conmutar el rotor en lugar de escobillas. Típicamente están hechos para menos de 1 caballo de fuerza.

Economizer Mechanical device used on HVAC equipment to reduce energy consumption by allowing outside air to be used for cooling purposes if air conditions are desirable.

Economizador Dispositivo mecánico utilizado en sistemas de calefacción, ventilación y acondicionamiento de aire para reducir el consumo de energía mediante el uso del aire del exterior para enfriamiento, siempre que las condiciones del aire sean apropiadas.

Eddy current test A test with an instrument to find potential failures in evaporator or condenser tubes.

Prueba para la corriente de Foucault Prueba que se realiza con un instrumento para detectar posibles fallas en los tubos del evaporador o del condensador.

EEPROM An acronym for electrical erasable programmable read-only memory.

EEPROM Un acrónimo para memoria electrónica, borrable, programable, de sólo-lectura (electrical erasable programmable read-only memory).

Effective temperature Different combinations of temperature and humidity that provide the same comfort level.

Temperatura efectiva Diferentes combinaciones de temperatura y humedad que proveen el mismo nivel de comodidad.

Electrical power Electrical power is measured in watts. One watt is equal to one ampere flowing with a potential of one volt. Watts = Volts 3 Amperes ($P = E \times I$)

Potencia eléctrica La potencia eléctrica se mide en watios. Un watio equivale a un amperio que fluye con una potencia de un voltio. Watios = voltios × amperios ($P = E \times I$)

Electrical shock When an electrical current travels through a human body.

Sacudida eléctrica Paso brusco de una corriente eléctrica a través del cuerpo humano.

Electrical test instruments Pieces of electrical testing equipment that are used to measure the electrical characteristics of a component or circuit.

Instrumentos de prueba eléctrica Piezas de equipo de prueba eléctrica que se utilizan para medir las características eléctricas de un componente o circuito.

Electric forced-air furnace An electrical resistance type of heating furnace used with a duct system to provide heat to more than one room.

Horno eléctrico de aire soplado Horno con resistencia eléctrica que se utiliza con un sistema de conductos para proporcionar calefacción a varias habitaciones.

Electric heat The process of converting electrical energy, using resistance, into heat.

Calor eléctrico Proceso de convertir energía eléctrica en calor a través de la resistencia.

Electric heat relay A relay that, when its coil is energized, will initiate a heat cycle.

Relé térmico eléctrico un relé que, cuando la bobina es energizada, iniciará un ciclo de calor.

Electric hydronic boiler A boiler using electrical resistance heat, which often has a closed-loop piping system to distribute heated water for space heating.

Caldera hidrónica eléctrica Caldera que utiliza calor proporcionado por una resistencia eléctrica. A menudo cuenta con un sistema cerrado para distribuir agua caliente para usos de calefacción.

Electrodes Electrodes carry high voltage to the tips, where an arc is created for the purpose of ignition for oil or gas furnaces.

Electrodos Los electrodos llevan alto voltaje hasta las puntas, donde se crea un arco con el propósito de encender los calefactores de aceite o de gas.

Electromagnet A coil of wire wrapped around a soft iron core that creates a magnet.

Electroimán Bobina de alambre devanado alrededor de un núcleo de hierro blando que crea un imán.

Electromechanical controls Electromechanical controls convert some form of mechanical energy to operate an electrical function, such as a pressure-operated switch.

Controles electromecánicos Los controles electromecánicos convierten algún tipo de energía mecánica para operar una función eléctrica, tal como un interruptor operado por presión.

Electromotive force A term often used for voltage indicating the difference of potential in two charges.

Fuerza electromotriz Término empleado a menudo para el voltaje, indicando la diferencia de potencia entre dos cargas.

Electron The smallest portion of an atom that carries a negative charge and orbits around the nucleus of an atom.

Electrón La parte más pequeña de un átomo, con carga negativa y que sigue

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. una órbita alrededor del núcleo de un átomo.

Electronic air filter A filter that charges dust particles using a high-voltage direct current and then collects these particles on a plate of an opposite charge.

Filtro de aire electrónico Filtro que carga partículas de polvo utilizando una corriente continua de alta tensión y luego las acumula en una placa de carga opuesta.

Electronic charging scale An electronically operated scale used to accurately charge refrigeration systems by weight.

Escala electrónica para carga Escala accionada electrónicamente que se utiliza para cargar correctamente sistemas de refrigeración por peso.

Electronic circuit board A phenolic type of plastic board that electronic components are mounted on. Typically, the circuits are routed on the back side of the board and the components are mounted on the front with prongs of wire that are soldered to the circuits on the back. These can be mass-produced and coated with a material that keeps the circuits separated if moisture and dust accumulate.

Tarjeta de circuitos electrónicos Un tipo fenólico de tarjeta plástica en la cual se montan los componentes electrónicos. La tarjeta generalmente tiene los circuitos trazados en la parte de atrás de la tarjeta y los componentes se colocan en el frente con cables que se sueldan al circuito por detrás. Éstas pueden producirse en masa y pueden recubrirse con un material que mantiene separado a los circuitos si se acumula humedad y polvo.

Electronic controls Controls that use solid-state semiconductors for electrical and electronic functions.

Controles electrónicos Controles que usan semiconductores de estado sólido para las funciones eléctricas y electrónicas.

Electronic expansion valve (EXV) A metering valve that uses a thermistor as a temperature-sensing element that varies the voltage to a heat motor–operated valve.

Válvula electrónica de expansión (EXV en inglés) Válvula de medición que utiliza un termistor como elemento sensor de temperatura para variar la tensión a una válvula de calor accionada por motor.

Electronic leak detector An instrument used to detect gases in very small portions by using electronic sensors and circuits.

Detector electrónico de fugas Instrumento que se emplea para detectar cantidades de gases sumamente pequeñas utilizando sensores y circuitos electrónicos.

Electronic or programmable thermostat A space thermostat that is electronic in nature with semiconductors that provide different timing programs for cycling the equipment.

Termostato electrónico o programable Un termostato de espacio que es de naturaleza electrónica con semiconductores que proveen diferentes programas de cronometraje para ciclar el equipo.

Electronic relay A solid-state relay with semiconductors used to stop, start, or modulate power in a circuit.

Relé electrónico Un relé de estado sólido con semiconductores para detener, iniciar o modular la electricidad en un circuito.

Electronics The use of electron flow in conductors, semiconductors, and other devices.

Electrónica La utilización del flujo de electrones en conductores, semiconductores y otros dispositivos.

Electroporation The high frequency, pulsing action of a signal generator damages the membrane of the planktonic bacteria in cooling tower and boiler water systems by creating small "pores" in their outer membrane.

Electroporación La acción pulsante de alta frecuencia de un generador de señal daña la membrana de las bacterias del plancton en sistemas de enfriamiento en torre y calderas, creando pequeños "poros" en su membrana exterior.

Electrostatic precipitator Another term for an electronic air cleaner.

Precipitador electrostático Otro término para un limpiador eléctrico del aire.

Emittance The ability of a material to emit radiant energy from its surface.

Emitancia Capacidad de un material de emitir energía radiante a través de su superficie.

Emitter A terminal on a semiconductor.

Emisor Punto terminal en un semiconductor.

Encapsulation Bacteria are attracted to the powder in cooling tower and boiler water systems and become entrapped in the powder particle.

Encapsulamiento El polvo de los sistemas de enfriamiento en torre y calderas atrae a las bacterias, las cuales quedan atrapadas entre las partículas de polvo.

End bell The end structure of an electric motor that normally contains the bearings and lubrication system.

Extremo acampanado Estructura terminal de un motor eléctrico que generalmente contiene los cojinetes y el sistema de lubricación.

End-mount motor An electric motor mounted with tabs or studs fastened to the motor housing end.

Motor con montaje en los extremos Motor eléctrico con lengüetas o espigas de montaje en el extremo de su caja.

End play The amount of lateral travel in a motor or pump shaft.

Holgadura Amplitud de movimiento lateral en un motor o en el árbol de una bomba.

Energy The capacity for doing work.

Energía Capacida para realizar un trabajo.

Energy conservation measure (ECM) A method or process that will conserve or decrease energy waste.

Medida de conservación de energía (ECM, por sus siglas en inglés) Método o proceso por el cual se conserva o disminuye la pérdida de energía.

Energy efficiency ratio (EER) An equipment efficiency rating that is determined by dividing the output in Btu/h by the input in watts. This does not take into account the start-up and shutdown for each cycle.

Relación del rendimiento de energía (EER en inglés) Clasificación del rendimiento de un equipo que se determina al dividir la salida en Btu/h por la entrada en watios. Esto no toma en cuenta la puesta en marcha y la parada de cada ciclo.

Energy Index A way to compare one home to another and to characterize their energy efficiency.

Índice de energía Modo de comparar una vivienda con otra y caracterizar su eficiencia energética.

Energy management The use of computerized or other methods to manage the power to a facility. This may include cycling off nonessential equipment, such as water fountain pumps or lighting, when it may not be needed. The air-conditioning and heating system is also operated at optimum times when needed instead of around the clock.

Manejo de energía Cualquier facilidad que usa métodos computarizados o de otro tipo para manejar el consumo de energía en la facilidad. Esto puede incluir apagar los equipos no esenciales en ciclos, tales como las bombas de las fuentes de agua o las luces cuando no son necesarias. Los sistemas de aire acondicionado y de calefacción también se operan en tiempos óptimos cuando son necesarios en vez de todo el tiempo.

Energy recovery ventilator (ERV) In winter, this ventilation equipment recovers heat and moisture from exhaust air. In summer, heat and moisture are removed from incoming air and transferred to exhaust air.

Ventilador de recuperación de energía (ERV en inglés) En el invierno, este equipo de ventilación recupera el calor y la humedad del aire de escape. En el verano remueve el calor y la humedad del aire de entrada y lo transfiere al aire de salida.

Enthalpy The amount of heat a substance contains from a predetermined base or point.

Entalpía Cantidad de calor que contiene una sustancia, establecida desde una base o un punto predeterminado.

Enthalpy control Device used on economizers to determine the heat content, in Btu/lb, of an air stream.

Controlador de entalpía Dispositivo utilizado en economizadores para determinar el contenido calórico, en Btu/lb, de una corriente de aire.

Entropy Term to describe the change in heat content of a pound of refrigerant per degree Rankine. Expressed in units of Btu/lb/°R.

Entropía Término utilizado para describir el cambio en el contenido de calor de una libra de refrigerante por grado Rankine. Expresado en unidades térmicas británicas (Btu)/libras/°Rankine.

Environment Our surroundings, including the atmosphere.

Medio ambiente Nuestros alrededores, incluyendo la atmósfera.

Environmental Protection Agency (EPA) A branch of the federal government dealing with the control of ozone-depleting refrigerants and other chemicals and the overall welfare of the environment.

Agencia de Protección Ambiental (EPA en inglés) Una rama del gobierno federal que trata con el control de los refrigerantes y otros químicos que repletan el ozono, y el bienestar completo del ambiente.

EPA Abbreviation for the Environmental Protection Agency.

EPA Acrónimo en inglés de Environmental Protection Agency (Agencia de protección ambiental).

Error The signed or mathematical difference between the set point and the control point of a control process that tells whether the control point is above or below the control set point.

Error La diferencia matemática o con signo entre el punto de ajuste y el punto de control en un proceso de control, y el cual dice si el punto de control está por encima o por debajo del punto de ajuste.

Error codes Codes that may read out on an electronic panel that tell the technician what the problem may be.

Códigos de error Códigos que pueden leerse en un panel electrónico y que le dicen al técnico cuál puede ser el problema.

ERV See Energy Recovery Ventilator.

ERV Ver Ventilador de recuperación de energía.

Ester A popular synthetic lubricant that performs best with HFCs and HFC blends.

Ester Lubricante sintético de uso común que da óptimos resultados con HFC y mezclas basadas en HFC.

Ethane gas The fossil fuel, natural gas, used for heat.

Gas etano Combustible fósil, gas natural, utilizado para generar calor.

Ethylene glycol An antifreeze commonly used in chilled water air conditioning systems to prevent the freezing of the water coils.

Etilenglicol Anticongelante utilizado generalmente en sistemas de acondicionamiento de aire mediante enfriamiento de agua para evitar el congelamiento del agua dentro de los serpentines.

Eutectic solution A mixture of two substances in such a ratio that it will provide for the lowest possible melting temperature for that solution.

Solución eutéctica Una mezcla de dos sustancias a una razón que proveerá la temperatura de derretimiento más baja para esa solución.

Evacuation The removal of any gases not characteristic to a system or vessel.

Evacuación Remoción de los gases no característicos de un sistema o depósito.

Evaporation The condition that occurs when heat is absorbed by liquid and it changes to vapor.

Evaporación Condición que ocurre cuando un líquido absorbe calor y se convierte en vapor.

Evaporative condenser (cooling tower) A combination water cooling tower and condenser. The refrigerant from the compressor is routed to the cooling tower where the tower evaporates water to cool the refrigerant. In the evaporative condenser the refrigerant is routed to the tower and the water circulates only in the tower. In a cooling tower, the water is routed to the condenser at the compressor location.

Condensador evaporatorio (torre de enfriamiento) Una combinación de una torre de enfriamiento de agua y un condensador. El refrigerante del compresor se desvía a la torre de enfriamiento donde la torre evapora agua para enfriar al refrigerante. En el condensador evaporatorio el refrigerante se lleva a la torre y el agua circula sólo en la torre. En una torre de enfriamiento, el agua se pasa por el condensador donde está ubicado el compresor.

Evaporative cooling Devices that provide this type of cooling use fiber mounted in a frame with water slowly running down the fiber. Fresh air is drawn in and through the water-soaked fiber and cooled by evaporation to a point close to the wet-bulb temperature of the air.

Enfriamiento por formación de vapor Los dispositivos que proporcionan este tipo de enfriamiento utilizan agua que corre sobre fibra colocada en un marco. Se pasa aire nuevo a través de la fibra húmeda, el aire se enfría por evaporación a una temperatura próxima a la de una bombilla húmeda.

Evaporative humidifier A humidifier that provides moisture on a media surface through which air is forced. The air picks up the moisture from the media as a vapor.

Humidificador por evaporación Humidificador que proporciona humedad en una superficie a través de la cual pasa aire soplado. El aire recoge la humedad de la superficie, en forma de vapor.

Evaporator The component in a refrigeration system that absorbs heat into the system and evaporates the liquid refrigerant.

Evaporador El componente en un sistema de refrigeración que absorbe el calor hacia el sistema y evapora el refrigerante líquido.

Evaporator fan A fan or blower used to improve the efficiency of an evaporator by air movement over the coil.

Abanico del evaporador Ventilador que se utiliza para mejorar el rendimiento de un evaporador por medio del movimiento de aire a través de la bobina.

Evaporator pressure-regulating valve (EPR valve) A mechanical control installed in the suction line at the evaporator outlet that keeps the evaporator pressure from dropping below a certain point.

Válvula reguladora de presión del evaporador (EPR en inglés) Reguladora mecánica instalada en el conducto de aspiración de la salida del evaporador; evita que la presión del evaporador caiga hasta alcanzar un nivel por debajo del nivel específico.

Evaporator types Flooded—an evaporator where the liquid refrigerant level is maintained to the top of the heat exchange coil. Dry type—an evaporator coil that achieves the heat exchange process with a minimum of refrigerant charge.

Clases de evaporadores Inundado—un evaporador en el que se mantiene el nivel del refrigerante líquido en la parte superior de la bobina de intercambio de calor. Seco—una bobina de evaporador que logra el proceso de intercambio de calor con una mínima cantidad de carga de refrigerante.

Even parallel system Parallel compressors of equal sizes mounted on a steel rack and controlled by a microprocessor.

Sistema paralelo homogéneo Compresores de capacidades iguales, montados en

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

paralelo en un bastidor de acero y controlados mediante un microprocesador.

Excess air Excess air consists of combustion air and dilution air.

Aire en exceso El aire en exceso se compone de aire de combustión y aire de dilución.

Exfiltration The outflow of air from a structure. Air flow out of a structure usually from a pressure difference, usually accompanied by an equal inflow of air.

Exfiltración Flujo de aire desde una estructura hacia el exterior. Flujo de aire proveniente de una estructura, generalmente debido a una diferencia de presión y generalmente acompañado de un flujo equivalente de aire hacia el interior.

Exhaust valve The movable component in a refrigeration compressor that allows hot gas to flow to the condenser and prevents it from refilling the cylinder on the downstroke.

Válvula de escape Componente móvil en un compresor de refrigeración que permite el flujo de gas caliente al condensador y evita que este gas rellene el cilindro durante la carrera descendente.

Expansion (metering) device The component between the high-pressure liquid line and the evaporator that feeds the liquid refrigerant into the evaporator.

Dispositivo de (medición) de expansión. Componente entre el conducto de líquido de alta presión y el evaporador que alimenta el refrigerante líquido hacia el evaporador.

Expansion joint A flexible portion of a piping system or building structure that allows for expansion of the materials due to temperature changes.

Junta de expansión Parte flexible de un sistema de tubería o de la estructura de un edificio que permite la expansión de los materiales debido a cambios de temperatura.

Explosion-proof motor A totally sealed motor and its connections that can be operated in an explosive atmosphere, such as in a natural gas plant.

Motor a prueba de explosión Un motor totalmente sellado y con conexiones que puede operarse en una atmósfera explosiva, tal como dentro de una planta de gas natural.

External drive An external type of compressor motor drive, as opposed to a hermetic compressor.

Motor externo Motor tipo externo de un compresor, en comparación con un compresor hermético.

External equalizer The connection from the evaporator outlet to the bottom of the diaphragm on a thermostatic expansion valve.

Equilibrador externo Conexión de la salida del evaporador a la parte inferior del diafragma en una válvula de expansión termostática.

External heat defrost A defrost system for a refrigeration system where the heat comes from some external source. It might be an electric strip heater in an air coil, or water in the case of an ice maker. ***External*** means other than hot gas defrost.

Descongelador de calor externo Un sistema de descongelación para un sistema de refrigeración en el cual el calor viene de una fuente externa. La misma puede ser un calentador de tira eléctrico en un serpentín o agua en caso de una hielera. ***Externo*** se refiere a otro tipo de descongelación aparte del de gas caliente.

External motor protection Motor overload protection that is mounted on the outside of the motor.

Protección externa para motor Protección para un motor contra la sobrecarga y que está montada en el exterior del motor.

F

Fahrenheit scale The temperature scale that places the boiling point of water at 212°F and the freezing point at 32°F.

Escala Fahrenheit Escala de temperatura en la que el punto de ebullición del agua se encuentra a 212°F y el punto de fusión del hielo a 32°F.

Fail-safe The timer on the time clock will eventually bring the system out of defrost if early defrost termination is inoperative.

Seguro El temporizador del reloj horario hará que el descongelamiento se detenga cuando el sistema de detención temprana del descongelamiento no funcione.

Fan A device that produces a pressure difference in air to move it.

Abanico Dispositivo que produce una diferencia de presión en el aire para moverlo.

Fan assisted draft A forced draft system that either pushes or pulls combustion gasses through the heat exchanger using a combustion blower motor and a fan. These systems can be either forced or induced draft systems.

Corriente asistida por ventiladores Sistema de circulación forzada de aire que expele o succiona los gases de combustión a través del intercambiador de calor utilizando un motor de ventilación de combustión y un ventilador. Estos sistemas pueden ser sistemas de corriente forzada o inducida.

Fan cycling The use of a pressure control to turn a condenser fan on and off to maintain a correct pressure within the system.

Funcionamiento cíclico La utilización de un regulador de presión para poner en marcha y detener el abanico de un condensador a fin de mantener una presión correcta dentro del sistema.

Fan relay coil A magnetic coil that controls the starting and stopping of a fan.

Bobina de relé del ventilador Bobina magnética que regula la puesta en marcha y la parada de un ventilador.

Farad The unit of capacity of a capacitor. Capacitors in our industry are rated in microfarads.

Faradio Unidad de capacidad de un capacitador. En nuestro medio, los capacitadores se clasifican en microfaradios.

Feedback loop The circular data route in a control loop that usually travels from the control medium's sensor to the controller, then to the controlled device, and back into the controlled process to the sensor again as a change in the control point.

Circuito de retroalimentación Ruta circular de la data en un circuito de control que generalmente va desde el sensor del medio de control al controlador y luego al aparato controlado, y de regreso al proceso controlado y al sensor nuevamente como un cambio en el punto de control.

Female thread The internal thread in a fitting.

Filete hembra Filete interno en un accesorio.

Fill or wetted-surface method Water in a cooling tower is spread out over a wetted surface while air is passed over it to enhance evaporation.

Método de relleno o de superficie mojada El agua en una torre de refrigeración se extende sobra una superficie mojada mientras el aire se dirige por encima de la misma para facilitar la evaporación.

Film factor The relationship between the medium giving up heat and the heat exchange surface (evaporator). This relates to the velocity of the medium passing over the evaporator. When the velocity is too slow, the film between the air and the evaporator becomes greater and becomes an insulator, which slows the heat exchange.

Factor de capa Relación entre el medio que emite calor y la superficie del intercambiador de calor (evaporador). Esto se refiere a la velocidad del medio que pasa sobre el evaporador. Cuando la velocidad es demasiado lenta, la capa entre el aire y el evaporador se expande y se convierte en un aislador, disminuyendo así la velocidad del intercambio del calor.

Filter A fine mesh or porous material that removes particles from passing fluids.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Filtro Malla fina o material poroso que remueve partículas de los fluidos que pasan por él.

Filter drier A type of refrigerant filter that includes a desiccant material that has an attraction for moisture. The filter drier will remove particles and moisture from refrigerant and oil.

Secador de filtro Un tipo de filtro de refrigerante que incluye un material desecante el cual tiene una atracción a la humedad. El secador de filtro removerá las partículas y la humedad del aceite y del refrigerante.

Fin comb A hand tool used to straighten the fins on an air-cooled condenser.

Herramienta para aletas Herramienta manual utilizada para enderezar las aletas en un condensador enfriado por aire.

Finned-tube evaporator A copper or aluminum tube that has fins, usually made of aluminum, pressed onto the copper lines to extend the surface area of the tubes.

Evaporador de tubo con aletas Un tubo de cobre o aluminio que tiene aletas, generalmente de aluminio, colocadas a presión contra las líneas de cobre para extender el área de superficie de los tubos.

Fixed-bore device An expansion device with a fixed diameter that does not adjust to varying load conditions.

Dispositivo de calibre fijo Dispositivo de expansión con un diámetro fijo que no se ajusta a las condiciones de carga variables.

Fixed resistor A nonadjustable resistor. The resistance cannot be changed.

Resistor fijo Resistor no ajustable. La resistencia no se puede cambiar.

Flame impingement When flame touches components where it is not supposed to. For example, the flame should not touch the heat exchanger in an oil or gas furnace. The flame should stay in the middle of the heat exchanger.

Impacto de llama Cuando una llama toca componentes que no está supuesta a tocar. Por ejemplo, la llama no debería tocar el intercambiador de calor en un calefactor de aceite o gas. La llama debería mantenerse en el centro del intercambiador de calor.

Flame-proving device A device in a gas or oil furnace to ensure there is a flame so that excess fuel will not be released, which may cause overheating in an oil furnace and explosion in a gas appliance.

Aparato probador de llama Un aparato en un calefactor de gas o aceite que asegura que hay una llama presente para que no se libere combustible de más, lo cual puede causar sobrecalentamiento en un calefactor de aceite y una explosión en enseres de gas.

Flame rectification In a gas furnace, the flame changes the normal current to direct current. The electronic components in the system will only energize and open the gas valve with a direct current.

Rectificación de llama En un horno de gas, el calor generado por la llama convierte la corriente normal en corriente directa. Los componentes electrónicos del sistema sólo se activarán para abrir el paso del gas con corriente directa.

Flapper valve See Reed valve.

Chapaleta Véase válvula de lámina.

Flare The angle that may be fashioned at the end of a piece of tubing to match a fitting and create a leak-free connection.

Abocinado Ángulo que puede formarse en el extremo de una pieza de tubería para emparejar un accesorio y crear una conexión libre de fugas.

Flare nut A threaded connector used in a flare assembly for tubing.

Tuerca abocinada Conector de rosca utilizado en un conjunto abocinado para tuberías.

Flash gas A term used to describe the pressure drop in an expansion device when some of the liquid passing through the valve is changed quickly to a gas and cools the remaining liquid to the corresponding temperature.

Gas instantáneo Término utilizado para describir la caída de la presión en un dispositivo de expansión cuando una parte del líquido que pasa a través de la válvula se convierte rápidamente en gas y enfría el líquido restante a la temperatura correspondiente.

Floating head pressure Letting the head pressure (condensing pressure) fluctuate with the ambient temperature from season to season for lower compression ratios and better efficiencies.

Fluctuar la presión de la carga Hecho de dejar que la presión de la carga (presión de condensación) fluctúe con la temperatura del ambiente en cada temporada del año, para obtener relaciones de compresión más bajas y mejores rendimientos.

Float valve or switch An assembly used to maintain or monitor a liquid level.

Válvula o conmutador de flotador Conjunto utilizado para mantener o controlar el nivel de un líquido.

Flooded evaporator A refrigeration system operated with the liquid refrigerant level very close to the outlet of the evaporator coil for improved heat exchange.

Sistema inundado Sistema de refrigeración que funciona con el nivel del refrigerante líquido bastante próximo a la salida de la bobina del evaporador para mejorar el intercambio de calor.

Flooding The term applied to a refrigeration system when the liquid refrigerant reaches the compressor.

Inundación Término aplicado a un sistema de refrigeración cuando el nivel del refrigerante líquido llega al compresor.

Flow-through receiver Flow-through receivers can store the cool subcooled liquid refrigerant for some time before releasing it to the liquid line and liquid header. This can cause a gain in temperature within the liquid and subcooling can be lost.

Depósitos de flujo Los depósitos de flujo pueden almacenar el líquido refrigerante subenfriado frío por algún tiempo antes de liberarlo hacia la línea de líquido y la cabecera de líquido. Esto puede generar una ganancia de temperatura en el líquido, provocando la pérdida del subenfriamiento.

Flue The duct that carries the products of combustion out of a structure for a fossil- or a solid-fuel system.

Conducto de humo Conducto que extraer los productos de combustión de una estructura en sistemas de combustible fósil o sólido.

Flue draft Another name for chimney draft and stack draft.

Corriente de conducto de humo Denominación alternativa para la corriente de chimenea y corriente de ventilación.

Flue-gas analysis instruments Instruments used to analyze the operation of fossil fuel–burning equipment such as oil and gas furnaces by analyzing the flue gases.

Instrumentos para el análisis del gas de combustión Instrumentos utilizados para llevar a cabo un análisis del funcionamiento de los quemadores de combustible fósil, como por ejemplo hornos de aceite pesado o gas, a través del estudio de los gases de combustión.

Fluid The state of matter of liquids and gases.

Fluido Estado de la materia de líquidos y gases.

Fluid expansion device Using a bulb or sensor, tube, and diaphragm filled with fluid, this device will produce movement at the diaphragm when the fluid is heated or cooled. A bellows may be added to produce more movement. These devices may contain vapor and liquid.

Dispositivo para la expansión del fluido Utilizando una bombilla o sensor, un tubo y un diafragma lleno de fluido, este dispositivo generará movimiento en el diafragma cuando se caliente o enfríe el fluido. Se le puede agregar un fuelle para generar aún más movimiento. Dichos dispositivos pueden contener vapor y líquido.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Flush The process of using a fluid to push contaminants from a system.

Descarga Proceso de utilizar un fluido para remover los contaminantes de un sistema.

Flux A substance applied to soldered and brazed connections to prevent oxidation during the heating process.

Fundente Sustancia aplicada a conexiones soldadas y broncesoldadas para evitar la oxidación durante el proceso de calentamiento.

Foaming A term used to describe oil when it has liquid refrigerant boiling out of it.

Espumación Término utilizado para describir el aceite cuando el refrigerante líquido se derrama del mismo.

Foot-pound The amount of work accomplished by lifting 1 lb of weight 1 ft; a unit of energy.

Libra-pie Medida de la cantidad de energía o fuerza que se requiere para levantar una libra a una distancia de un pie; unidad de energía.

Force Energy exerted.

Fuerza Energía ejercida sobre un objeto.

Forced convection The movement of fluid by mechanical means.

Convección forzada Movimiento de fluido por medios mecánicos.

Forced draft Forced draft systems push or blow combustion gases through the heat exchanger and cause a positive pressure in the heat exchanger. Forced-draft systems have the combustion blower motor on the inlet of the heat exchanger.

Corriente forzada Los sistemas de corriente forzada expelen o succionan los gases de combustión a través del intercambiador de calor, produciendo una presión positiva en el mismo. En los sistemas de corriente forzada el motor de ventilación de combustión se encuentra a la entrada del intercambiador de calor.

Forced-draft cooling tower A water cooling tower that has a fan on the side of the tower that pushes air through the tower, as opposed to an induced-draft tower, which has the fan on the side and draws air through the tower.

Torre de enfriamiento de ventilación forzada Una torre de enfriamiento que tiene un ventilador en el lado de la torre y empuja aire a través de la torre, contrario a una torre de ventilación inducida que tiene un ventilador en el lado de la torre y jala el aire a través de la torre.

Forced-draft evaporator An evaporator over which air is forced to spread the cooling more efficiently. This term usually refers to a domestic refrigerator or freezer.

Evaporador de tiro forzado Evaporador encima del cual se envía aire soplado para obtener una distribución más eficaz del frío. Este término suele aplicarse a refrigeradores o congeladores domésticos.

Fossil fuels Natural gas, oil, and coal formed millions of years ago from dead plants and animals.

Combustibles fósiles El gas natural, el petróleo y el carbón que se formaron hace millones de años de plantas y animales muertos.

Four-way valve The valve in a heat pump system that changes the direction of the refrigerant flow between the heating and cooling cycles.

Válvula con cuatro vías Válvula en un sistema de bomba de calor que cambia la dirección del flujo de refrigerante entre los ciclos de calentamiento y enfriamiento.

Fractionation When a zeotropic refrigerant blend phase changes, the different components in the blend all have different vapor pressures. This causes different vaporization and condensation rates and temperatures as they phase change.

Fraccionación Cuando se produce un cambio en la fase de una mezcla zeotrópica de refrigerantes, los diferentes componentes que forman la mezcla tienen presiones de vapor diferentes. Esto provoca diferentes temperaturas y tasas de vaporización y de condensación según cambien de fase.

Free-cooling The process of cooling a structure using only outside air without operating the mechanical air conditioning system.

Enfriamiento libre Proceso por el cual una estructura se enfría utilizando sólo aire del exterior, sin el funcionamiento mecánico del sistema de acondicionamiento de aire.

Freezer burn The term applied to frozen food when it becomes dry and hard from dehydration due to poor packaging.

Quemadura del congelador Término aplicado a la comida congelada cuando se seca y endurece debido a la deshidratación ocacionada por el empaque de calidad inferior.

Freezestat A temperature-sensing device typically intended to protect water coils from freezing.

Sensor de congelamiento Dispositivo de medición de temperatura, generalmente utilizado para evitar el congelamiento del agua dentro de los serpentines.

Freeze-up Excess ice or frost accumulation on an evaporator to the point that airflow may be affected.

Congelación Acumulación excesiva de hielo o congelación en un evaporador a tal extremo que el flujo de aire puede ser afectado.

Freezing The change of state of water from a liquid to a solid.

Congelamiento Cambio de estado del agua de líquido a sólido.

Freon The previous trade name for refrigerants manufactured by E. I. du Pont de Nemours & Co., Inc.

Freón Marca registrada previa para refrigerantes fabricados por la compañía E. I. du Pont de Nemours, S.A.

Frequency The cycles per second (cps) of the electrical current supplied by the power company. This is normally 60 cps in the United States.

Frecuencia Ciclos por segundo (cps), generalmente 60 cps en los Estados Unidos, de la corriente eléctrica suministrada por la empresa de fuerza motriz.

Friction loss The loss of pressure in a fluid flow system (air or water) due to the friction of the fluid rubbing on the sides. It is typically measured in feet of equivalent loss.

Pérdida por fricción La pérdida de presión en un sistema de flujo de fluido (aire o agua) debido a la fricción del fluido al frotar contra los lados. Típicamente se mide en pies de pérdida equivalente.

Front seated A position on a service valve that will not allow refrigerant flow in one direction.

Sentado delante Posición en una válvula de servicio que no permite el flujo de refrigerante en una dirección.

Frost back A condition of frost on the suction line and even the compressor body.

Obturación por congelación Condición de congelación que ocurre en el conducto de aspiración e inclusive en el cuerpo del compresor.

Frostbite When skin freezes.

Quemadura por frío Congelación de la piel.

Frozen The term used to describe water in the solid state; also used to describe a rotating shaft that will not turn.

Congelado Término utilizado para describir el agua en un estado sólido; utilizado también para describir un árbol giratorio que no gira.

Fuel oil The fossil fuel used for heating; a petroleum distillate.

Aceite pesado Combustible fósil utilizado para calentar; un destilado de petróleo.

Full-load amperage (FLA) A mathematical calculation used to get Underwriters Laboratories (UL) approval for a motor that was used by compressor manufacturer before 1972. FLA value was replaced with a rated-load amperage (RLA) value after 1972. It should not be used to determine the proper refrigerant charge, or to determine if a compressor motor is running properly.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Amperaje de carga completa (FLA, por sus siglas en inglés Cálculo matemático utilizado para obtener la aprobación de Underwriters Laboratory (UL) para un motor utilizado por un fabricante de compresores antes de 1972. El valor del FLA se reemplazó por el valor del amperaje de carga calificada (RLA) luego de 1972. No debe utilizarse para determinar la carga adecuada del refrigerante ni para determinar si un motor de compresor está funcionando correctamente.

Furnace Equipment used to convert heating energy, such as fuel oil, gas, or electricity, to usable heat. It usually contains a heat exchanger, a blower, and the controls to operate the system.

Horno Equipo utilizado para la conversión de energía calórica, como por ejemplo el aceite pesado, el gas o la electricidad, en calor utilizabe. Normalmente contiene un intercambiador de calor, un soplador y los reguladores para accionar el sistema.

Fuse A safety device used in electrical circuits for the protection of the circuit conductor and components.

Fusible Dispositivo de seguridad utilizado en circuitos eléctricos para la protección del conductor y los componentes del circuito.

Fusible link An electrical safety device normally located in a furnace that burns and opens the circuit during an overheat situation.

Cartucho de fusible Dispositivo eléctrico de seguridad ubicado por lo general en un horno, que quema y abre el circuito en caso de sobrecalentamiento.

Fusible plug A device (made of low-melting temperature metal) used in pressure vessels that is sensitive to high temperatures and relieves the vessel contents in an overheating situation.

Tapón de fusible Dispositivo utilizado en depósitos en presión, hecho de un metal que tiene una temperatura de fusión baja. Este dispositivo es sensible a temperaturas altas y alivia el contenido del depósito en caso de sobrecalentamiento.

Fusion iron A device used to heat plastic pipe to 500°F for a permanent, water-tight connection to another plastic pipe.

Plancha de fusión Dispositivo utilizado para calentar tuberías plásticas a 500 °F para lograr uniones permanentes y sin pérdidas de agua entre segmentos de cañería plástica.

G

Gain The term used to describe the sensitivity of a control, for example, how much change in output signal per degree of temperature change.

Ganancia El término se usa para describir la sensibilidad de un control, por ejemplo, cuanto cambio en la señal de salida por cada grado de cambio en temperatura.

Gas The vapor state of matter.

Gas Estado de vapor de una materia.

Gasket A thin piece of flexible material used between two metal plates to prevent leakage.

Guarnición Pieza delgada de material flexible utilizada entre dos piezas de metal para evitar fugas.

Gas-pressure switch Used to detect gas pressure before gas burners are allowed to ignite.

Conmutador de presión del gas Utilizado para detectar la presión del gas antes de que los quemadores de gas puedan encenderse.

Gas valve A valve used to stop, start, or modulate the flow of natural gas.

Válvula de gas Válvula utilizada para detener, poner en marcha o modular el flujo de gas natural.

Gate A terminal on a semiconductor.

Compuerta Punto terminal en un semi-conductor.

Gate valve Valve that has a sliding wedge-shaped piece (gate) inside it that is connected to a handle. The handle can be turned to force the sliding gate into a fitted seat to stop or control water flow. Gate valves have very little pressure drop or resistance to water or fluid flow when wide open because the gate moves all of the way out of the water stream flow.

Válvula de compuerta Válvula con una pieza (compuerta) deslizante en forma de una cuña que está conectada a un mango. Se gira el mango para forzar la compuerta sobre un asiento para parar or controlar el flujo del agua. Cuando están abiertas, las válvulas de compuerta tienen muy poca caída de la presión o resistencia al flujo del agua o fluido porque la compuerta se mueve fuera del corriente del flujo del agua.

Gauge An instrument used to indicate pressure.

Manómetro Instrumento utilizado para indicar presión.

Gauge manifold A tool that may have more than one gauge with a valve arrangement to control fluid flow.

Manómetro de distribución Herramienta que puede tener más de un manómetro con las válvulas arregladas a fin de regular el flujo de fluido.

Gauge port The service port used to attach a gauge for service procedures.

Orificio de manómetro Orificio de servicio utilizado con el propósito de fijar un manómetro para procedimientos de servicio.

Geothermal heat pump A heat pump that uses the earth or water in the earth for its heat sources and sinks.

Bomba de calor geotérmica Bomba de calor que utiliza el suelo o el agua de la tierra como fuente y depósito termal.

Geothermal well A well dedicated to a geothermal heat pump that draws water from the top of the water column and returns the same water to the bottom of the water column.

Pozo geotermal Pozo utilizado por una bomba de calor geotérmica que extrae agua de la parte superior de la columna de agua y la devuelve en la parte inferior de la misma columna.

Germanium A substance from which many semiconductors are made.

Germanio Sustancia de la que se fabrican muchos semiconductores.

Global warming An earth-warming process caused by the atmosphere's absorption of the heat energy radiated from the earth's surface.

Calentamiento de la Tierra Proceso de calentamiento de la Tierra provocado por la absorción de la energía radiada de la superficie de la Tierra, por la atmósfera, en forma de calor.

Global warming potential (GWP) An index that measures the direct effect of chemicals emitted into the atmosphere.

Potencial de calentamiento de la tierra (GWP en inglés) Índice que mide el efecto directo de los productos químicos que se emiten a la atmósfera.

Globe valve Valve that uses a disk and a seat to stop or vary water or fluid flow. The handle raises or lowers the disk over the valve seat, which is built into the valve body. When the valve is fully open, the water must make two 90° turns to pass through the valve, creating pressure drop.

Válvula de globo Válvula que utiliza un disco y un asiento para parar o variar el flujo del agua o fluido. El mango eleva o baja el disco sobre el asiento de la válvula construído en el cuerpo de la válvula. Cuando la válvula está completamente abierta, el agua debe girar 90° dos veces para pasar a través de la válvula, ocasionando así una caída de la presión.

Glow coil A device that automatically reignites a pilot light if it goes out.

Bobina encendedora Dispositivo que automáticamente vuelve a encender la llama piloto si ésta se apaga.

Glycol Antifreeze solution used in the water loop of geothermal heat pumps.

Glicol Líquido anticongelante que se emplea en el circuito de agua de las bombas de calor geotérmicas.

Graduated cylinder A cylinder with a visible column of liquid refrigerant used to measure the refrigerant charged into a system. Refrigerant temperatures can be dialed on the graduated cylinder.

Cilindro graduado Cilindro con una columna visible de refrigerante líquido utilizado para medir el refrigerante inyectado al sistema. Las temperaturas del refrigerante pueden marcarse en el cilindro graduado.

Grain Unit of weight. One pound = 7000 grains.

Grano Unidad de peso. Una libra equivale a 7.000 granos.

Gram (g) Metric measurement term used to express weight.

Gramo Término utilizado para referirse a la unidad básica de peso en el sistema métrico.

Green Companies looking to go "Green" incorporate sustainable design into their building and facilities.

Ecológico Las empresas que impulsan la ecología incorporan el diseño sustentable a sus edificios y áreas de producción.

Greenhouse effect An earth-warming process caused by the atmosphere's absorption of the heat energy radiated from the earth's surface. Often referred to as global warming.

Efecto invernadero Proceso de calentamiento de la tierra causado por la absorción atmosférica de la energía calórica irradiada desde la superficie terrestre. También se lo conoce como calentamiento global.

Grille A louvered, often decorative, component in an air system at the inlet or the outlet of the airflow.

Rejilla Componente con celosías, comúnmente decorativo, en un sistema de aire que se encuentra a la entrada o a la salida del flujo de aire.

Grommet A rubber, plastic, or metal protector usually used where wire or pipe goes through a metal panel.

Guardaojal Protector de caucho, plástico o metal normalmente utilizado donde un alambre o un tubo pasa a través de una base de metal.

Ground, electrical A circuit or path for electron flow to earth ground.

Tierra eléctrica Circuito o trayectoria para el flujo de electrones a la puesta a tierra.

Ground fault circuit interrupter (GFCI) A circuit breaker that can detect very small leaks to ground, which, under certain circumstances, could cause an electrical shock. This small leak, which may not be detected by a conventional circuit breaker, will cause the GFCI circuit breaker to open the circuit.

Disyuntor por pérdidas a tierra (GFCI en inglés) Disyuntor capaz de detectar fugas muy pequeñas hacia tierra, que en determinadas circunstancias pueden provocar descargas eléctricas. Existe la posibilidad de que un disyuntor convencional no sea capaz de detectar las fugas pequeñas, en cuyo caso el disyuntor GFCI abre el circuito.

Ground loop These loops of plastic pipe are buried in the ground in a closed-loop geothermal heat pump system and contain a heat transfer fluid.

Circuito de tierra Circuitos de tubos de plástico enterrados y que forman parte de un sistema de bomba geotérmica de circuito cerrado. Dichos tubos contienen un fluido que permite la transferencia de calor.

Ground wire A wire from the frame of an electrical device to be wired to the earth ground.

Alambre a tierra Alambre que va desde el armazón de un dispositivo eléctrico para ser conectado a la puesta a tierra.

Grout A cement-like material injected between the well casing and the drilled hole for a well. Grout adds rigidity and prevents contamination from entering the well.

Lechada Pasta fina obtenida mezclando cemento y agua, que se inyecta entre la pared del pozo y la perforación para el mismo. Proporciona rigidez e impide la penetración de agentes contaminantes en el pozo.

Guide vanes Vanes used to produce capacity control in a centrifugal compressor. Also called *prerotation guide vanes.*

Paletas directrices Paletas utilizadas para producir la regulación de capacidad en un compresor centrífugo. Conocidas también como paletas directrices para prerotación.

H

Halide refrigerants Refrigerants that contain halogen chemicals: R-12, R-22, R-500, and R-502 are among them.

Refrigerantes de hálido Refrigerantes que contienen productos químicos de halógeno: entre ellos se encuentran el R-12, R-22, R-500, y R-502.

Halide torch A torch-type leak detector used to detect the halogen refrigerants.

Soplete de hálido Detector de fugas de tipo soplete utilizado para detectar los refrigerantes de halógeno.

Halogens Chemical substances found in many refrigerants containing chlorine, bromine, iodine, and fluorine.

Halógenos Sustancias químicas presentes en muchos refrigerantes que contienen cloro, bromo, yodo y flúor.

Hand truck A two-wheeled piece of equipment that can be used for moving heavy objects.

Vagoneta para mano Equipo con dos ruedas que puede utilizarse para transportar objetos pesados.

Hanger A device used to support tubing, pipe, duct, or other components of a system.

Soporte Dispositivo utilizado para apoyar tuberias, tubos, conductos u otros componentes de un sistema.

Head Another term for pressure, usually referring to gas or liquid.

Carga Otro término para presión, refiriéndose normalmente a gas o líquido.

Header A pipe or containment to which other pipe lines are connected.

Conductor principal Tubo o conducto al que se conectan otras conexiones.

Head pressure control A control that regulates the head pressure in a refrigeration or air-conditioning system.

Regulador de la presión de la carga Regulador que controla la presión de la carga en un sistema de refrigeración o de acondicionamiento de aire.

Heat Energy that causes molecules to be in motion and to raise the temperature of a substance.

Calor Energía que ocasiona el movimiento de las moléculas provocando un aumento de temperatura en una sustancia.

Heat anticipator A device that anticipates the need for cutting off the heating system prematurely so the system does not overshoot the set point temperature.

Anticipador de calor Dispositivo que anticipa la necesidad de detener la marcha del sistema de calentamiento para que el sistema no exceda la temperatura programada.

Heat coil A device made of tubing or pipe designed to transfer heat to a cooler substance by using fluids.

Bobina de calor Dispositivo hecho de tubos, diseñado para transmitir calor a una sustancia más fría por medio de fluidos.

Heat exchanger A device that transfers heat from one substance to another.

Intercambiador de calor Dispositivo que transmite calor de una sustancia a otra.

Heat fusion A process that will permanently join sections of plastic pipe together.

Fusión térmica Proceso mediante el cual se unen dos piezas de tubo de plástico permanentemente.

Heat gain Rate at which heat enters a structure in the cooling season.

Ganancia calórica Velocidad a la que el calor entra a una estructura en la estación de enfriamiento.

Heating Seasonal Performance Factor (HSPF) HSPF is a ratio of the seasonal heat output in BTUs to the seasonal watt-hours used. The higher the HSPF, the more efficient the unit is in moving BTUs of heat energy per BTU of energy consumed. This efficiency factor is applied to heat pumps in the heating mode and takes into consideration the energy used during the entire heating season.

Factor de rendimiento estacional del calentamiento (HSPF, por sus siglas en inglés) Relación entre la generación estacional de calor, en BTU, y la energía estacional utilizada, en watts por hora. Mientras mayor sea el HSPF, más eficiente es el sistema para generar una BTU de energía calórica por cada BTU de energía consumida. Este factor de eficiencia se aplica a bombas calóricas cuando funcionan generando calor y toma en cuenta la energía utilizada durante la estación de calefacción completa.

Heat intensity Another term for temperature.

La intensidad de calor Otro término para la temperatura.

Heat island Urban air or surface temperatures that are higher than nearby rural areas.

Isla calórica Aire urbano o temperaturas de superficie mayores que las de áreas rurales cercanas.

Heat loss Rate at which heat leaks from a structure in the heating season.

Pérdida de calor Velocidad de pérdida de calor desde una estructura en la estación de calefacción.

Heat of compression That part of the energy from the pressurization of a gas or a liquid converted to heat.

Calor de compresión La parte de la energía generada de la presurización de un gas o un líquido que se ha convertido en calor.

Heat of fusion The heat released when a substance is changing from a liquid to a solid.

Calor de fusión Calor liberado cuando una sustancia se convierte de líquido a sólido.

Heat of respiration When oxygen and carbon hydrates are taken in by a substance or when carbon dioxide and water are given off. Associated with fresh fruits and vegetables during their aging process while stored.

Calor de respiración Cuando se admiten oxígeno e hidratos de carbono en una sustancia o cuando se emiten bióxido de carbono y agua. Se asocia con el proceso de maduración de frutas y legumbres frescas durante su almacenamiento.

Heat pump A refrigeration system used to supply heat or cooling using valves to reverse the refrigerant gas flow.

Bomba de calor Sistema de refrigeración utilizado para suministrar calor o frío mediante válvulas que cambian la dirección del flujo de gas del refrigerante.

Heat reclaim Using heat from a condenser for purposes such as space and domestic water heating.

Reclamación de calor La utilización del calor de un condensador para propósitos tales como la calefacción de espacio y el calentamiento doméstico de agua.

Heat recovery The process of transferring heat from one area to another as needed to help reduce energy consumption by the HVAC equipment.

Recuperación de calor Proceso de transferencia de calor de un área hacia otra, necesaria para reducir el consumo de energía del equipamiento de acondicionamiento de aire.

Heat recovery ventilator Units that recover heat only, used primarily in winter.

Ventilador de recuperación de calor Unidades que recuperan calor solamente, usados principalmente en el invierno.

Heat sink A low-temperature surface to which heat can transfer.

Fuente fría Superficie de temperatura baja a la que puede transmitírsele calor.

Heat tape Electric resistance wires embedded into a flexible housing usually wrapped around a pipe to keep it from freezing.

Cinta calefactora Resistencia eléctrica incrustada en una cubierta flexible normalmente instalada alrededor de un tubo para impedir su congelación.

Heat transfer The transfer of heat from a warmer to a colder substance.

Transmisión de calor Cuando se transmite calor de una sustancia más caliente a una más fría.

Helix coil A bimetal formed into a helix-shaped coil that provides longer travel when heated.

Bobina en forma de hélice Bimetal encofrado en una bobina en forma de hélice que provee mayor movimiento al ser calentado.

HEPA filter An abbreviation for high-efficiency particulate arrestor. These filters are used when a high degree of filtration is desired or required.

Filtro HEPA Abreviatura para filtro de partículas de alto rendimiento. Este tipo de filtro se utiliza cuando se requiere un elevado grado de filtrado.

Hermetic compressor A motor and compressor that are totally sealed by being welded in a container.

Compresor hermético Un motor y un compresor que están totalmente sellados al ser soldados al contenedor.

Hermetic system An enclosed refrigeration system where the motor and compressor are sealed within the same system with the refrigerant.

Sistema hermético Sistema de refrigeracíon cerrado donde el motor y el compresor se obturan dentro del mismo sistema con el refrigerante.

HERS index HERS is an acronym for Home Energy Rating Systems. It is a standardized rating procedure administered by the Residential Energy Services Network (RESNET).

Índice HERS HERS es el acrónimo de "Sistemas de evaluación de energía residencial". Es un procedimiento de puntuación estandarizado, administrado por la Cadena de servicios de energía residencial (RESNET, por sus siglas en inglés).

Hertz Cycles per second.

Hertz Ciclos por segundo.

Hg Abbreviation for the element mercury.

Hg Abreviatura del elemento mercurio.

Hidden heat See Latent heat.

Calor oculto Véase Calor latente.

High-pressure control A control that stops a boiler heating device or a compressor when the pressure becomes too high.

Regulador de alta presión Regulador que detiene la marcha del dispositivo de calentamiento de una caldera o de un compresor cuando la presión alcanza un nivel demasiado alto.

High-pressure (high-side) gauge The gauge used to measure the pressure on the high-pressure side of an air conditioning or refrigeration system.

Manómetro de presión alta (lado alto) el indicador utilizado para medir la presión en el lado de alta presión del sistema de aire acondicionado o refrigeración.

High side A term used to indicate the high-pressure or condensing side of the refrigeration system.

Lado de alta presión Término utilizado para indicar el lado de alta presión o de condensación del sistema de refrigeración.

High-side float A float-type metering device that is located in the liquid line at the inlet of the evaporator.

Flotador de lado alto Un dispositivo de medición tipo flotador que se encuentra en la tubería de líquido en la entrada del evaporador.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

High-temperature refrigeration A refrigeration temperature range starting with evaporator temperatures no lower than 35°F, a range usually used in air conditioning (cooling).

Refrigeración a temperatura alta Margen de la temperatura de refrigeración que comienza con temperaturas de evaporadores no menores de 35°F (2°C). Este margen se utiliza normalmente en el acondicionamiento de aire (enfriamiento).

High-vacuum pump A pump that can produce a vacuum in the low micron range.

Bomba de vacío alto Bomba que puede generar un vacío dentro del margen de micrón bajo.

Hoar frost The outer layers of frost that form on the hard surface of ice covering the evaporator coil often resemble snow or flaked ice and will hold a lot of entrained air.

Escarcha Las capas exteriores de hielo finamente dividido que se forman en la superficie dura del hielo y cubren el serpentín del evaporador muchas veces tienen la apariencia de nieve o copos de hielo y contienen gran cantidad de aire en su interior.

Hollow wall anchor Can be used in plaster, wallboard, gypsum board, and similar materials. Once the anchor has been set, the screw may be removed as often as necessary.

Anclaje hueco para pared Puede usarse en yeso, panel de yeso y materiales similares. Una vez se coloca el anclaje, el tornillo puede removerse tantas veces como sea necesario.

Horsepower (hp) A unit equal to 33000 ft-lb of work per minute.

Potencia en caballos (hp en inglés) Unidad equivalente a 33.000 libras-pies de trabajo por minuto.

Hot gas The refrigerant vapor as it leaves the compressor. This is often used to defrost evaporators.

Gas caliente El vapor del refrigerante al salir del compresor. Esto se utiliza con frecuencia para descongelar evaporadores.

Hot gas bypass Piping that allows hot refrigerant gas into the cooler low- pressure side of a refrigeration system usually for system capacity control.

Desviación de gas caliente Tubería que permite la entrada de gas caliente del refrigerante en el lado más frío de baja presión de un sistema de refrigeración, normalmente para la regulación de la capacidad del sistema.

Hot gas defrost A system where the hot refrigerant gases are passed through the evaporator to defrost it.

Descongelación con gas caliente Sistema en el que los gases calientes del refrigerante se pasan a través del evaporador para descongelarlo.

Hot gas line The tubing between the compressor and condenser.

Conducto de gas caliente Tubería entre el compresor y el condensador.

Hot junction That part of a thermocouple or thermopile where heat is applied.

Empalme caliente El lugar en un termopar o pila termoeléctrica donde se aplica el calor.

Hot pulldown The process of lowering the refrigerated space to the design temperature after it has been allowed to warm up considerably over this temperature.

Descenso caliente Proceso de bajar la temperatura del espacio refrigerado a la temperatura de diseño luego de habérsele permitido calentarse a un punto sumamente superior a esta temperatura.

Hot surface ignition A silicon carbide or similar substance is placed in the gas stream of a gas furnace and allowed to get very hot. When the gas impinges on this surface, immediate ignition should occur.

Encendido por superficie caliente Se coloca una sustancia de carburo de silicona o una semejante en el flujo de gas de un horno. Cuando se calienta la sustancia y el gas toca la superficie, se produce un encendido instantáneo.

Hot water heat A heating system using hot water to distribute the heat.

Calor de agua caliente Sistema de calefacción que utiliza agua caliente para la distribución del calor.

Hot wire The wire in an electrical circuit that has a voltage potential between it and another electrical source or between it and ground.

Conductor electrizado Conductor en un circuito eléctrico a través del cual fluye la tensión entre éste y otra fuente de elec tricidad o entre éste y la tierra.

Housing Term used to describe the casing or the shell of a motor.

Carcasa del motor término utilizado para describir la carcasa o la parte de afuera de un motor.

HRV See Heat Recovery Ventilator.

HRV Ver Ventilador de recuperación de calor.

Humidifier A device used to add moisture to the air.

Humedecedor Dispositivo utilizado para agregarle humedad al aire.

Humidistat A control operated by a change in humidity.

Humidistato Regulador activado por un cambio en la humedad.

Humidity Moisture in the air.

Humedad Vapor de agua existente en el ambiente.

Hunting The open and close throttling of a valve that is searching for its set point.

Caza El abrir y cerrar de una válvula que está buscando su punto de ajuste.

Hydraulics Producing mechanical motion by using liquids under pressure.

Hidráulico Generación de movimiento mecánico por medio de líquidos bajo presión.

Hydrocarbons (HCs) Organic compounds containing hydrogen and carbon found in many heating fuels.

Hidrocarburos (HCs en inglés) Compuestos orgánicos que contienen el hidrógeno y el carbón presentes en muchos combustibles de calentamiento.

Hydrochlorofluorocarbons (HCFCs) Refrigerants containing hydrogen, chlorine, fluorine, and carbon, thought to contribute to the depletion of the ozone layer, although not to the extent of chlorofluorocarbons.

Hidroclorofluorocarburos (HCFCs en inglés) Líquidos refrigerantes que contienen hidrógeno, cloro, flúor y carbono, y que, según algunos, han contribuido a la reducción de la capa de ozono aunque no en tal grado como los cloroflurocarburos.

Hydrofluorocarbon (HFC) A chlorine-free refrigerant containing hydrogen, fluorine, and carbon with zero ozone depletion potential.

Hidroflurocarbono (HFC en inglés) Refrigerante libre de cloro, compuesto de hidrógeno, fluoro y carbono que no tiene efectos perjudiciales sobre la capa de ozono.

Hydrofluoroether (HFE) A nontoxic, secondary fluid used in refrigeration systems. HFEs have a zero ozone depletion potential.

Hidrofluroéter (HFE en inglés) Fluido secundario no tóxico utilizado en sistemas de refrigeración. Los HFE no tienen efectos perjudiciales sobre la capa de ozono.

Hydrometer An instrument used to measure the specific gravity of a liquid.

Hidrómetro Instrumento utilizado para medir la gravedad específica de un líquido.

Hydronic Usually refers to a hot water heating system.

Hidrónico Normalmente se refiere a un sistema de calefacción de agua caliente.

Hydrostatic pressure Extreme pressure build-up when a cylinder is 100% full of liquid and increases in temperature.

Presión hidrostática Aumento extremo de presión que se produce cuando un cilindro está lleno de líquido (100 %) y su temperatura aumenta.

Hygrometer An instrument used to measure the amount of moisture in the air.

Higrómetro Instrumento utilizado para medir la cantidad de humedad en el aire.

I

IAQ See Indoor Air Quality.

IAQ Ver Calidad de aire interior.

IC Acronym for direct insulation contact. Applies to recessed light (can light) fixtures ratings.

IC Acrónimo de aislamiento de contacto directo. Se aplica a las clasificaciones referidas a la iluminación indirecta mediante lámparas dispuestas en fosas en paredes y techos.

ICAT An acronym for (insulation contact and air tightness). Applies to recessed light (can light) fixtures ratings.

ICAT Acrónimo de aislamiento de contacto y confinamiento del aire. Se aplica a las clasificaciones referidas a la iluminación indirecta mediante lámparas dispuestas en fosas en paredes y techos.

Idler A pulley on which a belt rides. It does not transfer power but is used to provide tension or reduce vibration.

Polea tensora Polea sobre la que se mueve una correa. No sirve para transmitir potencia, pero se utiliza para proveer tensión o disminuir la vibración.

Ignition or flame velocity The rate at which the flame travels through the air and fuel mixture. Different gases have a different rate. The faster the rate of travel, the more explosive the gas.

Velocidad de ignición o de llama La velocidad a la cual una llama viaja a través de la mezcla de aire y combustible. Diferentes gases tienen distintas velocidades. Mientras más rápido el velocidad del viaja, más explosivo en el gas.

Ignition transformer Provides a high-voltage current, usually to produce a spark to ignite a furnace fuel, either gas or oil.

Transformador para encendido Provee una corriente de alta tensión, normalmente para generar una chispa a fin de encender el combustible de uno horno, sea gas o aceite pesado.

Impedance A form of resistance in an alternating current circuit.

Impedancia Forma de resistencia en un circuito de corriente alterna.

Impeller The rotating part of a pump that causes the centrifugal force to develop fluid flow and pressure difference.

Impulsor Pieza giratoria de una bomba que hace que la fuerza centrífuga desarrolle flujo de fluido y una differencia en presión.

Impingement The condition in a gas or oil furnace when the flame strikes the sides of the combustion chamber, resulting in poor combustion efficiency.

Golpeo Condición que occurre en un horno de gas o de aceite pesado cuando la llama golpea los lados de la cámara de combustión. Esta condición trae como resultado un rendimiento de combustión pobre.

Inclined water manometer Indicates air pressures in very low-pressure systems.

Manómetro de agua inclinada Señala las presiones de aire en sistemas de muy baja presión.

Indoor air quality (IAQ) This term generally refers to the study or research of air quality within buildings and the procedures used to improve air quality.

Calidad del aire en el interior (IAQ en inglés) Generalmente, este término hace referencia al estudio o investigación de la calidad del aire en el interior de los edificios, así como a los procesos empleados para su mejora.

Induced draft Induced draft systems have a combustion blower motor located on the outlet of the heat exchanger. They pull or suck combustion gases through the heat exchanger usually causing a slight negative pressure in the heat exchanger itself.

Corriente inducida Los sistemas de corriente inducida constan de un motor de ventilación de combustión ubicado a la salida del intercambiador de calor. Éstos succionan los gases de combustión a través del intercambiador de calor, produciendo generalmente una leve presión negativa en el intercambiador de calor en sí mismo.

Induced magnetism Magnetism produced, usually in a metal, from another magnetic field.

Magnetismo inducido Magnetismo generado, normalmente en un metal, desde otro campo magnético.

Inductance An induced voltage producing a resistance in an alternating current circuit.

Inductancia Tensión inducida que genera una resistencia en un circuito de corriente alterna.

Induction motor An alternating current motor where the rotor turns from induced magnetism from the field windings.

Motor inductor Motor de corriente alterna donde el rotor gira debido al magnetismo inducido desde los devanados inductores.

Inductive circuit Electrical circuit that contains inductive loads or coils of wire. In this type of circuit, the current lags the voltage.

Circuito inductivo Un circuito que contiene cargas inductivas o bobinas de alambre. En esta clase de circuito, la corriente esta atras del voltaje.

Inductive reactance A resistance to the flow of an alternating current produced by an electromagnetic induction.

Reactancia inductiva Resistencia al flujo de una corriente alterna generada por una inducción electromagnética.

Inefficient equipment Equipment that is not operating at its design level of capacity because of some fault in the equipment, such as a cylinder not pumping in a multicylinder compressor.

Equipo ineficiente Equipo que no está operando al nivel de capacidad al que fue diseñado debido a alguna falla en el equipo, tal como que un cilindro no esté bombeando en un compresor de múltiples cilindros.

Inert gas A gas that will not support most chemical reactions, particularly oxidation.

Gas inerte Gas incapaz de resistir la mayoría de las reacciones químicas, especialmente la oxidación.

Infiltration Air that leaks into a structure through cracks, windows, doors, or other openings due to less pressure inside the structure than outside the structure. Usually accompanied by an equal outflow of air.

Infiltración Aire que se filtra hacia el interior de una estructura a través de grietas, ventanas, puertas u otras aberturas debido a la menor presión que existe dentro de la estructura que fuera de ella. Generalmente está acompañada de un flujo equivalente de salida de aire.

Infrared humidifier A humidifier that has infrared lamps with reflectors to reflect the infrared energy onto the water. The water evaporates rapidly into the duct airstream and is carried throughout the conditioned space.

Humidificador por infrarrojos Humidificador equipado con lámparas de infrarrojos cuyos reflectores reflejan la energía infrarroja sobre el agua haciendo que ésta se evapore rápidamente hacia el conducto de aire para ser transportada en el espacio acondicionado.

Infrared rays The rays that transfer heat by radiation.

Rayos infrarrojos Rayos que transmiten calor por medio de la radiación.

Inherent motor protection This is provided by internal protection such as a snap-disc or a thermistor.

Protección de motor inherente Ésta es provista por una protección interna tal como un disco de encaje o un termisor.

In. Hg vacuum The atmosphere will support a column of mercury 29.92 in. high. To pull a complete vacuum in a refrigeration system, the pressure inside the system must be reduced to 29.92 in. Hg vacuum.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Vacío en mm Hg La atmósfera soporta una columna de mercurio de 760 mm. Para poder crear un vacío completo en un sistema de refrigeración, la presión interna debe descender a 760 mm Hg.

Injection Term used to describe any hydronic system that uses a circulator pump to push water into a secondary heating loop or circuit.

Inyección Término utilizado para describir cualquier sistema hidrónico que usa una bomba de circulación para empujar el agua en un circuito de calefacción secundario.

In-phase When two or more alternating current circuits have the same polarity at all times.

En fase Cuando dos o más circuitos de corriente alterna tienen siempre la misma polaridad.

Input/output board A solid-state electronic board that receives a signal from a microprocessor and initiates a response to cycle compressors or initiate defrost.

Tarjeta de entrada/salida Placa electrónica de estado sólido que recibe una señal procedente de un microprocesador y activa o desactiva los compresores, o inicia el proceso de descongelación.

Insulation, electric A substance that is a poor conductor of electricity.

Aisamiento eléctrico Sustancia que es un conductor pobre de electricidad.

Insulation, thermal A substance that is a poor conductor of the flow of heat.

Aislamiento térmico Sustancia que es un conductor pobre de flujo de calor.

Insulator A material with several electrons in the outer orbit of the atom making them poor conductors of electricity or good insulators. Examples are glass, rubber, and plastic.

Aislamiento Material con varios electrones en la órbita exterior del átomo, que los convierte en malos conductores de electricidad o en buenos aislantes, por ejemplo vidrio, caucho y plástico.

Integral controller A control mode where the controller will change the output signal according to the length of time the error or offset exists. It will calculate the amount of error that exists over a specific time interval.

Controlador integral Un modo de control en cual el controlador cambia la señal de salida de acuerdo al tiempo de duración del error o de la compensación. El mismo calcula la cantidad de error que existe a través de un intervalo específico de tiempo.

Interlocking components Mechanical and electrical interlocks that are used to prevent a piece of equipment from starting before it is safe to start. For example, the chilled-water pump and the condenser water pump must both be started before the compressor in a water-cooled chilled-water system.

Componentes con enclavamiento Enclavamientos mecánicos y eléctricos se usan para evitar que una pieza de equipo se encienda antes de ser seguro que encienda. Por ejemplo, la bomba de agua enfriada y la bomba de agua del condensador deben encenderse antes que el compresor en un sistema de enfriamiento de agua enfriado por agua.

Intermediate zones Another name for unintentionally conditioned spaces.

Zonas intermedias Denominación alternativa para espacios acondicionados de manera no intencional.

Intermittent ignition Ignition system for a gas furnace that operates only when needed or when the furnace is operating.

Encendido interrumpido Sistema de encendido para un horno de gas que funciona solamente cuando es necesario o cuando el horno está trabajando.

Internal heat defrost Heat provided for defrost from inside the system, for example, hot gas defrost.

Descongelador por calor interno El calor para descongelar se provee desde adentro del sistema, por ejemplo, descongelación de gas caliente.

Internal motor overload An overload that is mounted inside the motor housing, such as a snap-disc or thermistor.

Sobrecarga interna del motor Una sobrecarga que se monta dentro del cárter del motor tal como disco de encaje o un termisor.

Interrupted ignition Ignition method that uses an electric spark only at the beginning of the burner's run cycle to ignite the atomized fuel.

Ignición interrumpida Un método de ignición que utiliza una chispa eléctrica solamente al comienzo del ciclo de marcha del quemador para encender el combustible atomizado.

Inverter The switching or transistor section of the variable frequency drive (VFD) that produces an AC voltage at just the right frequency for motor speed control. This section converts the DC voltage back to AC voltage.

Transformador Sección de transistores o interruptores en el impulsor de frecuencia variable (VFD, por sus siglas en inglés) que produce un voltaje de corriente alterna a la frecuencia exacta para el control de la velocidad del motor. Esta sección convierte el voltaje de corriente continua en voltaje de corriente alterna.

In. WC acronym for inches of water column.

In. WC Acrónimo de "pulgadas de columna de agua".

Ion generator A device that charges particles. These particles are then passed through positive- and negative-charged plates where the particles are repelled by the positive-charged plates and attracted to the negative-charged plates.

Generador de iones Dispositivo cargador de partículas, las cuales se pasan entre placas con carga positiva y negativa, causando el rechazo de las partículas por las placas con carga positiva, y la atracción por las placas con carga negativa.

Isobars Lines on a chart or graph that represent a constant pressure.

Isobarras Líneas en una gráfica que representan una presión constante.

Isolation relays Components used to prevent stray unwanted electrical feedback that can cause erratic operation.

Relés de aislación Componentes utilizados para evitar la realimentación eléctrica dispersa no deseada que puede ocasionar un funcionamiento errático.

Isotherms Lines on a chart or graph that represent a constant temperature.

Isotermas Líneas en una gráfica que representan una temperatura constante.

J

Joule (J) Metric measurement term used to express the quantity of heat.

Joule (J en inglés) Término utilizado para referirse a la unidad básica de cantidad de calor en el sistema métrico.

Junction box A metal or plastic box within which electrical connections are made.

Caja de empalme Caja metálica o plástica dentro de la cual se nacen conexiones eléctricas.

K

Kelvin A temperature scale where absolute 0 equals 0 or where molecular motion stops at 0. It has the same graduations per degree of change as the Celsius scale.

Escala absoluta Escale de temperaturas donde el cero absoluto equivale a 0 ó donde el movimiento molecular se detiene en 0. Tiene las mismas graduaciones por grado de cambio que la escala Celsio.

Kilopascal A metric unit of measurement for pressure used in the air-conditioning, heating, and refrigeration field. There are 6.89 kilopascals in 1 psi.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Kilopascal Unided métrica de medida de presión utilizada en el ramo del acondicionamiento de aire, calefacción y refrigeración. 6.89 kilopascales equivalen a 1 psi.

Kilowatt A unit of electrical power equal to 1000 watts.

Kilowatio Unidad eléctrica de potencia equivalente a 1.000 watios.

Kilowatt-hour 1 kilowatt (1000 watts) of energy used for 1 hour.

Kilowatio hora Unidad de energía equivalente a la que produce un kilowatio durante una hora.

Kinetic displacement compressor Term used to describe compressors that use large impellers to increase the kinetic energy and pressure of the refrigerant as opposed to compressors that use mechanical means for compression.

Compresor de desplazamiento cinético El término usado para describir los compresores que utilizan a grandes impulsores para aumentar la energía cinética y presión del refrigerante en comparación con compresores que utilizan medios mecánicos para la compresión.

King valve A service valve at the liquid receiver's outlet in a refrigeration system.

Válvula maestra Válvula de servicio ubicada en el receptor del líquido.

L

Ladder diagram A wiring diagram that separates each individual circuit of a piece of equipment or system into separate, often horizontal, lines to simplify the troubleshooting process.

Diagrama de escalera Un diagrama de cableado que separa cada circuito individual de una pieza de equipo o sistema en distintas, a menudo, las líneas horizontales para simplificar el proceso de solución de problemas.

Lag shield anchors Used with lag screws to secure screws in masonry materials.

Anclajes de tornillos barraqueros Se usan con tornillos barraqueros para asegurar tornillos en materiales de albañilería.

LAMEL An acronym for (lighting, appliance, and miscellaneous, electrical loads). Another way to express a base load of a residence.

LAMEL Acrónimo de "artefactos eléctricos para iluminación, electrodomésticos y misceláneos". Es otra manera de expresar el consumo básico de una vivienda.

Latent heat (hidden heat) Heat energy absorbed or rejected when a substance is changing state and there is no change in temperature.

Calor latente (calor oculto) Energía calórica absorbida o rechazada cuando una sustancia cambia de estado y no se experimentan cambios de temperatura.

Latent heat of condensation The latent heat given off when refrigerant condenses.

Calor latente de la condensación Calor latente producido por la condensación del refrigerante.

Latent heat of fusion The amount of heat energy required to change the state of a substance from a liquid to a solid or froma solid to a liquid.

Calor latente de fusión la cantidad de energía térmica necesaria para cambiar el estado de una sustancia de un líquido a un sólido o de un sólido a líquido.

Latent heat of vaporization The latent heat absorbed when refrigerant evaporates.

Calor latente de vaporización Calor latente absorbido por la evaporación del refrigerante.

Law of conservation of energy Law that states that energy cannot be created nor destroyed, but can be converted from one form to another.

Ley de conservación de la energía Ley que declara que la energía no puede ser creada ni destruida, pero puede ser convertida de una forma a otra.

Leadership in Energy and Environmental Design (LEED) A voluntary national rating system for developing high-performance, sustainable buildings. It is referred to as the LEED Green Building Rating System.

Liderazgo en diseño energético y medioambiental (LEED, por sus siglas en inglés) Sistema nacional voluntario de puntuación para el desarrollo de construcciones de alto rendimiento y sustentables. Se lo conoce como Sistema ecológico LEED de clasificación de construcciones.

Leads Extended surfaces inside a heat exchanger used to enhance the heat transfer qualities of the heat exchanger.

Extensiones Superficies extendidas dentro de un intercambiador de calor que se usan para mejorar las cualidades de transferencia de calor del intercambiador de calor.

Leak Fluid (gas and/or liquid) escaping at different times and at different rates from a system.

Pérdida Fluido (gas y/o líquido) que escapa de un sistema en diferentes momentos y a diferentes velocidades.

Leak detector Any device used to detect leaks in a pressurized system.

Detector de fugas Cualquier dispositivo utilizado para detectar fugas en un sistema presurizado.

LEED An acronym for Leadership in Energy and Environmental Design.

LEED Acrónimo de Liderazgo en diseño energético y medioambiental.

LEED (NC) An acronym for Leadership in Energy and Environmental Design (New Construction).

LEED (NC) Acrónimo de Liderazgo en diseño energético y medioambiental para construcciones nuevas (LEED (NC), por sus siglas en inglés).

Lever truck A long-handled, two-wheeled device that can be used to lift and assist in moving heavy objects.

Vagoneta con palanca Dispositivo con dos ruedas y una manivela larga que puede utilizarse para levantar y ayudar a transportar objetos pesados.

Light-emitting diode (LED) A diode that emits light and often is used as a self-diagnostic tool within a microprocessor. The lights can spell out error codes or flash numbers.

Diodo emisor de luz (LED en inglés) Diodo que emite una luz. A menudo se utiliza como dispositivo de autodiagnóstico en un microprocesador. Las luces pueden indicar códigos de error o números.

Lignin A fibrous material found in trees and that strengthens the cell wall.

Lignina Tejido fibroso presente en la madera y que sirve para reforzar la pared celular.

Limit control A control used to make a change in a system, usually to stop it when predetermined limits of pressure or temperature are reached.

Regulador de límite Regulador utilizado para realizar un cambio en un sistema, normalmente para detener su marcha cuando se alcanzan niveles predeterminados de presión o de temperatura.

Limit switch A switch that is designed to stop a piece of equipment before it does damage to itself or the surroundings, for example, a high limit on a furnace or an amperage limit on a motor.

Interruptor de límite Interruptor que está diseñado para detener una pieza de equipo antes que ésta se haga daño o dañe sus alrededores, por ejemplo, un límite alto en un calefactor o un límite de amperaje en un motor.

Line set A term used for tubing sets furnished by the manufacturer.

Juego de conductos Término utilizado para referise a los juegos de tubería suministrados por el fabricante.

Line tap valve A device that may be used for access to a refrigerant line.

Válvula de acceso en línea Dispositivo que puede utilizarse para acceder al tubo del refrigerante.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Line-voltage thermostat A thermostat that switches line voltage. For example, it is used for electric baseboard heat.

Termostato de voltaje de línea Un termostato que interrumpe el voltaje de línea. Por ejemplo, para los calentadores eléctricos de rodapié.

Line wiring diagram Sometimes called a ladder diagram, this type of diagram shows the power-consuming devices between the lines. Usually, the right side of the diagram consists of a common line.

Diagrama del cableado de línea También conocido como diagrama de escalera, este tipo de diagrama muestra los dispositivos de consumo de corriente que hay entre las líneas. Generalmente, la línea común está en el lado derecho del diagrama.

Liquid A substance where molecules push outward and downward and seek a uniform level.

Líquido Sustancia donde las moléculas empujan hacia afuera y hacia abajo y buscan un nivel uniforme.

Liquid charge bulb A type of charge in the sensing bulb of the thermostatic expansion valve. This charge is characteristic of the refrigerant in the system and contains enough liquid so that it will not totally boil away.

Bombilla de carga líquida Tipo de carga en la bombilla sensora de la válvula de expansión termostática. Esta carga es característica del refrigerante en el sistema y contiene suficiente líquido para que el mismo no se evapore completamente.

Liquid collector design A solar collector design in which either water or an antifreeze solution is passed through the collector and heated by the sun.

Colector de líquido Colector a través del cual pasa el agua o el anticongelante para ser calentados por la energía solar.

Liquid-filled remote bulb A remote-bulb thermostat that is completely liquid filled, such as the mercury bulb on some gas furnace pilot safety devices.

Bombillo remoto lleno de líquido Un termostato de bombillo remoto que está completamente lleno con líquido, tal como el bulbo de mercurio en algunos dispositivos de seguridad de los calefactores de gas.

Liquid floodback Liquid refrigerant returning to the compressor's crankcase during the running cycle.

Regreso de líquido El regresar del refrigerante líquido al cárter del cigüeñal del compresor durante el ciclo de marcha.

Liquid hammer The momentum force of liquid causing a noise or a disturbance when hitting against an object.

Martillo líquido La fuerza mecánica de un líquido que causa un ruido o un disturbio cuando choca con un objeto.

Liquid line A term applied in the industry to refer to the tubing or piping from the condenser to the expansion device.

Conducto de líquido Término aplicado en nuestro medio para referirse a la tubería que va del condensador al dispositivo de expansión.

Liquid nitrogen Nitrogen in liquid form.

Nitrógeno líquido Nitrógeno en forma líquida.

Liquid receiver A container in the refrigeration system where liquid refrigerant is stored.

Receptor del líquido Recipiente en el sistema de refrigeración donde se almacena el refrigerante líquido.

Liquid refrigerant charging The process of allowing liquid refrigerant to enter the refrigeration system through the liquid line to the condenser and evaporator.

Carga para refrigerante líquido Proceso de permitir la entrada del refrigerante líquido al condensador y al evaporador en el sistema de refrigeración a través del conducto de líquido.

Liquid refrigerant distributor This device is used between the expansion valve and the evaporator on multiple circuit evaporators to evenly distribute the refrigerant to all circuits.

Distribuidor de refrigerante líquido Este aparato se usa entre la válvula de expansión y el evaporador en los evaporadores de múltiples circuitos para distribuir el refrigerante a todos los circuitos.

Liquid slugging A large amount of liquid refrigerant in the compressor cylinder, usually causing immediate damage.

Relleno de líquido Acumulación de una gran cantidad de refrigerante líquido en el cilindro del compresor, que normalmente provoca una avería inmediata.

Liquefied petroleum Liquified propane, butane, or a combination of these gases. The gas is kept as a liquid under pressure until ready to use.

Petróleo licuado Propano o butano licuados, o una combinación de estos gases. El gas se mantiene en estado líquido bajo presión hasta que se encuentre listo para usar.

Lithium-bromide A type of salt solution used in an absorption chiller.

Bromuro de litio Tipo de solución salina utilizada en un enfriador por absorción.

Load matching Trying to always match the capacity of the refrigeration or air-conditioning system with that of the heat load put on the evaporators.

Adaptación de carga Hecho de intentar adaptar la capacidad del sistema de refrigeración o aire acondicionado a la carga térmica que deben soportar los evaporadores.

Load shed Part of an energy management system where various systems in a structure may be cycled off to conserve energy.

Despojo de carga Parte de un sistema de manejo de energía en el cual varios sistemas en una estructura pueden apagarse para conservar energía.

Locked-rotor amperage (LRA) The current an electric motor draws when power is applied to the motor, but its rotor is not yet turning. A rule-of-thumb often used by service technicians is that the LRA is normally five times the rated-load amperage (RLA).

Amperaje de rotor bloqueado (LRA, por sus siglas en inglés) Corriente que consume un motor eléctrico cuando se enciende, antes de que comience a girar el rotor. Generalmente, según lo estimado por técnicos mecánicos, el LRA es cinco veces mayor que el amperaje de carga calificada (RLA).

Low-ambient control Various types of controls that are used to control head pressure in air-cooled air-conditioning and refrigeration systems that must operate year-round or in cold weather.

Control de ambiente bajo Varios tipos de controles que se usan para controlar la presión en los sistemas de aires acondicionados y refrigeración, enfriados por aire, y que tienen que operar todo el año o en climas fríos.

Low-boy furnace This furnace is approximately 4 ft high, and the air intake and discharge are both at the top.

Horno bajo Este tipo de horno tiene una altura de aproximadamente 1,2 metros, con la toma y evacuación del aire situadas en la parte de arriba.

Lower exposure limit (LEL) Acceptable average exposure limit to a chemical, for example, over a short period of time, usually 10 or 15 minutes.

Límite de exposición inferior (LEL) límite promedio de exposición aceptable para un producto químico, por ejemplo, durante un corto período de tiempo, generalmente 10 ó 15 minutos.

Low-loss fitting A fitting that is fastened to the end of a gauge manifold that allows the technician to connect and disconnect gauge lines with a minimum of refrigerant loss.

Acoplamiento de poca pérdida Un tipo de acoplamiento que se conecta en un extremo de un manómetro de distribución y que le permite al técnico conectar

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

y desconectar las líneas de flujo con una pérdida mínima de refrigerante.

Low-pressure control A pressure switch that can provide low charge protection by shutting down the system on low pressure. It can also be used to control space temperature.

Regulador de baja presión Commudador de presión que puede proveer protección contra una carga baja al detener el sistema si éste alcanza una presión demasiado baja. Puede utilizarse también para regular la temperatura de un espacio.

Low side A term used to refer to that part of the refrigeration system that operates at the lowest pressure, between the expansion device and the compressor.

Lado bajo Término utilizado para referirse a la parte del sistema de refrigeración que functiona a niveles de presión más baja, entre el dispositivo de expansión y el compresor.

Low side float A float-type metering device that is located in the evaporator. As the level of liquid refrigerant drops, the valve opens to feed more refrigerant into the evaporator.

Flotador de lado bajo Un dispositivo de medición tipo flotador que se encuentra en el evaporador. A medida que el nivel de líquido refrigerante cae, la válvula se abre para alimentar más el refrigerante en el evaporador.

Low-side gauge The gauge that measures the low-side pressure in an air conditioning or refrigeration system.

El manómetro del lado bajo el indicador que mide la presión del lado bajo en un sistema de aire acondicionado o refrigeración.

Low-temperature refrigeration A refrigeration temperature range starting with evaporator temperatures no higher than 0°F for storing frozen food.

Refrigeración a temperatura baja Margen de la temperatura de refrigeración que comienza con temperaturas de evaporadores no mayores de 0°F (–18°C) para almacenar comida congelada.

Low-voltage thermostat The typical thermostat used for residential and commercial air-conditioning and heating equipment to control space temperature. The supplied voltage is 24 V.

Termostato de bajo voltaje El termostato típico que se usa en el equipo de aire acondicionado y de calefacción comercial y residencial para controlar la temperatura de un espacio. El voltaje suplido es de 24 voltios.

LP fuel Liquefied petroleum, propane, or butane. A substance used as a gas for fuel. It is transported and stored in the liquid state.

Combustible PL Petróleo licuado, propano, o butano. Sustancia utilizada como gas para combustible. El petróleo licuado se transporta y almacena en estado líquido.

M

Magnetic field A field or space where magnetic lines of force exist.

Campó magnético Campo o espacio donde existen líneas de fuerza magnética.

Magnetic overload protection This protection reads the actual current draw of the motor and is able to shut it off based on actual current, versus the heat-operated thermal overloads, which are sensitive to the ambient heat of a hot cabinet.

Protección de sobrecarga magnética Esta protección lee la toma de corriente actual del motor y es capaz de apagarlo basado en la corriente actual; esto es contrario a las sobrecargas termales operadas por calor, las cuales son sensibles al calor ambiental de un gabinete caliente.

Magnetism A force causing a magnetic field to attract ferrous metals, or where like poles of a magnet repel and unlike poles attract each other.

Magnetismo Fuerza que hace que un campo magnético atraiga metales férreos, o cuando los polos iguales de un imán se rechazan y los opuestos se atraen.

Makeup air Air, usually from outdoors, provided to make up for the air used in combustion.

Aire de compensación Aire, normalmente procedente del exterior, que se utiliza para compensar aquél utilizado en la combustión.

Makeup water Water that is added back into any circulating water system due to loss of water. Makeup water in a cooling tower may be quite a large volume.

Agua de compensación Agua que se añade a cualquier sistema de circulación de agua debido a la pérdida de agua. El agua de compensación en una torre de enfriamiento puede ser un volumen bastante grande.

Male thread A thread on the outside of a pipe, fitting, or cylinder; an external thread.

Filete macho Filete en la parte exterior de un tubo, accesorio o cilindro; filete externo.

Mandrel (clinching) Part of the pin rivet assembly that is pulled to the breaking point to swell the rivet into the drilled hole.

Mandrel (remachando) En la instalación con remanches, la parte que se tira hasta el límite para hinchar el remanche en el hueco perforado.

Manifold A device where multiple outlets or inlets can be controlled with valves or other devices. Our industry typically uses a gas manifold with orifices for gas-burning appliances and gauge manifolds used by technicians.

Colector Aparato desde el cual se pueden controlar varias entradas y salidas con válvulas u otros aparatos. Nuestra industria generalmente usa un colector de gas con orificios para los enseres que queman gas y manómetros de distribución que los usan los técnicos.

Manometer An instrument used to check low vapor pressures. The pressures may be checked against a column of mercury or water.

Manómetro Instrumento utilizado para revisar las presiones bajas de vapor. Las presiones pueden revisarse comparándolas con una columna de mercurio o de agua.

Manual reset A safety control that must be reset by a person, as opposed to automatically reset, to call attention to the problem. An electrical breaker is a manual reset device.

Reinicio manual Un control de seguridad que una persona tiene que reiniciar, contrario a un reinicio automático, para llamar atención al problema. Un cortacircuito eléctrico es un aparato de reinicio manual.

Mapp gas A composite gas similar to propane that may be used with air.

Gas Mapp Gas compuesto similar al propano que puede utilizarse con aire.

Marine water box A water box on a chiller or condenser with a removable cover.

Caja marina para agua Caja para agua en un enfriador o condensador con un capón desmontable.

Mass Matter held together to the extent that it is considered one body.

Masa Materia compacta que se considera un solo cuerpo.

Mass spectrum analysis An absorption machine factory leak test performed using helium.

Análisis del límite de masa Prueba para fugas y absorción llevada a cabo en la fábrica utilizando helio.

Matter A substance that takes up space and has weight.

Materia Sustancia que ocupa espacio y tiene peso.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Mechanical controls A control that has no connection to power, such as a water-regulating valve or a pressure relief valve.

Controles mecánicos Un control que no tiene conexión a corriente, tales como una válvula reguladora de agua o una válvula de alivio de presión.

Medium-temperature refrigeration Refrigeration where evaporator temperatures are 32°F or below, normally used for preserving fresh food.

Refrigeración a temperatura media Refrigeración, donde las temperaturas del evaporador son 32°F (0°C) o menos, utilizada generalmente para preservar comida fresca.

Megohmmeter An instrument that can detect very high resistances, in millions of ohms. A megohm is equal to 1,000,000 ohms.

Megaohmnímetro Un instrumento que puede detectar resistencias muy altas, de millones de ohmios. Un megaohmio es equivalente a 1.000.000 de ohmios.

Melting point The temperature at which a substance will change from a solid to a liquid.

Punto de fusión Temperatura a la que una sustancia se convierte de sólido a líquido.

Memory Electronic storage space located internally in a controller.

Memoria Almacenes internos electrónicos en la computadora.

Mercury bulb A glass bulb containing a small amount of mercury and electrical contacts used to make and break the electrical circuit in a low-voltage thermostat.

Bombilla de mercurio Bombilla de cristal que contiene una pequeña cantidad de mercurio y que funciona como contacto eléctrico, utilizada para conectar y desconectar el circuito eléctrico en un termostato de baja tensión.

Metering device A valve or small fixed-size tubing or orifice that meters liquid refrigerant into the evaporator.

Dispositivo de medida Válvula o tubería pequeña u orificio que mide la cantidad de refrigerante líquido que entra en el evaporador.

Methane Natural gas composed of 90% to 95% methane, a combustible hydrocarbon.

Metano El gas natural se compone de un 90% a un 95% de metano, un hidrocarburo combustible.

Metric system System International (SI); system of measurement used by most countries in the world.

Sistema métrico Sistema internacional; el sistema de medida utilizado por la mayoría de los países del mundo.

Micro A prefix meaning 1/1,000,000.

Micro Prefijo que significa una parte de un millón.

Microfarad Capacitor capacity equal to 1/1,000,000 of a farad.

Microfaradio Capacidad de un capacitador equivalente a 1/1.000.000 de un faradio.

Micro-foam solution A solution usually sprayed or brushed in the vicinity of a system leak which will form small cocoons of foam when in contact with a refrigerant or other type of gas leak.

Solución de microespuma Solución que generalmente se pulveriza o pincela en las proximidades de una pérdida y que forma pequeños globos de espuma cuando entra en contacto con un refrigerante u otro tipo de pérdida de gas.

Micrometer A precision measuring instrument.

Micrómetro Instrumento de precisión utilizado para medir.

Micron A unit of length equal to 1/1,000 of a millimeter, 1/1,000,000 of a meter.

Micrón Unidad de largo equivalente a 1/1,000 de un milímetro, o 1/1.000.000 de un metro.

Micron gauge A gauge used when it is necessary to measure pressure close to a perfect vacuum.

Manómetro de micrón Manómetro utilizado cuando es necesario medir la presión de un vacío casi perfecto.

Microprocessor A small, preprogrammed, solid-state microcomputer that acts as a main controller.

Microprocesador Un microordenador de estado sólido preprogramado que actúa de controlador principal.

Midseated (cracked) A position on a service valve that allows refrigerant flow in all directions.

Sentado en el medio (agrietado) Posición en una válvula de servicio que permite el flujo de refrigerante en cualquier dirección.

Migration of oil or refrigerant When the refrigerant moves to some place in the system where it is not supposed to be, such as when oil migrates to an evaporator or when refrigerant migrates to a compressor crankcase.

Migración de aceite o refrigerante Cuando el refrigerante se mueve a cualquier lugar en el sistema donde no debe estar, como cuando aceite migra a un evaporador o cuando refrigerante se transplanta al cárter del cigüeñal del compresor.

Milli A prefix meaning 1/1,000.

Mili Prefijo que significa una parte de mil.

Mineral oil A traditional refrigeration lubricant used in CFC and HCFC systems.

Aceite mineral Lubricante de refrigeración utilizado tradicionalmente en los sistemas de CFC y HCFC.

Minimum efficiency reporting value (MERV) Air filter rating system ranging from 1 to 20, with upper levels providing the most filtering.

Valor mínimo de reporte de eficacia (MERV en inglés) Sistema de clasificación de filtros de aire que va desde el 1 al 20 con los niveles mayores indicando más filtración.

Modulating flow Controlling the flow between maximum or no flow. For example, the accelerator on a car provides modulating flow.

Flujo modulante Controlado el flujo entre flujo que no es flujo máximo o ningún flujo. Por ejemplo, el acelerador de un carro provee un flujo modulante.

Modulator A device that adjusts by small increments or changes.

Modulador Dispositivo que se ajusta por medio de incrementos o cambios pequeños.

Moisture indicator A device for determining moisture.

Indicador de humedad Dispositivo utilizado para determinar la humedad.

Mold A fungus found where there is moisture that develops and releases spores. Can be harmful to humans.

Moho Un hongo en con trado donde hay humedad que se desarrolla y libera esporas. Puede ser nocivo a los humanos.

Molecular motion The movement of molecules within a substance.

Movimiento molecular Movimiento de moléculas dentro de una sustancia.

Molecule The smallest particle that a substance can be broken into and still retain its chemical identity.

Molécula La particula más pequeña en la que una sustancia puede dividirse y aún conservar sus propias características.

Monochlorodifluoromethane The refrigerant R-22.

Monoclorodifloremetano El refrigerante R-22.

Montreal Protocol An agreement signed in 1987 by the United States and other countries to control the release of ozone-depleting substances.

Protocolo de Montreal Un acuerdo firmado en 1987 por los Estados Unidos y otros países para controlar la liberación de sustancias que destruyen el ozono.

Motor service factor A factor above an electric motor's normal operating design parameters, indicated on the nameplate, under which it can operate.

Factor de servicio del motor Factor superior a los parametros de diseño normales de funcionamiento de un motor eléctrico, indicados en el marbete; este factor indica su nivel de funcionamiento.

Motor starter Electromagnetic contactors that contain motor protection and are used for switching electric motors on and off.

Arrancador de motor Contactadores electromagnéticos que contienen protección para el motor y se utilizan para arrancar y detener motores eléctricos.

Motor temperature-sensing thermostat A thermostat that monitors the motor temperature and shuts it off for the motor's protection.

Termostato que detecta la temperatura del motor Un termostato que vigila la temperatura del motor y lo apaga para la protección del motor.

Muffler, compressor Sound absorber at the compressor.

Silenciador del compresor Absorbedor de sonido ubicado en el compresor.

Mullion Stationary frame between two doors.

Parteluz Armazón fijo entre dos puertas.

Mullion heater Heating element mounted in the mullion of a refrigerator to keep moisture from forming on it.

Calentador del parteluz Elemento de calentamiento montado en el parteluz de un refrigerador para evitar la formación de humedad en el mismo.

Multimeter An instrument that will measure voltage, resistance, and milliamperes.

Multímetro Instrumento que mide la tensión, la resistencia y los miliamperios.

Multiple circuit coil An evaporator or condenser coil that has more than one circuit because of the coil length. When the coil is too long, there will be an unacceptable pressure drop and loss of efficiency.

Serpentín de circuito múltiple Un serpentín de evaporador o condensador que tiene más de un circuito por causa de la longitud del serpentín. Cuando el serpentín es demasiado largo, habrá una pérdida de presión y eficacia inaceptable.

Multiple evacuation A procedure for evacuating a system. A vacuum is pulled, a small amount of refrigerant allowed into the system, and the procedure duplicated. This is often done three times.

Evacuación múltiple Procedimiento para evacuar o vaciar un sistema. Se crea un vacío, se permite la entrada de una pequeña cantidad de refrigerante al sistema, y se repite el procedimiento. Con frecuencia esto se lleva a cabo tres veces.

N

Naphthenic oil A refrigeration mineral oil refined from California and Texas crude oil.

Aceite nafténico Aceite mineral refinado utilizado en la refrigeración, obtenido del petróleo crudo de California y Texas.

National Electrical Code® (NEC®) A publication that sets the standards for all electrical installations, including motor overload protection.

Código estadounidense de electridad Publicación que establece las normas para todas las instalaciones eléctricas, incluyendo la protección contra la sobrecarga de un motor.

National Fire Protection Association (NFPA) An association organized to prevent fires through establishing standards, providing research, and providing public education.

Asociación nacional para la protección contra incendios (NFPA en inglés) Asociación cuyo objetivo es prevenir incendios estableciendo normativas y facilitando la investigación y concienciación del público.

National pipe taper (NPT) The standard designation for a standard tapered pipe thread.

Cono estadounidense para tubos (NPT en inglés) Designación estándar para una rosca cónica para tubos estándar.

Natural convection The natural movement of a gas or fluid caused by differences in temperature.

Convección natural Movimiento natural de un gas o fluido ocasionado por diferencias en temperatura.

Natural-draft tower A water cooling tower that does not have a fan to force air over the water. It relies on the natural breeze or airflow.

Torre de corriente de aire natural Una torre de enfriamiento de agua que no tiene un ventilador para forzar el aire sobre el agua; depende de la brisa o flujo natural del aire.

Natural gas A fossil fuel formed over millions of years from dead vegetation and animals that were deposited or washed deep into the earth.

Gas natural Combustible fósil formado a través de millones de años de la vegetación y los animales muertos que fueron depositados or arrastrados a un gran profundidad dentro la tierra.

Natural refrigerants Natural refrigerants occur naturally in nature.

Refrigerantes naturales Los refrigerantes naturales se obtienen directamente de fuentes naturales.

Near-azeotropic blend Two or more refrigerants mixed together that will have a small range of boiling and/or condensing points for each system pressure. Small fractionation and temperature glides will occur but are often negligible.

Mezcla casi-azeotrópica Mezcla de dos o más refrigerantes, que tiene un bajo rango de punto de ebullición y/o condensación para cada presión del sistema. Puede producirse una cierta fraccionación y variación de temperatura, aunque suelen ser insignificantes.

Needlepoint valve A device having a needle and a very small orifice for controlling the flow of a fluid.

Válvula de aguja Dispositivo que tiene una aguja y un orificio bastante pequeño para regular el flujo de un fluido.

Negative electrical charge An atom or component that has an excess of electrons.

Carga eléctrica negativa Átomo o componente que tiene un exceso de electrones.

Neoprene Synthetic flexible material used for gaskets and seals.

Neopreno Material sintético flexible utilizado en guarniciones y juntas de estanqueidad.

Net oil pressure Difference in the crankcase pressure and the compressor oil pump outlet pressure.

Presión neta del aceite Diferencia en la presión del cárter y la presión a la salida de la bomba de aceite del compresor.

Net refrigeration effect (NRE) The quantity of heat in Btu/lb that the refrigerant absorbs from the refrigerated space to produce useful cooling.

Efecto neto de refrigeración (NRE en inglés) La cantidad de calor expresado en Btu/lb que el refrigerante absorbe del espacio refrigerado para producir refrigeración útil.

Net stack temperature The temperature difference between the ambient temperature and the flue-gas temperature, typically for oil- and gas-burning equipment.

Temperatura neta de chimenea La diferencia en temperatura entre la temperatura ambiental y la del conducto de gas, normalmente para equipo que quema aceite y gas.

Neutralizer A substance used to counteract acids.

Neutralizador Sustancia utilizada para contrarrestar ácidos.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Neutron Neutrons and protons are located at the center of the nucleus of an atom. Neutrons have no charge.

Neutrón Los neutrones y protones están situados en le centro del núcleo del átomo. Los neutrones carecen de carga.

Newton/meter² Metric unit of measurement for pressure. Also called a pascal.

Metro-Newton² Unidad métrica de medida de presión. Conocido también como pascal.

Nichrome A metal made of nickel chromium that when formed into a wire is used as a resistance heating element in electric heaters and furnaces.

Níquel-cromio Metal fabricado de níquel-cromio que al ser convertido en alambre, se utiliza como un elemento de calentamiento de resistencia en calentadores y hornos eléctricos.

Nitrogen An inert gas often used to "sweep" a refrigeration system to help ensure that all refrigerant and contaminants have been removed.

Nitrógeno Gas inerte utilizado con frecuencia para purgar un sistema de refrigeración. Esta gas ayuda a asegurar la remoción de todo el refrigerante y los contaminantes del sistema.

Nitrogen dioxide A combustion pollutant that causes irritation of the respiratory tract and can cause shortness of breath.

Bióxido de nitrógeno Un contaminante por combustión que causa irritación a las vías respiratorias y puede causar falta de aliento.

Nominal A rounded-off stated size. The nominal size is the closest rounded-off size.

Nominal Tamaño redondeado establecido. El tamaño nominal es el tamaño redondeado más cercano.

Nominal Term used to describe the outside diameter of ACR tubing and the inside diameter of piping used for plumbing applications.

Nominal término utilizado para describir el diámetro exterior del tubo de ACR y el diámetro interior de la tubería utilizada para aplicaciones de plomería.

Noncatalytic stove Wood-burning stoves without catalytic combustors and that were manufactured after July 1, 1990, are allowed to emit no more than 7.5 g/hr of particulates.

Estufa no catalítica Estufa de madera sin quemadores catalíticos. Las estufas fabricadas después del 1 de julio de 1990 no pueden emitir más de 7,5 g/hr de partículas.

Noncondensable gas A gas that does not change into a liquid under normal operating conditions.

Gas no condensable Gas que no se convierte en líquido bajo condiciones de functionamiento normales.

Nonferrous Metals containing no iron.

No férreos Metales que no contienen hierro.

Nonpolycyclic organic matter Air pollutants from wood-burning stoves considered to be health hazards.

Materia orgánica no policíclica Contaminantes del aire procedentes de estufas de madera. Se considera que son peligrosos para la salud.

Non-power-consuming devices Devices that do not consume power, such as switches, that pass power to power-consuming devices.

Aparatos que no consumen corriente Aparatos que no consumen corriente, tales como interruptores que trasmiten corriente a aparatos que consumen corriente.

North Pole, magnetic One end of a magnet or the magnetic north pole of the earth.

Polo norte magnético El extremo de un imán o el polo norte magnético del mundo.

Nozzle A drilled opening that measures liquid flow, such as an oil burner nozzle.

Tobera Una apertura taladrada que mide el flujo de líquido, tal como la tobera de un quemador de aceite.

N-type material Semiconductor material with an excess of electrons that move from negative to positive when a voltage is applied.

Material tipo N Material semiconductor con un exceso de electrones que pasan de negativo a positivo al aplicarles una corriente.

Nut driver These tools have a socket head used primarily to turn hex head screws on air- conditioning, heating, and refrigeration cabinets.

Extractor de tuercas Estas herramientas tienen una cabeza hueca hexagonal usadas principalmente para darle vuelta a tuercas de cabeza hexagonal en gabinetes de acondicionamiento de aire, de calefacción y de refrigeración.

O

Off cycle A period when a system is not operating.

Ciclo de apagado Período de tiempo cuando un sistema no está en funcionamiento.

Off-cycle defrost Used for medium-temperature refrigeration where the evaporator coil operates below freezing but the air in the cooler is above freezing. The coil is defrosted by the air inside the cooler while the compressor is off cycle.

Descongelación de período de reposo Se usa para refrigeración de temperatura media en la cual el serpentín del evaporador funciona por debajo del punto de congelación, pero el aire en el enfriador está por encima del punto de congelación. El serpentín se descongela por el aire dentro del enfriador mientras el compresor está en reposo.

Offset (controls application) The absolute (not signed + or -) difference between the set point and the control point of a control process.

Desplazamiento (aplicación de control) La absoluta (no firmado + o -) diferencia entre el punto de ajuste y el punto de control de un proceso de control.

Offset (duct application) A fitting that is used when a duct system must be routed around an obstacle.

Desplazamiento (aplicación de tubería) Un accesorio que se utiliza cuando un conducto sistema debe colocarse alrededor de un obstáculo.

Offset The absolute (not signed + or −) difference between the set point and the control point of a control process.

Compensación La diferencia absoluta (sin signo + o −) entre el punto de ajuste y el punto de control de un proceso de control.

Offset The position of ductwork that must be rerouted around an obstacle.

Desviación El posición de un conducto que tiene que desviarse alrededor de un obstáculo.

Ohm A unit of measurement of resistance to electric current flow.

Ohmio Unidad de medida de la resistencia eléctrica al flujo de corriente.

Ohmmeter A meter that measures electrical resistance.

Ohmiómetro Instrumento que mide la resistencia eléctrica.

Ohm's law A law involving electrical relationships discovered by Georg Ohm: $E = I \times R$.

Ley de Ohm Ley que define las relaciones eléctricas, descubierta por Georg Ohm: $E = I \times R$.

Oil, refrigeration Oil used in refrigeration systems.

Aceite de refrigeración Aceite utilizado en sistemas de refrigeración.

Oil level regulator A needle valve and float system located on each compressor of a parallel compressor system. It senses the oil level in the compressor's crankcase and adds oil if necessary. It receives its oil from the oil reservoir.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Regulador del nivel de aceite Sistema de válvula de aguja y flotador que se encuentra en cada compresor de un sistema de compresores en paralelo. Detecta el nivel del aceite en el cárter del compresor y permite la entrada de más aceite procedente de un depósito, en caso necesario.

Oil-pressure safety control (switch) A control used to ensure that a compressor has adequate oil lubricating pressure.

Regulador de seguridad para la presión de aceite (conmutador) Regulador utilizado para asegurar que un compresor tenga la presión de lubrificación de aceita adecuada.

Oil reservoir A storage cylinder for oil usually used on parallel compressor systems. It is located between the oil separator and the oil level regulators. It receives its oil from the oil separator.

Depósito de aceite Cilindro en el que se almacena el aceite utilizado en los sistemas de compresores en paralelo. Está ubicado entre el separador de aceite y el regulador del nivel. Recibe el aceite del separador.

Oil separator Apparatus that removes oil from a gaseous refrigerant.

Separador de aceite Aparato que remueve el aceite de un refrigerante gaseoso.

Onetime relief valve A pressure relief valve that has a diaphragm that blows out due to excess pressure. It is set at a higher pressure than the spring-loaded relief valve in case it fails.

Válvula de alivio de una vez Una válvula de alivio de presión que tiene un diafragma que revienta debido a la presión excesiva. La misma se fija a una presión más alta que la válvula de alivio de resorte para en caso de que ésta falle.

One ton of refrigeration Term used to describe the transfer of heat at a rate of 12,000 Btu/h.

Una tonelada de refrigeración Término utilizado para describir la transferencia de calor a una velocidad de 12,000 Btu/h.

Open combustion device An atmospheric draft heating appliance.

Dispositivo de combustión abierta Calefactor de corriente atmosférico.

Open compressor A compressor with an external drive.

Compresor abierto Compresor con un motor externo.

Open-loop control configuration In an open-loop control configuration, the sensor is located upstream of the location where the control agent is causing a change in the controlled medium.

Configuración de control de circuito abierto En una configuración de control de circuito abierto, el sensor está ubicado a contracorriente de donde el agente de control está causando un cambio en el medio controlado.

Open-loop heat pump Heat pump system that uses the water in the earth as the heat transfer medium and then expels the water back to the earth in some manner.

Bomba de calor de circuito abierto Sistema de bomba de calor que utiliza el agua de la tierra como medio de transferencia del calor y luego devuelve el agua a la tierra de cierta manera.

Open winding The condition that exists when there is a break and no continuity in an electric motor winding.

Devanado abierto Condición que se presenta cuando hay una interrupción en la continuidad del devanado de un motor.

Operating pressure The actual pressure under operating conditions.

Presión de funcionamiento La presión real bajo las condiciones de funcionamiento.

Organic Materials formed from living organisms.

Orgánico Materiales formados de organismos vivos.

Orifice A small opening through which fluid flows.

Orificio Pequeña abertura a través de la cual fluye un fluido.

OSHA Abbreviation for the Occupational Safety and Health Administration.

OSHA Siglas de la Administración de salud y seguridad ocupacional.

Outward clinch tacker A stapler or tacker that will anchor staples outward and can be used with soft materials.

Grapadora de agarre hacia fuera Grapadora o tachueladora que ancla las grapas hacia fuera y que puede usarse con materiales suaves.

Overload protection A system or device that will shut down a system if an overcurrent condition exists.

Protección contra sobrecarga Sistema o dispositivo que detendrá la marcha de un sistema si existe una condición de sobreintensidad.

Over-the-fire draft Draft taken over the fire and will be a lower reading lower than chimney draft.

Corriente sobre el fuego Corriente que pasa sobre el fuego; la lectura de presión será menor que la lectura para una corriente de chimenea.

Oxidation The combining of a material with oxygen to form a different substance. This results in the deterioration of the original substance. Rust is oxidation.

Oxidación La combinación de un material con oxígeno para formar una sustancia diferente, lo que ocasiona el deterioro de la sustancia original. Herrumbre es oxidación.

Oxyacetylene Term used to describe a fuel made up of pure oxygen and acetylene.

Oxiacetileno término utilizado para describir un combustible compuesto de oxígeno puro y acetileno.

Oxyacetylene welding units A torch kit that utilizes a mixture of pure oxygen and acetylene in order to produce a much hotter flame than an air-acetylene torch kit.

Unidades de soldadura oxiacetilénica un juego de soplete que utiliza una mezcla de oxígeno puro y acetileno para producir una llama mucho más caliente que la llama de un juego de soplete de aire-acetileno.

Ozone A form of oxygen (O_3). A layer of ozone is in the stratosphere that protects the earth from some of the sun's ultraviolet radiation.

Ozono Forma de oxígeno (O_3). Una capa de ozono en la estratosfera protege la Tierra de parte de la radiación ultravioleta proveniente del sol.

Ozone depletion The breaking up of the ozone molecule by the chlorine atom in the stratosphere. Stratosphere ozone protects us from ultraviolet radiation emitted by the sun.

Reducción del ozono Descomposición de la molécula de ozono por el átomo de cloro en la estratosfera. El ozono presente en la estratosfera nos protege de las radiaciones ultravioletas del sol.

Ozone depletion potential (ODP) A scale used to measure how much a substance will deplete stratospheric ozone ODP ranges from 0 to 1.

Potencial de depleción de ozono (ODP en inglés) Una escala que se usa para medir cuánta depleción del ozono de la estratosfera una sustancia va a causar El ODP varía entre 0 y 1.

P

Package equipment (unit) A refrigerating system where all major components are located in one cabinet.

Equipo (unidad) completo Sistema de refrigeración donde todos los componentes principales se encuentran en un solo gabinete.

Packing A soft material that can be shaped and compressed to provide a seal. It is commonly applied around valve stems.

Empaquetadura Material blando que puede formarse y comprimirse para proveer una junta de estanqueidad. Comúnmente se aplica alrededor de los vástagos de válvulas.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Paraffinic oil A refrigeration mineral oil containing some paraffin wax, which is refined from eastern U.S. crude oil.

Aceite de parafina Aceite mineral que contiene parafina y que se utiliza en sistemas de refrigeración. El aceite se obtiene mediante el refinado de petróleo extraído en los EE.UU del este.

Parallel circuit An electrical or fluid circuit where the current or fluid takes more than one path at a junction.

Circuito paralelo Corriente eléctrica o fluida donde la corriente o el fluido siguen más de una trayectoria en un empalme.

Parallel compressor Many compressors piped in parallel and mounted on a steel rack. The compressors are usually cycled by a microprocessor.

Compresor en paralelo Varios compresores conectados en paralelo y montados en un bastidor de acero. Normalmente, se sirve de un microprocesador para activarlos y desactivarlos.

Parallel flow A flow path in which many paths exist for the fluid to flow.

Flujo paralelo Vía de flujo que consta de varias vías que permiten el flujo de un fluido.

Part-winding start A large motor that is actually two motors in one housing. It starts on one and then the other is energized. This is to reduce inrush current at start-up. For example, a 100-hp motor may have two 50-hp motors built into the same winding. It will start using one motor followed by the start of the other one. They will both run under the load.

Arranque de bobina parcial Un motor grande que es, en efecto, dos motores bajo un mismo cárter. El mismo arranca con uno y luego se activa el segundo. El propósito de esto es reducir la co rriente interna al arrancar. Por ejemplo, un motor de 100 caball os de fuerza puede tener dos motores de 50 caballos de fuerza construidos con la misma bobina. El motor arrancará usando un motor, seguido por el arranque del otro motor. Los dos motores correrán bajo carga.

Pascal A metric unit of measuring pressure. One Pascal is equivalent to 0.004 inches of water column.

Pascal Unidad del sistema métrico de medición de presión. Un Pascal equivale a 0,004 pulgadas de columna de agua.

Passive recovery Recovering refrigerant with the use of the refrigeration system's compressor or internal vapor pressure.

Recuperación pasiva Recuperación de un refrigerante utilizando el compresor del sistema de refrigeración o la presión del vapor interno.

Passive sensor Sensors that send information back to the controller in terms of resistance (ohms).

Sensor pasivo Sensores que devuelven información al controlador a través de la resistencia (ohmios).

Passive solar design The use of nonmoving parts of a building to provide heat or cooling, or to eliminate certain parts of a building that cause inefficient heating or cooling.

Diseño solar pasivo La utilización de piezas fijas de un edificio para proveer calefacción o enfriamiento, o para eliminar ciertas piezas de un edificio que causan calefacción o enfriamiento ineficientes.

PE (polyethylene) Plastic pipe used for water, gas, and irrigation systems.

Polietileno Tubo plástico utilizado en sistemas de agua, de gas y de irrigación.

Pellet stove A stove that burns small compressed pellets made from sawdust, cardboard, or sunflower or cherry seeds.

Estufa de gránulos Estufa que quema gránulos comprimidos fabricados con aserrín, cartón y semillas de girasol o de cereza.

Percent refrigerant quality Percent vapor.

Calidad porcentual de refrigerante Porcentaje de vapor.

Permanent magnet An object that has its own permanent magnetic field.

Imán permanente Objeto que tiene su propio campo magnético permanente.

Permanent split-capacitor motor (PSC) A split-phase motor with a run capacitor only. It has a very low starting torque.

Motor permanente de capacitador separado (PSC en inglés) Motor de fase separada que sólo tiene un capacitador de funcionamiento. Su par de arranque es sumamente bajo.

PEX tubing PEX stands for polyethylene cross (X)-linked tubing, a common name for polyethylene tubing.

Tubería PEX PEX significa tubería polietilena unida al través y es un nombre que se usa frecuentemente para tubería polietilena.

Phase One distinct part of a cycle.

Fase Una parte específica de un ciclo.

Phase-change loop The loop of piping, usually in a geothermal heat pump system, where there is a change of phase of the heat transfer fluid from liquid to vapor or vapor to liquid.

Circuito de cambio de fase Circuito de tubería, generalmente en un sistema de bombeo de calor geotermal, en el cual hay un cambio de fase del fluido de transferencia de calor de líquido a vapor o de vapor a líquido.

Phase failure protection Used on three-phase equipment to interrupt the power source when one phase becomes deenergized. The motors cannot be allowed to run on the two remaining phases or damage will occur.

Protección de fallo de fase Se usa en equipo trifásico para interrumpir la fuente de potencia cuando se energiza una fase. No se puede permitir que los motores corran con las dos fases restantes o podría ocurrir una avería.

Phase reversal Phase reversal can occur if someone switches any two wires on a three-phase system. Any system with a three-phase motor will reverse, and this cannot be allowed on some equipment.

Inversión de fase La inversión de fase puede ocurrir si por cualquier razón alguien intercambia cualquier par de cables en un sistema trifásico. Cualquier sistema con un motor trifásico irá en dirección contraria y esto no puede permitirse en algunos sistemas.

Pick-up voltage The back electromotive force (BEMF) voltage that must be generated across the potential relay's coil to cause the relay armature to move and open the relay contacts between terminals 1 and 2.

Voltaje de inicio El voltaje de la fuerza contraelectromotriz (BEMF) que debe generarse a lo largo de la bobina del relé de potencial para que su estructura se mueva y abra los contactos del relé entre las terminales 1 y 2.

Pictorial wiring diagram This type of diagram shows the location of each component as it appears to the person installing or servicing the equipment.

Diagrama representativo del cableado Este tipo de diagrama indica la ubicación de cada componente tal y como lo verá el personal técnico.

Piercing valve A device that is used to pierce a pipe or tube to obtain a pressure reading without interrupting the flow of fluid. Also called a line tap valve.

Válvula punzante Aparato que se usa para punzar un tubo para obtener una lectura de la presión sin interrumpir el flujo del fluido. También se llama una válvula de toma.

Pilot = duty relay A small relay that is used in control circuits for switching purposes. It is small and cannot take a lot of current flow, such as to start a motor.

Relé de función piloto Un pequeño relé que se usa en los circuitos de control con propósitos de interrupción. Es pequeño y no puede tolerar un flujo alto de corriente, como para arrancar un motor.

Pilot light The flame that ignites the main burner on a gas furnace.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Llama piloto Llama que enciende el quemador principal en un horno de gas.

Pilot positioner Used in a pneumatic air system to control the large volume of air that must be used to operate large pneumatic devices. The pneumatic thermostat sends a very small air signal to the pilot positioner in a 1/4" line and the pilot positioner controls the airflow in a 3/8" line for the large volume of air to the controlled device.

Posicionador piloto Se usa en un sistema neumático de aire para controlar el gran volumen de aire necesario para operar los aparatos neumáticos grandes. El termostato neumático envía una señal de aire pequeña al posicionador piloto por una línea de 1/4 de pulgada, y el posicionador piloto controla el flujo de aire, una línea de 3/8 de pulgada para el gran volumen de aire, al aparato controlado.

Pin rivet assembly Also known as a ***blind rivet***, this is a fastener assembly of hollow rivets assembled on a pin, often called a mandrel. The rivets are used to join two pieces of sheet metal and are inserted and set from only one side of the metal.

Instalación con remaches También llamados remaches ciegos, estos son remaches huecos con clavija. Los remaches se utilizan para unir dos láminas metálicas, y se introducen y se colocan desde una de las caras de las láminas.

Piston The part that moves up and down in a cylinder.

Pistón La pieza que asciende y desciende dentro de un cilindro.

Piston displacement The volume within the cylinder that is displaced with the movement of the piston from top to bottom.

Despiazamiento del pistón Volumen dentro del cilindro que se desplaza de arriba a abajo con el movimiento del pistón.

Pitch pocket Flanged piece of roof flashing that is positioned around irregularly shaped roof penetrations.

Material para impermeabilización Porción de membrana impermeabilizante de techos colocada de manera de cubrir inserciones irregulares en los techos.

Pitot tube Part of an instrument for measuring air velocities.

Tubo pitot Pieza de un instrumento para medir velocidades de aire.

Planned defrost Shutting the compressor off with a timer so that the space temperature can provide the defrost.

Descongelación proyectada Detención de la marcha de un compresor con un temporizador para que la temperatura del espacio lleve a cabo la descongelación.

Plenum A sealed chamber at the inlet or outlet of an air handler. The duct attaches to the plenum.

Plenum Cámara sellada a la entrada o a la salida de un tratante de aire. El conducto se fija al plenum.

Pneumatic atomizing humidifier Air pressure is used to break up the water into a mist of tiny droplets and to disperse them.

Humidificador por pulverización neumática Se utiliza aire a presión para convertir el agua en neblina y dispersarla.

Pneumatic controls Controls operated by low-pressure air, typically 20 psig.

Controles neumáticos Controles que se operan por aire de baja presión, generalmente 20 libras por pulgada cuadrada de presión de manómetro (Puig).

Polyalkylene glycol (PAG) A popular synthetic glycol-based lubricant used with HFC refrigerants, mainly in automotive systems. This was the first generation of oil used with HFC refrigerants.

Glicol polialkilénico (PAG en inglés) Lubricante sintético de uso común basado en glicol, usado con refrigerantes HFC, principalmente en sistemas de automóviles. Ésta fue la primera generación de aceites usados con refrigerantes HFC.

Polybutylene A material used for the buried piping in geothermal heat pumps.

Polibutileno Material utilizado para la fabricación de tubos enterrados, en sistemas de bombas de calor geotérmicas.

Polycyclic organic matter By-products of wood combustion found in smoke and considered to be health hazards.

Materna orgánica policíclica Subproductos de la combustión de madera presentes en el humo y considerados nocivos para la salud.

Polyethylene A material used for the buried piping in geothermal heat pumps.

Polietileno Material utilizado para la fabricación de tubos enterrados, en sistemas de bombas de calor geotérmicas.

Polyol ester (POE) A very popular ester-based lubricant often used in HFC refrigerant systems.

Poliol éster (POE en inglés) Lubricante muy popular basado en éster usado frecuentemente en sistemas con refrigerantes HFC.

Polyphase Three or more phases.

Polifase Tres o más fases.

Polyphosphate A scale inhibitor with many phosphate molecules.

Polifosfato Un inhibidor de escama que contiene muchas moléculas de fosfato.

Polyvinylether (PVE) A type of refrigerant oil that is specifically intended for use in refrigeration systems that utilize hydrofluorocarbon (HFC) refrigerants.

Poli-vinil-éter (PVE) Un tipo de aceite refrigerante que está específicamente diseñado para su uso en sistemas de refrigeración que utilizan refrigerantes de hidrofluorocarbono (HFC).

Porcelain A ceramic material.

Porcelana Material cerámico.

Portable dolly A small platform with four wheels on which heavy objects can be placed and moved.

Carretilla portátil Plataforma pequeña con cuatro ruedas sobre la que pueden colocarse y transportarse objetos pesados.

Positive displacement A term used with a pumping device such as a compressor that is designed to move all matter from a volume such as a cylinder or it will stall, possibly causing failure of a part.

Desplazamiento positivo Término utilizado con un dispositivo de bombeo, como por ejemplo un compresor, diseñado para mover toda la materia de un volumen, como un cilindro, o se bloqueará, posiblemente causándole fallas a una pieza.

Positive electrical charge An atom or component that has a shortage of electrons.

Carga eléctrica positiva Átomo o componente que tiene una insuficiencia de electrones.

Positive temperature coefficient (PTC) start device A thermistor used to provide start assistance to a permanent split-capacitor motor.

Dispositivo de arranque de coeficiente de temperatura positiva (PTC en inglés) Termistor utilizado para ayudar a arrancar un motor permanente de capacitador separado.

Potential relay A switching device used with hermetic motors that breaks the circuit to the start capacitor and/or start windings after the motor has reached approximately 75% of its running speed.

Relé de potencial Dispositivo de conmutación utilizado con motores herméticos que interrumpe el circuito del capacitador y/o de los devandos de arranque antes de que el motor haya alcanzado aproximadamente un 75% de su velocidad de marcha.

Potential voltage The voltage measured across the start winding in a single-phase motor while it is turning at full speed. This voltage is much greater than the applied voltage to the run winding. For example, the run winding may have 230 V applied to it, and a measured voltage across the start winding may be 300 V. This is

created by the motor stator turning in the magnetic field of the run winding.

***Voltage potential* is the difference in voltage between any two parts of a circuit.**

Potencial de voltaje El voltaje medido a través de la bobina de arranque en un motor de fase sencilla mientras está girando a velocidad completa. Este voltaje es mucho mayor que el voltaje aplicado a la bobina de marcha. Por ejemplo, a la bobina de marcha se le puede aplicar 230 V, y el voltaje medido a través de la bobina de arranque puede ser 300 V. Este voltaje lo crea el estator del motor al girar en el campo magnético de la bobina de marcha. ***Potencial de voltaje*** es la diferencia en voltaje entre cualesquiera dos partes del circuito.

Potentiometer An instrument that controls electrical current.

Potenciómetro Instrumento que regula corriente eléctrica.

Powder actuated tool (PAT) A tool with a powder load that forces a pin, threaded stud, or other fastener into masonry.

Herramienta activada por pólvora (PAT en inglés) Una herramienta con una carga de pólvora que inserta una clavija, una clavija con rosca u otro sujetador en la albañilería.

Power The rate at which work is done.

Potencia Velocidad a la que se realiza un trabajo.

Power-consuming devices A power- consuming device is considered the electrical load. For example, in a lightbulb circuit, the switch is a power-passing device that passes power to the lightbulb that consumes the power and produces light.

Aparatos consumidores de potencia Un aparato consumidor de potencia se considera la carga eléctrica. Por ejemplo, en un circuito de bombilla de luz, el interruptor es un dispositivo que pasa corriente que pasa la corriente a la bombilla, la cual consume electricidad y produce luz.

Power drafted A fan assisted draft.

Corriente generada Corriente de aire producida por un ventilador.

Precipitation A process where dissolved minerals in a solution reach a certain concentration and become solid.

Precipitación Proceso por el cual los minerales disueltos en una solución alcanzan una cierta concentración y solidifican.

Pressure Force per unit of area.

Presión Fuerza por unidad de área.

Pressure control A sitch or control that responds to changes in pressure.

Control de presión un interruptor o control que responde a los cambios de presión.

Pressure access ports Places in a system where pressure can be taken or registered.

Puerto de acceso a presión Lugares en un sistema donde se puede tomar o registrar la presión.

Pressure control A sitch or control that responds to changes in pressure.

Pressure differential valve A valve that senses a pressure differential and opens when a specific pressure differential is reached.

Válvula de presión diferencial Válvula que detecta diferencia de presiones y se abre cuando se alcanza una diferencia específica.

Pressure drop The difference in pressure between two points.

Caída de presión Diferencia en presión entre dos puntos.

Pressure/enthalpy diagram A chart indicating the pressure and heat content of a refrigerant and the extent to which the refrigerant is a liquid and vapor.

Diagrama de presión y entalpía Esquema que indica la presión y el contenido de calor de un refrigerante y el punto en que el refrigerante es líquido y vapor.

Pressure limiter A device that opens when a certain pressure is reached.

Dispositivo limitador de presión Dispositivo que se abre cuando se alcanza una presión específica.

Pressure-limiting TXV A valve designed to allow the evaporator to build only to a predetermined pressure when the valve will shut off the flow of refrigerant.

Válvula electrónica de expansión limitadora de presión Válvula diseñada para permitir que la temperatura del evaporador alcance una presión predeterminada cuando la válvula detenga el flujo de refrigerante.

Pressure regulator A valve capable of maintaining a constant outlet pressure when a variable inlet pressure occurs. Used for regulating fluid flow such as natural gas, refrigerant, and water.

Regulador de presión Válvula capaz de mantener una presión constante a la salida cuando ocurre una presión variable a la entrada. Utilizado para regular el flujo de fluidos, como por ejemplo el gas natural, el refrigerante y el agua.

Pressure switch A switch operated by a change in pressure.

Commutador accionado por presión Commutador accionado por un cambio en presión.

Pressure tank A pressurized tank for water storage located in the water piping of an open-loop geothermal heat pump system. It prevents short cycling of the well pump.

Depósito de presión Depósito presurizado que sirve para almacenar el agua contenida en la tubería de un sistema de bomba de calor geotérmica de circuito abierto. Impide el funcionamiento de la bomba del pozo en ciclos cortos.

Pressure/temperature relationship This refers to the pressure/ temperature relationship of a liquid and vapor in a closed container. If the temperature increases, the pressure will also increase. If the temperature is lowered, the pressure will decrease.

Relación entre presión y temperatura Se refiere a la relación entre la presión y la temperatura de un líquido y un vapor en un recipiente cerrado. Si la temperatura aumenta, la presión también aumentará. Si la temperatura baja, habrá una caída de presión.

Pressure test instruments Pieces of test equipment that are used to measure the pressure or pressures in a system or vessel.

Instrumentos de prueba de presión piezas de equipo de prueba que se utiliza para medir la presión o presiones en un sistema o buque.

Pressure transducer A pressure-sensitive device located in the piping of a refrigeration system that will transform a pressure signal to an electronic signal. The electronic signal will then feed a microprocessor.

Transductor de presión Dispositivo sensible a la presión, situado en la tubería del sistema de refrigeración y que convierte una señal de presión en señal eléctrica. Seguidamente, la señal eléctrica se envía a un microprocesador.

Pressure vessels and piping Piping, tubing, cylinders, drums, and other containers that have pressurized contents.

Depósitos y tubería con presión Tubería, cilindros, tambores y otros recipientes que tienen un contenido presurizado.

Preventive maintenance The action of performing regularly scheduled maintenance on a unit, including inspection, cleaning, and servicing.

Mantenimiento preventivo La acción de dar mantenimiento regular a una unidad incluyendo inspección, limpieza, y servicio.

Primary air Air that is introduced to a furnace's burner before the combustion process has taken place.

Aire primario Aire que se introduce en el quemador de un calefactor antes de que ocurra el proceso de combustión.

Primary control Controlling device for an oil burner to ensure ignition within a specific time span, usually 90 seconds.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Regulador principal Dispositivo de regulación para un quemador de aceite pesado. El regulador principal asegura el encendido dentro de un período de tiempo específico, normalmente 90 segundos.

Programmable thermostat An electronic thermostat that can be set up to provide desired conditions at desired times.

Termostato programable Un termostato electrónico que se puede programar para proveer las condiciones deseadas en tiempos deseados.

Propane An LP (liquified petroleum) gas used for heat.

Propano Gas de petróleo licuado que se utiliza para producir calor.

Propane gas torch A torch that usess propane as its fuel.

Soplete de gas propano una antorcha que usa propano como combustible.

Propeller fan This fan is used in exhaust fan and condenser fan applications. It will handle large volumes of air at low-pressure differentials.

Ventilador helicoidal Se utiliza en ventiladores de evacuación y de condensador. Es capaz de mover grandes volúmenes de aire a bajas diferenciales de presión.

Proportional controller A modulating control mode where the controller changes or modifies its output signal in proportion to the size of the change in the error.

Controlador proporcional Un modo de control modulante donde el controlador cambia o modifica su señal de salida en proporción al tamaño del cambio en el error.

Proportional Integral (PI) controls Electronic controls that sense and react to the error between the actual and desired states of a system.

Controles proporcionales integrales (PI) Controles electrónicos que miden y reaccionan ante el error entre el estado real y el estado deseado de un sistema.

Propylene glycol An antifreeze fluid cooled by a primary (phase-change) refrigerant, which then is circulated by pumps throughout the refrigeration system to absorb heat.

Glicol propílico Líquido anticongelante enfriado por un refrigerante primario (cambio de fase). Seguidamente, una bomba lo hace circular por el sistema de refrigeración para que absorba el calor.

Proton That part of an atom having a positive charge.

Protón Parte de un átomo que tiene carga positiva.

Protozoa A microscopic organism with a complex life cycle.

Protozoario Un organismo microscópico con un ciclo de vida complejo.

PSC motor See Permanent split-capacitor motor.

Motor PSC Véase motor permanente de capacitador separado.

psi Abbreviation for pounds per square inch.

psi Abreviatura de libras por pulgada cuadrada.

psia Abbreviation for pounds per square inch absolute.

psia Abreviatura de libras por pulgada cuadrada absoluta.

psig Abbreviation for pounds per square inch gauge.

psig Abreviatura de indicador de libras por pulgada cuadrada de presión manométrica.

Psychrometer An instrument for determining relative humidity.

Sicrómetro Instrumento para medir la humedad relativa.

Psychrometric chart A chart that shows the relationship of temperature, pressure, and humidity in the air.

Esquema psicrométrico Esquema que indica la relación entre la temperatura, la presión y la humedad en el aire.

Psychrometrics The study of air and its properties, particularly the moisture content.

Psicrometría El estudio del aire y sus propiedades, particularmente el contenido de humedad.

P-type material Semiconductor material with a positive charge.

Material tipo P Material con carga positiva utilizado en semiconductores.

Pulse furnace This furnace ignites minute quantities of gas 60 to 70 times per second. Small amounts of natural gas and air enter the combustion chamber and are ignited with a spark igniter that forces the combustion materials down a tailpipe to an exhaust decoupler. The pulse is reflected back to the combustion chamber, igniting another gas and air mixture.

Horno de impulsos Este tipo de horno enciende pequeñas cantidades de gas, 60 a 70 veces por segundo. Pequeñas cantidades de gas natural y aire entran en la cámara de combustión y son encendidas mediante chispa. A continuación son forzadas por un tubo hacia un desconectador de evacuación. El impulso se devuelve a la cámara de combustión para encender otra mezcla de gas y aire.

Pulse-width modulator (PWM) An electronic device in a motor circuit that is used to control motor speed for variable-speed motors.

Modulador de ancho de pulso (PWM en inglés) Un aparato electrónico en un circuito de motor que se usa para controlar la velocidad del motor para motores de velocidad variable.

Pump A device that forces fluids through a system.

Bomba Dispositivo que introduce fluidos por fuerza a través de un sistema.

Pump down To use a compressor to pump the refrigerant charge into the condenser and/or receiver.

Extraer con bomba Utilizar un compresor para bombear la carga del refrigerante dentro del condensador y/o receptor.

Pure compound A substance formed in definite proportions by weight with only one molecule present.

Componente puro Una sustancia formada en proporciones por peso definidas con sólo una molécula presente.

Pure hydrocarbons (HCs) Pure hydrocarbons are compounds that are made up of only hydrogen and carbon atoms. Some common hydrocarbons are methane, ethane, propane, butane and octane.

Los hidrocarburos puros (HC) los hidrocarburos puros son compuestos que se compone sólo de átomos de hidrógeno y de carbono. Algunos hidrocarburos comunes son el metano, etano, propano, butano y el octano.

Purge To remove or release fluid from a system.

Purga Remover o liberar el fluido de un sistema.

PVC (Polyvinyl chloride) Plastic pipe used in pressure applications for water and gas as well as for sewage and certain industrial applications.

Cloruro de polivinilo (PVC en inglés) Tubo plástico utilizado tanto en aplicaciones de presión para agua y gas, como en ciertas aplicaciones industriales y de aguas negras.

Q

Quench To submerge a hot object in a fluid for cooling.

Entriamiento por inmersión Sumersión de un objeto caliente en un fluido para enfriarlo.

Quick-connect coupling A device designed for easy connecting or disconnecting of fluid lines.

Acoplamiento de conexión rápida Dispositivo diseñado para facilitar la conexión o desconexión de conductos de fluido.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

R

R-12 Dichlorodifluoromethane, once a popular refrigerant for refrigeration systems. It can no longer be manufactured in the United States and many other countries.

R-12 Diclorodifloremetano, que fue una vez un refrigerante muy utilizado en sistemas de refrigeración. Ya no se puede fabricar ni en los Estados Unidos ni en muchos otros países.

R-22 Monochlorodifluoromethane, a popular HCFC refrigerant for air-conditioning systems.

R-22 Monoclorodifloremetano, refrigerante HCFC muy utilizado en sistemas de acondicionamiento de aire.

R-123 Dichlorotrifluoroethane, an HCFC refrigerant developed for low-pressure application.

R-123 Diclorotrifloroetano, refrigerante HCFC elaborado para aplicaciones de baja presión.

R-134a Tetrafluoroethane, an HFC refrigerant developed for refrigeration systems and as a replacement for R-12.

R-134a Tetrafloroetano, refrigerante HFC elaborado para sistemas de refrigeración y como sustituto del R-12.

R-410A An HFC binary refrigerant blend that contains R-32 and R-125. This refrigerant has an ODP of 0.

R-410A Refrigerante mezcla binaria de HFC que contiene R-32 y R-125. Este refrigerante tiene un ODP de 0.

R-502 An azeotropic mixture of R-22 and R-115, a once popular refrigerant for low-temperature refrigeration systems. It can no longer be manufactured in the United States and many other countries.

R-502 Mezcla azeotrópica de R-22 y R-115, que fue una vez un refrigerante muy utilizado en sistemas de refrigeración de temperatura baja. Ya no se puede fabricar ni en los Estados Unidos ni en muchos otros países.

Rack system Many compressors piped in parallel and mounted on a steel rack. The compressors are usually cycled by a microprocessor.

Sistema de bastidor Varios compresores conectados en paralelo y montados en un bastidor de acero. Normalmente, un microprocesador se encarga de activar y desactivar los compresores.

Radiant heat Heat that passes through air, heating solid objects that in turn heat the surrounding area.

Calor radiante Calor que pasa a través del aire y calienta objetos sólidos que a su vez calientan el ambiente.

Radiation Heat transfer. See Radiant heat.

Radiación Transferencia de calor. Véase Calor radiante.

Radon A colorless, odorless, and radioactive gas. Radon can enter buildings through cracks in concrete floors and walls, floor drains, and sumps.

Radón Gas incoloro, inodoro y radioactivo. El radón puede penetrar en los edificios a través de las grietas en el hormigón y suelos, desagües y sumideros.

Random or off-cycle defrost Defrost provided by the space temperature during the normal off cycle.

Descongelación variable o de ciclo apagado Descongelación llevada a cabo por la temperatura del espacio durante el ciclo normal de apagado.

Range The pressure or temperature settings of a control defining certain boundaries of temperature or pressure.

Rango Los valores de presión o temperatura para un control que definen los límites de la temperatura o presión.

Rankine The absolute Fahrenheit scale with 0 at the point where all molecular motion stops.

Rankine Escala absoluta de Fahrenheit con el 0 al punto donde se detiene todo movimiento molecular.

Rapid oxidation A reaction between the fuel, oxygen, and heat that is known as rapid oxidation or the process of burning.

Oxidación rápida Reacción producida entre el combustible y el oxígeno. El calor producido se conoce como oxidación rápida o proceso de quemado.

Rated-load amperage (RLA) A mathematical calculation used to get Underwriters Laboratory's (UL) approval for a motor. The RLA value is used by a service technician to size wires, fuses, overloads, and contactors for the motor. It should not be used to determine the proper refrigerant charge, or to determine if a compressor motor is running properly.

Amperaje de carga calificada (RLA) Cálculo matemático utilizado para obtener la aprobación de Underwriters Laboratory (UL) para un motor. Los técnicos mecánicos utilizan el valor del RLA para medir el tamaño de los cables, fusibles, contactores y medidores de sobrecarga. No debe utilizarse para determinar la carga adecuada del refrigerante ni para determinar si un motor de compresor está funcionando correctamente.

Reactance A type of resistance in an alternating current circuit.

Reactancia Tipo de resistencia en un circuito de corriente alterna.

Reamer Tool to remove burrs from inside a pipe after it has been cut.

Escariador Herramienta utilizada para remover las rebabas de un tubo después de haber sido cortado.

Receiver-drier A component in a refrigeration system for storing and drying refrigerant.

Receptor-secador Componente en un sistema de refrigeración que almacena y seca el refrigerante.

Reciprocating Back-and-forth motion.

Movimiento alternativa Movimiento de atrás para adelante.

Reciprocating compressor A compressor that uses a piston in a cylinder and a back-and-forth motion to compress vapor.

Compresor alternativo Compresor que utiliza un pistón en un cilindro y un movimiento de atrás para adelante a fin de comprir el vapor.

Recirculated water system A system where water is used over and over, such as a chilled water or cooling tower system.

Sistema de agua recirculada Sistema donde el agua se usa una y otra vez, tal como en un sistema de agua enfriada o de torre enfriamiento.

Recovery cylinder A cylinder into which refrigerant is transferred; should be approved by the Department of Transportation as a recovery cylinder. The color code for these cylinders is a yellow top with a gray body.

Cilindro de recuperación Cilindro al que se transfiere el refrigerante y que debe ser homologado por el departamento de transporte como cilindro de recuperación. Este tipo de cilindro se identifica pintando su parte superior en amarillo y el resto del cuerpo en gris.

Rectifier A device for changing alternating current to direct current.

Rectificador Dispositivo utilizado para convertir corriente alterna en corriente continua.

Reed valve A thin steel plate used as a valve in a compressor.

Válvula de lámina Placa delgada de acero utilizada como una válvula en un compresor.

Reflectivity The ability of a materials surface to reflect radiant energy. Also referred to as reflectance.

Reflectividad Capacidad de la superficie de los materiales de reflejar la energía radiante. Se conoce también como reflectancia.

Refrigerant The fluid in a refrigeration system that changes from a liquid to a vapor and back to a liquid at practical pressures.

Refrigerante Fluido en un sistema de refrigeración que se convierte de líquido

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

en vapor y nuevamente en líquido a presiones prácticas.

Refrigerant blend Two or more refrigerants blended or mixed together to make another refrigerant. Blends can combine as either azeotropic or zeotropic blends.

Mezcla de refrigerante Dos o más refrigerantes mezclados para crear otro. Las mezclas pueden ser de tipo azeotrópico o zeotrópico.

Refrigerant loop The heat pump's refrigeration system, which exchanges energy with the fluid in the ground loop and the air side of the system.

Circuito de refrigeración Sistema de refrigeración de la bomba de calor que sirve para intercambiar energía entre el fluido en el circuito de tierra y la parte del sistema que contiene el aire.

Refrigerant receiver A storage tank in a refrigeration system where the excess refrigerant is stored. Since many systems use different amounts of refrigerant during the season, the excess is stored in the receiver tank when not needed. The refrigerant can also be pumped to the receiver when repairs on the low- pressure side of the system are made.

Recibidor de refrigerante Tanque de almacenamiento en un sistema de refrigeración donde se almacena el exceso de refrigerante. Como muchos sistemas usan diferentes cantidades de refrigerantes durante la temporada, el exceso se almacena en el tanque cuando no se necesita. El refrigerante también puede bombearse al recibidor cuando se hacen reparaciones al extremo de baja presión del sistema.

Refrigerant reclaim "To process refrigerant to new product specifications by means which may include distillation. It will require chemical analysis of the refrigerant to determine that appropriate product specifications are met. This term usually implies the use of processes or procedures available only at a reprocessing or manufacturing facility."

Recuperación del refrigerante "Procesar refrigerante según nuevas especificaciones para productos a través de métodos que pueden incluir la destilación. Se requiere un análisis químico del refrigerante para asegurar el cumplimiento de las especificaciones para productos a través de métodos que pueden incluir la destilación. Se requiere un análisis químico del refrigerante para asegurar el cumplimiento de las especificaciones para productos adecuadas. Por lo general este término supone la utilización de procesos o de procedimientos disponibles solamente en fábricas de reprocesamiento o manufactura."

Refrigerant recovery "To remove refrigerant in any condition from a system and store it in an external container without necessarily testing or processing it in any way."

Recobrar refrigerante líquido "Remover refrigerante en cualquier estado de un sistema y almacenarlo en un recipiente externo sin ponerlo a prueba o elaborarlo de ninguna manera."

Refrigerant recycling "To clean the refrigerant by oil separation and single or multiple passes through devices, such as replaceable core filter driers, which reduce moisture, acidity, and particulate matter. This term usually applies to procedures implemented at the job site or at a local service shop."

Recirculación de refrigerante "Limpieza del refrigerante por medio de la separación del aceite y pasadas sencillas o múltiples a traves de dispositivos, como por ejemplo secadores filtros con núcleos reemplazables que disminuyen la humedad, la acidez y las partículas. Por lo general este término se aplica a los procedi mientos utilizados en el lugar del trabajo o en un taller de servicio local."

Refrigerated air driers A device that removes the excess moisture from compressed air.

Secadores de aire refrigerados Aparato que remueve el exceso de humedad del aire comprimido.

Refrigeration The process of removing heat from a place where it is not wanted and transferring that heat to a place where it makes little or no difference.

Refrigeración Proceso de remover el calor de un lugar donde no es deseado y transferirlo a un lugar donde no afecte la temperatura.

Register A terminal device on an air-distribution system that directs air but also has a damper to adjust airflow.

Registro Dispositivo de terminal en un sistema de distribución de aire que dirige el aire y además tiene un desviador para ajustar su flujo.

Regulator A valve used to control the pressure in liquid systems to some value. Many households have a water pressure regulator to reduce the pressure from the main to a more usable pressure in the house. Gas systems all have pressure regulators to stabilize the pressure to the burners.

Regulador Una válvula que se usa para controlar y fijar la presión en los sistemas líquidos a algún valor. Muchas casas tienen un regulador de presión de agua para reducir la presión de la tubería principal a una presión más útil en la casa. Todos los sistemas de gas tienen reguladores de presión para estabilizar la presión en el quemador.

Relative humidity The amount of moisture contained in the air as compared to the amount the air could hold at that temperature.

Humedad relativa Cantidad de humedad presente en el aire, comparada con la cantidad de humedad que el aire pueda contener a dicha temperatura.

Relay A small electromagnetic device to control a switch, motor, or valve.

Relé Pequeño dispositivo electromagnético utilizado para regular un conmutador, un motor o una válvula.

Relief valve A valve designed to open and release vapors at a certain pressure.

Válvula para alivio Válvula diseñada para abrir y liberar vapores a una presión específica.

REM/Rate The HERS index score is determined by computer modeling the home by Residential Energy Analysis and Rating Software named REM/Rate.

REM/Rate El puntaje del índice HERS se determina mediante el modelado computarizado de la residencia, utilizando un software para el análisis energético y clasificación residencial llamado REM/Rate.

Remote system Often called a split system where the condenser is located away from the evaporator and/or other parts of the system.

Sistema remoto Llamado muchas veces sistema separado donde el condensador se coloca lejos del evaporador y/o otras piezas del sistema.

Residential Energy Services Network (RESNET) A nationally recognized energy certification for home energy auditors and contractors.

Cadena de servicios de energía residencial (RESNET) Certificación energética nacional para auditores y contratistas de energía residencial.

Resilient-mount motor Electric motor that uses various materials to isolate the motor noise from metal framework. This type of motor requires a ground strap.

Motor con montaje antivibratorio Motor eléctrico que utiliza varios materiales para aislar el ruido del bastidor metálico. Este tipo de motor requiere conexión a tierra.

Resistance The opposition to the flow of an electrical current or a fluid.

Resistencia Oposición al flujo de una corriente eléctrica o de un fluido.

Resistor An electrical or electronic component with a specific opposition to electron flow. It is used to create voltage drop or heat.

Resistor Componente eléctrico o electrónico con una oposición específica al flujo de electrones; se utiliza para producir una caída de tensión o calor.

Restrictor A device used to create a planned resistance to fluid flow.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Limitador Dispositivo utilizado para producir una resistencia proyectada al flujo de fluido.

Retrofit guidelines Guidelines intended to make the transition from a CFC/mineral oil system to a system containing an alternative refrigerant and its appropriate oil.

Directrices de reconversión Directrices destinadas a facilitar la transición entre un sistema de aceite CFC/mineral y otro con refrigerante alternativo y su aceite correspondiente.

Return well A well for return water after it has experienced the heat exchanger of the geothermal heat pump.

Pozo de retorno Pozo donde se acumula el agua de retorno una vez ha pasado por el intercambiador térmico de la bomba de calor geotérmica.

Reverse cycle The ability to direct the hot gas flow into the indoor or the outdoor coil in a heat pump to control the system for heating or cooling purposes.

Ciclo invertido Capacidad de dirigir el flujo de gas caliente dentro de la bobina interior o exterior en una bomba de calor a fin de regular el sistema para propósitos de calentamiento o enfriamiento.

Rigging The process of using a crane to set HVAC equipment to a roof.

Elevación Proceso de utilización de una grúa para colocar el equipamiento de acondicionamiento de aire en un techo.

Rigid-base mount Term used to describe a motor that has its base fastened to the motor body.

Montaje de base rígida término utilizado para describir un motor que tiene su base fijada al cuerpo del motor.

Rigid-mount motor Electric motor that is bolted metal-to-metal to a frame. This type of motor will transmit noise.

Motor con montaje rígido Motor eléctrico que se encuentra sujeto directamente a un bastidor mediante pernos. Este tipo de motor genera ruido.

Rod and tube The rod and tube are each made of a different metal. The tube has a high expansion rate and the rod a low expansion rate.

Varilla y tubo La varilla y el tubo se fabrican de un metal diferente. El tubo tiene una tasa de expansión alta y la varilla una tasa de expansión baja.

Room heater A gas stove or appliance considered by ANSI to be a heating appliance. This heater will have an efficiency rating.

Calentador de sala Estufa de gas u otro dispositivo que, según ANSI, es un dispositivo de calefacción. Este tipo de calentador cuenta con una clasificación de eficacia.

Root mean square (RMS) voltage The alternating current voltage effective value. This is the value measured by most voltmeters. The RMS voltage is 0.707 × the peak voltage.

Voltaje de la raíz del valor medio cuadrado (RMS en inglés) El valor efectivo del voltaje de corriente alterna. Este valor es el que miden la mayoría de los voltímetros. El voltaje RMS es 0.707 por el voltaje pico.

Rotary compressor A compressor that uses rotary motion to pump fluids. It is a positive displacement pump.

Compresor giratorio Compresor que utiliza un movimiento giratorio para bombear fluidos. Es una bomba de desplazamiento positivo.

Rotor The rotating or moving component of a motor, including the shaft.

Rotor Componente giratorio o en movimiento de un motor, incluyendo el arbol.

Running time The time a unit operates. Also called the "on time".

Período de funcionamiento El período de tiempo en que funciona una unidad. Conocido también como *período de conexión*.

Run winding The electrical winding in a motor that draws current during the entire running cycle.

Devanado de funcionamiento Devanado eléctrico en un motor que consume corriente durante todo el ciclo de funcionamiento.

Rupture disk Pressure safety device for a centrifugal low-pressure chiller.

Disco de ruptura Dispositivo de seguridad para un enfriador centrífugo de baja presión.

R-Value Indicates an insulation's resistance to heat transfer, or thermal resistance. This is the inverse of a material's U-value.

Índice R Indica la resistencia de una aislación a la transferencia de calor, o la resistencia térmica. Es la inversa del índice U de un material.

S

Saddle valve A valve that straddles a fluid line and is fastened by solder or screws. It normally contains a device to puncture the line for pressure readings.

Válvula de silleta Válvula que está sentada a horcajadas en un conducto de fluido y se fija por medio de la soldadura o tornillos. Por lo general contiene un dispositivo para agujerear el conducto a fin de que se puedan tomar lecturas de presión.

Safety control An electrical, electronic, mechanical, or electromechanical control to protect the equipment or public from harm.

Regulador de seguridad Regulador eléctrico, electrónico, mecánico o electromecánico para proteger al equipo de posibles averías o al público de sufrir alguna lesión.

Safety plug A fusible plug that blows out when high temperature occurs.

Tapón de seguridad Tapón fusible que se sale cuando se presentan temperaturas altas.

Sail switch A safety switch with a lightweight, sensitive sail that operates by sensing an airflow.

Conmutador con vela Conmutador de seguridad con una vela liviana sensible que funciona al advertir el flujo de aire.

Salt solution Antifreeze solution used in a closed water loop of geothermal heat pumps.

Solucion de sal Líquido anticongelante utilizado en el circuito cerrado de agua de una bomba de calor geotérmica.

Satellite compressor The compressor on a parallel compressor system that is dedicated to the coldest evaporators.

Compresor auxiliar Compresor montado en un sistema paralelo y que está dedicado a los evaporadores más fríos.

Saturated vapor The refrigerant when all of the liquid has just changed to a vapor.

Vapor saturada El refrigerante cuando todo el líquido acaba de convertirse en vapor.

Saturation A term used to describe a substance when it contains all of another substance it can hold.

Saturación Término utilizado para describir una sustancia cuando contiene lo más que puede de otra sustancia.

Saturation pressure The pressure at which a refrigerant will change state.

Presión de saturación la presión a la cual un refrigerante cambia de estado.

Saturation temperature The temperature at which a refrigerant will change state.

Temperatura de saturación la temperatura a la cual el refrigerante cambia de estado.

Scale Dissolved minerals such as calcium carbonate (limestone) which reach a certain concentration and become solid, usually clinging to HVACR equipment and piping surfaces.

Sarro Minerales disueltos como el carbonato de calcio (piedra caliza) que alcanzan una cierta concentración y solidifican, generalmente adhiriéndose a los equipos de acondicionamiento de aire y a las superficies internas de las cañerías.

Scavenger pump A pump used to remove the fluid from a sump.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Bomba de barrido Bomba utilizada para remover el fluido de un sumidero.

Schematic wiring diagram Sometimes called a line or ladder diagram, this type of diagram shows the electrical current path to the various components.

Diagrama de cableado esquematizado También conocido como de línea o de escalera, este tipo de diagrama muestra la ruta actual que sigue la electricidad para llegar a los diferentes componentes.

Schrader valve A valve similar to the valve on an auto tire that allows refrigerant to be charged or discharged from the system.

Válvula Schrader Válvula similar a la válvula del neumático de un automóvil que permite la entrada o la salida de refrigerante del sistema.

Scotch yoke A mechanism used to create reciprocating motion from the electric motor drive in very small compressors.

Yugo escocés Mecanismo utilizado para producir movimiento alternativo del accionador del motor eléctrico en compresores bastante pequeños.

Screw compressor A form of positive displacement compressor that squeezes fluid from a low-pressure area to a high-pressure area, using screw-type mechanisms.

Compresor de tornillo Forma de compresor de desplazamiento positivo que introduce por fuerza el fluido de un área de baja presión a un área de alta presión, a través de mecanismos de tipo de tornillo.

Scroll compressor A compressor that uses two scroll-type components, one stationary and one orbiting, to compress vapor.

Compresor espiral Compresor que utiliza dos componentes de tipo espiral para comprimir el vapor.

Sealed unit The term used to describe a refrigeration system, including the compressor, that is completely welded closed. The pressures can be accessed by saddle valves.

Unidad sellada Término utilizado para describir un sistema de refrigeración, incluyendo el compresor, que es soldado completamente cerrado. Las presiones son accesibles por medio de válvulas de dilleta.

Seasonal energy efficiency ratio (SEER) An equipment efficiency rating that is calculated on the basis of the total amount of cooling (in Btu) the system will provide over the entire season, divided by the total number of watt-hours it will consume.

Relación estacional de eficiencia energética (SEER, por sus siglas en inglés) La eficiencia de un equipamiento que se calcula en base al enfriamiento total (en BTU) que el sistema proporcionará a lo largo de toda la estación, dividido entre el número total de watts por hora que consuma dicho sistema.

Seat The stationary part of a valve that the moving part of the valve presses against for shutoff.

Asiento Pieza fija de una válvula contra la que la pieza en movimiento de la válvula presiona para cerrarla.

Secondary air Air that is introduced to a furnace after combustion takes place and that supports combustion.

Aire secundario Aire que se introduce en un calefactor después que occure la combustión y que ayuda la combustión.

Secondary fluid An antifreeze fluid cooled by a primary (phase-change) refrigerant, which is then circulated by pumps throughout the refrigeration system to absorb heat.

Fluido secundario Líquido anticongelante refrigerado por otro primario (cambio de fase), que luego es propulsado por las bombas a través del sistema de refrigeración para absorber el calor.

Semiconductor A component in an electronic system that is considered neither an insulator nor a conductor but a partial conductor. It conducts current in a controlled and predictable manner.

Semiconductor Componente en un sistema eléctrico que no se considera ni aislante ni conductor, sino conductor parcial. Conduce la corriente de una manera controlada y predecible.

Semi-hermetic compressor A motor compressor that can be opened or disassembled by removing bolts and flanges. Also known as a ***serviceable hermetic***.

Compresor semihermético Compresor de un motor que puede abrirse o desmontarse al removerle los pernos y bridas. Conocido también como ***hermético utilizable***.

Sensible heat Heat that causes a change in temperature.

Calor sensible Calor que produce un cambio en la temperatura.

Sensitivity See Gain.

Sensibilidad Vea Ganancia.

Sensors Devices that can measure some type of environmental parameter or controlled variable and convert this parameter to a value that the controller can understand.

Sensores Dispositivos que miden algún tipo de parámetro ambiental o variable controlado y convierten este parámetro a un valor que el controlador puede entender.

Sequencer A control that causes a staging of events, such as a sequencer between stages of electrical heat.

Regulador de secuencia Regulador que produce una sucesión de acontecimientos, como por ejemplo etapas sucesivas de calor eléctrico.

Series circuit An electrical or piping circuit where all of the current or fluid flows through the entire circuit.

Circuito en serie Cicuito eléctrico o de tubería donde toda la corriente o todo el fluido fluye a través de todo el circuito.

Series flow A flow path in which only one path exists for fluid to flow.

Flujo en serie Ruta de flujo única para el líquido.

Serviceable hermetic See Semi-hermetic compressor.

Compresor hermético utilizable Véase Compresor semihermético.

Service factor amps (SFA) The current the motor is drawing at its service factor loading.

Amperaje de factor de servicio (SFA, por sus siglas en inglés) Corriente que utiliza el motor cuando funciona a su factor de servicio.

Service valve A manually operated valve in a refrigeration system used for various service procedures.

Válvula servicio Válvula de un sistema de refrigeración accionada manualmente que se utiliza en varios procedimientos de servicio.

Servo pressure regulator A sensitive pressure regulator located inside a combination gas valve that senses the outlet or working pressure of the gas valve.

Regulador de presión por servomotor Un regulador de presión sensible que está ubicado dentro de una válvula de gas de combinación que detecta la presión de salida o de trabajo de la válvula de presión.

Sessile bacteria The bacteria that live in a biofilm and adhere to the equipment surfaces. They represent 99% of the total bacteria in a cooling tower or boiler water system.

Bacterias sésiles Bacterias que habitan en un biofilm y se adhieren a las superficies de los equipamientos. Representan un 99% de las bacterias totales presentes en sistemas de enfriamiento en torre o calderas.

Set point The desired control point's magnitude in a control process.

Punto de ajuste La magnitud deseada de un punto de control en un proceso de control.

S fastener A device used to connect square and rectangular sheet metal duct together, in conjunction with a drive cleat. Also referred to as a "slip".

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Sujetador tipo "S" Aparato que se usa para unir conductos cuadrados y rectangulares de metal en lámina en conjunción con una grapa direccional. También se lo denomina "engrapadora".

Shaded-pole motor An alternating current motor used for very light loads.

Motor polar en sombra Motor de corriente alterna utilizado en cargas sumamente livianas.

Shell The floors, roof, and walls of a building, which is often referred to as the exterior envelope of the building.

Coraza Los pisos, techos, y paredes de una construcción, que generalmente se conocen como la funda exterior de la construcción.

Shell and coil A vessel with a coil of tubing inside that is used as a heat exchanger.

Coraza y bobina Despósito con una bobina de tubería en su interior que se utiliza como intercambiador de calor.

Shell and tube A heat exchanger with straight tubes in a shell that can normally be mechanically cleaned.

Coraza y tubo Intercambiador de calor con tubos rectos en una coraza que por lo general puede limpiarse mecánicamente.

Short circuit A circuit that does not have the correct measurable resistance: too much current flows and will overload the conductors.

Cortocircuito Corriente que no tiene la resistencia medible correcta: un exceso de corriente fluye a través del circuito provocando una sobrecarga de los conductores.

Short cycle The term used to describe the running time (on time) of a unit when it is not running long enough.

Cico corto Término utilizado para describir el período de funcionamiento (de encendido) de una unidad cuando no funciona por un período de tiempo suficiente.

Shorted motor winding Part of an electric motor winding is shorted out because one part of the winding touches another part, where the insulation is worn or in some way defective.

Devanado de motor en cortocircuito Debido a un aislamiento deficiente u otro defecto, una parte de los elementos del devanado en un motor eléctrico entran en contacto con otra, causando un cortocircuito.

Shroud A fan housing that ensures maximum airflow through the coil.

Boveda Alojamiento del abanico que asegura un flujo máximo de aire a través de la bobina.

Sick building syndrome (SBS) A condition that affects the health of office workers that is often attributed to poor ventilation or air quality.

Síndrome del edificio enfermo (SBS) una condición que afecta la salud de los trabajadores de oficina que a menudo se atribuye a la falta de ventilación o la calidad del aire.

Sight glass A clear window in a fluid line.

Mirilla para observación Ventana clara en un conducto de fluido.

Signal converter An electronic device that converts one signal type to another.

Convertidor de señales Un aparato electrónico que convierte un tipo de señal a otro.

Silica gel A chemical compound often used in refrigerant driers to remove moisture from the refrigerant.

Gel silíceo Compuesto químico utilizado a menudo en seca dores de refrigerantes para remover la humedad del refrigerante.

Silicon A substance from which many semiconductors are made.

Silicio Sustancia de la cual se fabrican muchos semiconductores.

Silicon-controlled rectifier (SCR) A semiconductor control device.

Rectificador controlado por silicio Dispositivo para regular un semiconductor.

Silver brazing A high-temperature (above 800°F) brazing process for bonding metals.

Soldadura con plata Soldadura a temperatura alta (sobre los 800°F ó 430°C) para unir metales.

Sine wave The graph or curve used to describe the characteristics of alternating current and voltage.

Onda sinusoidal Gráfica o curva utilizada para describir las características de tensión y de corriente alterna.

Single phase The electrical power supplied to equipment or small motors, normally under 7 1/2 hp.

Monofásico Potencia eléctrica suministrada a equipos o motores pequeños, por lo general menor de 7 1/2 hp.

Single-phase hermetic motor A sealed motor, such as with a small compressor, that operates off single-phase power.

Motor de fase sencilla hermético Un motor sellado, tal como un compresor pequeño, que opera con electricidad de fase sencilla.

Single phasing The condition in a three-phase motor when one phase of the power supply is open.

Fasaje sencillo Condición en un motor trifásico cuando una fase de la fuente de alimentación está abierta.

Slinger ring A ring attached to the blade tips of a condenser fan. This ring throws condensate onto the condenser coil, where it is evaporated.

Anillo tubular Anillo instalado en los extremos de las palas de un ventilador de condensación. Sirve para lanzar la condensación sobre el serpentín de refrigeración donde es evaporada.

Sling psychrometer A device with two thermometers, one a wet bulb and one a dry bulb, used for checking air conditions, wet-bulb and dry-bulb.

Sicrómetro con eslinga Dispositivo con dos termómetros, uno con una bombilla húmeda y otro con una bombilla seca, utilizados para revisar las condiciones del aire, de la temperatura y de la humedad.

Slinky loop A flattened, circular coil of plastic pipe resembling a Slinky, which is used as a ground loop.

Espiral Tubo plástico plano en forma helicoidal que se utiliza como circuito de tierra.

Slip The difference in the rated rpm of a motor and the actual operating rpm when under a load.

Deslizamiento Diferencia entre las rpm nominales de un motor y las rpm de functionamiento reales.

Slugging A term used to describe the condition when large amounts of liquid enter a pumping compressor cylinder.

Relleno Término utilizado para describir la condición donde grandes cantidades de líquido entran en el cilindro de un compresor de bombeo.

Smart recovery That start-up of a building air-conditioning or heating system whereby the system is started up earlier and allowed to run at a reduced capacity for the purpose of recording a low demand metering for the billing period.

Recuperación inteligente El encendido del sistema de aire acondicionado o de calefacción de un edificio en el cual el sistema se enciende más temprano y se deja correr a una capacidad reducida con el propósito de registrar una medición por demanda baja por el período de facturación.

Smoke test A test performed to determine the amount of unburned fuel in an oil burner flue-gas sample.

Prueba de humo Prueba llevada a cabo para determinar la cantidad de combustible no quemado en una muestra de gas de combustión que se obtiene de un quemador de aceite pesado.

Snap-disc An application of the bimetal. Two different metals fastened together in the form of a disc that provides a warping condition when heated. This also provides a snap action that is beneficial in

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

controls that start and stop current flow in electrical circuits.

Disco de acción rápida Aplicación del bimetal. Dos metales diferentes fijados entre sí en forma de un disco que provee un deformación al ser calentado. Esto provee también una acción rápida, ventajosa para reguladores que ponen en marcha y detienen el flujo de corriente en circuitos eléctricos.

Snap or detent action The quick opening of a control that is used to minimize the arc when making and breaking an electrical circuit.

Acción de encaje o de detén El abrir rápido de un control que se usa para minimizar el arco al abrir y cerrar un circuito eléctrico.

Soapstone A stone used sometimes in the manufacture of woodstoves.

Esteatita Piedra que se utiliza algunas veces en la fabricación de estufas de madera.

Software Computer programs written to give specific instructions to computers.

Software Programas de computadoras escritos para darles instrucciones específicas a las computadoras.

Solar collectors Components of a solar system designed to collect the heat from the sun, using air, a liquid, or refrigerant as the medium.

Colectores solares Componentes de un sistema solar diseñados para acumular el calor emitido por el sol, utilizando el aire, un líquido o un refrigerante como el medio.

Solar constant The rate of solar energy reaching the outer limits of the earth's atmosphere has been determined to be 429 Btu/ft^2/h on a surface perpendicular (90°) to the sun's rays.

Constante solar Se ha determinado que el índice de energía solar que alcanza los límites exteriores del atmósfera de la Tierra es de 429 Btu/pies^2/h, en una superficie perpendicular (90°) a los rayos solares.

Solar heat Heat from the sun's rays.

Calor solar Calor emitido por los rayos del sol.

Solar influence The heat that the sun imposes on a structure.

Influencia solar El calor que el sol impone en una estructura.

Solar radiant heat Solar-heated water or an antifreeze solution is piped through heating coils embedded in concrete in the floor or in plaster in ceilings or walls.

Calor de radiación solar El agua o líquido anticongelante calentado por energía solar se canaliza a través de serpentines de calefacción instalados en el hormigón del suelo o en el yeso de los techos o paredes.

Soldering Fastening two base metals together by using a third, filler metal that melts at a temperature below 800°F.

Soldadura La fijación entre sí de dos metales bases utilizando un tercer metal de relleno que se funde a una temperatura menor de 800°F (430°C).

Soldering gun Tool used primarily to solder electrical connections.

Pistola de soldadura Herramienta que se utiliza principalmente para soldar las conexiones eléctricas.

Solderless terminals Used to fasten stranded wire to various terminals or to connect two lengths of stranded wire together.

Terminales sin soldadura Se usan para fijar cable trenzado a varios terminales o para unir dos pedazos de cable.

Solder pot A device using a low-melting solder and an overload heater sized for the amperage of the motor it is protecting. The solder will melt, opening the circuit when there is an overload. It can be reset.

Olla para soldadura Dispositivo que utiliza una soldadura con un punto de fusión bajo y un calentador de sobrecarga diseñado para el amperaje del motor al que provee protección. La soldadura se fundirá, abriendo así el circuito cuando ocurra una sobrecarga. Puede ser reconectado.

Solenoid A coil of wire designed to carry an electrical current producing a magnetic field.

Solenoide Bobina de alambre diseñada para conducir una corriente eléctrica generando un campo magnético.

Solid Molecules of a solid are highly attracted to each other, forming a mass that exerts all of its weight downward.

Sólido Las moléculas de un sólido se atraen entre sí y forman una masa que ejerce todo su peso hacia abajo.

Space cooling and heating thermostat The device used to control the temperature of a space, such as a home thermostat that controls the temperature in a home or office.

Termostato de enfriamiento o calefacción de espacio Aparato usado para controlar la temperatura de un espacio, tal como un termostato de hogar que controla la temperatura en un hogar u oficina.

Specific gravity The weight of a substance compared to the weight of an equal volume of water.

Gravedad específica El peso de una sustancia comparada con el peso de un volumen igual de agua.

Specific heat The amount of heat required to raise the temperature of 1 lb of a substance 1°F.

Calor específico La cantidad de calor requerida para elevar la temperatura de una libra de una sustancia 1°F (–17°C).

Specific volume The volume occupied by 1 lb of a fluid.

Volumen específico Volumen que ocupa una libra de fluido.

Splash lubrication system A system of furnishing lubrication to a compressor by agitating the oil.

Sistema de lubrificación por salpicadura Método de proveerle lubrificación a un compresor agitando el aceite.

Splash method A method of water dropping from a higher level in a cooling tower and splashing on slats with air passing through for more efficient evaporation.

Método de salpicaduras Método dé dejar caer agua desde un nivel más alto en una torre de refrigeración y salpicándola en listones, mientras el aire pasa a través de los mismos con el propósito de lograr una evaporación más eficaz.

Split-phase motor A motor with run and start windings.

Motor de fase separada Motor con devandos de functionamiento y de arranque.

Split suction When the common suction line of a parallel compressor system has been valved in such a way as to provide for multiple temperature applications in one refrigeration package.

Succión dividida Cuando la línea común de succión de un sistema de compresor paralelo ha sido dividida de tal manera que provee para aplicaciones de múltiples temperaturas en un empaque de refrigeración.

Split system A refrigeration or air-conditioning system that has the condensing unit remote from the indoor (evaporator) coil.

Sistema separado Sistema de refrigeración o de acondicionamiento de aire cuya unidad de condensación se encuentra en un sitio alejado de la bobina interior del evaporador.

Spray pond A pond with spray heads used for cooling water in water-cooled air-conditioning or refrigeration systems.

Tanque de rociado Tanque con una cabeza rociadora utilizada para enfriar el agua en sistemas de acondicionamiento de aire o de refrigeración enfriados por agua.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Spring-loaded relief valve A fluid (refrigerant, air, water, or steam) relief valve that can function more than one time because a spring returns the valve to a seat.

Válvula de alivio de resorte Una válvula de alivio de fluido (refrigerante, aire, agua o vapor de agua) que puede funcionar más de una vez porque el resorte regresa la válvula a su asiento.

Squirrel cage blower A cylindrically shaped fan assembly used to move air.

Abanico con jaula de ardilla Conjunto cilíndrico de abanico utilizado para mover el aire.

Squirrel cage rotor Describes the construction of a motor rotor.

Rotor de jaula de ardilla Describe la construcción del rotor de un motor.

SSE An acronym for (steady state efficiency).

SSE Acrónimo de "eficiencia en estado estable".

Stack draft Draft taken in the vent stack between the combustion device and the draft diverter.

Corriente de ventilación Corriente de aire que pasa a través del conducto de ventilación, entre el dispositivo de combustión y el deflector de corriente.

Stack switch A safety device placed in the flue of an oil furnace that proves combustion within a time frame.

Interruptor de chimenea Un aparato de seguridad que se coloca en la chimenea de un calefactor de aceite para comprueba combustión dentro de un período de tiempo.

Stack temperature A combustion appliance's flue gas temperature measured before the introduction of dilution air, which means before the draft diverter or draft hood of the combustion appliance if one is used.

Temperatura de ventilación Temperatura del gas de combustión de un calefactor, medida antes de la introducción de aire de dilución, es decir, antes de utilizar el deflector de corriente o la campana de corriente del equipo de combustión.

Stamped evaporator An evaporator that has stamped refrigerant passages in sheet steel or aluminum.

Evaporador estampado Un evaporador que tiene pasajes para el refrigerante estampados en lata o aluminio.

Standard atmosphere or standard conditions Air at sea level at 70°F when the atmosphere's pressure is 14.696 psia (29.92 in. Hg). Air at this condition has a volume of 13.33 ft^3/lb.

Atmósfera estándar o condiciones estándares El aire al nivel del mar a una temperatura de 70°F (15°C) cuando la presión de la atmósfera es 14.696 psia (29.92 pulgadas Hg). Bajo esta condición, el aire tiene un volumen de 13.33 ft^3/lb (pies^3/ libras).

Standing pilot Pilot flame that remains burning continuously.

Piloto constante Llama piloto que se quema de manera continua.

Start capacitor A capacitor used to help an electric motor start.

Capacitador de arranque Capacitador utilizado para ayudar en el arranque de un motor eléctrico.

Starting relay An electrical relay used to disconnect the start capacitor and/or start winding in a hermetic compressor.

Relé de arranque Relé eléctrico utilizado para desconectar el capacitador y/o el devanado de arranque en un compresor hermético.

Starting winding The winding in a motor used primarily to give the motor extra starting torque.

Devanado de arranque Devanado en un motor utilizado principalmente para proveerle al motor mayor para el arranque.

Starved coil The condition in an evaporator when the metering device is not feeding enough refrigerant to the evaporator.

Bobina estrangulada Condición que ocurre en un evaporador cuando el dispositivo de medida no le suministra suficiente refrigerante al evaporador.

Static pressure The bursting pressure or outward force in a duct system.

Presión estática La presión de estallido o la fuerza hacia fuera en un sistema de conductos.

Stator The component in a motor that contains the windings: it does not turn.

Estátor Componente en un motor que contiene los devanados y que no gira.

Steady-state condition A stabilized condition of a piece of heating or cooling equipment where not much change is taking place.

Condición de régimen estable Condición estabilizada de un dispositivo de calefacción o de refrigeración en el cual no hay muchos cambios.

Steady-state efficiency Refers to combustion efficiency when the flue gas temperature (stack temperature) has stabilized and the flue gas samples reach equilibrium.

Eficiencia en estado estable Se refiere a la eficiencia de la combustión cuando la temperatura del gas de combustión (temperatura de ventilación) está estable y las muestras de gas de combustión llegan a un equilibrio.

Steam The vapor state of water.

Vapor Estado de vapor del agua.

Step motor An electric motor that moves with very small increments or "steps," usually in either direction, and is usually controlled by a microprocessor with input and output controlling devices.

Motor a pasos Un motor eléctrico que se mueve en incrementos muy pequeños o "pasos", generalmente en cualquier dirección, y generalmente son controlados por un microprocesador de aparatos de control con entradas y salidas.

Strainer A fine-mesh device that allows fluid flow and holds back solid particles.

Colador Dispositivo de malla fina que permite el flujo de fluido a través de él y atrapa partículas sólidas.

Stratification The condition where a fluid appears in layers.

Estratificación Condición que ocurre cuando un fluido aparece en capas.

Stratosphere An atmospheric level that is located from 7 to 30 miles above the earth. Good ozone is found in the stratosphere.

Estratosfera Capa del atmósfera que se encuentra a una altura entre 11 y 48 kilómetros encima de la Tierra. Contiene una buena capa de ozono.

Stress crack A crack in piping or other component caused by age or abnormal conditions such as vibration.

Grieta por tensión Grieta que aparece en una tubería u otro componente ocasionada por envejecimiento o condiciones anormales, como por ejemplo vibración.

Subbase The part of a space temperature thermostat that is mounted on the wall and to which the interconnecting wiring is attached.

Subbase Pieza de un termóstato que mide la temperatura de un espacio que se monta sobre la pared y a la que se fijan los conductores eléctricos interconectados.

Subcooled The temperature of a liquid when it is cooled below its condensing temperature.

Subenfriado La temperatura de un líquido cuando se enfría a una temperatura menor que su temperatura de condensación.

Subcritical cycle Refrigeration cycles that take place above the refrigerants triple point, and below the refrigerant's critical point.

Ciclo subcrítico Ciclos de refrigeración que se producen por encima del punto triple del refrigerante y por debajo de su punto crítico.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Sublimation When a substance changes from the solid state to the vapor state without going through the liquid state.

Sublimación Cuando una sustancia cambia de sólido a vapor sin covertirse primero en líquido.

Suction gas The refrigerant vapor in an operating refrigeration system found in the tubing from the evaporator to the compressor and in the compressor shell.

Gas de aspiración El vapor del refrigerante en un sistema de refrigeración en funcionamiento presente en la tubería que va del evaporador al compresor y en la coraza del compresor.

Suction line The pipe that carries the heat-laden refrigerant gas from the evaporator to the compressor.

Conducto de aspiración Tubo que conduce el gas de refrigerante lleno de calor del evaporador al compresor.

Suction-line accumulator A reservoir in a refrigeration system suction line that protects the compressor from liquid floodback.

Acumulador de la línea de succión Un estanque en la línea de succión de un sistema de refrigeración que protege al compresor de una inundación de líquido.

Suction pressure The pressure created by the boiling refrigerant on the evaporator or low-pressure side of the system.

Presión de succión La presión creada por el refrigerante hirviendo en el evaporador o en el lado de baja presión del sistema.

Suction service valve A manually operated valve with front and back seats located at the compressor.

Válvula de aspiración para servicio Válvula accionada manualmente que tiene asientos delanteros y traseros ubicados en el compresor.

Suction valve The valve at the compressor cylinder that allows refrigerant from the evaporator to enter the compressor cylinder and prevents it from being pumped back out to the suction line.

Válvula de succión La válvula en el cilindro de un compresor que permite que el refrigerante del evaporador entre al cilindro del compresor y evita que se bombee nuevamente a la línea de succión.

Suction-valve-lift unloading The suction valve in a reciprocating compressor cylinder is lifted, causing that cylinder to stop pumping.

Descarga por levantamiento de la válvula de aspiración La válvula de aspiración en el cilindro de un compresor alternativo se levanta, provocando que el cilindro deje de bombear.

Sulfur dioxide A combustion pollutant that causes eye, nose, and respiratory tract irritation and possibly breathing problems.

Bióxido de azufre Un contaminante por combustión que causa irritación en los ojos, la nariz y las vías respiratorias, y posiblemente problemas respiratorios.

Sump A reservoir at the bottom of a cooling tower to collect the water that has passed through the tower.

Sumidero Tanque que se encuentra en el fondo de una torre de refrigeración para acumular el agua que ha pasado a través de la torre.

Supercritical region A region above the critical point of the refrigerant. No liquid refrigerant can be produced above a refrigerant's critical point.

Región supercrítica Región por encima del punto crítico del refrigerante. Ningún refrigerante líquido puede producirse por encima de su punto crítico.

Superheat The temperature of vapor refrigerant above its saturation (change-of-state) temperature.

Sobrecalor Temperatura del refrigerante de vapor mayor que su temperatura de cambio de estado de saturación.

Surge When the head pressure becomes too great or the evaporator pressure too low, refrigerant will flow from the high- to the low-pressure side of a centrifugal compressor system, making a loud sound.

Movimiento repentino Cuando la presión en la cabeza aumenta demasiado o la presión en el evaporador es demasiado baja, el refrigerante fluye del lado de alta presión al lado de baja presión de un sistema de compresor centrífugo. Este movimiento produce un sonido fuerte.

Surge-type receiver A receiver that preserve the liquid subcooling made in the condenser during the cooler ambient months when free subcooling is available. A solenoid operated diverting valve is opened and the subcooled liquid coming from the condenser's bottom is closed off to the receiver.

Depósito de reflujo Depósito que puede almacenar el líquido refrigerante subenfriado durante los meses más frescos, cuando puede utilizarse el subenfriado libre. Se abre una válvula de deflección operada por solenoide y el líquido subenfriado que proviene del fondo del condensador se desvía hacia el depósito.

Sustainability Term used to describe our ability, as humans, to exist, without jeopardizing the ability of future generations to do the same.

Sostenibilidad término utilizado para describir nuestra capacidad, como seres humanos, existiendo, sin comprometer la capacidad de las futuras generaciones para hacer lo mismo.

Sustainable design Meets the needs of the present without compromising the ability of future generations to meet their own needs.

Diseño sustentable Se adecua a las necesidades actuales sin perjuicio de que las generaciones futuras tengan la posibilidad de cubrir sus propias necesidades.

Swaged joint The joining of two pieces of copper tubing by expanding or stretching the end of one piece of tubing to fit over the other piece.

Junta estampada La conexión de dos piezas de tubería de cobre dilatando o alargando el extremo de una pieza de tubería para ajustarla sobre otra.

Swaging See Swaged joint.

Estampar Véase Junta estampada.

Swaging tool A tool used to enlarge a piece of tubing for a solder or braze connection.

Herramienta de estampado Herramienta utilizada para agrandar una pieza de tubería a utilizarse en una conexión soldada o broncesoldada.

Swamp cooler A slang term used to describe an evaporative cooler.

Nevera pantanosa Término del argot utilizado para describir una nevera de evaporación.

Sweating A word used to describe moisture collection on a line or coil that is operating below the dew point temperature of the air.

Exudación Término utilizado para describir la acumulación de humedad en un conducto o una bobina que está funcionando a una temperatura menor que la del punto de rocío de aire.

Switch frequency The speed at which the variable frequency drive's power device switches the waveform's positive and negative halves on and off is referred to as the switch frequency or carrier frequency.

Frecuencia de intercambio La velocidad a la que el dispositivo de alimentación de frecuencia variable intercambia las mitades positiva y negativa de una onda se denomina frecuencia de intercambio o frecuencia de onda portadora.

Synthetic refrigerants Man-made refrigerants.

Refrigerantes sintéticos Refrigerantes fabricados por el hombre.

System charge The refrigerant in a system, both liquid and vapor. The correct charge is a balance where the system will give the most efficiency.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Carga del sistema El refrigerante en un sistema, tanto líquido y vapor. La carga correcta es un balance donde el sistema dará la mayor eficiencia.

System lag The temperature drop of the controlled space below the set point of the thermostat.

Retardo del sistema Caída de temperatura de un espacio controlado, por debajo del nivel programado en el termostato.

System overshoot The temperature rise of the controlled space above the set point of the thermostat.

Exceso del sistema Subida de la temperatura de un espacio controlado, por encima del nivel programado en el termostato.

System pressure-regulating valve (SPR valve) A valve located between the compressor and receiver of a refrigeration system. This valve controls the amount of liquid refrigerant that bypasses a parallel liquid receiver.

Válvula reguladora de presión del sistema (SPR en inglés) Válvula situada entre el compresor y el destino de un sistema de refrigeración. Esta válvula controla la cantidad de refrigerante que no entra en un receptor de líquido paralelo.

System superheat The total amount of superheat picked up in the evaporator and the suction line. Can be calculated as the compressor inlet temperature minus the evapoartor saturation temperature.

Recalentamiento del sistema la cantidad total de recalentamiento recogido en el evaporador y la tubería de aspiración. Puede calcularse como la temperatura de admisión del compresor evapoartor menos la temperatura de saturación.

T

Tank A closed vessel used to contain a fluid.

Tanque Desposito cerrado utilizado para contener un fluido.

Tap A tool used to cut internal threads in a fastener or fitting.

Macho de roscar Herramienta utilizada para cortar filetes internos en un aparto fijador o en un accesorio.

Tare weight The tare weight of a cylinder is the weight the cylinder would weigh if it were empty.

Tara La tara de un cilindro es el peso que el mismo tendría si estuviese vacío.

Technician A person who performs maintenance, service, testing, or repair to air-conditioning or refrigeration equipment. Note: the EPA defines this person as someone who could reasonably be expected to release CFCs or HCFCs into the atmosphere.

Técnicos Una persona que lleva a cabo mantenimiento, servicio o reparaciones a equipos de aire acondicionado o refrigeración. Nota: Esta persona, según defunido por la EPA, es una persona del cual razonablemente se estaría esparado que libere CFC (clorofluorocarbonos) a la atmósfera.

Temperature A word used to describe the level of heat or molecular activity, expressed in Fahrenheit, Rankine, Celsius, or Kelvin units.

Temperatura Término utilizado para describir el nivel de calor o actividad molecular, expresado en unidades Fahrenheit, Rankine, Celsio o Kelvin.

Temperature difference (TD) The difference between the inlet temperature and outlet temperature of a heat exchanger. For example, an evaporator may have a 20°F TD: 75°F air in and 55°F air out.

Diferencia entre temperaturas La diferencia existente entre la temperatura de entrada y la de salida de un intercambiador de calor. Por ejemplo, en un evaporador puede existir una diferencia de 20°F entre la temperatura de entrada y la de salida: 75°F (la toma del aire) y 55°F (la evacuacíon del aire).

Temperature glide When a refrigerant blend has different temperatures when it evaporates and condenses at a single given pressure.

Variación de temperatura Una mezcla de refrigerantes tiene varias temperaturas a las cuales se produce una evaporación a una presión determinada.

Temperature-measuring instruments Devices that accurately measure the level of temperature.

Instrumentos que miden temperatura Aparatos que miden el nivel de la temperatura con precisión.

Temperature/pressure relationship This refers to the temperature/pressure relationship of a liquid and vapor in a closed container. If the temperature increases, the pressure will also increase. If the temperature is lowered, the pressure will decrease.

Relación entre temperatura y presión Se refiere a la relación entre la presión y la temperatura de un líquido y un vapor en un recipiente cerrado. Si la temperatura aumenta, la presión también aumentará. Si la temperatura baja, habrá una caída de presión.

Temperature reference points Various points that may be used to calibrate a temperature-measuring device, such as boiling or freezing water.

Puntos de referencia de temperatura Varios puntos que pueden usarse para calibrar un aparato que mide temperatura, tales como agua congelada o hirvienda.

Temperature-sensing elements Various devices in a system that are used to detect temperature.

Elementos que detectan temperatura Varios aparatos en un sistema que se usan para detectar temperatura.

Temperature swing The temperature difference between the low and high temperatures of the controlled space.

Oscilación de temperatura Diferencia existente entre las temperaturas altas y bajas de un espacio controlado.

Terminal unit The piece of equipment that facilitates the transfer of heat from the appliance to the heated space. A radiator is an example of a terminal unit.

Unidad de terminal la pieza de equipo que facilita la transferencia de calor del aparato al espacio calentado. Un radiador es un ejemplo de una unidad terminal.

Terminal venting When one or more terminal pins blows out of its ceramic fusite terminal, allowing a pressurized refrigerant and oil spray to escape into the atmosphere.

Ventilación de terminal Cuando uno o más terminales pins sale de su cerámica fusite terminal, permitiendo un spray de refrigerante y de aceite presurizado para escapar a la atmósfera.

Testing, Adjusting and Balancing Bureau (TABB) A certification bureau for individuals involved in working with ventilation.

Agencia de Prueba, Ajuste y Balanceo (TABB en inglés) Agencia de certificación para los individuos involucrados en el trabajo de ventilación.

Test light A lightbulb arrangement used to prove the presence of electrical power in a circuit.

Luz de prueba Arreglo de bombillas utilizado para probar la presencia de fuerza eléctrica en un circuito.

Therm Quantity of heat, 100,000 Btu.

Therm Cantidad de calor, mil unidades térmicas inglesas.

Thermal boundary Insulation and air barrier that surrounds a conditioned space.

Límite térmico Aislación y barrera de aire que rodea a un espacio acondicionado.

Thermal break A gasket material made of a poor thermally conductive material, installed between two conductive materials that combats and lessens thermal bridging.

Aislante térmico Junta de un material de muy baja conductividad térmica, instalada entre dos materiales conductores, que combate y disminuye el calentamiento por puente térmico.

Thermal bridging Thermal bridging is rapid heat being conducted through the structure's shell by materials in direct contact with one another that are very thermally conductive.

Calentamiento por puente térmico Es la conducción rápida del calor a través de la coraza de la estructura, de materiales de muy alta conductividad térmica que están en contacto directo.

Thermal bypass A break in the thermal boundary where air can either infiltrate or exfiltrates.

Desvío térmico Ruptura en el límite térmico, a través de la cual el aire puede infiltrarse o exfiltrarse.

Thermistor A semiconductor electronic device that changes resistance with a change in temperature.

Termistor Dispositivo eléctrico semiconductor que cambia su resistencia cuando se produce un cambio en temperatura.

Thermocouple A device made of two unlike metals that generates electricity when there is a difference in temperature from one end to the other. Thermocouples have a hot and cold junction.

Thermopar Dispositivo hecho de dos metales distintos que genera electricidad cuando hay una diferencia en temperatura de un extremo al otro. Los termopares tienen un empalme caliente y uno frío.

Thermometer An instrument used to detect differences in the level of heat.

Termómetro Instrumento utilizado para detectar diferencias en el nivel de calor.

Thermopile A group of thermocouples connected in series to increase voltage output.

Pila termoeléctrica Grupo de termopares conectados en serie para aumentar la salida de tensión.

Thermostat A device that senses temperature change and changes some dimension or condition within to control an operating device.

Termostato Dispositivo que advierte un cambio en temperatura y cambia alguna dimensión o condición dentro de sí para regular un dispositivo en funcionamiento.

Thermostatic expansion valve (TXV) A valve used in refrigeration systems to control the superheat in an evaporator by metering the correct refrigerant flow to the evaporator. Also often abbrevaiated TEV.

Válvula de gobierno termostático para expansión Válvula utilizada en sistemas de refrigeración para regular el sobrecalor en un evaporador midiendo el flujo correcto de refrigerante al evaporador. También puede denominarse con la abreviatura "TEV".

Three-phase power A type of power supply usually used for operating heavy loads. It consists of three sine waves that are out of phase by 120° with each other.

Potencia trifásica Tipo de fuente de alimentación normalmente utilizada en el funcionamiento de cargas pesadas. Consiste de tres ondas sinusoidales que no están en fase la una con la otra por 120°.

Throttling Creating a planned or regulated restriction in a fluid line for the purpose of controlling fluid flow.

Estrangulamiento Que ocasiona una restricción intencional o programada en un conducto de fluido, a fin de controlar el flujo del fluido.

Thrust surface A term that usually applies to bearings that have a pushing pressure to the side and that therefore need an additional surface to absorb the push. Most motor shifts cradle in their bearings because they operate in a horizontal mode, like holding a stick in the palm of your hand. When a shaft is turned to the vertical mode, a thrust surface must support the weight of the shaft along with the load the shaft may impose on the thrust surface. The action of a vertical fan shaft that pushes air up is actually pushing the shaft downward.

Superficie de empuje Un término que generalmente se aplica a cojinetes que sostienen una presión de empuje a un lado y que necesitan una superficie adicional para absorber este empuje. La mayoría de los ejes de motor están al abrigo en sus cojinetes, porque funcionen en una modalidad horizontal, como cuando uno sostiene una vara en la mano. Cuando un eje está sintonizado a la modalidad vertical, una superficie de empuje debe sostener el peso del eje junto con la carga que el eje puede imponer sobre la superficie de empuje. La moción de un eje vertical de un ventilador que empuja aire hacia arriba está en realidad empujando el eje hacia abajo.

Time delay A device that prevents a component from starting for a prescribed time. For example, many systems start the fans and use a time delay relay to start the compressor at a later time to prevent too much inrush current.

Retraso de tiempo Un aparato que evita que un componente se encienda por un período prescrito de tiempo. Por ejemplo, muchos sistemas encienden los ventiladores y, usando un relé de retraso, encienden el compresor un tiempo después para evitar mucha corriente interna.

Timers Clock-operated devices used to time various sequences of events in circuits.

Temporizadores Dispositivos accionados por un reloj utilizados para medir el tiempo de varias secuencias de eventos en circuitos.

Toggle bolt Provides a secure anchoring in hollow tiles, building block, plaster over lath, and gypsum board. The toggle folds and can be inserted through a hole, where it opens.

Tornillo de fiador Proveen un anclaje seguro en losetas huecas, bloques de construcción, yeso sobre listón y tablón de yeso. El fiador se dobla y puede insertarse a través de un roto y después se abre.

Ton of refrigeration The amount of heat required to melt a ton (2000 lb) of ice at 32°F in 24 hours, 288,000 Btu/24 h, 12000 Btu/h, or 200 Btu/min.

Tonelada de refrigeración Cantidad de calor necesario para fundir una tonelada (2.000 libras) de hielo a 32°F (0°C en 24 horas), 288.000 Btu/24 h 12.000 Btu/h o 200 Btu/min.

Torque The twisting force often applied to the starting power of a motor.

Par de torsión Fuerza de torsión aplicada con frecuencia a la fuerza de arranque de un motor.

Torque wrench A wrench used to apply a prescribed amount of torque or tightening to a connector.

Llave de torsión Llave utilizada para aplicar una cantidad específica de torsión o de apriete a un conector.

Total equivalent warming impact (TEWI) A global warming index that takes into account both the direct effects of chemicals emitted into the atmosphere and the indirect effects caused by system inefficiencies.

Impacto de calentamiento equivalente total (TEWI en inglés) Índice de calentamiento de la Tierra que tiene en cuenta los efectos directos de los productos químicos emitidos en la atmósfera, y los efectos indirectos causados por la ineficacia de un sistema.

Total heat The total amount of sensible heat and latent heat contained in a substance from a reference point. Also referred to as enthalpy.

Calor total Cantidad total de calor sensible o de calor latente presente en una sustancia desde un punto de referencia. Se lo denomina también entalpía.

Total pressure The sum of the velocity and the static pressure in an air duct system.

Presión total La suma de la velocidad y la presión estática en un sistema de conducto de aire.

Tower approach The temperature difference between the water leaving the tower and the wet bulb temperature of the air entering the cooling tower.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Enfoque de torre Diferencia de temperatura entre el agua que sale de la torre y la temperatura a bulbo húmedo del aire que entra a la torre de enfriamiento.

Tower range The temperature difference between the entering and leaving water of the cooling tower is referred to as the tower range.

Rango de torre La diferencia de temperatura entre el agua que entra y el agua que sale de la torre se denomina rango de torre.

Trace gas A small amount of refrigerant introduced into an empty system for electronic leak detection or as a holding charge, which is then backed by nitrogen to build pressure. CFCs cannot be used as trace gasses.

Gas detector Pequeña cantidad de refrigerante que se introduce en un sistema vacío para la detección de pérdidas o como carga de sustento, la cual se completa con nitrógeno para crear presión. Los CFC no pueden utilizarse como gases detectores.

Transcritical cycle Thermodynamic refrigeration processes that span above the subcritical region and into the supercritical region of the pressure/enthalpy diagram.

Ciclo transcrítico Procesos de refrigeración termodinámicos que tienen lugar por encima de la región subcrítica y en la región supercrítica del diagrama presión/entalpía.

Transformer A coil of wire wrapped around an iron core that induces a current to another coil of wire wrapped around the same iron core. Note: A transformer can have an air core.

Transformador Bobina de alambre devanado alrededor de un núcleo de hierro que induce una corriente a otra bobina de alambre devanado alrededor del mismo núcleo de hierro. Nota: un transformador puede tener un núcleo de aire.

Transistor A semiconductor often used as a switch or amplifier.

Transistor Semiconductor que suele utilizarse como conmutador o amplificador.

TRIAC A semiconductor switching device.

TRIAC Dispositivo de conmutación para semiconductores.

Triple point The triple point is where a refrigerant, like CO_2, can exist as all three phases (vapor, liquid, and solid) simultaneously in equilibrium.

Punto triple El punto triple es aquel en el que un refrigerante, como el CO_2, puede existir en sus tres fases (vapor, líquido, y sólido) simultáneamente y en equilibrio.

Troposphere The lower atmospheric level that extends upward from ground level to about 7 miles. Global warming takes place in the troposphere.

Troposfera Capa más baja de la del atmósfera que va desde el nivel del suelo hasta una altura de aproximadamente 11 kilómetros. El efecto del calentamiento de la tierra se produce en la troposfera.

Tube-within-a-tube coil A coil used for heat transfer that has a pipe in a pipe and is fastened together so that the outer tube becomes one circuit and the inner tube another.

Bobina de tubo dentro de un tubo Bobina utilizada en la transferencia de calor que tiene un tubo dentro de otro y se sujeta de manera que el tubo exterior se convierte en un circuito y el tubo interior en otro circuito.

Tubing Pipe with a thin wall used to carry fluids.

Tubería Tubo que tiene una pared delgada utilizada para conducir fluidos.

Twinning Two furnaces connected side by side and sharing a common ducting system.

Aparear Dos calefactores conectados lado a lado o que comparten un sistema de conductos común.

Two-pole, split-phase motor This motor runs at 3600 rpm when not loaded and at about 3450 rpm when loaded. A four-pole motor runs at about 1800 rpm not loaded and at about 1725 fully loaded.

Motor de dos polos, de fase dividida Este motor corre a 3.600 revoluciones por minuto cuando no está cargado y cuando está cargado corre a 3.450 revoluciones por minuto. Un motor de 4 polos corre a 1.800 revoluciones por minuto si no está cargado y alrededor de 1.725 revoluciones con carga completa.

Two-speed compressor motor Can be a four-pole motor that can be connected as a two-pole motor for high speed (3450 rpm) and connected as a four-pole motor for running at 1725 rpm for low speed. This is accomplished with relays outside the compressor.

Motor de compresor de dos velocidades Puede ser un motor de 4 polos que puede conectarse como un motor de 2 polos para velocidades altas (3.450 revoluciones por minuto) y conectarse como un motor de 4 polos para correr a 1.725 revoluciones por minuto para velocidades bajas. Esto se hace con relés fuera del compresor.

Two-temperature valve A valve used in systems with multiple evaporators to control the evaporator pressures and maintain different temperatures in each evaporator. Sometimes called a ***holdback valve***.

Válvula de dos temperaturas Válvula utilizada en sistemas con evaporadores múltiples para regular las presiones de los evaporadores y mantener temperaturas diferentes en cada uno de ellos. Conocida también como ***válvula de retención***.

U

Ultrasound leak detector Detectors that use sound from escaping refrigerant to detect leaks.

Detector de escapes ultrasónico Detectores que usan sonido del refrigerante que está escapando para detectar escapes.

Ultraviolet Light waves that can only be seen under a special lamp.

Ultravioleta Ondas de luz que pueden observarse solamente utilizando una lámpara especial.

Ultraviolet light Light frequency between 200 and 400 nanometers.

Luz ultravioleta Luz con frecuencia entre 200 y 400 nanómetros.

Unconditioned space Areas of a structure or residence that are not heated or cooled.

Espacio no acondicionado Áreas de una estructura o residencia que no están calefaccionadas ni enfriadas.

Uneven parallel system Parallel compressors of unequal sizes mounted on a steel rack and controlled by a micro processor.

Sistema paralelo heterogéneo Compresores de capacidades distintas montados en paralelo en un bastidor de acero y controlados mediante microprocesador.

Unintentionally conditioned space These spaces are usually warmed by waste heat and include boiler rooms or furnace rooms.

Espacio acondicionado no intencionalmente Estos espacios se calientan generalmente debido al calor de desecho e incluyen a las salas donde se encuentran estufas o calderas.

Updraft A draft that flows upward.

Corriente hacia arriba Corriente que fluye de abajo hacia arriba.

Upflow furnace This furnace takes in air from the bottom or from sides near the bottom and discharges hot air out the top.

Horno de flujo ascendente La entrada del aire en este tipo de horno se hace desde abajo o en los laterales, cerca del suelo. La evacuación se realiza en la parte superior.

Upper exposure limit (UEL) The maximum concentration of a chemical that an individual can be exposed to for a short period of time, usually 10 or 15 minutes.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Límite de exposición superiores (UEL) La concentración máxima de un producto químico que una persona puede estar expuesta a por un corto período de tiempo, generalmente 10 ó 15 minutos.

Urethane foam A foam that can be applied between two walls for insulation.

Espuma de uretano Espuma que puede aplicarse entre dos paredes para crear un aislamiento.

U-Tube mercury manometer A U-tube containing mercury, which indicates the level of vacuum while evacuating a refrigeration system.

Manómetro de mercurio de tubo en U Tubo en U que contiene mercurio y que indica el nivel del vacío mientras vacía un sistema de refrigeración.

U-Tube water manometer Indicates natural gas and propane gas pressures. It is usually calibrated in inches of water.

Manómetro de agua de tubo en U Indica las presiones del gas natural y del propano. Se calibra normalmente en pulgadas de agua.

U-Value Indicates the thermal conductivity of a material. This is the inverse of a material's R-value.

Índice U Indica la conductividad térmica de un material. Es la inversa del índice R del material.

V

Vacuum The pressure range between the earth's atmospheric pressure and no pressure, normally expressed in inches of mercury (in. Hg) vacuum.

Vacío Margen de presión entre la presión de la atmósfera de la Tierra y cero presión, por lo general expresado en pulgadas de mercurio (pulgadas Hg) en vacío.

Vacuum gauge An instrument that measures the vacuum when evacuating a refrigeration, air-conditioning, or heat pump system.

Vacuómetro Instrumento que se utiliza para medir el vacío al vaciar un sistema de refrigeración, de aire acondicionado, o de bomba de calor.

Vacuum pump A pump used to remove some fluids such as air and moisture from a system at a pressure below the earth's atmosphere.

Bomba de vacío Bomba utilizada para remover algunos fluidos, como por ejemplo aire y humedad de un sistema a una presión menor que la de la atmósfera de la Tierra.

Valve A device used to control fluid flow.

Válvula Dispositivo utilizado para regular el flujo de fluido.

Valve plate A plate of steel bolted between the head and the body of a compressor that contains the suction and discharge reed or flapper valves.

Placa de válvula Placa de acero empernado entre la cabeza y el cuerpo de un compresor que contiene la lámina de aspiración y de descarga o las chapaletas.

Valve seat That part of a valve that is usually stationary. The movable part comes in contact with the valve seat to stop the flow of fluids.

Asiento de la válvula Pieza de una válvula que es normalmente fija. La pieza móvil entra en contacto con el asiento de la válvula para detener el flujo de fluidos.

Valve stem depressor A service tool used to access pressure at a Schrader valve connection.

Depresor de vástago de válvula Una herramienta de servicio que se usa para acceder la presión en una conexión de válvula Schrader.

Vapor The gaseous state of a substance.

Vapor Estado gaseoso de una sustancia.

Vapor barrier A thin film used in construction to keep moisture from migrating through building materials.

Película impermeable Película delgada utilizada en construcciones para evitar que la humedad penetre a través de los materiales de construcción.

Vapor charge bulb A charge in a thermostatic expansion valve bulb that boils to a complete vapor. When this point is reached, an increase in temperature will not produce an increase in pressure.

Válvula para la carga de vapor Carga en la bombilla de una válvula de expansión termostática que hierve a un vapor completo. Al llegar a este punto, un aumento en temperatura no produce un aumento en presión.

Vaporization The changing of a liquid to a gas or vapor.

Vaporización Cuando un líquido se convierte en gas o vapor.

Vapor lock A condition where vapor is trapped in a liquid line and impedes liquid flow.

Bolsa de vapor Condición que ocurre cuando el vapor queda atrapado en el conducto de líquido e impide el flujo de líquido.

Vapor pressure The pressure exerted on top of a saturated liquid.

Presión del vapor Presión que se ejerce en la superficie de un líquido saturado.

Vapor pump Another term for compressor.

Bomba de vapor Otro término para compresor.

Vapor refrigerant charging Adding refrigerant to a system by allowing vapor to move out of the vapor space of a refrigerant cylinder and into the low-pressure side of the refrigeration system.

Carga del refrigerante de vapor Agregarle refrigerante a un sistema permitiendo que el vapor salga del espacio de vapor de un cilindro de refrigerante y que entre en el lado de baja presión del sistema de refrigeración.

Variable Air Volume, VAV The control strategy that varies the volume of air that is delivered to an area in the conditioned space depending on the airflow requirements for that area.

Volumen de aire variable, VAV Estrategia de control mediante la que se varía el volumen de aire que se dirige hacia un área en el espacio acondicionado, dependiendo de las necesidades de flujo de aire para dicha área.

Variable-frequency drive (VFD) An electrical device that varies the frequency (hertz) for the purpose of providing a variable speed.

Propulsión de frecuencia variable (VFD en inglés) Un aparato eléctrico que varía la frecuencia (hertz) con el propósito de proveer velocidad variable.

Variable pitch pulley A pulley whose diameter can be adjusted.

Polea de paso variable Polea cuyo diámetro puede ajustarse.

Variable Refrigerant Flow, VRF The control strategy that varies the volume of refrigerant that is delivered to an air handler based on the heating or cooling needs of the area being served by that air handler.

Flujo variable de refrigerante, VRF Estrategia de control mediante la que se varía el volumen de refrigerante que se dirige hacia una unidad de tratamiento de aire, basada en los requerimientos de enfriamiento o calefacción del área que acondiciona dicha unidad de tratamiento de aire.

Variable Refrigerant Volume, VRV See Variable Refrigerant Flow, VRF.

Volumen variable de refrigerante, VRV Ver Flujo variable de refrigerante, VRF.

Variable resistor A type of resistor where the resistance can be varied.

Resistor variable Tipo de resistor donde la resistencia puede variarse.

Variable-speed motor A motor that can be controlled, with an electronic system, to operate at more than one speed.

Motor de velocidad variable Un motor que puede controlarse, con un sistema electrónico, para operar a más de una velocidad.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

VAV See Variable Air Volume.

VAV Ver Volumen de aire variable.

V belt A belt that has a V-shaped contact surface and is used to drive compressors, fans, or pumps.

Correa en V Correa que tiene una superficie de contacto en forma de V y se utiliza para accionar compresores, abanicos o bombas.

Velocity The speed at which a substance passes a point.

Velocidad Rapidez a la que una sustancia sobrepasa un punto.

Velocity meter A meter used to detect the velocity of fluids, air, or water.

Velocimetro Instrumento utilizado para medir la velocidad de fluidos, aire, o agua.

Velocity pressure The pressure in a duct system that is created by the moving air. Velocity pressure is a function of the density of the air and its speed.

Velocidad de presión La presión en un sistema de conductos que es creado por el aire que se mueve. Presión de velocidad es una función de la densidad del aire y su velocidad.

Velometer An instrument used to measure the air velocity in a duct system.

Velómetro Instrumento utilizado para medir la velocidad del aire en un conducto.

Vent-free Certain gas stoves or gas fireplaces are not required to be vented; therefore, they are called "vent-free."

Sin ventilación Ciertas estufas de gas y chimeneas de gas no requieren una ventilación, por lo que se conocen como estufas "sin ventilación."

Ventilation The process of supplying and removing air by natural or mechanical means to and from a particular space.

Ventilación Proceso de suministrar y evacuar el aire de un espacio determinado, utilizando procesos naturales o mecánicos.

Venting products of combustion Venting flue gases that are generated from the burning process of fossil fuels.

Descargar productos de combustión Descargar los gases de la chimenea que se generan del proceso de combustión de los combustibles fósiles.

Venturi A smoothly tapered device used in fluid flow to increase the velocity of the fluid.

Venturi Un aparato que está ahusado lisamente y que se usa en el flujo de fluido para aumentar la velocidad del fluido.

Volt A unit of voltage.

Voltio unidad de voltaje o tensión.

Voltage The potential electrical difference for electron flow from one line to another in an electrical circuit.

Tensión Diferencia de potencial eléctrico del flujo de electrones de un conducto a otro en un circuito eléctrico.

Voltage feedback Voltage potential that travels through a power-consuming device when it is not energized.

Retroalimentación de voltaje El voltaje que viaja a través de un aparato de consumo de electricidad cuando no está energizado.

Volt-amperes Also referred to as VA. Used to represent the apparant power of a transformer. Calculated as the voltage multiplied by the currrent.

Voltios-amperios también conocido como "VA". Utilizado para representar la potencia aparente de un transformador. Calculado como el voltaje multiplicado por el corriente.

Voltmeter An instrument used for checking electrical potential.

Voltimetro Instrumento utilizado para revisar la potencia eléctrica.

Volt-ohm-milliammeter (VOM) A multimeter that measures voltage, resistance, and current in milliamperes.

Voltio-ohmio-miliamperimetro (VOM en inglés) Multímetro que mide tensión, resistencia, y corriente en miliamperios.

Volumetric efficiency The pumping efficiency of a compressor or vacuum pump that describes the pumping capacity in relationship to the actual volume of the pump.

Rendimiento volumétrico Rendimiento de bombeo de un compresor o de una bomba de vacío que describe la capacidad de bombeo con relación al volumen real de la bomba.

Vortexing A whirlpool action in the sump of a cooling tower.

Acción de vórtice Torbellino en el sumidero de una torre de refrigeración.

VRF See Variable Refrigerant Flow.

VRF Ver Flujo variable de refrigerante.

VRV See Variable Refrigerant Volume.

VRV Ver Volumen variable de refrigerante.

W

Walk-in cooler A large refrigerated space used for storage of refrigerated products.

Nevera con acceso al interior Espacio refrigerado grande utilizado para almacenar productos refrigerados.

Wastewater system A refrigeration system that uses water one time and then exhausts it to a waste system.

Sistema de aguas residuales Sistema de refrigeración que usa agua una vez y luego la vacía en el sistema de aguas residuales.

Water box A container or reservoir at the end of a chiller where water is introduced and contained.

Caja de agua Recipiente o depósito al extremo de un enfriador por donde entra y se retiene el agua.

Water capacity The water capacity of a cylinder is the weight of the cylinder if it were full of water. The water capacity (W.C.) of the cylinder is stamped on the outside of the cylinder and its units are in pounds.

Capacidad de agua La capacidad de agua de un cilindro es el peso de dicho cilindro si el mismo estuviese lleno de agua. La capacidad de agua (W.C.) del cilindro está marcada en su parte exterior y su unidad de medida está expresada en libras.

Water column (WC) The pressure it takes to push a column of water up vertically. One inch of water column is the amount of pressure it would take to push a column of water in a tube up one inch.

Columna de agua (WC en inglés) Presión necesaria para levantar una columna de agua verticalmente. Una pulgada de columna de agua es la cantidad de presión necesaria para levantar una columna de agua a una distancia de una pulgada en un tubo.

Water-cooled condenser A condenser used to reject heat from a refrigeration system into water.

Condensador enfriado por agua Condensador utilizado para dirigir el calor de un sistema de refrigeración al agua.

Water cooler A small refrigeration machine that is typically used to refrigerate water for drinking purposes.

Enfriador de agua Una máquina de refrigeración pequeña que típicamente se usa para refrigerar agua para beber.

Water hammer A loud pressure pulse that occurs when valves close fast.

Martillo de agua Impulso de presión fuerte que se produce cuando una válvula se cierra rápidamente.

Water loop These loops of plastic pipe are buried in the ground in a closed-loop geothermal heat pump system and contain a heat transfer fluid.

Circuito de agua Estos circuitos de tubos de plástico se encuentran enterrados en el suelo, en el caso de una bomba de calor geotérmica de circuito cerrado y contiene un líquido que transpaso lo caliente.

Water manometer A device that uses a column of water to measure low pressures in air or gas systems.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Manómetro de agua Un aparato que usa una columna de agua para medir bajas presiones en sistemas de aire o de gas.

Water pump Used to pump water or other fluids from one pressure level to another to promote water flow in piping systems. See Centrifugal pump.

Bomba de agua Bomba utilizada para bombear agua u otros fluidos de un nivel de presión a otro para mejorar el flujo de agua através de los sistemas de tubería. Véase Bomba centrífuga.

Water-regulating valve An operating control regulating the flow of water.

Válvula reguladora de agua Regulador de mando que controla el flujo de agua.

Watt (W) A unit of power applied to electron flow. One watt equals 3.414 Btu.

Watio (W en inglés) Unidad de potencia eléctrica aplicada al flujo de electrones. Un watio equivale a 3414 Btu.

Watt-hour The unit of power that takes into consideration the time of consumption. It is the equivalent of a 1-watt bulb burning for 1 hour.

Watio hora Unidad de potencia eléctrica que toma en cuenta la duración de consumo. Es el equivalente de una bombilla de 1 watio encendida por espacio de una hora.

Weatherization The process of improving the energy efficiency in a home or building which will have a direct effect on energy consumption and comfort within the home or building.

Acondicionamiento Proceso de optimización de la eficiencia energética en una vivienda o construcción que tendrá un impacto directo en el consumo de energía y la comodidad dentro de dicha vivienda o construcción.

Weep holes Holes that connect each cell in an ice machine's cell-type evaporator that allow air entering from the edges of the ice to travel along the entire ice slab to relieve the suction force and allow the ice to fall off of the evaporator.

Aberturas de exudación Aberturas que conectan cada célula en el evaporador de tipo celular de una hielera, que permiten que el aire que entra de los bordes del hielo viaja a lo largo de todo el pedazo de hielo para aliviar la fuerza de succión y permitir que el hielo se caiga del evaporador.

Weighing refrigerant The process of adding refrigerant to a system by weight.

Refrigerante de pesaje El proceso de adición de refrigerante a un sistema por peso.

Weight The force that matter (solid, liquid, or gas) applies to a supporting surface when it is at rest.

Peso La fuerza que la materia (sólido, líquido, o gas) en reposo aplica a una superficie de apoyo.

Welded hermetic compressor A compressor that is completely sealed by welding, versus a semi-hermetic compressor that is sealed by bolts and flanges.

Compresor hermético soldado Un compresor que está completamente sellado por soldadura, contrario a un compresor semi-hermético que está sellado con tornillos y bridas.

Wet-base boiler A boiler configuration where the water in the system is both above and below the combustion chamber.

Caldera de base mojada Una caldera configuración donde el agua en el sistema tanto por encima y por debajo de la cámara de combustión.

Wet-bulb depression The difference between the wet-bulb and the dry-bulb reading when readings are taken in air.

Depresión de bulbo mojado La diferencia entre la lectura de bulbo mojado y bulbo seco cuando las lecturas están tomadas en aire.

Wet-bulb temperature A wet-bulb temperature of air is used to evaluate the humidity in the air. It is obtained with a wet thermometer bulb to record the evaporation rate with an airstream passing over the bulb to help in evaporation.

Temperatura de una bombilla húmeda La temperatura de una bombilla húmeda se utiliza para evaluar la humedad presente en el aire. Se obtiene con la bombilla húmeda de un termómetro para registrar el margen de evaporación con un flujo de aire circulando sobre la bombilla para ayudar en evaporar el agua.

Wet compression Saturated refrigerant vapors being compressed by the compressor, which will turn into liquid refrigerant droplets when compressed.

Compresión mojada Vapores saturados de refrigerante que están siendo comprimidos por el compresor y que a su vez se convertirán en gotitas de refrigerantes al comprimirse.

Wet heat A heating system using steam or hot water as the heating medium.

Calor húmedo Sistema de calentamiento que utiliza vapor o agua caliente como medio de calentamiento.

Whipline Typically the smaller of two hoisting lines on a crane.

Línea auxiliar En general, la más corta de dos líneas de elevación de una grúa.

Winding thermostat A safety device used in electric motor windings to detect overtemperature conditions.

Termostato de bobina Un aparato de seguridad usado en un motor eléctrico para detectar condiciones de exceso de temperatura.

Window unit An air conditioner installed in a window that rejects the heat outside the structure.

Acondicionador de aire para la ventana Acondicionador de aire instalado en una ventana que desvía el calor proveniente del exterior de la estructura.

Wire connectors (screw-on) Used to connect two or more wires together.

Conectores de cables (de rosca) Se usan para conectar dos o más cables.

Work A force moving an object in the direction of the force. Work = Force × Distance.

Trabajo Fuerza que mueve un objeto en la dirección de la fuerza. Trabajo = Fuerza × Distancia.

Work hardening Term used to describe the strengthening of a metal by bending or deforming it.

Endurecimiento de trabajo término usado para describir el fortalecimiento de un metal por flexión o deformarlo.

WRT With reference to.

WRT En referencia a.

WYE transformer connection Typically furnishes 208 V and 115 V to a customer.

Conexión de transformador WYE Típicamente provee 208 voltios y 115 voltios a los consumidores.

Z

Zeotropic blend Two or more refrigerants mixed together that will have a range of boiling and/or condensing points for each system pressure. Noticeable fractionation and temperature glide will occur.

Mezcla zeotrópica Mezcla de dos o más refrigerantes que tiene un rango de ebullición y/o punto de condensación para cada presión en el sistema. Se produce una fraccionación y una variación de temperatura notables.

Zip code insulation calculator A tool that provides insulation levels for your new or existing home based on your zip code and other basic information about your home.

Calculador del código postal de la aislación Herramienta que proporciona los niveles de aislación para su vivienda nueva o actual, basada en su código postal y otra información básica acerca de su vivienda.

Zone valve Zone control valves are thermostatically controlled valves that control water flow in various zones in a hydronic heating system.

Válvula de sector Se trata de válvulas controladas termostáticamente, que controlan el flujo del agua en varios sectores en un sistema de calefacción hidrónico.

  equipment overview, 1489–1490, 1490*f*–1491*f*
  evaporator, 1491, 1492*f*
  heat exchange equipment, 1492–1493, 1493*f*, 1497–1498, 1498*f*
  operation and maintenance, 1552–1553, 1552*f*
  purge system, 1496–1497, 1496*f*–1497*f*
  solution strength, 1493–1494, 1494*f*
  startup, 1551–1552, 1551*f*
Accessibility issues, split-system condenser installation, 1159
Access ports, cooling towers, 1518, 1518*f*–1519*f*
AC clamp-on ammeter, 129, 130*f*
Accumulators, suction-line, 654–656, 655*f*–656*f*
Acetylene
  oxyacetylene torches, 164–168, 165*f*, 166*f*, 168*f*
  regulator gauge for, 166–167, 168*f*
  safety of, 89–90, 89*f*
  torch tips, 173–174, 173*f*
Acidic water, 738
Acid test, refrigerant recovery, 251–252, 252*f*
A coil, air conditioning evaporators, 1077–1078, 1078*f*
Acoustical lining, metal ducts, 1146, 1147*f*
Acrylonitrilebutadiene styrene (ABS) piping, 182
Activated charcoal air purifier, 1036, 1037*f*
Active charge control, geothermal pump refrigerants, 1364–1365, 1364*f*
Active recovery, refrigerants, 246–247
Active sensors, direct digital controls, 405
Active solar design, 1014–1015, 1014*f*–1015*f*
Adapter hoses, 131, 131*f*
Adapters, electrical safety, 92–95, 92*f*
Adiabatic expansion
  closed-circuit cooling tower, 1512–1514, 1513*f*
  refrigerant cycling, 67–69, 70*f*
Air acetylene unit, 125, 126*f*
  soldering and brazing, 162–164, 163*f*, 164*f*
Air balancing meter, 127, 127*f*, 128*f*
Air cargo hauling, refrigeration systems, 767–768, 768*f*
Air changes per hour (ACH) airflow measurement, 1176–1178, 1177*f*
Air coil, direct geothermal heat pump, 1354, 1354*f*
Air compressor system, pneumatic controls, 396–403, 396*f*–403*f*
Air conditioning systems
  absolute and relative humidity, 1053–1054, 1054*f*
  air-conditioning and refrigeration (ACR) copper tubing, 156–157, 156*f*
  air-side components, 1089, 1089*f*
  blended conditioned air and room air, 1123–1124, 1124*f*, 1125*f*
  building specifications, 1068–1069, 1069*f*, 1070*f*
  chilled-water systems, 1464–1505
  cold anticipator, 343–344, 344*f*
  comfort and psychrometrics, 1048–1070
  compressor equipment, 1083–1087, 1083*f*–1087*f*
  condenser equipment, 1087–1089, 1087*f*–1088*f*
  design conditions, 1080–1082, 1081*f*
  dew point temperature, 1057, 1057*f*
  dry- and wet-bulb temperatures, 1055–1057, 1056*f*, 1058*f*
  ductwork installation, 1143–1148
  electrical installation, 1148–1150, 1148*f*–1150*f*
  enthalpy and, 1057–1058
  evaporative cooling, 1074, 1074*f*–1075*f*
  evaporator equipment, 1077–1079, 1078*f*–1079*f*, 1082, 1082*f*
  evaporator function, 1079, 1080*f*
  evaporator temperatures, 259
  expansion device, 1089
  fresh air, infiltration and ventilation, 1061, 1063–1068, 1065*f*–1067*f*
  heat transfer, 498–499, 499*f*
  installation procedures, 1089–1091, 1090*f*, 1091*f*, 1143–1165
  liquid refrigerant charging, 271–272
  moisture in air and, 1052–1053, 1053*f*
  mold and, 1029
  package equipment, 1076
  pressure controls, 353–354, 353*f*, 354*f*
  preventive maintenance, 1256–1257
  psychrometrics and, 1050, 1052*f*, 1053*f*, 1058–1061, 1059*f*–1064*f*
  refrigerant properties, 77
  refrigerated cooling systems, 1076–1079, 1076*f*–1079*f*
  refrigeration applications in, 1072–1091
  refrigeration heat-pumping mechanism, 41–43, 42*f*
  refrigeration system/component matching for, 56–58, 56*f*
  room air conditioners, 1433–1460
  split-system equipment, 1076–1077, 1076*f*, 1077*f*
  structural heat gain, 1072–1073, 1073*f*–1075*f*
  superheated gases in air and, 1054–1055, 1054*f*
  tools for, 111, 111*f*
  troubleshooting, 372–373, 373*f*, 376–377, 376*f*–377*f*, 1233–1261
Air-cooled chillers, maintenance, 1546–1547, 1547*f*
Air cooled condensers
  characteristics, 538–540, 538*f*–541*f*
  head pressure calculations, 775–776, 775*f*–776*f*
  high-pressure chillers, 1480–1481, 1480*f*
  operating conditions, 774–775, 775*f*
  troubleshooting, 784–786, 785*f*–786*f*
Air distribution system
  air movement for balancing, measurement, 1128–1130, 1129*f*–1130*f*
  air quantity requirements, 1094, 1094*f*, 1095*f*
  balancing dampers, 1118, 1118*f*, 1119*f*
  blended conditioned and room air, 1123–1124, 1124*f*, 1125*f*
  blower, 1094, 1096–1097, 1096*f*, 1097*f*
  conditioning equipment, 1093, 1093*f*
  drive assemblies, fans and blowers, 1102–1103, 1102*f*–1103*f*
  duct air movement, 1117, 1117*f*–1118*f*
  fans and blowers, 1099–1102, 1100*f*–1102*f*
  forced-air systems, 1094, 1095*f*
  measuring instruments, 1098–1099, 1098*f*–1099*f*
  package rooftop air conditioning, 1580–1583, 1583*f*
  pressures, 1097, 1097*f*
  split-system air conditioning, 1158–1159, 1158*f*–1159*f*
  supply duct systems, 1103–1107, 1103*f*–1107*f*
  troubleshooting techniques, 1138–1141
  truck refrigeration systems, 756, 757*f*, 758*f*
  zoning, 1119–1122, 1119*f*–1121*f*
Air driers, refrigeration systems, 700–701, 700*f*–701*f*
Airflow. *See also* Air distribution system
  air distribution fans and blowers, 1101–1102, 1101*f*
  air-measuring instruments, 1098–1099, 1098*f*–1099*f*

Airflow (*Continued*)
blower door testing, 1176–1178, 1177*f*
cooling towers, 1515–1516, 1516*f*
duct air movement, 1117, 1117*f*–1118*f*
evaporators, 1381–1382, 1381*f*–1382*f*
forced-air electric furnaces, 830, 832*f*
forced-air oil furnaces, 952–954
furnace efficiency testing, 1198–1199, 1198*f*
gas heating systems, 842–843, 843*f*–844*f*
high-efficiency gas furnaces, 872, 872*f*
indoor air quality, 1034, 1034*f*
induced draft condensers, 1387, 1389*f*
measurement for balancing, 1128–1130, 1129*f*–1130*f*
room air conditioning installation and, 1441–1447, 1442*f*–1445*f*
Air fraction chart, 1130–1138, 1131*f*–1138*f*
Air handlers, split-system air conditioner installation, 1155–1156, 1155*f*–1156*f*
Air leaks
sealing, 1185–1188, 1185*f*–1188*f*
thermal imaging, 1178–1185, 1178*f*–1185*f*
Air loop, geothermal heat pump, 1342, 1343*f*
Air-measuring instruments, 1098–1099, 1098*f*–1099*f*
Air pressure, control systems, 361, 361*f*
Air quality
air cleaning systems, 1034–1038, 1034*f*–1037*f*
common pollutants, 1027–1032, 1027*f*, 1028*f*, 1030*f*, 1031*f*
contamination detection and elimination, 1032, 1032*f*
duct cleaning systems, 1038, 1039*f*
energy audit, 1174–1175, 1175*f*
humidification, 1039–1043, 1040*f*–1043*f*
service, troubleshooting and preventive maintenance, 1043–1044
sources of pollution, 1025–1027, 1026*f*
ventilation systems, 1032–1034, 1033*f*–1034*f*
Air quantity, requirements for, 1094, 1094*f*, 1095*f*
Air separator and scoop, hydronic heating systems, 981, 981*f*, 982*f*
Air shutters/dampers, condenser head pressure control, 546, 546*f*
Air-side components, air conditioning systems, 1089, 1089*f*
Air source heat pumps, 1285–1332
applications, 1321–1322, 1322*f*
charge monitoring, 1321, 1321*f*
coefficient of performance, 1299–1300, 1299*f*–1300*f*
compressor, 1320, 1320*f*
control systems, 1304–1311, 1304*f*–1310*f*
defrost cycle, 1311–1314, 1312*f*–1315*f*
electronic expansion valves, 1296
four-way reversing valve, 1285, 1287–1290, 1288*f*–1292*f*
indoor fan motor controls, 1314
indoor unit, 1300–1301, 1301*f*
metering devices, 1292, 1295, 1295*f*
orifice metering devices, 1296
outdoor unit, 1302–1303, 1303*f*
preventive maintenance, 1324
refrigerants, 1290, 1292, 1293*f*
reverse-cycle refrigeration, 1285
room air conditioning systems, 1437–1438, 1440, 1440*f*–1441*f*
scroll compressors, 1322–1323, 1322*f*–1323*f*
second-stage electric heat, 1314–1316
service control protocols, 1325–1332
thermostatic expansion valves, 1292, 1294, 1294*f*
thermostats, 1292, 1294, 1294*f*, 1304, 1304*f*–1305*f*, 1308–1310, 1310*f*–1311*f*
variable-speed motors, 1323
Air-to-air air conditioning units, 1150, 1150*f*, 1154*f*
Air-to-air heat pump, 1286, 1287*f*, 1290, 1292*f*
application, 1298–1300
auxiliary heating systems, 1298–1299
balance point, 1299
controls, 1304–1311, 1304*f*–1310*f*
cooling cycle, 1304–1306, 1305*f*–1306*f*
electrical system servicing, 1316–1317, 1316*f*
electronic thermostats, 1309, 1311, 1311*f*
heat anticipator, 1310
package air-to-air pumps, 1303–1304, 1303*f*–1304*f*
servicing and troubleshooting, 1316–1318, 1316*f*
space heating controls, 1306, 1307*f*–1308*f*, 1308–1309
split-type pump, 1300–1303, 1301*f*–1303*f*
Air-to-water unit, air conditioning systems, 1150–1151, 1150*f*
Air tubes, gun-type oil burners, 932–934, 933*f*
Air velocity measurement, 127, 127*f*, 1128–1130, 1129*f*–1130*f*
air fraction charts, 1132–1134, 1134*f*–1136*f*
supply duct systems, 1104
Air vents, hydronic heating systems, 981–983, 982*f*–983*f*
Air volume controls, refrigeration systems, 629–630, 630*f*
Alarm systems, truck refrigeration, 758, 758*f*
Alcohols, geothermal heat pump, 1346
Algorithms
direct digital controls, 404, 404*f*
numerical analysis and reporting, 1212
proportional, integral, and derivative controllers, 614
Alignment, cooling tower coupling, 1529, 1529*f*–1530*f*
Alkaline water, 738
Alternating current (AC), 299
Alternative heating systems, 1608–1616
Aluminum ducts, 1108–1109, 1108*f*–1111*f*
Aluminum parallel-flow, flat-plate-and-fin heat exchanger, 506, 506*f*
Ambient temperature
domestic refrigerator metering, 1390–1391, 1391*f*
dry coolers, 1604, 1605*f*
refrigerators, 1374*f*
American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE), 101, 229, 237, 239–240, 739, 770, 1025, 1032, 1067, 1269
direct geothermal heat pump, 1356, 1360
package rooftop air conditioning standard, 1578–1579
Ammeter, 300, 300*f*
calibration, 289–291, 290*f*, 291*f*
electricity measurements, 311–314, 311*f*–314*f*
low-voltage circuit amperage troubleshooting, 377–378, 377*f*
thermostat heat anticipator, 343, 343*f*
Ammonia refrigerants, marine refrigeration, 765
Ampacity, 315
Amperage
compressors, 1230, 1230*f*
full-load and locked-rotor amperage, 421, 469
low-voltage circuit troubleshooting, 377–378, 377*f*
measurement, 311–314, 311*f*–314*f*
Analog inputs, direct digital controls, 405, 406*f*
Analog thermostats, 343, 343*f*
Anchor shields, 143, 143*f*
Anemometer, 1098, 1098*f*
Aneroid barometer, 26, 27*f*
Angular misalignment, cooling tower coupling, 1529, 1529*f*
Annealing, copper tubing, 240
Annual Fuel Utilization Efficiency (AFUE), 873, 1199, 1204
Antifreeze solutions
chilled-water variable air volume systems, 1585–1587
geothermal heat pump, 1346
Anti-recycle control, chilled-water motor protection, 1506
Appearance, customer interaction and, 12–15
split-system air conditioning installation, 1159
Appliances
heat gain from, 1281
small appliances, 255–258, 256*f*–258*f*
Approach temperature and temperature difference, 783, 1237–1238
absorption air-conditioning chillers, 1497–1498, 1497*f*
cooling towers, 1510–1511, 1510*f*
flooded evaporator chillers, 1476, 1476*f*–1477*f*
high-pressure chiller condensers, 1479–1480, 1479*f*
Aquastat controls, hydronic heating systems, 983–984, 984*f*

Arcs, automatic controls for, 333, 333*f*–334*f*
Asbestos, 1031
Ash content, fuel oils, 914
Association for Energy Engineers (AEE), 1168
Atmospheric burners, gas heating systems, 853
Atmospheric draft heating, 1208
Atmospheric pressure
  boiling point of water and, 43–44, 44*f*
  defined, 16
  properties of, 26–27
Atomic structure, 296–297, 296*f*
Atomization, fuel oils, 922, 922*f*
Atomizing humidifiers, 1041–1043, 1042*f*
Attics, heat loss through, 1273–1274, 1274*f*, 1277–1278, 1277*f*
Audiffren, Marcel, 3
Audiffren-Singrün refrigerating machine, 3
Auger, flake ice production, 705–706, 705*f*
  troubleshooting, 707
Auto exhaust, carbon monoxide emissions, 1030
Automatic combination gas valves (ACGV), gas heating systems, 847–852, 847*f*–851*f*
Automatic controls
  air pressure controls, 361, 361*f*
  bimetal device, 328–329, 328*f*–329*f*
  direct digital controls, 394, 403–410
  electronic temperature-sensing devices, 336–337, 336*f*–337*f*
  fluid expansion, 331–333, 331*f*, 332*f*–334*f*
  fluid flow, 361–362, 362*f*
  forced-air electric furnaces, 822–830, 823*f*–830*f*
  gas pressure, 361, 363, 363*f*
  mechanical and electromechanical controls, 363–365, 364*f*–365*f*
  motors, 468–477
  parallel compressor systems, 675, 677–680, 679*f*
  pneumatics, 394–414
  pressure sensing devices, 352–365
  residential electronic controls, 410–414, 411*f*–414*f*
  rod and tube system, 329–330, 329*f*, 330*f*
  thermal change devices, 326–327, 327*f*
  thermocouples, 333–336, 334*f*–336*f*
  types of, 326
  water pressure regulators, 362–363, 362*f*
Automatic expansion valves (AXVs), 594, 596*f*, 616–619, 616*f*–619*f*
  geothermal pump liquid flow control, 1363–1364, 1363*f*
  ice machines, 706
Automatic pumpdown systems, 635–638, 635*f*–638*f*
Autotransformer start, chilled-water systems, 1500–1501, 1501*f*
Auxiliary contacts, electric motors, 471–472
Auxiliary drains, condensate drain piping, air conditioning systems, 1157–1158, 1158*f*
Auxiliary heating systems
  active solar design and, 1014–1015, 1014*f*–1015*f*
  air-to-air heat pump, 1298–1299
  liquid collection/water storage/auxiliary conventional hot water boiler, 1015, 1016*f*
  oil heating systems, auxiliary fuel supply, 919, 919*f*
Auxiliary refrigeration systems, liquid subcooling, 676*f*–677*f*, 681–683, 682*f*, 683*f*
Awl, 108*f*
Azeotropic refrigerants, 234–235, 234*f*, 235*f*
  system charging, 279–282, 279*f*–282*f*

B

Backdrafting
  carbon monoxide emissions, 1030, 1031*f*
  furnace systems, 1201–1202, 1201*f*–1203*f*
  heating systems, 1173–1174
Back electromotive force (BEMF), electric motors, potential relay, 433–434, 433*f*–434*f*
Bacterial control, cooling tower water treatment, 1532–1533, 1533*f*–1534*f*
Baffles, compressor pumping capacity, 1418–1419, 1419*f*
Balanced-port thermostatic expansion valve, 609, 610*f*
Balance points, air-to-air heat pump, 1299, 1306, 1307*f*–1308*f*, 1308–1309
Balancing valves, hydronic heating system, 986, 988*f*, 989
Ball valves, 658, 660*f*
  large air conditioning systems, 1543, 1543*f*
Bare-pipe evaporators, 503, 503*f*
Barometer, atmospheric pressure, 26–27
Barometric dampers, 1207, 1208*f*
Baseboard heating systems, 820, 820*f*
  finned baseboard units, 990–991, 991*f*–992*f*
Base load inspection, 1174
  seasonal use *vs.*, 1212, 1213*f*
Base-mounted pumps, cooling towers, 1523–1524, 1524*f*
Batts, insulation, 1170–1171
Bearings, electric motors, 418–419, 419*f*
Bearing washout, evaporator defrosting, 517–518
Bell jar
  boiling point of water in, 44, 44*f*
  system evacuation, 200, 200*f*
Bellows
  fluid expansion control systems, 333
  line-voltage space temperature controls, 346–347, 346*f*
Below-grade walls, heat loss through, 1274–1275, 1275*f*
Belt-drive blowers, 1102, 1102*f*
Belt-drive compressor, 563, 564*f*, 575–576, 575*f*–576*f*
Belt tension, troubleshooting, 481–482, 481*f*–482*f*
Bevel gear assembly, cooling tower fan section, 1517–1518, 1517*f*–1518*f*
Bidirectional thermostatic expansion valves, air source heat pumps, 1294
Biflow drier, air source heat pump, 1296, 1298*f*
Bimetallic devices
  limit switches, gas heating systems, 858–859, 858*f*–859*f*
  line-voltage space temperature controls, 346–347, 346*f*
  motor temperature-sensing devices, 348–349, 348*f*–350*f*
  safety devices, gas heating systems, 862, 862*f*
  thermal change detection, 328–329, 328*f*–329*f*
Binary (digital) sensors, direct digital controls, 405–407, 407*f*
Bin controls, ice machines, 710–712, 723–724, 724*f*
Biological contaminants, 1027–1028, 1027*f*, 1028*f*
Bipolar ionization, indoor air quality, 1037
Bipolar step motor, electric evaporator pressure-regulating (EEPR) valve, 625, 625*f*
Blanket insulation, 1170–1171
Blast freezing tunnel, 762–763, 764*f*
Bleeding procedures, oil fuel lines, 918, 918*f*, 957, 957*f*
Bleed resistor, capacitor troubleshooting, 488–491, 488*f*–491*f*
Blowdown assembly
  cooling towers, 1520–1522, 1520*f*–1522*f*
  evaporative condensers, 538
Blowers and blower motors
  air distribution systems, 1094, 1096–1097, 1096*f*, 1097*f*, 1099–1102, 1100*f*–1102*f*
  circuits, forced-air electric furnaces, 826–829, 826*f*–829*f*
  combustion blower, gas heating systems, 853, 853*f*
  combustion efficiency and safety, 1194–1196, 1197*f*, 1201*f*, 1203*f*
  door testing, 1175–1178, 1175*f*–1177*f*
  drive assemblies, 1102–1103, 1102*f*–1103*f*
  duct pressurization test, 1193–1194, 1193*f*–1196*f*
  gun-type oil burners, 924–925, 925*f*
  package rooftop air conditioning units, 1565, 1565*f*–1566*f*
  power draft systems, 1208, 1208*f*
  thermal imaging, 1178–1185, 1178*f*–1185*f*
  variable-air volume systems, 1580–1581
  variable-speed blowers, 1122
  wiring diagram, oil furnace, 941, 941*f*
  zoned air distribution, 1120–1122, 1120*f*–1121*f*
Bluetooth technology
  mechanical troubleshooting, 1237, 1237*f*
  micron gauges, 202, 202*f*
Body temperature
  calibration, 288, 288*f*
  overheating and, 96*f*

Boiler systems
cast-iron boilers, 971–972, 972*f*
condensing boilers, 971, 971*f*–972*f*
copper water-tube boilers, 973–974, 974*f*
electric boilers, 971, 971*f*
gas-fired boiler, 970, 970*f*
hydronic boilers, 820–821, 821*f*, 970–973, 970*f*–973*f*
liquid collection/water storage/auxiliary conventional hot water boiler, 1015, 1016*f*
oil-fired boiler, 970–971, 971*f*
radiant heating low-mass boiler, 1005–1006, 1006*f*
steel boilers, 972, 973*f*
Boiling point
refrigerants, 62, 245–246
of water, 43, 43*f*, 44*f*
Boiling temperature, evaporator, 499–500, 500*f*
Booster compressors, 680–681, 681*f*
Booster pumps, oil furnace supply system, 919, 919*f*
Bourdon tube, 27, 27*f*
fluid expansion control systems, 333, 333*f*–334*f*
pressure controls, 352, 352*f*
Boyle's law, 32, 32*f*
Brass-to-steel joints, soldering and brazing, 172–173
Brazing
fluxing and, 168–169, 168*f*
heat application, 171–172, 171*f*
heat sources, 162–168, 162*f*–168*f*, 173–174, 173*f*
high-temperature, 172
joint types, 172–173
piping and tubing, 161–162, 162*f*
techniques, 171–172, 174–175, 174*f*, 175*f*
Brine circulation system, marine refrigeration, 767, 767*f*, 768*f*
British thermal unit (Btu), 18, 18*f*
refrigeration equipment ratings, 41
Bubble solution, evaporator leak detection, 190, 190*f*
Bubbling
fuel oil pumps, 927, 930*f*
gas piping leaks, 886, 886*f*
Buffer tanks
radiant heating systems, 1005–1006, 1006*f*
water-to-water geothermal heat pump, 1350–1352, 1350*f*–1351*f*
Building envelope, inspection, 1169–1170, 1170*f*
Building Performance Institute (BPI), 1168
Building specifications, air conditioning systems, 1068–1069, 1069*f*, 1070*f*
Building technology
green awareness and, 6–8
heating systems, 8–9
Burners
flame adjustment, 901*f*
gas heating systems, 852–853, 852*f*, 853*f*
gun-type oil burners, 923–939, 941, 942*f*, 956–957
heat exchange equipment and, 855–856, 855*f*–856*f*
pilots and, 860–862, 860*f*–862*f*
Burn injuries, electrical burns, 92–94
Burr
gas piping, 884–886, 885*f*–886*f*
removal of, 158, 159*f*
steel pipe, 179, 180*f*
Butane
chemistry, 912, 912*f*
refrigerants, 230
torch, 162, 162*f*
Butterfly valve, water-cooled condensers, 1550
B-vent, gas stoves, 1615
Bypass duct system, zoned air distribution, 1121, 1121*f*
Bypass humidifier, 1039, 1040*f*
Bypass plug, fuel oil pumps, 926, 928*f*, 957, 957*f*
Bypass valves, cooling towers, 1527–1528, 1528*f*–1529*f*

C

Cabinet design
air conditioning condensers, 1089
freezers and refrigerators, 1404–1405, 1405*f*
Cad cell relay
flame safeguards, 1204
oil burners, 937–939, 938*f*–939*f*
wiring diagrams, 945, 946*f*, 947, 948*f*–953*f*
Calcium carbonate, cooling tower water, 1530–1531, 1531*f*
Calibration
defined, 284
electrical test instruments, 289–291, 290*f*–291*f*
electronic leak detectors, 291–292, 291*f*
flue-gas indicators, 292–293, 292*f*
pressure test instruments, 288–289, 288*f*, 289*f*
temperature-measuring instruments, 284–288, 284*f*–288*f*
Canvas connector, supply duct systems, 1103–1104, 1103*f*, 1104*f*
Capacitance, electricity production, 308–309, 308*f*, 309*f*
Capacitive pressure transducers, 356–357, 356*f*, 357*f*, 358*f*
Capacitor
electricity production, 308–309, 308*f*, 309*f*
troubleshooting, 488–491, 488*f*–491*f*
Capacitor-start, capacitor-run motors, 427, 427*f*
Capacitor-start electric motors, 426, 426*f*
Capacity check
absorption air-conditioning chillers, 1495–1496, 1495*f*
air conditioning systems, 1068–1069, 1070*f*
centrifugal compressor, 1472–1473, 1473*f*
Capacity steps, parallel compressor systems, 675, 677–680, 679*f*
Capillary attraction, soldering and brazing, 162, 162*f*
Capillary tube system
air source heat pumps, 1294–1295, 1295*f*
cutter, 131, 132*f*
domestic refrigerator metering, 1390–1391, 1391*f*
low refrigerant charge, 780–781
metering device, 617–619, 617*f*–619*f*, 1247–1249, 1248*f*
refrigerant flow restriction, 787–789, 788*f*
refrigerant overcharge, 781–782, 782*f*
repairs, refrigerators and freezers, 1417–1418, 1418*f*
room air conditioning systems, 1436–1437, 1437*f*, 1453
Carbon dioxide
combustion efficiency tester, 959–960, 959*f*, 961–962, 962*f*
greenhouse effect and, 6–8, 225–226, 225*f*, 226*f*
indicators, 127, 128*f*
R-744 refrigeration systems, 685–689, 686*f*–689*f*
sensor, 1579–1580, 1579*f*
truck refrigeration systems, 752–754, 753*f*–754*f*
Carbonizing flame, oxyacetylene torch, 168, 168*f*
Carbon monoxide
combustion and production of, 1029–1031, 1030*f*–1031*f*
digital carbon monoxide tester, 134*f*
furnace efficiency testing, 1197, 1197*f*, 1201–1202, 1201*f*–1203*f*
incomplete fuel combustion, 921–922, 922*f*
indicator, 127, 128*f*
Carbon residue, fuel oils, 913
Cardboard partitions, induced draft condensers, 1387, 1389*f*
Career opportunities, home and commercial heating, 8–9
Carré, Ferdinand, 2–3
Carrier frequency, variable frequency drivers, 445–446, 445*f*
Carrier, Willis, 3
Cascade refrigeration systems, 687–688, 688*f*, 762, 763*f*
Cast-iron boilers, 971–972, 972*f*
Cast-iron burner, gas heating systems, 852–853, 852*f*, 853*f*
Catalytic combustion, wood-burning stove, 1610–1611, 1610*f*–1611*f*
Caulking, sealing air leaks with, 1185–1188, 1186*f*–1192*f*
Ceiling heaters, 820, 820*f*
Ceilings
heat gain through, 1279–1280, 1279*f*
heat loss through, 1273–1274, 1274*f*, 1277–1278, 1277*f*

Cellulose, in wood, 1608
Celsius temperature scale, 17–18, 17*f*–18*f*
Central forced-air furnaces, 821–832, 821*f*, 822*f*, 823*f*
Centrifugal atomizing humidifier, 1042, 1042*f*
Centrifugal blower, air distribution systems, 1100–1101, 1100*f*
Centrifugal chiller, 1541–1542, 1546
Centrifugal compressor, 560, 562*f*, 588, 589*f*–590*f*
  high-pressure chillers, 1470–1473, 1470*f*–1474*f*
  low-pressure chillers, 1484–1487, 1485*f*–1487*f*
Centrifugal pumps
  cooling towers, 1522–1530, 1522*f*–1530*f*
  hydronic heating systems, 975–979, 976*f*–979*f*
Centrifugal separator, cooling tower water treatment, 1531–1532, 1532*f*–1533*f*
Centrifugal switch, electric motors, 424–425, 425*f*
Centrifugal water pump, cube ice production, 715–716, 716*f*
Certification programs
  importance of, 10
  mandatory and voluntary programs, 10
  technician certification, 9–10, 246–247
CFC-11 refrigerant, 239
CFC-12 refrigerant, 239
CFC-502 refrigerant, 239
Charging procedures
  air source heat pumps, 1321, 1321*f*
  curves, 274–277, 275*f*–277*f*
  low refrigerant charge, 1408–1409, 1410*f*
  room air conditioning units, 1451–1452, 1452*f*
  troubleshooting, 1247–1249, 1248*f*–1249*f*
Charging scales, refrigerant weighing, 272–273, 272*f*, 273*f*
Charles' law, 33, 33*f*
Check valves, refrigerants, 652, 652*f*
  satellite compressors, 681
  scroll compressors, high-pressure chillers, 1468–1469, 1468*f*–1469*f*
Chemical-free water treatment, cooling towers, 1530–1533, 1530*f*–1533*f*
Chemicals, safety issues, 101, 102*f*
Chest-type displays, refrigeration systems, 694–695, 695*f*
Chest-type freezers, 1379, 1379*f*–1380*f*, 1407, 1407*f*
Chilled-water air-conditioning systems. *See also* specific chiller systems, e.g., Absorption air-conditioning chillers
  absorption air-conditioning chillers, 1488–1498
  autotransformer start, 1500–1501, 1501*f*
  chiller classification, 1465–1466
  chiller components, 515–516, 515*f*–516*f*
  components, 1464–1465, 1465*f*
  cooling towers, 1509–1534
  cylinder unloading and variable-frequency drives, 1467–1468, 1467*f*–1468*f*
  electronic starters, 1503–1504, 1503*f*
  high-pressure chillers, 1466–1484
  low-pressure chillers, 1484–1488
  maintenance, 1546–1555, 1547*f*–1555*f*
  motor protection, 1504–1506, 1505*f*–1506*f*
  motors and drives, 1498–1506
  operating conditions, 1536–1555
  operation log sheet, 1476, 1477*f*
  service call protocols, 1555–1561
  startup procedures, 1536–1542, 1537*f*–1542*f*
  variable air volume systems, 1584–1589, 1585*f*–1592*f*
  winding start, 1500, 1500*f*
  wye-delta start, 1501–1503, 1502*f*–1503*f*
Chimney draft, 1209
Chloramines, 738
Chlorinated polyvinyl chloride (CPVC) piping, 182–183, 183*f*
Chlorinated water, 738
Chlorofluorocarbon (CFC) refrigerants, 4–5, 227, 243
Choke coil, 443–446, 443*f*–445*f*
Circuit breakers, 317, 317*f*
  space temperature controls, 339
  troubleshooting, 1256, 1256*f*
Circuit jumping, thermostat troubleshooting, 375–377, 375*f*–377*f*
Circuits, electrical, 299–300, 299*f*
  automatic controls for, 333, 333*f*–334*f*
  blower motor circuits, forced-air furnaces, 826–829, 826*f*–829*f*
  chilled-water air-conditioning systems, 1538–1539, 1539*f*
  coil circuits, air conditioning evaporators, 1078, 1079*f*
  forced-air electric furnace, 824–825, 825*f*–826*f*
  low-voltage thermostats, 341, 341*f*
  motors, 468, 468*f*
  package rooftop air conditioning installation, 1571, 1573*f*
  parallel circuits, 300, 302*f*, 304–305
  pressure controls, 352, 353*f*
  protection devices, 316–319, 316*f*–319*f*
  room air conditioning installation, 1441–1442, 1442*f*–1443*f*
  series circuits, 300, 302*f*, 304
  troubleshooting, 370–375, 371*f*–374*f*, 379–385, 380*f*–384*f*, 1256, 1256*f*
Circulating pumps
  absorption air-conditioning chillers, 1494, 1495*f*
  hydronic heating systems, 975–979, 976*f*–979*f*, 999–1001, 999*f*–1001*f*
Clamp-on ammeter, 302*fi*
  calibration, 289–291, 290*f*, 291*f*
  low-voltage circuit amperage troubleshooting, 377–378, 377*f*, 1250–1251, 1250*f*
Cleanable tube-within-a-tube condensers, 526–527, 527*f*
Clean Air Act, 4
Cleaning techniques
  air compressor system, 397, 397*f*
  refrigeration systems, 218–221, 219*f*
Clean technology, ice machine microprocessors, 731–735, 731*f*–737*f*
Climate conditions, air conditioning systems, 1080–1082, 1081*f*
Closed chest fixtures, 695–696, 696*f*
Closed-circuit cooling tower, 1512–1514, 1513*f*–1514*f*
Closed-collector piping system, active solar design, 1014–1015, 1014*f*–1015*f*
Closed-loop running bench test, compressor troubleshooting, 790–791, 790*f*, 791*f*
Closed-loop running field test, compressor troubleshooting, 792, 792*f*
Closed-loop systems
  configuration, 408–410, 409*f*, 410*f*
  dedicated geothermal wells, 1347, 1349*f*
  dry coolers, 1602–1605, 1603*f*–1605*f*
  geothermal heat pump, 1335, 1338–1342, 1338*f*–1345*f*
Closed-pump assembly, cooling tower water pumps, 1523, 1523*f*
Close on rise of outlet pressure (CRO) valve, 626–627, 627*f*
Close-to-design conditions, equipment temperature and pressure in, 1225–1228, 1225*f*–1228*f*
Coal, heating systems, 8
Coefficient of performance (COP)
  air source heat pumps, 1299–1300, 1299*f*–1300*f*
  air-to-air heat pump controls, 1304–1311, 1304*f*–1310*f*
  split-type air-to-air heat pump, 1302, 1302*f*
Coil structure
  air conditioning condensers, 1088
  air conditioning evaporators, 1077–1078, 1078*f*
  air-to-air heat pump, 1290, 1292*f*
  cased coils air conditioning evaporators, 1082, 1082*f*
  closed-circuit cooling tower, 1512, 1513*f*
  evaporator component, 48–50, 48*f*–50*f*, 1383–1384, 1384*f*
  evaporator troubleshooting, 783–784, 784*f*
  inductance and, 306–307, 307*f*
  package rooftop air conditioning, 1583–1584, 1583*f*–1584*f*
  split-type air-to-air system, 1300, 1301*f*
  truck refrigeration systems, 758
Coin-operated air vents, 982, 983*f*
Cold anticipator, 343–344, 344*f*
Cold control, refrigerator compressor, 1395–1396, 1396*f*
Cold junction, thermocouples, 334, 335*f*
Cold plates, truck refrigeration systems, 754–755, 754*f*–755*f*

Compression expansion tank, hydronic heating system, 974, 974*f*–975*f*
Compression fittings, 177–178, 178*f*
  mechanical piping connections, 184–185, 184*f*–185*f*
Compression ratio, 558–560, 559*f*
  compressor efficiency and, 590–591, 591*f*–592*f*
  low refrigerant charge, 780, 780*f*
  two-stage refrigeration, 761–762, 761*f*–762*f*
Compressors
  air conditioning systems, 1083–1087, 1083*f*–1087*f*
  air source heat pumps, 1320, 1320*f*, 1440
  belt-drive mechanism, 575–576, 575*f*–576*f*
  changeout, 1414–1416, 1414*f*–1416*f*
  chilled-water systems, 1498–1499, 1499*f*–1500*f*, 1536–1542, 1537*f*–1542*f*
  circuit troubleshooting, 384–385, 384*f*–385*f*
  cleaning procedures, 218–221, 219*f*
  closed-loop running bench test, 790–791, 790*f*, 791*f*
  closed-loop running field test, 792, 792*f*
  contactor coil troubleshooting, 383–384, 384*f*
  defrost cycle, 1400, 1400*f*
  discharge temperature, 71, 71*f*
  discus valve design, 578–579, 578*f*
  domestic refrigerators, 1384–1386, 1385*f*–1386*f*
  electrical systems, 1252–1255, 1253*f*–1255*f*
  evacuation procedures, 212, 213*f*, 214*f*
  evaporator defrosting, 517–518, 517*f*
  extra-low-temperature refrigeration, 761–762, 761*f*–762*f*
  full-load current, 1230
  function, 558–560, 559*f*–560*f*
  geothermal heat pump, 1359, 1360*f*, 1361*f*
  head of, 568, 571*f*
  heat transfer in, 498–499, 498*f*–499*f*
  high-pressure chillers, 1466
  high voltage and current draw, 1230–1231
  housing, 568*f*, 569–570
  liquid in cylinder of, 588–590, 590*f*
  low-pressure chillers, 1484–1487, 1485*f*–1487*f*
  low refrigerant charge, 779–781, 779*f*–781*f*, 1409–1410, 1410*f*
  maintenance and efficiency, 590–591, 591*f*–592*f*
  marine refrigeration, 765–767, 765*f*
  monitoring technology, 579–580, 579*f*
  motor temperature-sensing devices, 349, 350*f*, 351*f*
  mufflers, 568, 571*f*
  oil charging pump, 124, 125*f*
  oil check valve and partition wall, 665–666, 665*f*–666*f*
  oil pressure safety control, 640–643, 640*f*–643*f*
  overloads, 327, 327*f*, 572–573, 572*f*–573*f*, 1251–1252
  parallel compressor systems, 675–683, 676*f*–683*f*
  pneumatic control systems, 396–403, 396*f*–403*f*
  pressure controls, 352, 352*f*
  pumping capacity, 1418–1419, 1419*f*
  reciprocating components, 565–578, 565*f*–578*f*, 1083–1084
  refrigerant cylinder valves, 568, 568*f*–569*f*
  refrigeration systems, 3–5, 50–52, 50*f*–52*f*, 558–592
  room air conditioning systems, 1437, 1437*f*, 1439*f*–1440*f*, 1454, 1456
  running amperage, 1230, 1230*f*
  running test in system, 792, 794
  satellite/booster compressors, 680–681, 681*f*
  shaft seal, 573–575, 574*f*–575*f*
  single-compressor systems, 672–675, 672*f*–675*f*
  speeds, 1083
  start circuit, 1396–1398, 1397*f*–1398*f*
  suction-line accumulators, 654–656, 655*f*–656*f*
  technology innovation, 579–588, 579*f*–589*f*
  terminal venting, 230, 232
  three-phase motors, 437–438, 437*f*–438*f*
  troubleshooting, 789–792, 789*f*–792*f*, 794, 794*f*, 1251–1255, 1252*f*–1255*f*
  truck refrigeration systems, 755–756, 755*f*–756*f*, 759*f*
  two-speed compressor motors, 436, 1231
  types of, 560–565. 560*f*–565*f*
  vacuum test, 790, 790*f*
  variable refrigerant flow systems, 1592, 1593*f*–1594*f*
  wiring and controls, 1395–1399, 1396*f*–1399*f*
  zoned air distribution systems, 1122
Concrete screw fasteners, 146–147, 147*f*
Condensate removal
  drain piping, split-system air conditioning, 1156–1158, 1156*f*–1158*f*
  equipment, 698–699, 699*f*
  evaporator configuration, 506–507, 507*f*–508*f*, 1383, 1383*f*
  mold and, 1029
  refrigerator condensers for, 1389–1390, 1390*f*
  room air conditioning installation, 1445–1446, 1446*f*–1447*f*
  room air conditioning systems, 1437, 1438*f*
  self-contained refrigeration, 670–671, 670*f*–671*f*
Condensation, latent heat of, 22, 74, 540
Condensers
  absorption air-conditioning chillers, 1491, 1492*f*
  air conditioning systems, 1087–1089, 1087*f*–1088*f*
  air-cooled, 538–540, 538*f*–541*f*, 774–775, 775*f*
  air-to-air heat pump, 1290, 1292*f*
  chilled-water air-conditioning systems, 1536–1537, 1537*f*–1538*f*
  condensate removal configuration, 506–507, 507*f*–508*f*, 1389–1390, 1390*f*
  cooling towers, 533–535, 533*f*–535*f*, 1509, 1510*f*, 1521
  domestic refrigerators, 1386–1390, 1388*f*–1390*f*
  evaporative, 535, 537–538, 538*f*
  evaporator load, 1219, 1220*f*–1221*f*, 1221
  fan-cycling head pressure controls, 544–546, 544*f*–546*f*, 628–629, 628*f*–629*f*
  fan motors, 1402–1403, 1403*f*
  flooding, 546–554, 547*f*–554*f*, 630–631, 631*f*
  grading of, 1222–1223, 1222*f*–1223*f*
  head pressure controls, 544–554, 544*f*–554*f*, 630–631, 631*f*
  heat exchangers and, 855–856, 855*f*–856*f*
  heat reclamation, 554
  high-efficiency models, 541–542, 541*f*
  high-pressure chillers, 1478–1481, 1479*f*–1481*f*
  individual condensing units, 671
  inspection protocols, 1173
  leak detection, 190–191, 190*f*, 1413–1414, 1413*f*–1414*f*
  low ambient conditions, 542–544, 542*f*–543*f*
  low-pressure chillers, 1487–1488, 1487*f*–1488*f*

Demand metering, 409
Density, 31, 31f
Derivative (differential) controller, expansion valves, 615, 615*f*
Design conditions
air conditioning systems, 1080–1082, 1081*f*
heat transfer and, 1268–1269, 1268*f*–1269*f*
Desuperheating
condensers, 53–54
condenser troubleshooting, 784–786, 785*f*–786*f*
Dew point, 280
Dew point temperature (DPT)
air conditioning systems, 1057, 1057*f*
excess air, 1204
furnace efficiency testing, 1197
high-efficiency gas furnaces, 871–872, 871*f*
refrigerator box, 1377, 1377*f*
Diacs, 323, 323*f*
Diagnostic testing, energy audits, 1175–1215
Diagonal drilling, direct geothermal heat pump, 1358, 1359*f*, 1360
Diaphragm
expansion devices, 597, 598*f*
fluid expansion control systems, 331–333, 331*f*–334*f*
pneumatic control system, 398–399, 398*f*
pressure controls, 352, 352*f*
Diaphragm expansion tank, hydronic heating system, 974–975, 975*f*
Diaphragm valves
gas heating systems, 845–846, 846*f*
large air conditioning systems, 1542–1543, 1542*f*
refrigeration systems, 658, 660*f*
Dielectric constant, capacitance, 309
Differential adjustments, pressure controls, 352, 353*f*, 355–356, 355*f*
Differential dry-bulb control, package rooftop air conditioning, 1574
Differential enthalpy, package rooftop air conditioning, 1574, 1576, 1577*f*
Diffuse radiation, 1013, 1013*f*
Diffusers, blended conditioned air and room air, 1123–1124, 1124*f*, 1125*f*
Difluoromethane, 230
Digital anemometer, 1098, 1098*f*
Digital capacitor testers, 490, 490*f*
Digital capacity control, scroll compressor, 584–587, 585*f*–586*f*
Digital carbon monoxide tester, 134*f*
Digital electronic manometer, 130, 130*f*, 1096–1097, 1096*f*
Digital electronic psychrometer, 1055, 1055*f*
Digital laser distance meter, 137*f*
Digital linear actuator, step-motor valves, 612, 612*f*
Digital moisture meter, 1028, 1028*f*
Digital pressure gauges, 28, 28*f*
mechanical troubleshooting, 1234–1237, 1235*f*
Digital stem thermometer, 285, 285*f*
Digital temperature and humidity meter, 135*f*
Digital temperature gauges, mechanical troubleshooting, 1234–1237, 1235*f*
Digital thermostats, 343, 343*f*
Digital vacuum gauge, 119, 119*f*, 208, 208*f*
Dilution air device, 1208
Diode bridge rectifier, 441–442, 442*f*

Diodes, 320–321, 320*f*, 321*f*
Direct-acting four-way reversing valve, 1288–1289
Direct burner automatic gas valves, 851–852, 851*f*
Direct conversion, 34–35
Direct current (DC), 299
  electric motor converters, 441–442, 442*f*
Direct digital controls (DDCs), 403–410, 403*f*–409*f*
  variable frequency drivers, 444–446, 444*f*–446*f*
Direct-drive blowers, 1102–1103, 1103*f*
Direct-drive compressors, 563, 565*f*, 576, *576f*
  low-pressure chillers, 1484–1487, 1485*f*–1487*f*
Direct-expansion liquid cooling evaporator, 515–516, 515*f*–516*f*
  high-pressure chillers, 1474, 1475*f*
Direct-fired absorption chillers, 1498, 1498*f*, 1499*f*
Direct GeoExchange systems, 1356, 1361
Direct geothermal heat pump, 1354–1365, 1354*f*–1364*f*
Direct piping systems, radiant heating, 1007*f*, 1009
Direct radiation, 1013, 1013*f*
Direct-spark ignition system, 863–864, 864*f*
Direct-vent, gas stoves, 1615
Discharge line
  condensers, 52–54, 52*f*–54*f*
  ice machines, 724, 727*f*
  temperature, 1244–1245, 1246*f*
Discharge service valves, 658, 659*f*
  large air conditioning systems, 1545, 1545*f*
Discus valve, compressor design, 578–579, 578*f*–579*f*
Display cases
  chest-type display fixtures, 694–695, 695*f*
  closed chest fixtures, 695–696, 696*f*
  reach-in refrigeration, 668–669, 668*f*–669*f*
  store ambient conditions, maintenance of, 696–697, 697*f*
  sweating controls, 696, 696*f*
Disposal, small appliances, 258, 258*f*
Distillation quality, fuel oils, 914
Distributed refrigeration systems, 691–692, 691*f*–692*f*
Distributors
  air conditioning systems, 1079, 1079*f*
  liquid refrigerants, 652–653, 653*f*, 654*f*
Diverter tee, one-pipe hydronic heating system, 995–996, 995*f*, 996*f*
Diverting valve, cooling towers, 1528, 1528*f*
Domestic appliances. *See* Appliances; Freezers; Refrigerators
Domestic hot water loop, geothermal heat pump, 1342, 1343*f*
Doors
  heat gain through, 1278–1280, 1279*f*
  heat loss through, 1273
Dope, pipe dope, 182, 182*f*
Doping, semiconductors, 319–320, 319*f*–320*f*
Double-pole-single-throw relay, 469, 469*f*
Double-thickness flare, 176, 176*f*
Downflow furnaces
  gas furnace, 837, 838*f*
  oil furnaces, 911
Draft diverter, 1208
  gas furnace ventilation, 881–882, 882*f*
Draft, furnace systems, 1207–1209, 1208*f*–1209*f*
Draft gauge, 129, 129*f*
Draft hood systems, 1208
  gas furnace ventilation, 881–882, 882*f*
Draft test, combustion efficiency, 959–960, 959*f*
Drain pan heaters, condensate removal, 698–699, 699*f*
Drain piping
  chilled-water variable air volume systems, 1588–1589, 1589*f*–1592*f*
  condensate drain piping, air conditioning systems, 1156–1158, 1156*f*–1158*f*
  split-system condenser unit, 1159, 1159*f*
Drilled-port burner, gas heating systems, 852–853, 852*f*, 853*f*
Drilled wells, geothermal open-loop systems, 1347, 1347*f*–1348*f*
Drills, electric drill, 109*f*
Drip time, internal heat defrost cycle, 646, 646*f*
Drip-type evaporative cooler, air conditioning systems, 1074, 1074*f*–1075*f*
Drive assemblies, removal of, 480–481, 480*f*–481*f*
Drivers, 110–111
Drop-out voltage, back electromotive force, 433–434
Drum-type evaporator, 504, 505*f*
Dry-base cast-iron boilers, 972, 972*f*
Dry-bulb temperature
  air conditioning systems, 1055–1057, 1056*f*
  charging curves, 274–277, 275*f*–277*f*
  package rooftop air conditioning, 1573–1574, 1574*f*–1575*f*
Dry coolers, package rooftop air conditioning, 1602–1605, 1602*f*–1605*f*
Dry ice, truck refrigeration systems, 752–753
Drying techniques, air compressor system, 397, 397*f*
Dry-mode cooling towers, 1514, 1514*f*
Dry nitrogen, evacuation systems, 216, 218, 218*f*
Dry tubing applications, radiant heating systems, 1008, 1008*f*
Dry-type evaporator, 511, 511*f*
Drywall fasteners, 143–146, 143*f*–146*f*
Dry well, condensate drain piping, air conditioning systems, 1156–1158, 1157*f*–1158*f*
Dry wells, geothermal systems, 1347, 1349*f*
Dry/wet mode, closed-circuit cooling tower, 1512, 1513*f*
Dual flow switch, water fill system, ice machines, 709–710, 709*f*–710*f*
Dual in-line pair (DIP) switches
  gas furnaces, 857–858, 857*f*
  residential thermostats, 413
Dual-pressure controls, 354, 354*f*
Dual-pressure relief valves, 240*f*
Dual-voltage motor, 424, 424*f*
  compressors, 437–438, 437*f*–438*f*
Ductless split air conditioning system, 1076–1077, 1076*f*, 1077*f*
Duct systems
  air fraction charts, 1130–1138, 1131*f*–1138*f*
  air-measuring instruments, 1098–1099, 1098*f*–1099*f*

numerical analysis and reporting, 1212–1213, 1214*f*–1215*f*
residential, 1167–1215
screening, 1169
tools for, 134*f*–137*f*
visual inspection, 1169–1170, 1170*f*
Energy conservation measures (ECMs), 1169
Energy efficiency ratio (EER), defrost cycle, air source heat pumps, 1311–1314, 1312*f*–1313*f*
Energy index reporting, 1212–1213
Energy recovery ventilators (ERVs), 1032–1033, 1033*f*
Energy-saver switch
refrigerator/freezer, 1402, 1402*f*
room air conditioning units, 1448–1450, 1448*f*–1451*f*
ENERGY STAR, 1168
Enthalpy
air conditioning systems, 1057–1058
package rooftop air conditioning, 1574, 1576, 1576*f*–1577*f*
refrigerant cycle, 64–65, 65*f*, 66*f*
Entropy, refrigerant cycling, 69*f*, 71
Environment
DuPont™ Suva® retrofitting guidelines and, 260
refrigerants and, 223–225, 224*f*, 225*f*
Environmental Protection Agency (EPA)
ozone-depleting refrigerants and, 4–5
refrigerant restrictions, 58–60
technician certification programs, 9–10
wood stove regulations, 1609
Environmental tobacco smoke (ETS), 1027
Equipment
capacity, refrigerant retrofitting, 259–260
documentation, 1223–1224, 1223*f*–1224*f*
efficiency rating, 1228, 1229*f*
electrical operating conditions, 1229–1231, 1230*f*
operating conditions and grading, 1222–1223, 1222*f*–1223*f*
reference points, 1224–1225, 1224*f*
size, refrigerant retrofitting, 260
startup, 1163–1165, 1163*f*–1164*f*, 1224*f*
Ester-based oils, 241
Ethane
chemistry, 912, 912*f*
refrigerants, 230
Eutectic solution, truck refrigeration systems, 754–755, 754*f*–755*f*
Evaporative condensers, 535, 537–538, 538*f*
Evaporative cooler, air conditioning systems, 1074, 1074*f*–1075*f*
Evaporative humidifiers, 1039
Evaporator pressure-regulating (EPR) valve, 621–624, 622*f*–624*f*
electric valve, 624–625, 625*f*
parallel compressor systems, 675–680, 676*f*–680*f*
temperature control, 692
Evaporators
absorption air-conditioning chillers, 1491, 1492*f*
accumulated moisture defrost, 517–518, 517*f*, 518*f*
air conditioning systems, 1077–1079, 1078*f*–1080*f*, 1082, 1082*f*
air-conditioning *vs.* refrigeration temperatures for, 259
air-to-air heat pump, 1290, 1292*f*
cased coils, 1082, 1082*f*
coil construction, 1383–1384, 1384*f*
cube ice production, 713–714, 713*f*
defrost efficiency controller, 518–521, 519*f*–520*f*
defrost systems, 1383–1384, 1383*f*–1384*f*
dry-type evaporator, 511, 511*f*
energy savings, 518–519, 519*f*
evaluation, 509–510, 509*f*–510*f*
external equalizer, 597, 598*f*, 605–607, 607*f*–608*f*
fan circuit troubleshooting, 383–384, 384*f*
fan motors, 1402–1403, 1403*f*
fin spacing, hoar frost and, 644–645
flooding, 511
freezers, 1379–1380, 1379*f*–1380*f*, 1381–1384, 1381*f*–1384*f*
frost removal, 519–520, 519*f*, 520*f*
header configuration, 506–507, 507*f*–508*f*
heat exchange characteristics, 500, 502–503, 502*f*–503*f*
high-pressure chillers, 1474–1478, 1475*f*–1478*f*
hot pulldown (excessive loading), 512–513, 513*f*
ice machines, 705–706, 705*f*–706*f*, 716, 719*f*–727*f*, 724–727
latent heat in, 511
leak detection, 189–190, 189*f*, 190*f*, 1412–1413, 1412*f*–1413*f*
liquid cooling systems, 515–516, 515*f*–516*f*
low-pressure chillers, 1486–1487, 1487*f*
low refrigerant charge troubleshooting, 1410
low-temperature applications, 516–517, 516*f*
marine refrigeration, 765–767
mechanical-draft, 1381–1382, 1382*f*
merchandising and design of, 693
moisture removal, 500, 502*f*
multiple evaporators, 624, 624*f*, 672–675, 672*f*–675*f*
natural-draft, 1381–1382, 1382*f*
operating conditions, 1219–1221, 1219*f*–1221*f*
outlet temperature, 1243
piping, multiple-evaporator installations, 692–693, 692*f*–693*f*
pressure controls, 513–514, 513*f*–514*f*, 621–625, 622*f*–625*f*
pump-down cycle, 520
refrigeration effect in, 510, 510*f*
refrigeration systems, 48–50, 48*f*–50*f*, 499–517
refrigerators, 1381–1384, 1381*f*–1384*f*
room air conditioning systems, 1436–1437, 1437*f*–1439*f*
superheating, 57, 512–514, 512*f*–514*f*
temperature control, 692
troubleshooting, 782–784, 783*f*–784*f*
truck refrigeration systems, 756, 758
two-evaporator box design, 1381–1382, 1382*f*
types of, 503–509, 503*f*–508*f*
walk-in coolers, 698, 698*f*
Even parallel compressors, 678–680
Excess air, furnace systems, 1204, 1205*f*
Expansion devices
air conditioning systems, 1089
automatic expansion valves, 616–619, 616*f*–619*f*
basic features, 594–595, 594*f*–596*f*
capillary tube metering, 617–619, 617*f*–619*f*
diaphragm, 597, 598*f*
hydronic expansion joint, 991, 992*f*
hydronic expansion tank, 974–975, 974*f*–975*f*
needle and seat control, 598–599, 599*f*, 602*f*
room air conditioning systems, 1436, 1437*f*
sensing bulb and transmission tube, 601–604, 601*f*–604*f*
spring, 600–601, 600*f*–601*f*
step-motor valves, 611–615
thermostatic expansion valve, 594–611
valve body, 597–598, 597*f*–598*f*
vapor charge bulb, 603–604, 603*f*–604*f*
Exposed walls
heat gain through, 1278, 1279*f*
heat loss through, 1271–1275, 1272*f*–1275*f*
Extended plenum system, supply ducts, 1104, 1106*f*

Fuel oil pumps
  gun-type oil burners, 925–932, 925*f*–931*f*
  nozzles, 927–934, 929*f*, 931*f*–934*f*, 958
  screen and gaskets, 927, 930*f*
  service procedures, 955–956, 956*f*, 957*f*
Fuel sources
  gas heat, 840–841, 840*f*–841*f*
  oil heating systems, 911–914, 911*f*–914*f*, 922–923, 922*f*–923*f*
  oil storage, 914–916, 915*f*–916*f*
  oil supply systems, 916–921, 917*f*–921*f*
Full-load amperage (FLA)
  compressors, 1230
  electrical troubleshooting, 1250–1251, 1250*f*–1252*f*
  electric motors, 421, 469, 474–476
Furnaces, oil-fired forced-air furnaces, 910–916, 911*f*–916*f*
Furnace systems
  damper efficiency, 1207, 1207*f*
  efficiency testing, 1197–1199, 1197*f*–1198*f*
  electric furnace heat pumps, 1321, 1322*f*
  energy audits, 1197–1210
  excess air, 1204, 1205*f*
  flame safeguards, 1202, 1204
  forced-air electric furnaces, 821–832, 821*f*, 822*f*, 823*f*
  forced-air gas furnaces, 837–840, 837*f*–840*f*
  gas furnace wiring diagrams, 886–888, 888*f*
  gun-type oil burners, 923–939
  high-efficiency gas furnaces, 869–878, 869*f*–871*f*
  integrated furnace controller (IFC), 849–851, 850*f*
  manifold pressures, gas heat, 841, 841*f*
  modulating gas furnaces, 879–880
  oil-fired forced-air furnaces, 910–921, 911*f*–916*f*
  oil heating systems, 8, 910–965
  preventive maintenance, 1200–1201, 1200*f*–1201*f*
  spillage and backdrafting, 1201–1202, 1201*f*–1203*f*
  split-system air conditioner installation, 1155, 1155*f*
  two-stage gas furnaces, 878–879, 881*f*
  venting, gas systems, 881–884, 882*f*–884*f*
  venting maintenance, 1204–1207, 1205*f*–1207*f*
Fuses, electrical, 316, 317*f*–319*f*
  motor protection, 473–476, 474*f*–476*f*
  troubleshooting, 1256, 1256*f*
Fusion, latent heat of, 22

G

Gain parameter
  control loop systems, 409–410, 410*f*
  pneumatic control system, 401–402, 402*f*
Galvanized steel
  cooling towers, 1516–1517, 1516*f*
  ducts, 1108–1109, 1108*f*–1111*f*
Gas ballast, vacuum pumps, 210, 212*f*
Gas-burning appliances, thermocouples, 334–335, 335*f*
Gases. *See also* specific gases
  chemistry, 30, 31*f*
  gas heating systems, 840–841, 840*f*–841*f*
  superheated gases, 1054–1055, 1054*f*
Gas-fired boiler, 970, 970*f*
Gas fireplace inserts, 1616
Gas fuels, 840–841, 840*f*–841*f*
Gas heating systems
  atmospheric burners, 842
  burners, 852–853, 852*f*, 853*f*
  combustion principles, 841–843, 843*f*–844*f*
  downflow furnace, 837, 838*f*
  efficiency ratings, 872–873, 872*f*
  electrical diagram, 891*f*

Gas heating systems (*Continued*)
electronic ignition systems, 873–879
excess air, 1204, 1205*f*
flame rectification, 866–868, 866*f*–868*f*
forced-air furnaces, 837–840, 837*f*–840*f*
fuel sources, 840–841, 840*f*–841*f*
heat exchangers, 854–856, 854*f*–856*f*
high-efficiency gas furnaces, 869–878, 869*f*–871*f*
horizontal gas furnace, 837, 838*f*
ignition systems, 862–866, 863*f*–866*f*, 873–879
low-boy furnace, 837, 838*f*
manifold device, 852, 852*f*
manifold pressures, 841, 841*f*
modulating gas furnaces, 879–880
multipoise/multipositional furnaces, 838–840, 838*f*–839*f*
oil heating systems *vs.*, 911, 911*f*
orifice, 852
pilot lights, 859–862, 860*f*–862*f*, 888, 897*f*–898*f*
piping, 884–886, 885*f*–886*f*
preventive maintenance, 901–902
regulators, 844–845, 844*f*
service call protocols, 903–907
switching devices, 856–859, 857*f*–859*f*
troubleshooting, 886–897, 888*f*–897*f*
two-stage gas furnaces, 878–879, 881*f*
upflow forced-air furnaces, 837, 837*f*
valves, 845–852
venting, 881–884, 882*f*–884*f*, 1204–1207, 1205*f*–1207*f*
wiring diagrams, 886–888, 888*f*
Gaskets, refrigerator box, 1374–1378, 1375*f*–1378*f*
Gas laws, 32–34
Gas pressure
regulators, 363, 363*f*
switches, 361
Gas stoves, 1615, 1615*f*
combustion pollutants, 1029–1031, 1030*f*–1031*f*
Gas valves, 845, 845*f*
automatic combination gas valves, 847–852, 847*f*–851*f*
direct burner automatic gas valves, 851–852, 851*f*
intermittent pilot automatic gas valves, 849–851, 850*f*
standing pilot automatic gas valves, 847–849, 848*f*–850*f*
Gate valves, water-cooled condensers, 1549, 1550*f*–1551*f*
Gauge adapters, evacuation procedures, 214–215, 215*f*
Gauge manifold, 117, 118*f*, 119
closed-loop running bench test, 790–791, 790*f*, 791*f*
compressor changeout, 1416, 1416*f*
evacuation procedures, 212–215, 214*f*
hoses, 216, 216*f*
refrigerators and freezers, 1407–1408, 1408*f*
troubleshooting, 1238–1240, 1239*f*–1241*f*
Gauges, 117, 118*f*, 119
belt tension, 481–482, 481*f*–482*f*
compressor changeout, 1416, 1416*f*
digital vacuum gauge, 119, 119*f*
draft gauge, 129, 129*f*
electronic thermistor vacuum gauge, 119, 119*f*
mechanical troubleshooting, 1233–1237, 1234*f*–1237*f*
pressure test instrument calibration, 288–289, 288*f*–289*f*
refrigerators and freezers, 1407–1408, 1408*f*
room air conditioning units, 1451–1452, 1451*f*
Gearbox
centrifugal compressor, 1470–1471, 1471*f*
low-pressure chiller compressors, 1484–1485, 1485*f*
Gear-drive compressor, chilled-water systems, 1499, 1499*f*
General law of perfect gas, 33–34
Generator, electricity production, 298, 299*f*
Geothermal heat pump, 973–974
classification, 1335–1336, 1336*f*–1337*f*
closed-loop systems, 1335, 1338–1342, 1338*f*–1345*f*
direct systems, 1354–1365, 1354*f*–1364*f*
installation, 1356–1360, 1356*f*–1360*f*
materials and heat exchange fluids, 1345–1347, 1346*f*
open-loop systems, 1335–1336, 1336*f*–1337*f*
radiant heating systems, 1005–1006
refrigerant-management system, 1361–1365, 1363*f*–1364*f*
reverse-cycle refrigeration, 1335
service call protocols, 1365–1368
troubleshooting, 1352, 1353*f*
water quality, 1337–1338, 1338*f*
water-to-water heat pumps, 1349–1352, 1350*f*–1351*f*
wells and water sources, 1347–1349, 1347*f*–1349*f*
Germanium semiconductors, 319
Ghost flow, 989
Glass thermometers, calibration, 287
Global warming, 225–226, 225*f*, 226*f*

Head pressure controls
air-cooled condensers, 775–776, 775*f*–776*f*
air volume controls, 629–630, 630*f*
compressors, 568, 571*f*
condenser systems, 544–554, 544*f*–554*f*, 630–631, 631*f*
domestic refrigerator operations, 1392–1394, 1393*f*–1394*f*
fan-cycling device, 628–629, 628*f*–629*f*
floating head pressure, 691
low-ambient control, 639–640, 640*f*
refrigerant overcharge troubleshooting, 1410–1411, 1411*f*
Heat
basic principles of, 18–19, 19*f*
crankcase heat, 663–664, 664*f*
defined, 16
energy contained in, 35, 35*f*
escape, thermal imaging, 1179–1185, 1180*f*–1185*f*
external heat defrost, 647–648, 647*f*–648*f*
internal heat defrost cycle, 646, 646*f*
latent heat, 22–24
refrigeration heat-pumping mechanism, 41–42, 41*f*
safety issues with, 95–96, 95*f*–96*f*
sensible heat, 22
soldering and brazing, sources for, 162–168, 162*f*–168*f*
sources for winter, 1286, 1286*f*
specific heat, 24
Heat anticipator
air-to-air heat pump, 1310
low-voltage thermostats, 823
thermostats, 341–342, 342*f*
troubleshooting, 373, 373*f*
Heat exchange equipment
absorption air-conditioning chillers, 1492–1493, 1493*f*, 1497–1498, 1498*f*
calibration, 287, 287*f*
direct geothermal heat pump, 1354, 1354*f*–1355*f*, 1356
dry coolers, 1603–1605, 1603*f*–1605*f*
evaporators, 500, 502–503, 502*f*–503*f*
flooded evaporator chillers, 1475, 1476*f*
furnace maintenance, 1202
gas heating systems, 854–856, 854*f*–856*f*
geothermal heat pump, 1345–1347, 1346*f*
leak repair, 507–509, 508*f*
liquid heat exchangers, 504, 505*f*
oil-based furnaces, 950–953, 954*f*
refrigeration systems, 653–654, 654*f*
room air conditioning systems, 1436, 1437*f*
water-to-water geothermal heat pump, 1349–1352, 1350*f*–1351*f*
Heat gain. *See* Heat transfer
Heat guns, 123, 123*f*
Heating mode
closed-loop geothermal heat pump, 1342, 1343*f*
direct geothermal heat pump, 1354, 1355*f*, 1361, 1361*f*, 1362*f*
open-loop geothermal heat pump, 1335–1336, 1336*f*
package rooftop air conditioning economizer, 1576, 1578*f*
Heating Seasonal Performance Factor (HPSF), gas furnace efficiency, 873
Heating systems
alternative heating systems, 1608–1616
combustion pollutants, 1029–1031, 1030*f*–1031*f*

refrigeration systems, 643, 643*f*–644*f*
Over-the-fire draft, 1208–1209, 1209*f*
Oxidizing flame, oxyacetylene torch, 168, 168*f*
Oxyacetylene torches
soldering and brazing, 164–168, 165*f*, 166*f*, 168*f*
tips for, 173–174, 173*f*
Oxygen
indicators, 127, 128*f*
ozone depletion and, 4, 224–225, 224*f*, 225*f*
safety of, 89–90, 89*f*
Oxygen cylinder pressure gauge, oxyacetylene torches, 166, 166*f*
Oxygen regulator gauge, 166–167, 168*f*
Ozone depletion, 4, 224–225, 224*f*, 225*f*
Ozone depletion potential (ODP), 224–225

P

Package air conditioning systems, 1076, 1150–1151, 1150*f*–1151*f*
air-to-air heat pumps, 1303–1304, 1303*f*–1304*f*
rooftop units, 1564–1580
unit insulators, 1090, 1090*f*
Package heat pumps, 1290, 1292, 1292*f*
Package refrigeration systems, 700, 700*f*
duct connections, 1152–1154, 1153*f*–1154*f*
ice-making equipment, flake ice, 704–706, 705*f*–706*f*
preventive maintenance, 793
troubleshooting, 1250–1251, 1250*f*–1251*f*
Package sequencer, forced-air electric furnaces, 824, 824*f*
Panel heaters, refrigerator box, 1377, 1377*f*
Pantone Matching System (PMS) #185, 230
Parallel circuits, 300, 302*f*
forced-air electric furnaces, 824–825, 825*f*–826*f*
heat reclaim systems, 672–675, 674*f*
switch troubleshooting, 379–380, 379*f*
Parallel compressor systems, 675–680, 676*f*–680*f*
liquid subcooling, 676*f*–677*f*, 681–683, 682*f*, 683*f*
satellite/booster compressors, 680–681, 681*f*
Parallel loop system, geothermal heat pumps, 1344, 1345*f*
Parallel misalignment, cooling tower coupling, 1529, 1529*f*
Particle separation, cooling tower water treatment, 1531–1532, 1532*f*
Partition walls, heat loss through, 1274, 1274*f*
Pascal unit, 1176
Passive recovery, refrigerants, 246
Passive sensors, direct digital controls, 405
Passive solar design, 1010, 1012–1013, 1013*f*
Pellet stoves, 1611–1612, 1611*f*–1612*f*
Penny nails, 139, 139*f*
PE (polyethylene) piping, 182, 182*f*
Percentage of quality, refrigerant cycle, 66–67
Percent oxygen, furnace efficiency testing, 1197
Perforated strap, 148, 149f
Perimeter loop system, supply ducts, 1106–1107, 1108*f*
Perkins, Jacob, 2
Permanent split-capacitor, 336–337, 336*f*–337*f*
gun-type oil burners, 924–925, 925*f*
positive temperature coefficient resistor, 435–436, 436*f*
Permanent split-capacitor motors, 427–429, 427*f*–428*f*
Pesticide, air pollution from, 1031
Phase angle, start capacitor, 426, 426*f*
Phase change solution, truck refrigeration systems, 754–755, 754*f*–755*f*
Phase-controlled rectifier, 441–442, 442*f*
Phase failure protection, chilled-water motor protection, 1506
Phase reversal, chilled-water motor protection, 1506
PH levels, water quality, 738
Photocatalytic oxidation (PCO) filter, 1037–1038, 1037*f*
Pickup truck, 99*f*
Pick-up voltage, back electromotive force, 433–434, 433*f*–434*f*
Pictet, Raoul, 2–3
Pictorial wiring diagrams, 385–387, 386*f*–387*f*
Piercing valves, refrigerant recovery, 256–257, 256*f*
Piggyback railway refrigeration systems, 760, 760*f*
Pilot acting solenoid valve, 632–633, 633*f*
Pilot devices
gas heating systems, 859–862, 860*f*–862*f*, 889
ignition systems, 832–866, 863*f*–866*f*
safety devices, 860–862, 860*f*–862*f*, 888, 897*f*–898*f*
thermocouple detection, 335–336, 335*f*, 336*f*
Pilot-duty relays, 469
Pilot-operated four-way reversing valve, 1288–1289, 1289*f*
Pilot-operated solenoid condenser, 552, 552*f*, 672–675, 672*f*–675*f*
Pilot-operated valves, evaporators, 623*f*, 624
Pilot positioner, pneumatic control system, 400, 400*f*
Pinch-off tool, refrigerator connections, 1408, 1409*f*
Pin rivets, 140, 140*f*
Pipe cutters, steel pipe, 179, 179*f*
Pipe hook, 148, 148*f*
Pipe-in-pipe evaporator, 504, 505*f*
Pipe strap, 148, 148*f*
Pipe thread, 179, 179*f*
Piping systems
chilled-water variable air volume systems, 1588–1589, 1589*f*–1592*f*
closed-collector piping system, active solar design, 1014–1015, 1014*f*–1015*f*
combination high- and low-temperature heating systems, 1009, 1011*f*
compressors, 1385–1386, 1385*f*–1386*f*
condensate drain piping, air conditioning systems, 1156–1158, 1156*f*–1158*f*
dry coolers, 1602–1605, 1603*f*–1605*f*
gas furnace ventilation, 883–884, 883*f*, 884*f*
gas piping, 884–886, 885*f*–886*f*
geothermal heat pump, 1345–1347, 1346*f*, 1354, 1354*f*, 1356–1360, 1356*f*–1360*f*
high-temperature hydronic piping systems, 991–1000, 993*f*–1000*f*
insulation, 157, 157*f*
mechanical connections, 184–185, 184*f*–185*f*
multiple-evaporator installations, 692–693, 692*f*–693*f*
oil burner fuel supply, 916–918, 917*f*, 957, 957*f*
package rooftop air conditioning units, 1564, 1564*f*
plastic pipe, 182–183, 182*f*, 183*f*
purpose of, 155
radiant, low-temperature piping systems, 1003–1009, 1003*f*–1009*f*
refrigerants, 230, 1159–1163, 1159*f*–1162*f*
refrigeration systems, 699–700, 699*f*, 700*f*
slab-on-grade piping, 1007, 1007*f*

Piping systems (*Continued*)
soldering and brazing, 161–162, 162*f*
split-system condenser unit, 1158–1159, 1158*f*–1159*f*
steel and wrought iron pipe, 178–182
thin slab piping, 1007–1008, 1008*f*
variable refrigerant flow systems, 1595–1602, 1602*f*
water-to-water geothermal heat pump, 1350–1352, 1351*f*
Piston, reciprocating compressor, 567–568, 568*f*
Pitot tube, 1099, 1099*f*, 1100*f*
Plastic piping, 182–183, 182*f*, 183*f*
geothermal heat pump, 1339, 1342*f*
Plastic toggle drywall anchors, 143–144, 144*f*
Plastic tubing shear, 116, 116*f*, 117*f*
Plate-type evaporator, 504, 505*f*
freezers, 1379, 1379*f*–1380*f*
marine refrigeration, 765, 765*f*
refrigerators, 1382, 1382*f*
Pleated filters, 1034, 1035*f*
Plenum configurations, supply duct systems, 1104–1107, 1105*f*, 1106*f*, 1107*f*
Plenum-mount humidifier, 1039, 1040*f*
Pliers, 106*f*
refrigerant recovery pliers, 131, 132*f*
Plumbing, copper tubing, 156, 156*f*
Plume hazards, cooling towers, 1514
Plunger, pneumatic control system, 398–399, 398*f*
Pneumatic atomizing humidifier, 1042
Pneumatic-electric (PE) device, 402
Pneumatics
control systems, 396–403, 396*f*–403*f*
thermostat, 394–395, 395*f*
Pocket filters, 1035, 1035*f*
Point of no pressure change, 980–981, 980*f*
Polarized filtration, 1037
Pollution, indoor air
common pollutants, 1027–1032, 1027*f*, 1028*f*, 1030*f*, 1031*f*
sources of, 1025–1027, 1026*f*
Polyalkylene glycol (PAG) lubricants, 241
R-134a refrigerant, 236
Polybutylene piping, geothermal heat pump, 1345–1347, 1346*f*
Polycyclic organic matter (POM), combustion pollutants, 1030
Polyethylene (PE) piping, 182, 182*f*
geothermal heat pump, 1345–1347, 1346*f*
radiant heating systems, 1004–1009, 1005*f*, 1006*f*, 1008*f*
Polyethylene/steel oil storage tanks, 915–916, 916*f*
Polyol ester (POE)
R-134a refrigerant, 236
refrigerant oils, 241–242, 241*f*, 242*f*
refrigerant retrofitting, 260
Polyphosphates, scale inhibition, 739
Polyvinyl chloride (PVC) piping, 182–183, 183*f*
Polyvinyl ether (PVE) lubricant, 242
Ponds, closed-loop systems in, geothermal heat pump, 1342*f*, 1344
Pool heating systems, solar-powered systems, 1016–1017, 1019*f*, 1020*f*
Portable dollly, 99*f*
Portable heating devices, electric heat, 818–819, 818*f*
Positive displacement device
air conditioning compressors, 1083, 1083*f*
chillers, 1546
compressor cylinders, 588–589, 589*f*–590*f*
Positive temperature coefficient resistor (PTCR), 435–436, 436*f*
compressor start circuit, 1396–1398, 1397*f*–1398*f*
Postpurge
ignition systems, 876, 876*f*
oil burner controls, 939
Potential magnetic relay (PMR), electric motors, 432–434, 432*f*–433*f*, 468, 468*f*
Pounds per square inch (psi), pressure measurements, 25–28
Pour point, fuel oils, 914
Powder-actuated tools (PAT), fastener systems, 147, 147*f*
Power circuits, refrigerator connections, 1404–1405, 1405*f*
Power draft systems, 1208, 1208*f*
Power-passing devices
blower motor circuits, forced-air furnaces, 827–829, 827*f*–829*f*
forced-air electric furnaces, 824–825, 825*f*–826*f*
Power quality analyzer, 136*f*
Power supply
electrical power, 37, 304*f*, 305
electric motors, 422–424, 422*f*–433*f*
energy as, 36
properties of, 36–37, 36*f*
refrigeration heat-pumping mechanism, 41–42, 42*f*
room air conditioning systems, 1454, 1456, 1456*f*
three-phase electric motors, 430–431, 430*f*
truck refrigeration systems, 755–756, 755*f*
unit matching to, 1229
Power tools, 110, 110*f*
Precharged line sets, 158, 158*f*
air conditioning refrigerants, 1162–1163, 1162*f*–1163*f*
Prepurging
ignition systems, 875, 875*f*
oil burner controls, 939
Prerotation vanes
centrifugal compressor, 1472–1473, 1473*f*
chilled-water motor protection, 1504, 1504*f*
Press-type fittings, mechanical piping connections, 185, 185*f*
Pressure. *See also* Head pressure controls; Temperature-pressure relationship
access ports, 662–663, 662*f*–663*f*
air pressure controls, 361, 361*f*
Boyle's law, 32, 32*f*
chilled-water air-conditioning systems, 1537–1538, 1537*f*–1538*f*
control systems, 352–365
crankcase pressure regulation, 625–627, 625*f*–627*f*
critical pressure, 66
defined, 16
domestic refrigerator operations, 1392–1394, 1392*f*–1393*f*
evaporator pressure controls, 513–514, 513*f*–514*f*, 622–624, 622*f*–624*f*
fan-cycling head pressure controls, 628–629, 628*f*–629*f*
forced-air refrigeration, pressure ranges, 771–773, 772*f*–773*f*
fuel oil pumps, 927, 930*f*
gas pressure, 361, 363, 363*f*
high-pressure control systems, 357–358, 639, 639*f*
low-pressure control systems, 358–359, 358*f*
lubrication system, reciprocating compressor, 567, 567*f*
manifold pressures, gas heat, 841, 841*f*, 842*f*
mechanical and electromechanical controls, 363–365, 364*f*–365*f*
oil pressure safety controls, 359–361, 359*f*, 360*f*, 640–643, 640*f*–643*f*
operating conditions, 1225–1228, 1225*f*–1228*f*
pitot tube measurements, 1099, 1099*f*, 1100*f*
point of no pressure change, 980–981, 980*f*
properties of, 25–28
refrigeration cleanup and drop in, 220–221, 220*f*
regulator, standing pilot automatic gas valves, 849, 849*f*
relief valves, 627–628, 627*f*–628*f*
sensing devices, 352–365
switching devices, 633–635, 634*f*–635*f*
test instrument calibration, 288–289, 288*f*–289*f*
thermostatic expansion valves, 601, 602*f*
transducers, 356–357, 356*f*, 357*f*, 360, 360*f*
water pressure regulators, 362–363, 362*f*
Pressure-actuated holdback, condenser flooding, 547, 548*f*
Pressure-dependent leaks, 188, 191
Pressure differential bypass valve, hydronic heating systems, 986, 988*f*, 989
Pressure/enthalpy chart, evaporator refrigeration effect, 510, 510*f*
Pressure gauges
components, 27–28, 27*f*
leak detection, 193–194, 194*f*
oil furnaces, 956, 956*f*, 957*f*
pneumatic control systems, 402, 402*f*
Pressure-regulating valves
gas-type oil burners, 926–928, 927*f*
hydronic heating systems, 984, 984*f*
pressure-limiting TXV, 609, 610*f*

Rigid foam insulation, 1171
Ring valves, refrigerant cylinders, 568, 568*f*–569*f*
Riveting gun, 140, 140*f*
Rivets, 140–141, 140*f*
Rod and tube control systems, 329–330, 329*f*, 330*f*
Rolls, insulation, 1170–1171
Roofing nails, 139, 139*f*
Roof-mount air conditioning systems, 1151–1154, 1152*f*, 1154*f*
curb installation, 1567–1568, 1567*f*–1568*f*
package units, 1564–1580
positioning of, 1566, 1566*f*–1567*f*
recreational vehicles, 1435, 1436*f*
roof penetration, 1567
Roofs
heat gain through, 1279–1280, 1279*f*
heat loss through, 1272*f*, 1273, 1273*f*
Room air conditioning systems
control systems, 1447–1450, 1447*f*–1451*f*
cooling-only units, 1434–1435, 1434*f*–1440*f*
heat-pump-style units, 1437–1438, 1440, 1440*f*–1441*f*
installation, 1440–1447, 1441*f*–1449*f*
maintenance and service, 1450–1456, 1450*f*–1456*f*
refrigeration cycle, 1435–1437, 1436*f*–1437*f*
room units, 1433–1434, 1433*f*
service call protocols, 1457–1460
Rotary compressor, 50–52, 51*f*, 560, 561*f*, 563–564, 565*f*
room air conditioning systems, 1437, 1439*f*
Rotary compressors, air conditioning systems, 1084–1085, 1085*f*–1086*f*
Rotary screw compressor
chilled-water systems, 1541
high-pressure chillers, 1469–1470, 1469*f*–1470*f*
Rotary vacuum pump, 205–206, 205*f*
Rotary vane compressors, 1085, 1086*f*
Rotating equipment
safety issues, 96–97, 96*f*
single-phase motor, 424, 424*f*
three-phase electric motors, 430–431
Rotor components, electric motors, 418–420, 419*f*
Round ducts
air distribution, 1109, 1110*f*, 1111–1114, 1123*f*, 1129*f*–1130*f*, 1130–1131, 1138
installation, 1145–1146, 1146*f*
Rowland, Sherwood, 4
Rule, 108*f*
Run capacitors, 490–491, 490*f*
compressors, 1398, 1398*f*
Running bench test, compressor troubleshooting, 790–791, 790*f*, 791*f*
Running tests, compressor in system, 792, 794
Running times, air source heat pumps, 1321
Run windings, electric motors, 419–420, 419*f*

Total equivalent warming impact (TEWI), 226
secondary-fluid refrigeration systems, 684–685
Total heat difference, air conditioning systems, 1065
Total heat of rejection (THOR)
air source heat pump, 1300
refrigerant cycling, 71
Total pressure, air distribution systems, 1097, 1097*f*
Tower range, 1511
Trace gas, pressure-dependent leaks, 188
Transcritical carbon dioxide cycle, refrigeration applications, 686–689, 686*f*, 689*f*–690*f*
Transducers
oil safety controllers, 642–643, 642*f*–643*f*
parallel compressor systems, 675, 677–680, 678*f*–680*f*
pressure transducers, 356–357, 356*f*, 357*f*
Transformers
electricity production, 307–308, 307*f*, 308*f*
ignition systems, 934–935, 935*f*–936*f*, 941, 943*f*
thermostats, 340, 340*f*, 341*f*
Transistors, 322, 322*f*
variable speed electric motors, 439, 439*f*
Transmission tube, thermostatic expansion valves, 601–604, 601*f*–604*f*
Transport refrigeration, 752–760
Trapeze hanger, split-system air conditioner installation, 1155, 1155*f*
Treatment systems, water quality, 738, 741–742, 741*f*
Triacs, 323, 323*f*
cad cell relays, 945, 946*f*
Triple evacuation, 207–208
Triple point, carbon dioxide refrigerants, 685–686
Troubleshooting
air conditioning systems, 372–373, 373*f*, 376–377, 376*f*–377*f*, 1233–1261
air distribution systems, 1138–1141
air quality systems, 1043–1044
air-to-air heat pumps, 1316–1318, 1316*f*
approach temperature and temperature difference, 783, 1237–1238
belt tension, 481–482, 481*f*–482*f*
capacitors, 488–491, 488*f*–491*f*
charging procedures, 1247–1249, 1248*f*–1249*f*
circuit electrical protectors, 1256, 1256*f*
compressors, 789–792, 789*f*–792*f*, 794, 794*f*, 1251–1255, 1252*f*–1255*f*, 1320, 1320*f*
condensers, 784–786, 785*f*–786*f*
condenser splitting, 553–554
control systems, 370–392
drive assembly removal, 480–481, 480*f*–481*f*
electrical circuits, 370–375, 371*f*–374*f*
electrical systems, 1250–1255, 1250*f*–1251*f*, 1253*f*–1255*f*
electric motors, 433*f*, 434, 436, 479–494
evaporators, 782–784, 783*f*–784*f*
fan motors, domestic refrigerators, 1402–1403, 1403*f*
fixed-bore metering devices, 1247–1249, 1248*f*
flame rectification systems, 867–868
four-way reversing valve, 1318–1320, 1319*f*
freezers and refrigerators, 1404–1419
gas furnace systems, 886–897, 888*f*–897*f*
gauge manifold, 1238–1240, 1239*f*–1241*f*
geothermal heat pump, 1352, 1353*f*
high-side gauge readings, 1240, 1242*f*
high-temperature applications, 771–773, 772*f*–773*f*
ice machine microprocessors, 734–735, 734*f*–737*f*
ice machines, 706–709, 707*f*–708*f*, 724, 727*f*, 734–735, 734*f*–737*f*, 742–746
low refrigerant charge, 779–781, 779*f*–781*f*, 1408–1409, 1410*f*
low-side gauge readings, 1240
low-temperature refrigeration system, 773*f*, 774
low-voltage circuit amperage, 377–378, 377*f*
low-voltage circuit voltage, 378, 378*f*
mechanical equipment, 1233–1237, 1234*f*–1237*f*
mechanical motor problems, 479
medium-temperature refrigeration, 773–774, 773*f*
organized troubleshooting, 770–771, 771*f*
pictorial and ladder diagrams, 385–387, 386*f*–387*f*
positive temperature coefficient resistor, 436
pulley alignment, 482, 482*f*
refrigerants, 781–782, 781*f*–782*f*, 786–789, 786*f*–789*f*, 1410–1411, 1411*f*
room air conditioning units, 1450–1456, 1452*f*–1456*f*
safety pilot-proving device, 888, 897*f*–898*f*
service call protocols, 492–494, 794–813, 1257–1261
single-phase motor starting problems, 488, 488*f*
spark ignition and intermittent pilot systems, 888–889, 890*f*, 892, 893*f*, 897, 900*f*, 901
switches and loads, 378–385
temperature readings, 1242–1246, 1243*f*–1246*f*
thermostat, 372–377, 372*f*–377*f*
thermostatic expansion valves (TXVs), 1249, 1249*f*
wiring and connectors, 491

Truck refrigeration systems, 752–759, 753*f*–759*f*
Tube benders, 113, 114*f*, 115*f*, 116*f*, 159–161, 160*f*, 161*f*
Tube brushes, 115, 116*f*
Tube cutter, 112, 113*f*
Tube-in-tube heat exchanger, dry coolers, 1603–1605, 1604*f*
Tube-piercing valve, refrigerator compressors, 1385, 1387*f*
Tube-within-a-tube condensers, 524–525, 524*f*–526*f*
  cleanable condensers, 526–527, 527*f*
Tube-within-a-tube heat exchanger, open-loop geothermal heat pump, 1335–1336, 1339*f*
Tubing. *See also* Line sets
  bending of, 159–161, 160*f*, 161*f*
  compressor changeout, 1414–1415, 1415*f*
  cutting, 158, 159*f*
  dry tubing applications, radiant heating systems, 1008, 1008*f*
  flooded evaporator chillers, 1475, 1475*f*, 1477–1478, 1478*f*
  insulation, 156–157, 156*f*, 157*f*
  leak test and evacuation, 1161, 1161*f*
  line sets, 158, 158*f*
  purpose of, 155
  radiant heating systems, 1004, 1005*f*, 1006*f*
  refrigerants, 230, 1159–1163, 1159*f*–1162*f*
  refrigerator connections, 1404–1405, 1405*f*
  soldering and brazing, 161–162, 162*f*
  types and sizes, 155–156
  water-cooled condensers, 1549, 1549*f*
Tubing pinch-off tool, 116, 116*f*, 117*f*
Tubing tools, 112–117, 113*f*–117*f*
Tunnel quick cooling, 763, 764*f*
Turbidity, water quality, 739
Turbulence, duct air movement, 1117, 1118*f*
Turning vanes, ductwork systems, 1117, 1118*f*
Twinning, ignition postpurging, 876–877, 876*f*
Two-pipe direct return system, hydronic heating, 997–998, 998*f*
Two-pipe direct variable refrigerant flow systems, 1595, 1596*f*–1598*f*, 1598
Two-pipe reverse return system, hydronic heating systems, 998, 998*f*
Two-speed compressor motors, 436
  current draw, 1231
Two-stage compression, 560, 560*f*
  extra-low-temperature refrigeration, 761–762, 761*f*
Two-stage gas furnaces, 878–879, 881*f*
Two-stage pump
  air-to-air heat pumps, 1304–1306, 1305*f*–1306*f*
  gun-type oil burners, 926, 926*f*, 928*f*
Two-stage vacuum pumps, 206
Two-step capacity control, scroll compressors, 583–584, 583*f*–584*f*
Two-temperature controls, refrigeration systems, 621, 622*f*
Two-way modulating valves, package rooftop air conditioning, 1583–1584, 1583*f*–1584*f*
TXV. *See* Thermostatic expansion valves (TXVs)
Type B venting systems, gas furnace ventilation, 882–883, 882*f*

U

Ultrasound leak detection, 122, 122*f*, 195, 195*f*
Ultraviolet (UV) fluorescent leak detector, 195, 196*f*
Ultraviolet (UV) light, indoor air cleaning and, 1037–1038, 1037*f*
Ultraviolet (UV) radiation, ozone depletion and, 4, 224–225, 224*f*, 225*f*
Unconditioned spaces
  heat gain in, 1281–1282, 1282*f*
  heat loss through, 1277–1278
Under-belly units, truck refrigeration systems, 756, 756*f*
Under-duct humidifier, 1039, 1040*f*
Underground tanks, oil storage, 915, 915*f*
Uneven parallel compressors, 678–680
United States Green Building Council (USGBC), 6
Unit heaters, 820, 820*f*
Unit pads or foundations, air conditioning systems, 1151–1153, 1153*f*
Updraft, furnace systems, 1208
Upflow forced-air furnaces
  gas furnaces, 837, 837*f*
  oil furnaces, 910*f*, 911
Upper exposure limit (UEL), refrigerant safety, 232–233
Upshot burner, gas heating systems, 852–853, 852*f*, 853*f*
Utility knife, 109*f*
U-values
  heat loss through floors, 1275–1276, 1275*f*
  heat loss through walls, 1272, 1272*f*
  heat transfer, 1269–1270, 1270*f*–1271*f*

V

Vacuum
  evacuation theory, 200–201
  evaporator leak repair, 1412–1413, 1412*f*
  fuel oil pumps, 927, 930*f*, 956, 956*f*
  measurement of, 201–206
Vacuum pump, 120, 120*f*, 201–206, 203*f*, 204*f*, 205*f*
  moisture removal, 209–210, 210*f*, 211*f*, 212*f*
  system evacuation and cleanup, 206–207, 207*f*
Vacuum test, compressors, 790, 790*f*
Valve-delay-on, oil burner controls, 939
Valve plate, reciprocating compressors, 568, 570*f*
Valves. *See also* specific valves, e.g., Thermostatic expansion valve
  automatic combination gas valves, 847–852, 847*f*–851*f*
  balancing valves, 986, 988*f*, 989
  ball valves, 658, 660*f*, 1543, 1543*f*
  butterfly valve, 1550
  bypass valves, 1527–1528, 1528*f*–1529*f*
  check valves, 652, 652*f*
  compressor troubleshooting, 789–790
  cooling tower makeup water assembly, 1519–1520, 1519*f*–1520*f*
  crankcase pressure regulator valve, 625–627, 625*f*–627*f*
  diaphragm valves, 658, 660*f*, 1542–1543, 1542*f*
  direct burner automatic gas valves, 851–852, 851*f*
  discharge service valves, 658, 659*f*, 1545, 1545*f*
  discus valves, 578–579, 578*f*–579*f*
  diverting valve, 1528, 1528*f*
  electric evaporator pressure-regulating valve, 624–625, 625*f*
  evacuation systems, 216, 217*f*, 218*f*
  evaporator pressure-regulating valve, 621–624, 622*f*–624*f*
  expansion devices, 594–619
  flow control valves, 989, 989*f*
  four-way reversing valve, 1285, 1287–1290, 1288*f*–1292*f*, 1308–1309, 1309*f*–1311*f*, 1318–1320, 1319*f*
  gas heating systems, 845–852
  gate valves, 1549, 1550*f*–1551*f*
  globe valves, 1549, 1550*f*
  hand valve, 1521–1522, 1521*f*–1522*f*
  heat motor-controlled valves, 846–847, 847*f*
  intermittent pilot automatic gas valves, 849–851, 850*f*
  king valve, 269–270, 270*f*–271*f*, 540, 541*f*, 616, 616*f*, 650, 650*f*, 1545, 1545*f*
  large air conditioning systems, 1542–1545, 1542*f*–1545*f*
  line tap valves, 1451, 1451*f*
  low-ambient control valve, 549–550, 550*f*, 551*f*
  low-water cutoff valve, 984–985, 985*f*
  mixing valves, 1009, 1009*f*, 1527–1528, 1528*f*
  modulating valves, 1583–1584, 1583*f*–1584*f*
  oil check valve, 665–666, 665*f*–666*f*
  oil safety valves, 921
  ORI/ORD valves, 547, 548*f*–549*f*, 549, 550*f*
  pressure access ports, 567, 567*f*
  pressure differential bypass valve, 986, 988*f*, 989
  pressure relief valves, 353, 353*f*, 956, 956*f*, 957*f*, 984, 984*f*
  primary-secondary hydronic pumping systems, 1001–1003, 1002*f*–1003*f*
  radiant heating systems, 1009, 1009*f*, 1010*f*, 1011*f*

smart valves, 877–878, 878*f*–880*f*
solenoid valve, 631–633, 632*f*–633*f*, 932, 933*f*, 1347, 1348*f*, 1519–1520, 1519*f*–1520*f*
standing pilot automatic gas valves, 847–849, 848*f*–850*f*
stem packing, 1543, 1544*f*
step-motor valves, 611–615
suction service valves, 657–658, 657*f*–659*f*, 1467–1468, 1467*f*–1468*f*, 1545, 1545*f*
thermostatic radiator valves, 989, 990*f*
troubleshooting, 1238–1240, 1239*f*–1240*f*
water-regulation valves, 353, 354*f*, 362–363, 362*f*
zone valves, 985–986, 985*f*–987*f*
Valve stem depressors, evacuation procedures, 214–215, 215*f*
Vapor charge bulb, expansion devices, 603–604, 603*f*–604*f*
Vapor condensation, 24
Vaporization, latent heat of, 22
Vapor pressure
refrigerants, 45, 47, 47*f*, 245–246, 249–255, 250*f*–251*f*
superheating and, 57–58
Vapor pump, compressor as, 50–52, 50*f*–52*f*
Vapor refrigerants, charging, 267–269, 268*f*, 269*f*
Vapor-to-vapor heat exchange, evaporators, 502, 503*f*
Variable air volume (VAV) flow
chilled-water systems, 1584–1589, 1585*f*–1592*f*
fan-cycling head pressure controls, 629, 629*f*
package rooftop air conditioning, 1580–1583, 1583*f*
Variable capacity equipment, air conditioning systems, 1082
Variable frequency drives (VFDs)
condenser fan motors, 545–546, 546*f*
cooling tower fan section, 1517–1518, 1517*f*–1518*f*
electric motors, 443–446, 443*f*–445*f*
fan-cycling head pressure controls, 629, 629*f*
reciprocating compressor, 1467–1468, 1467*f*–1468*f*
scroll compressors, 586–588, 588*f*
Variable-output programmable thermostat, 880, 881*f*
Variable refrigerant flow (VRF) systems, package rooftop air conditioning, 1589, 1592–1602, 1593*f*–1602*f*
Variable-speed blowers, zoned air distribution, 1122
Variable-speed motors, 438–441, 439*f*–441*f*
air source heat pumps, 1323
Velocity pressure, air distribution systems, 1097, 1097*f*
Velometer, 1098, 1098*f*
Vent alarm, 918, 918*f*
Vent-free stoves, 1615
Ventilation
air conditioning systems, 1061, 1063–1068, 1065*f*–1067*f*
demand control ventilation, 1579–1580, 1579*f*
indoor air quality and, 1032–1033, 1032*f*–1033*f*
safety and, 98, 99*f*
store ambient conditions, maintenance of, 696–697, 697*f*
Venting systems
compressor terminal, 230, 232
gas furnaces, 881–884, 882*f*–884*f*, 1204–1207, 1205*f*–1207*f*
gas stoves, 1615, 1615*f*
hydronic heating, 981–983, 982*f*–983*f*
oil fuel lines, 918, 918*f*
preventive maintenance, 1200–1201, 1200*f*–1201*f*
Venturi, gas heating systems, 842
Vertical ground loops, geothermal heat pumps, 1342, 1358, 1359*f*–1360*f*
Vertical runs, venting systems, 1206, 1206*f*
Vibration-dependent leaks, 188, 192, 192*f*
Vibration eliminators
air conditioning systems, 1151–1152, 1153*f*
refrigeration systems, 661–662, 662*f*
supply duct systems, 1103, 1103*f*
Viscosity, fuel oils, 913, 913*f*
Volatile organic carbons (VOCs), indoor air pollution and, 1028, 1038
Voltage imbalance, chilled-water motor protection, 1506
Voltage measurement, 299–300, 300*f*, 302–303, 302*f*–303*f*, 311–314, 311*f*–314*f*
compressors, 1230–1231
inductance and, 306–307, 307*f*
low-voltage circuit troubleshooting, 378, 378*f*
Voltage quality recorder, 136*f*
VoltAlert meters, 136*f*
Volt-amperes, low-voltage circuit troubleshooting, 377–378, 377*f*
Volt-ohm-miliammater (VOM), 129, 129*f*, 310–311, 310*f*
calibration, 289–291, 290*f*, 291*f*
digital tool, 136*f*
electrical troubleshooting, 1250–1251, 1250*f*–1251*f*
low-voltage circuit voltage troubleshooting, 378, 378*f*
Vortexing, cooling towers, 1527, 1527*f*

W

Walk-in refrigeration, 697–698, 697*f*–698*f*
package refrigeration, 700, 700*f*
Wall anchors, 143, 143*f*
Wall-mounted unit heaters, 820, 820*f*

pressure regulators, 362–363, 362*f*
saturation points, 201, 201*f*
Water boxes
flooded evaporator chillers, 1475–1476, 1475*f*–1476*f*
shell-and-coil condensers, 528, 528*f*–529*f*
Water capacity, refrigerant recovery, 253, 254*f*
Water-cooled condensers
basic properties, 523–524, 523*f*
high-pressure chillers, 1478, 1479*f*, 1547*f*–1551*f*, 1548–1551
operating conditions, 776, 777*f*
Water distribution and flow
cooling towers, balancing, 1522, 1522*f*–1523*f*
cube ice production, 714, 714*f*
Water fill system, ice machines, 709–710, 709*f*–710*f*
Water hammer, 1347
Water level probes, cube ice production, 716, 716*f*
Water loop, geothermal heat pump, 1339
Water pressure, water-regulating valves, 353, 354*f*
Water pump systems
cooling towers, 1522–1530, 1522*f*–1530*f*
cube ice production, 716, 717*f*
Water quality
geothermal heat pump, 1337–1338, 1338*f*
ice machines, 735–742
Water softeners, 739
Water-source heat pumps, 1286
geothermal heat pump, 1335–1336, 1336*f*–1337*f*
geothermal open-loop systems, 1347–1349, 1347*f*–1349*f*

Water temperature, hydronic heating systems, primary-secondary pumping, 1000–1003, 1001*f*
Water-to-air unit, air conditioning systems, 1151, 1151*f*
Water-to-water unit
air conditioning systems, 1151, 1151*f*
geothermal heat pump, 1349–1352, 1350*f*–1351*f*
Water vapor, superheated gases and, 1054–1055, 1054*f*
Watt, as electrical power, 37
Weatherization techniques, 1168–1169
Weatherstripping, 1185–1188, 1186*f*–1192*f*
Webster pumps, oil burner servicing, 957
Weep holes, ice machines, 724, 728*f*
Weight, 31
refrigerants, 272–273, 272*f*, 273*f*
Welded hermetic compressor, 561–562, 562*f*–563*f*
Wells, geothermal open-loop systems, 1347–1349, 1347*f*–1349*f*
Wet-base cast-iron boiler, 972, 972*f*, 973*f*
Wet-bulb depression chart, 1056–1057, 1056*f*
Wet bulb temperature (WBT)
air conditioning systems, 1055–1057, 1056*f*, 1058*f*
condenser wastewater systems, 531
recirculating water condensers, 778, 779*f*
Wet compression, evaporator defrosting, 518
Wetted-surface material, cooling towers, 1515, 1515*f*
Wheel systems, domestic refrigerators, 1385, 1385*f*
Windings
chilled-water systems, 1500, 1500*f*
compressor electrical systems, 1252–1255, 1253*f*–1254*f*
electric motors, 419–422, 419*f*, 421*f*–422*f*
short circuit to ground frame, 485–487, 485*f*–487*f*
temperature control, 339–340, 340*f*
troubleshooting, 482–485, 483*f*–485*f*
Windows
heat gain through, 1280, 1280*f*
heat loss through, 1273
room air conditioning installation in, 1441–1447, 1442*f*–1445*f*
Wire, conduction wire, 315–316, 315*f*–317*f*
Wiring diagrams
air conditioning installation, 1148–1150, 1149*f*–1150*f*
automatic pumpdown systems, 636–638, 636*f*–638*f*
cad cell, intermittent ignition, 945, 946*f*
cad cell, interrupted ignition, 947, 948*f*–953*f*
compressors, 1252–1253, 1253*f*, 1398–1399, 1399*f*
defrost cycle, air source heat pump, 1313*f*–1314*f*
defrost timer, 1399*f*, 1401, 1401*f*
domestic refrigerators and freezers, 1395, 1395*f*–1396*f*
energy-saver switch, 1402, 1402*f*
forced-air electric furnaces, 824, 825*f*, 829*f*, 831*f*
gas furnace, 886–888, 888*f*
humidistat, 1041, 1041*f*
ice flake machine, 710, 711*f*
low-voltage thermostats, 822–823, 823*f*
multiple speed motor, 1103, 1103*f*
oil furnace, 939, 940*f*–941*f*, 941, 942*f*, 943*f*, 944
permanent split-capacitor motor, 924–925, 925*f*
refrigerators and freezer lights, 1402, 1403*f*
self-contained refrigeration, 669–670, 670*f*–671*f*
split-system air conditioning, 1252*f*
stack relay safety control, 944, 944*f*–945*f*
step-control expansion valve, 1483, 1484*f*
tools, 111–112, 111*f*
troubleshooting, 491, 491*f*
Wood-burning fireplace inserts, 1615–1616, 1615*f*
Wood-burning stoves, 1608–1614
combustion pollutants, 1029–1031, 1030*f*–1031*f*
construction, 1612
installation, 1613–1614, 1613*f*–1614*f*
safety, 1613
wood characteristics, 1608–1609, 1608*f*–1609*f*
Wood characteristics, 1608–1609, 1608*f*–1609*f*
Wood screws, 141, 141*f*
Work, energy as, 36
Work hardening, copper tubing, 156
Worksheets, energy audits, 1212
Wrenches, 110–111
pipe wrenches, 182, 182*f*
service wrench/adapters, 131, 132*f*
Wrenches, 105*f*–106*f*
Wright, L. W., 2
Wrought iron pipe, 178–182
Wrought steel pipe, 178–182, 178*f*–182*f*
Wye-delta start, chilled-water systems, 1501–1503, 1502*f*–1503*f*

Z

Z-coil circuit, troubleshooting, 383
Zeotropic refrigerants, 79, 81–82, 81*f*
system charging, 279–282, 279*f*=282*f*
Zip Code Insulation Calculator, 1170, 1170*f*
Zone systems
air distribution, 1119–1122, 1119*f*–1121*f*
hydronic two-zone system, 969–970, 970*f*
Zone valves, hydronic heating systems, 985–986, 985*f*–987*f*
