Refrigeration and Air Conditioning Technology, Eighth Edition

John A. Tomczyk, Eugene Silberstein, William C. Whitman, William M. Johnson

Vice President, GM Skills & Product Planning: Dawn Gerrain

Product Team Manager: James DeVoe

Senior Director Development: Marah Bellegarde

Senior Product Development Manager: Larry Main

Senior Content Developer: John Fisher

Product Assistant: Jason Koumourdous

Vice President Marketing Services: Jennifer Ann Baker

Marketing Manager: Scott Chrysler

Senior Production Director: Wendy A. Troeger

Production Director: Andrew Crouth

Senior Content Project Manager: Kara A. DiCaterino

Senior Art Director: Jack Pendleton

Technology Project Manager: Joe Pliss

BRIEF CONTENTS

SECTION 1: Theory of Heat

Introduction 2
Unit 1 Heat, Temperature, and Pressure 16
Unit 2 Matter and Energy 30
Unit 3 Refrigeration and Refrigerants 39

SECTION 2: Safety, Tools and Equipment, and Shop Practices

Unit 4 General Safety Practices 86
Unit 5 Tools and Equipment 104
Unit 6 Fasteners 139
Unit 7 Tubing and Piping 155
Unit 8 Leak Detection, System Evacuation, and System Cleanup 187
Unit 9 Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting 223
Unit 10 System Charging 267
Unit 11 Calibrating Instruments 284

SECTION 3: Automatic Controls

Unit 12 Basic Electricity and Magnetism 296
Unit 13 Introduction to Automatic Controls 326
Unit 14 Automatic Control Components and Applications 339
Unit 15 Troubleshooting Basic Controls 370
Unit 16 Advanced Automatic Controls—Direct Digital Controls (DDCs) and Pneumatics 394

SECTION 4: Electric Motors

Unit 17 Types of Electric Motors 418
Unit 18 Application of Motors 450
Unit 19 Motor Controls 468
Unit 20 Troubleshooting Electric Motors 479

SECTION 5: Commercial Refrigeration

Unit 21 Evaporators and the Refrigeration System 498
Unit 22 Condensers 523
Unit 23 Compressors 558
Unit 24 Expansion Devices 594
Unit 25 Special Refrigeration System Components 621
Unit 26 Applications of Refrigeration Systems 668
Unit 27 Commercial Ice Machines 704
Unit 28 Special Refrigeration Applications 752
Unit 29 Troubleshooting and Typical Operating Conditions for Commercial Refrigeration 770

SECTION 6: Air-Conditioning (Heating and Humidification)

Unit 30 Electric Heat 818
Unit 31 Gas Heat 836
Unit 32 Oil Heat 910
Unit 33 Hydronic Heat 969
Unit 34 Indoor Air Quality 1025

SECTION 7: Air-Conditioning (Cooling)

Unit 35 Comfort and Psychrometrics 1048
Unit 36 Refrigeration Applied to Air-Conditioning 1072
Unit 37 Air Distribution and Balance 1093
Unit 38 Installation 1143
Unit 39 Residential Energy Auditing 1167
Unit 40 Typical Operating Conditions 1218
Unit 41 Troubleshooting 1233

SECTION 8: All-Weather Systems

Unit 42 Heat Gains and Heat Losses in Structures 1266
Unit 43 Air Source Heat Pumps 1285
Unit 44 Geothermal Heat Pumps 1335

SECTION 9: Domestic Appliances

Unit 45 Domestic Refrigerators and Freezers 1372
Unit 46 Room Air Conditioners 1433

SECTION 10: Commercial Air-Conditioning and Chilled-Water Systems

Unit 47 High-Pressure, Low-Pressure, and Absorption Chilled-Water Systems 1464
Unit 48 Cooling Towers and Pumps 1509
Unit 49 Operation, Maintenance, and Troubleshooting of Chilled-Water Air-Conditioning Systems 1536
Unit 50 Commercial, Packaged Rooftop, Variable Refrigerant Flow, and Variable Air Volume Systems 1563

Appendix A Alternative Heating (Stoves and Fireplace Inserts) 1608
Appendix B Temperature Conversion Chart 1617

CONTENTS

Preface xiii

SECTION 1: Theory of Heat

Introduction 2

History of Refrigeration and Air-Conditioning (Cooling) 2
Green Awareness 6
History of Home and Commercial Heating 8
Career Opportunities 8
Technician Certification Programs 9
Programmatic Accreditation 10
National Skill Standards 11
Customer Relations and Technician Soft Skills 12

Unit 1 Heat, Temperature, and Pressure 16

1.1 Heat, Temperature, and Pressure 16
1.2 Temperature 17
1.3 Introduction to Heat 18
1.4 Conduction 20
1.5 Convection 20
1.6 Radiation 21
1.7 Sensible Heat 22
1.8 Latent Heat 22
1.9 Specific Heat 24
1.10 Sizing Heating Equipment 24
1.11 Pressure 25
1.12 Atmospheric Pressure 26
1.13 Pressure Gauges 27

Unit 2 Matter and Energy 30

2.1 Matter 30
2.2 Mass and Weight 31
2.3 Density 31
2.4 Specific Gravity 31
2.5 Specific Volume 31
2.6 Gas Laws 32
2.7 Energy 34
2.8 Conservation of Energy 35
2.9 Energy Contained in Heat 35
2.10 Energy in Magnetism 35
2.11 Purchase of Energy 36
2.12 Energy Used as Work 36
2.13 Power 36
2.14 Electrical Power—the Watt 37

Unit 3 Refrigeration and Refrigerants 39

3.1 Introduction to Refrigeration 39
3.2 Refrigeration 40
3.3 Rating Refrigeration Equipment 40
3.4 The Refrigeration Process 41
3.5 Temperature and Pressure Relationship 43
3.6 Refrigeration Components 48
3.7 The Evaporator 48
3.8 The Compressor 50
3.9 The Condenser 52
3.10 The Refrigerant Metering Device 54
3.11 Matching Refrigeration Systems and Components 56
3.12 Refrigerants 58
3.13 Refrigerants Must Be Safe 60
3.14 Refrigerants Must Be Detectable 60
3.15 The Boiling Point of the Refrigerant 62
3.16 Pumping Characteristics 62
3.17 Popular Refrigerants and their Important Characteristics 62
3.18 Refrigerant Cylinder Color Codes 62
3.19 Recovery, Recycling, or Reclaiming of Refrigerants 65
3.20 Plotting the Refrigerant Cycle 65
3.21 Plotting the Refrigerant Cycle for Blends with Noticeable Temperature Glide (Zeotropic Blends) 79

SECTION 2: Safety, Tools and Equipment, and Shop Practices

Unit 4 General Safety Practices 86

4.1 Pressure Vessels and Piping 86
4.2 Electrical Hazards 90
4.3 Heat 95
4.4 Cold 96
4.5 Mechanical Equipment 96
4.6 Moving Heavy Objects 98
4.7 Refrigerants in Your Breathing Space 98
4.8 Using Chemicals 101

Unit 5 Tools and Equipment 104

5.1 General Tools 104
5.2 Specialized Hand Tools 110
5.3 Tubing Tools 112
5.4 Specialized Service and Installation Equipment 117
5.5 Refrigerant Leak Detectors 120
5.6 Other Tools 122
5.7 Miscellaneous Tools and Equipment for Specialized Needs 131

Unit 6 Fasteners 139

6.1 Nails 139
6.2 Staples and Rivets 140
6.3 Threaded Fasteners 141
6.4 Concrete Fasteners 146
6.5 Other Fasteners 147

Unit 7 Tubing and Piping 155

7.1 Purpose of Tubing and Piping 155
7.2 Types and Sizes of Tubing 155
7.3 Tubing Insulation 156
7.4 Line Sets 158

7.5 Cutting Tubing 158
7.6 Bending Tubing 159
7.7 Soldering and Brazing Processes 161
7.8 Heat Sources for Soldering and Brazing 162
7.9 Fluxing 168
7.10 Soldering Techniques 169
7.11 Brazing Techniques 171
7.12 Practical Soldering and Brazing Tips 172
7.13 Making Flare Joints 175
7.14 Swaging Techniques 176
7.15 Compression Fittings 177
7.16 Steel and Wrought Iron Pipe 178
7.17 Installing Steel Pipe 182
7.18 Plastic Pipe 182
7.19 Alternative Mechanical Piping Connections 184

Unit 8 Leak Detection, System Evacuation, and System Cleanup 187

8.1 Leaks 187
8.2 Basic Refrigerant Leak Detection 189
8.3 Advanced Leak Detection 191
8.4 Standing Pressure Test 193
8.5 Leak Detection Tips 195
8.6 Repairing Leaks 198
8.7 System Evacuation 199
8.8 General Evacuation Procedures 210
8.9 Cleaning a Dirty System 218

Unit 9 Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting 223

9.1 Refrigerants and the Environment 223
9.2 Ozone Depletion 224
9.3 Global Warming 225
9.4 Refrigerants 226
9.5 CFC Refrigerants 227
9.6 HCFC Refrigerants 227
9.7 HFC Refrigerants 228
9.8 Hydrofluoro-Olefin (HFO) Refrigerants 228
9.9 Hydrocarbon (HC) Refrigerants 229
9.10 Naming Refrigerants 233
9.11 Refrigerant Blends 234
9.12 Popular Refrigerants and Their Compatible Oils 235
9.13 Refrigerant Oils and Their Applications 240
9.14 Oil Groups 241
9.15 Regulations 242
9.16 Recover, Recycle, or Reclaim 243
9.17 Methods of Recovery 245
9.18 Mechanical Recovery Systems 248
9.19 Recovering Refrigerant from Small Appliances 255
9.20 Reclaiming Refrigerant 258
9.21 Refrigerant Retrofitting 258
9.22 Refrigerants and Tools in the Future 264

Unit 10 System Charging 267

10.1 Charging a Refrigeration System 267
10.2 Vapor Refrigerant Charging 267
10.3 Liquid Refrigerant Charging 269
10.4 Weighing Refrigerant 272
10.5 Using Charging Devices 273
10.6 Using Charging Charts 274
10.7 Subcooling Charging Method for TXV Systems 277
10.8 Charging Near-Azeotropic (Zeotropic) Refrigerant Blends 279

Unit 11 Calibrating Instruments 284

11.1 Calibration 284
11.2 Temperature-Measuring Instruments 284
11.3 Pressure Test Instruments 288
11.4 Electrical Test Instruments 289
11.5 Electronic Refrigerant Leak Detection Devices 291
11.6 Flue-Gas Analysis Instruments 292
11.7 General Maintenance 293

SECTION 3: Automatic Controls

Unit 12 Basic Electricity and Magnetism 296

12.1 Atomic Structure 296
12.2 Movement of Electrons 297
12.3 Conductors 298
12.4 Insulators 298
12.5 Electricity Produced from Magnetism 298
12.6 Current 299
12.7 Units of Electrical Measurement 299
12.8 The Basic Electric Circuit 299
12.9 Making Electrical Measurements 300
12.10 Ohm's Law 300
12.11 Characteristics of Series Circuits 304
12.12 Characteristics of Parallel Circuits 304
12.13 Electrical Power 305
12.14 Magnetism 305
12.15 Inductance 306
12.16 Transformers 307
12.17 Capacitance 308
12.18 Impedance 310
12.19 Electrical Measuring Instruments 310
12.20 Sine Waves 314
12.21 Wire Sizes 315
12.22 Circuit Protection Devices 316
12.23 Semiconductors 319

Unit 13 Introduction to Automatic Controls 326

13.1 Types of Automatic Controls 326
13.2 Devices that Respond to Thermal Change 326
13.3 The Bimetal Device 328
13.4 Control by Fluid Expansion 331
13.5 The Thermocouple 333
13.6 Electronic Temperature-Sensing Devices 336

Unit 14 Automatic Control Components and Applications 339

14.1 Temperature Controls 339
14.2 Low-Voltage Space Temperature Controls 341
14.3 Line-Voltage Space Temperature Controls 345
14.4 Sensing the Temperature of Solids 347
14.5 Measuring the Temperature of Fluids 349
14.6 Pressure-Sensing Devices 352
14.7 Pressure Transducers 356
14.8 High-Pressure Controls 357
14.9 Low-Pressure Controls 358
14.10 Oil Pressure Safety Controls 359

14.11 Air Pressure Controls 361
14.12 Gas Pressure Switches 361
14.13 Switchless Devices That Control Fluid Flow 361
14.14 Water Pressure Regulators 362
14.15 Gas Pressure Regulators 363
14.16 Mechanical and Electromechanical Controls 363
14.17 Maintenance of Mechanical Controls 364
14.18 Maintenance of Electromechanical Controls 364
14.19 Service Technician Calls 365

Unit 15 Troubleshooting Basic Controls 370

15.1 Introduction to Troubleshooting 370
15.2 Troubleshooting a Simple Circuit 371
15.3 Troubleshooting a Complex Circuit 372
15.4 Troubleshooting the Thermostat 375
15.5 Troubleshooting Amperage in the Low-Voltage Circuit 377
15.6 Troubleshooting Voltage in the Low-Voltage Circuit 378
15.7 Troubleshooting Switches and Loads 378
15.8 Pictorial and Ladder Diagrams 385
15.9 Service Technician Calls 387

Unit 16 Advanced Automatic Controls—Direct Digital Controls (DDCs) and Pneumatics 394

16.1 Control Applications 394
16.2 Types of Control Systems 394
16.3 Pneumatic Controls 396
16.4 Cleaning and Drying Control Air 397
16.5 Control Components 398
16.6 Direct Digital Controls (DDCs) 403
16.7 Residential Electronic Controls 410

SECTION 4: Electric Motors

Unit 17 Types of Electric Motors 418

17.1 Uses of Electric Motors 418
17.2 Parts of an Electric Motor 418
17.3 Electric Motors and Magnetism 419
17.4 Determining a Motor's Speed 420
17.5 Start Windings 421
17.6 Starting and Running Characteristics 421
17.7 Electrical Power Supplies 422
17.8 Single-Phase Open Motors 424
17.9 Split-Phase Motors 424
17.10 The Centrifugal Switch 424
17.11 The Electronic Relay 426
17.12 Capacitor-Start Motors 426
17.13 Capacitor-Start, Capacitor-Run Motors 427
17.14 Permanent Split-Capacitor Motors 427
17.15 Shaded-Pole Motors 429
17.16 Three-Phase Motors 429
17.17 Single-Phase Hermetic Motors 431
17.18 The Potential Relay 432
17.19 Troubleshooting 434
17.20 The Current Relay 434
17.21 Positive Temperature Coefficient Resistor (PTCR) 435
17.22 Troubleshooting the PTCR 436
17.23 Two-Speed Compressor Motors 436
17.24 Special Application Motors 437
17.25 Three-Phase Compressor Motors 437
17.26 Variable-Speed Motors 438
17.27 DC Converters (Rectifiers) 441
17.28 Inverters and Variable Frequency Drives (VFDs) 443
17.29 Electronically Commutated Motors (ECMs) 446
17.30 Cooling Electric Motors 447

Unit 18 Application of Motors 450

18.1 Motor Applications 450
18.2 The Power Supply 450
18.3 Electric-Motor Working Conditions 457
18.4 Insulation Type or Class 458
18.5 Types of Bearings 458
18.6 Motor Mounting Characteristics 460
18.7 Motor Drives 462

Unit 19 Motor Controls 468

19.1 Introduction to Motor Control Devices 468
19.2 Full-Load and Locked-Rotor Amperage 469
19.3 The Relay 469
19.4 The Contactor 470
19.5 Motor Starters 472
19.6 Motor Protection 473
19.7 Inherent Motor Protection 474
19.8 External Motor Protection 474
19.9 National Electrical Code® Standards 476
19.10 Temperature-Sensing Devices 476
19.11 Magnetic Overload Devices 477
19.12 Restarting the Motor 477

Unit 20 Troubleshooting Electric Motors 479

20.1 Motor Troubleshooting 479
20.2 Mechanical Motor Problems 479
20.3 Removing Drive Assemblies 480
20.4 Belt Tension 481
20.5 Pulley Alignment 482
20.6 Electrical Problems 482
20.7 Open Windings 482
20.8 Shorted Motor Windings 484
20.9 Short Circuit to Ground (Frame) 485
20.10 Single-Phase Motor Starting Problems 488
20.11 Checking Capacitors 488
20.12 Identification of Capacitors 490
20.13 Wiring and Connectors 491
20.14 Troubleshooting Hermetic Motors 492
20.15 Service Technician Calls 492

SECTION 5: Commercial Refrigeration

Unit 21 Evaporators and the Refrigeration System 498

21.1 Refrigeration 498
21.2 Temperature Ranges of Refrigeration 499
21.3 The Evaporator 499
21.4 Boiling and Condensing 500
21.5 The Evaporator and Boiling Temperature 500
21.6 Removing Moisture 500
21.7 Heat Exchange Characteristics of the Evaporator 500
21.8 Types of Evaporators 503
21.9 Evaporator Evaluation 509
21.10 Latent Heat in the Evaporator 511
21.11 The Flooded Evaporator 511

21.12 Dry-Type Evaporator Performance 511
21.13 Evaporator Superheat 512
21.14 Hot Pulldown (Excessively Loaded Evaporator) 512
21.15 Pressure Drop in Evaporators 513
21.16 Liquid Cooling Evaporators (Chillers) 515
21.17 Evaporators for Low-Temperature Applications 516
21.18 Defrost of Accumulated Moisture 517
21.19 Evaporator and Defrost Efficiency Controller 518

Unit 22 Condensers 523

22.1 The Condenser 523
22.2 Water-Cooled Condensers 523
22.3 Tube-Within-a-Tube Condensers 524
22.4 Mineral Deposits 524
22.5 Cleanable Tube-Within- a-Tube Condensers 526
22.6 Shell-and-Coil Condensers 527
22.7 Shell-and-Tube Condensers 528
22.8 Wastewater Systems 528
22.9 Refrigerant-to-Water Temperature Relationship for Wastewater Systems 531
22.10 Recirculating Water Systems 533
22.11 Cooling Towers 533
22.12 Natural-Draft Towers 533
22.13 Forced- or Induced-Draft Towers 534
22.14 Evaporative Condensers 535
22.15 Air-Cooled Condensers 538
22.16 High-Efficiency Condensers 541
22.17 The Condenser and Low Ambient Conditions 542
22.18 Head Pressure Controls 544
22.19 Using the Condenser Superheat 554
22.20 Heat Reclaim 554
22.21 Floating Head Pressures 554
22.22 Service Technician Calls 555

Unit 23 Compressors 558

23.1 The Function of the Compressor 558
23.2 Types of Compressors 560
23.3 Reciprocating Compressor Components 565
23.4 Belt-Drive Mechanism Characteristics 575
23.5 Direct-Drive Compressor Characteristics 576
23.6 Reciprocating Compressor Efficiency 576
23.7 Discus Valve Design 578
23.8 New Technology in Compressors 579
23.9 Liquid in the Compressor Cylinder 588
23.10 System Maintenance and Compressor Efficiency 590

Unit 24 Expansion Devices 594

24.1 Expansion Devices 594
24.2 Thermostatic Expansion Valve 594
24.3 TXV Components 596
24.4 The Valve Body 597
24.5 The Diaphragm 597
24.6 Needle and Seat 598
24.7 The Spring 600
24.8 The Sensing Bulb and Transmission Tube 601
24.9 Types of Bulb Charge 601
24.10 The Liquid Charge Bulb 601
24.11 The Cross Liquid Charge Bulb 603
24.12 The Vapor (Gas) Charge Bulb 603
24.13 The Cross Vapor Charge Bulb 604
24.14 Example of a TXV Functioning with an Internal Equalizer 604
24.15 TXV Functioning with External Equalizers 605
24.16 TXV Response to Load Changes 609
24.17 Selection of TXV Valves 609
24.18 Balanced-Port TXV 609
24.19 The Pressure-Limiting TXV 609
24.20 Servicing the TXV 609
24.21 Installing the Sensing Element 610
24.22 Step-Motor Expansion Valves 611
24.23 Algorithms and PID Controllers 614
24.24 The Automatic Expansion Valve 615
24.25 Automatic Expansion Valve Response to Load Changes 616
24.26 Special Considerations for the TXV and AXV 616
24.27 The Capillary Tube Metering Device 617
24.28 Operating Charge for the Capillary Tube System 618

Unit 25 Special Refrigeration System Components 621

25.1 The Four Basic Components 621
25.2 Mechanical Controls 621
25.3 Two-Temperature Controls 621
25.4 Evaporator Pressure Control 621
25.5 Multiple Evaporators 624
25.6 Electric Evaporator Pressure-Regulating Valve 624
25.7 Crankcase Pressure Regulator 625
25.8 Adjusting the CPR Valve 627
25.9 Relief Valves 627
25.10 Fan-Cycling Head Pressure Controls 628
25.11 Fan Speed Control for Controlling Head Pressure 629
25.12 Air Volume Control for Controlling Head Pressure 629
25.13 Condenser Flooding and Condenser Splitting for Controlling Head Pressure 630
25.14 Electrical Controls 631
25.15 Pressure Switches 633
25.16 Low-Pressure Switch 633
25.17 Low-Pressure Control Applied as a Thermostat 633
25.18 Automatic Pumpdown Systems 635
25.19 High-Pressure Control 639
25.20 Low-Ambient Fan Control 639
25.21 Oil Pressure Safety Control 640
25.22 The Defrost Cycle 643
25.23 Medium-Temperature Refrigeration 645
25.24 Random or Off-Cycle Defrost 645
25.25 Planned Defrost 645
25.26 Low-Temperature Evaporator Defrost 645
25.27 Internal Heat Defrost (Hot Gas and Cool Gas Defrost) 646
25.28 External Heat Defrost 647
25.29 Defrost Termination and Fan Delay Control 648
25.30 Refrigeration Accessories 649
25.31 Receivers 649
25.32 The King Valve on the Receiver 650
25.33 Filter Driers 650
25.34 Refrigerant Check Valves 652
25.35 Refrigerant Sight Glasses 652
25.36 Liquid Refrigerant Distributors 652
25.37 Heat Exchangers 653
25.38 Suction-Line Accumulators 654

25.39 Suction-Line Filter Driers 656
25.40 Suction Service Valves 657
25.41 Discharge Service Valves 658
25.42 Refrigeration Line Service Valves 658
25.43 Diaphragm Valves 658
25.44 Ball Valves 658
25.45 Oil Separators 660
25.46 Vibration Eliminators 661
25.47 Pressure Access Ports 662
25.48 Crankcase Heat 663
25.49 Oil Pumps 664
25.50 Compressor Oil Check Valve and Partition Wall 665

Unit 26 Applications of Refrigeration Systems 668

26.1 Application Decisions 668
26.2 Reach-in Refrigeration 668
26.3 Self-Contained Reach-in Fixtures 669
26.4 Individual Condensing Units 671
26.5 Single-Compressor Applications and Multiple Evaporators 672
26.6 Parallel Compressor Systems 675
26.7 Secondary-Fluid Refrigeration Systems 683
26.8 Carbon Dioxide (R-744) Refrigeration Systems 685
26.9 Pressurized Liquid Systems 689
26.10 Distributed Refrigeration Systems 691
26.11 Evaporator Temperature Control 692
26.12 Interconnecting Piping in Multiple-Evaporator Installations 692
26.13 Fixture Temperature Control 693
26.14 The Evaporator and Merchandising 693
26.15 Chest-Type Display Fixtures 694
26.16 Refrigerated Shelves 695
26.17 Closed Chest Fixtures 695
26.18 Controlling Sweating on Fixture Cabinets 696
26.19 Maintaining Store Ambient Conditions 696
26.20 Walk-in Refrigeration 697
26.21 Knock-Down Walk-in Coolers 697
26.22 Evaporators in a Walk-in Cooler 698
26.23 Condensate Removal 698
26.24 Refrigeration Piping 699
26.25 Package Refrigeration for Walk-in Coolers 700
26.26 Refrigerated Air Driers 700

Unit 27 Commercial Ice Machines 704

27.1 Packaged-Type Ice-Making Equipment 704
27.2 Making Flake Ice 704
27.3 Making Cube Ice 713
27.4 Microprocessors 730
27.5 Water and Ice Quality 735
27.6 Package Ice Machine Location 742
27.7 Troubleshooting Ice Makers 742
27.8 Service Technician Calls 746

Unit 28 Special Refrigeration Applications 752

28.1 Special Refrigeration Applications 752
28.2 Transport Refrigeration 752
28.3 Truck Refrigeration Systems 752
28.4 Railway Refrigeration 759
28.5 Extra-Low-Temperature Refrigeration 760
28.6 Cascade Systems 762
28.7 Quick-Freezing Methods 762
28.8 Marine Refrigeration 763
28.9 Air Cargo Hauling 767

Unit 29 Troubleshooting and Typical Operating Conditions for Commercial Refrigeration 770

29.1 Organized Troubleshooting 770
29.2 Troubleshooting High-Temperature Applications 771
29.3 Troubleshooting Medium-Temperature Applications 773
29.4 Troubleshooting Low-Temperature Applications 774
29.5 Typical Air-Cooled Condenser Operating Conditions 774
29.6 Calculating the Correct Head Pressure for Air-Cooled Equipment 775
29.7 Typical Operating Conditions for Water-Cooled Equipment 776
29.8 Typical Operating Conditions for Wastewater Condenser Systems 776
29.9 Typical Operating Conditions for Recirculated Water Systems 776
29.10 Six Typical Problems 778
29.11 Low Refrigerant Charge 779
29.12 Refrigerant Overcharge 781
29.13 Inefficient Evaporator 782
29.14 Inefficient Condenser 784
29.15 Refrigerant Flow Restrictions 786
29.16 Inefficient Compressor 789
29.17 Compressor Vacuum Test 790
29.18 Closed-Loop Compessor Running Bench Test 790
29.19 Closed-Loop Compressor Running Field Test 792
29.20 Compressor Running Test in the System 792
29.21 Diagnostic Chart for Commercial Refrigeration 794
29.22 Service Technician Calls 796

SECTION 6: Air-Conditioning (Heating and Humidification)

Unit 30 Electric Heat 818

30.1 Introduction 818
30.2 Portable Electric Heating Devices 818
30.3 Radiant Heating Panels 819
30.4 Electric Baseboard Heating 820
30.5 Unit and Wall Heaters 820
30.6 Electric Hydronic Boilers 820
30.7 Central Forced-Air Electric Furnaces 821
30.8 Automatic Controls for Forced-Air Electric Furnaces 822
30.9 The Low-Voltage Thermostat 822
30.10 Controlling Multiple Stages 824
30.11 Wiring Diagrams 824
30.12 Control Circuits for Forced-Air Electric Furnaces 824
30.13 Blower Motor Circuits 826
30.14 Contactors for Controlling Electric Furnaces 830
30.15 Airflow in Electric Furnaces 830
30.16 Diagnostic Chart for Electric Heat 833
30.17 Service Technician Calls 833

Unit 31 Gas Heat 836

31.1 Introduction to Gas-Fired, Forced-Hot-Air Furnaces 837

31.2 Types of Furnaces 837
31.3 Gas Fuels 840
31.4 Gas Combustion 841
31.5 Gas Regulators 844
31.6 Gas Valve 845
31.7 Solenoid Valve 845
31.8 Diaphragm Valve 845
31.9 Heat Motor–Controlled Valve 846
31.10 Automatic Combination Gas Valve 847
31.11 Manifold 852
31.12 Orifice 852
31.13 Burners 852
31.14 Heat Exchangers 854
31.15 Fan Switch 856
31.16 Limit Switch 858
31.17 Pilots 859
31.18 Safety Devices at the Standing Pilot 860
31.19 Ignition Systems 862
31.20 Flame Rectification 866
31.21 High-Efficiency Gas Furnaces 869
31.22 Electronic Ignition Modules and Integrated Furnace Controllers 873
31.23 Two-Stage Gas Furnaces 878
31.24 Modulating Gas Furnaces 879
31.25 Venting 881
31.26 Gas Piping 884
31.27 Gas Furnace Wiring Diagrams and Troubleshooting Flowcharts 886
31.28 Troubleshooting the Safety Pilot-Proving Device—the Thermocouple 888
31.29 Troubleshooting Spark Ignition and Intermittent Pilot Systems 888
31.30 Combustion Efficiency 897
31.31 Service Technician Calls 903

Unit 32 Oil Heat 910

32.1 Introduction to Oil-Fired, Forced-Warm-Air Furnaces 910
32.2 Physical Characteristics 911
32.3 Fuel Oils 911
32.4 Oil Storage 914
32.5 Fuel Oil Supply Systems 916
32.6 Combustion 921
32.7 Preparation of Fuel Oil for Combustion 922
32.8 By-Products of Combustion 923
32.9 Gun-Type Oil Burners 923
32.10 Oil Furnace Wiring Diagrams 939
32.11 Wiring Diagram for the Stack Switch Safety Control 944
32.12 Wiring Diagram for Cad Cell Primary Control with Intermittent Ignition 945
32.13 Wiring Diagram for Cad Cell Primary Control with Interrupted Ignition 947
32.14 Combustion Chamber 948
32.15 Heat Exchanger 950
32.16 Condensing Oil Furnace 954
32.17 Service Procedures 955
32.18 Combustion Efficiency 959
32.19 Diagnostic Chart for Oil Heat 963
32.20 Service Technician Calls 964

Unit 33 Hydronic Heat 969

33.1 Introduction to Hydronic Heating 969
33.2 The Heat Source 970
33.3 The Basic Hydronic System 974
33.4 The Point of No Pressure Change 980
33.5 Other Hydronic System Components 981
33.6 High-Temperature Hydronic Piping Systems 991
33.7 Radiant, Low-Temperature Hydronic Piping Systems 1003
33.8 Combination (High- and Low-Temperature) Piping Systems 1009
33.9 Tankless Domestic Hot Water Heaters 1009
33.10 Solar Heating as a Supplemental Heat Source 1010
33.11 Service Technician Calls 1021

Unit 34 Indoor Air Quality 1025

34.1 Introduction 1025
34.2 Sources of Indoor Air Pollution 1025
34.3 Common Pollutants 1027
34.4 Detecting and Eliminating the Source of Contamination 1032
34.5 Ventilation 1032
34.6 Air Cleaning 1034
34.7 Duct Cleaning 1038
34.8 Air Humidification 1039
34.9 Sizing Humidifiers 1043
34.10 Installation 1043
34.11 Service, Troubleshooting, and Preventive Maintenance 1043
34.12 Diagnostic Chart for Filtration and Humidification Systems 1044

SECTION 7: Air-Conditioning (Cooling)

Unit 35 Comfort and Psychrometrics 1048

35.1 Comfort 1048
35.2 Food Energy and the Body 1048
35.3 Heat Transfer to and from the Body 1049
35.4 The Comfort Chart 1050
35.5 Psychrometrics 1050
35.6 Moisture in Air 1052
35.7 Absolute and Relative Humidity 1053
35.8 Superheated Gases in Air 1054
35.9 Dry-Bulb and Wet-Bulb Temperatures 1055
35.10 Dew Point Temperature 1057
35.11 Enthalpy 1057
35.12 The Psychrometric Chart 1058
35.13 Plotting on the Psychrometric Chart 1061
35.14 Fresh Air, Infiltration, and Ventilation 1061

Unit 36 Refrigeration Applied to Air-Conditioning 1072

36.1 Refrigeration 1072
36.2 Structural Heat Gain 1072
36.3 Evaporative Cooling 1074
36.4 Refrigerated Cooling or Air-Conditioning 1076
36.5 The Evaporator 1077
36.6 The Function of the Evaporator 1079
36.7 Design Conditions 1080
36.8 Evaporator Application 1082
36.9 The Compressor 1083
36.10 The Reciprocating Compressor 1083
36.11 Compressor Speeds (RPM) 1083
36.12 Cooling the Compressor and Motor 1083
36.13 Compressor Mountings 1084
36.14 The Rotary Compressor 1084
36.15 The Scroll Compressor 1086

36.16 The Condenser 1087
36.17 Expansion Devices 1089
36.18 Air-Side Components 1089
36.19 Installation Procedures 1089

Unit 37 Air Distribution and Balance 1093

37.1 Conditioning Equipment 1093
37.2 Correct Air Quantity 1094
37.3 The Forced-Air System 1094
37.4 The Blower 1094
37.5 System Pressures 1097
37.6 Air-Measuring Instruments for Duct Systems 1098
37.7 Types of Fans and Blowers 1099
37.8 Types of Drive Assemblies 1102
37.9 The Supply Duct System 1103
37.10 Duct System Standards 1107
37.11 Duct Materials 1107
37.12 Duct Air Movement 1117
37.13 Balancing Dampers 1118
37.14 Zoning 1119
37.15 Duct Insulation 1122
37.16 Blending the Conditioned Air with Room Air 1123
37.17 The Return-Air Duct System 1124
37.18 Sizing Duct for Moving Air 1124
37.19 Measuring Air Movement for Balancing 1128
37.20 The Air Friction Chart 1130
37.21 Practical Troubleshooting Techniques 1138

Unit 38 Installation 1143

38.1 Introduction to Equipment Installation 1143
38.2 Installing Square and Rectangular Duct 1143
38.3 Installing Round Metal Duct Systems 1145
38.4 Insulation and Acoustical Lining for Metal Duct 1146
38.5 Installing Ductboard Systems 1146
38.6 Installing Flexible Duct 1148
38.7 Electrical Installation 1148
38.8 Installing the Refrigeration System 1150
38.9 Installing Split-System Air Conditioners 1154
38.10 The Split-System Condensing Unit 1158
38.11 Installing Refrigerant Piping on Split-Systems 1159
38.12 Equipment Start-Up 1163

Unit 39 Residential Energy Auditing 1167

39.1 Introduction 1167
39.2 Residential (Home) Energy Auditing 1168
39.3 Performing a Home Energy Audit 1169
39.4 Diagnostic Testing 1175
39.5 Blower Door Testing 1175
39.6 Infrared Scanning Using a Thermal Imaging Camera 1178
39.7 Sealing Air Leaks 1185
39.8 Duct Leakage Testing 1188
39.9 Duct Pressurization Test for Total Air Leakage 1193
39.10 Duct Leakage to the Outdoors 1194
39.11 Combustion Efficiency and Safety Testing 1194
39.12 Furnace Efficiency Testing 1197
39.13 Furnace Efficiency Ratings 1199
39.14 Flame Color 1199
39.15 Furnace Preventive Maintenance 1200
39.16 Spillage and Backdrafting 1201
39.17 Flame Safeguard Controls 1202
39.18 Excess Air 1204
39.19 Venting 1204
39.20 Draft 1207
39.21 High-Efficiency Gas Furnace Anatomy 1209
39.22 HVAC/R System Testing 1211
39.23 Numerical Analysis and Reporting 1212

Unit 40 Typical Operating Conditions 1218

40.1 Mechanical Operating Conditions 1218
40.2 Relative Humidity and the Load 1218
40.3 Relationships of System Component Under Load Changes 1219
40.4 Evaporator Operating Conditions 1219
40.5 High Evaporator Load and a Cool Condenser 1219
40.6 Grades of Equipment 1222
40.7 Documentation with the Unit 1223
40.8 Establishing a Reference Point on Unknown Equipment 1224
40.9 System Pressures and Temperatures for Different Operating Conditions 1225
40.10 Equipment Efficiency Rating 1228
40.11 Typical Electrical Operating Conditions 1229
40.12 Matching the Unit to the Correct Power Supply 1229
40.13 Starting the Equipment with the Correct Data 1229
40.14 Finding a Point of Reference for an Unknown Motor Rating 1229
40.15 Determining the Compressor Running Amperage 1230
40.16 Compressors Operating at Full-Load Current 1230
40.17 High Voltage, the Compressor, and Current Draw 1230
40.18 Current Draw and the Two-Speed Compressor 1231

Unit 41 Troubleshooting 1233

41.1 Introduction 1233
41.2 Mechanical Troubleshooting 1233
41.3 Approach Temperature and Temperature Difference 1237
41.4 Gauge Manifold Usage 1238
41.5 When to Connect the Gauges 1239
41.6 Low-Side Gauge Readings 1240
41.7 High-Side Gauge Readings 1240
41.8 Temperature Readings 1242
41.9 Charging Procedures in the Field 1247
41.10 Electrical Troubleshooting 1250
41.11 Compressor Overload Problems 1251
41.12 Compressor Electrical Checkup 1252
41.13 Troubleshooting the Circuit Electrical Protectors—Fuses and Breakers 1256
41.14 Diagnostic Chart for Air-Conditioning (Cooling) Systems 1257
41.15 Service Technician Calls 1258

SECTION 8: All-Weather Systems

Unit 42 Heat Gains and Heat Losses in Structures 1266

42.1 Introduction to Heat Gain and Heat Loss 1266

42.2 Methods to Determine the Heat Gain and Heat Loss of a Structure 1267
42.3 Indoor and Outdoor Design Conditions for Heating and Cooling 1268
42.4 U-Values and R-Values 1269
42.5 Introduction to Heat Gain and Heat Loss Calculations 1271
42.6 Elements of Structural Heat Loss (Heating Mode) 1271
42.7 Elements of Structural Heat Gain (Cooling Mode) 1278

Unit 43 Air Source Heat Pumps 1285

43.1 Reverse-Cycle Refrigeration 1285
43.2 Heat Sources for Winter 1286
43.3 The Four-Way Reversing Valve 1287
43.4 The Air-to-Air Heat Pump 1290
43.5 Refrigerant Line Identification 1290
43.6 Metering Devices 1292
43.7 Thermostatic Expansion Valves 1292
43.8 The Capillary Tube 1294
43.9 Combinations of Metering Devices 1295
43.10 Electronic Expansion Valves 1296
43.11 Orifice Metering Devices 1296
43.12 Liquid-Line Accessories 1296
43.13 Application of the Air-to-Air Heat Pump 1298
43.14 Auxiliary Heat 1298
43.15 Balance Point 1299
43.16 Coefficient of Performance 1299
43.17 The Split-Type, Air-to-Air Heat Pump 1300
43.18 The Indoor Unit 1300
43.19 Temperature of the Conditioned Air 1301
43.20 The Outdoor Unit 1302
43.21 Package Air-to-Air Heat Pumps 1303
43.22 Controls for the Air-to-Air Heat Pump 1304
43.23 The Defrost Cycle 1311
43.24 Indoor Fan Motor Control 1314
43.25 Second-Stage Electric Heat 1314
43.26 Servicing the Air-to-Air Heat Pump 1316
43.27 Troubleshooting the Electrical System 1316
43.28 Troubleshooting Mechanical Problems 1317
43.29 Troubleshooting the Four-Way Reversing Valve 1318
43.30 Troubleshooting the Compressor 1320
43.31 Checking the Charge 1321
43.32 Special Applications for Heat Pumps 1321
43.33 Heat Pumps using Scroll Compressors 1322
43.34 Heat Pump Systems with Variable-Speed Motors 1323
43.35 Diagnostic Chart for Heat Pumps in the Heating Mode 1325
43.36 Service Technician Calls 1325

Unit 44 Geothermal Heat Pumps 1335

44.1 Reverse-Cycle Refrigeration 1335
44.2 Geothermal Heat Pump Classifications 1335
44.3 Open-Loop Systems 1336
44.4 Water Quality 1337
44.5 Closed-Loop Systems 1338
44.6 Ground-Loop Configurations and Flows 1342
44.7 System Materials and Heat Exchange Fluids 1345
44.8 Geothermal Wells and Water Sources for Open-Loop Systems 1347
44.9 Water-to-Water Heat Pumps 1349
44.10 Troubleshooting 1352
44.11 Direct Geothermal Heat Pump Systems 1354
44.12 Service Technician Calls 1365

SECTION 9: Domestic Appliances

Unit 45 Domestic Refrigerators and Freezers 1372

45.1 Refrigeration 1372
45.2 Capacity of Domestic Systems 1380
45.3 The Evaporator 1381
45.4 The Compressor 1384
45.5 The Condenser 1386
45.6 Metering Device 1390
45.7 Typical Operating Conditions 1392
45.8 Ice-Maker Operation 1394
45.9 Wiring and Controls 1395
45.10 Servicing the Appliance 1404
45.11 Service Technician Calls 1419

Unit 46 Room Air Conditioners 1433

46.1 Air-Conditioning and Heating with Room Units 1433
46.2 Room Air-Conditioning—Cooling 1434
46.3 The Refrigeration Cycle—Cooling 1435
46.4 Heat-Pump-Style Room Units 1437
46.5 Installation 1440
46.6 Controls for Cooling-Only Room Units 1447
46.7 Controls in Cooling and Heating Units 1450
46.8 Maintaining and Servicing Room Units 1450
46.9 Service Technician Calls 1457

SECTION 10: Commercial Air-Conditioning and Chilled-Water Systems

Unit 47 High-Pressure, Low-Pressure, and Absorption Chilled-Water Systems 1464

47.1 Chillers 1465
47.2 Compression Cycle in High-Pressure Chillers 1466
47.3 Reciprocating Compressors in High-Pressure Chillers 1466
47.4 Scroll Compressors in High-Pressure Chillers 1468
47.5 Rotary Screw Compressors in High-Pressure Chillers 1469
47.6 Centrifugal Compressors in High-Pressure Chillers 1470
47.7 Evaporators for High-Pressure Chillers 1474
47.8 Condensers for High-Pressure Chillers 1478
47.9 Metering Devices for High-Pressure Chillers 1481
47.10 Low-Pressure Chillers 1484
47.11 Compressors for Low-Pressure Chillers 1484
47.12 Condensers for Low-Pressure Chillers 1487
47.13 Metering Devices for Low-Pressure Chillers 1487
47.14 Purge Units 1487
47.15 Absorption Air-Conditioning Chillers 1488
47.16 Motors and Drives for Chillers 1498

Unit 48 Cooling Towers and Pumps 1509

48.1 Cooling Tower Function 1509
48.2 Types of Cooling Towers 1511
48.3 Fire Protection 1514
48.4 Fill Material 1515
48.5 Flow Patterns 1515
48.6 Tower Materials 1516
48.7 Fan Section 1517
48.8 Tower Access 1518
48.9 Tower Sump 1518
48.10 Makeup Water 1519
48.11 Blowdown 1520
48.12 Balancing the Water Flow in a Cooling Tower 1522
48.13 Water Pumps 1522
48.14 Chemical-Free Treatment of Cooling Tower Water 1530

Unit 49 Operation, Maintenance, and Troubleshooting of Chilled-Water Air-Conditioning Systems 1536

49.1 Chiller Start-Up 1536
49.2 Valves for Large Systems 1542
49.3 Scroll and Reciprocating Chiller Operation 1545
49.4 Large Positive-Displacement Chiller Operation 1546
49.5 Centrifugal Chiller Operation 1546
49.6 Air-Cooled Chiller Maintenance 1546
49.7 Water-Cooled Chiller Maintenance 1548
49.8 Absorption Chilled-Water System Start-Up 1551
49.9 Absorption Chiller Operation and Maintenance 1552
49.10 General Maintenance for all Chillers 1553
49.11 Low-Pressure Chillers 1553
49.12 High-Pressure Chillers 1555
49.13 Refrigerant Safety 1555
49.14 Service Technician Calls 1555

Unit 50 Commercial, Packaged Rooftop, Variable Refrigerant Flow, and Variable Air Volume Systems 1563

50.1 Rooftop Package Units 1564
50.2 Installation of Packaged Rooftop Units 1565
50.3 Economizers 1571
50.4 Economizer Modes of Operation 1576
50.5 Ashrae Standard 62 1578
50.6 Demand Control Ventilation (DCV) 1579
50.7 Traditional Constant-Volume Air Distribution Methods 1580
50.8 Variable Air Volume (VAV) Systems 1580
50.9 Blowers on VAV Systems 1580
50.10 VAV Boxes and Terminal Units 1581
50.11 Hot Water in the Reheat Coils 1583
50.12 Chilled-Water VAV Systems 1584
50.13 Variable Refrigerant Flow (VRF) Systems 1589
50.14 Dry Coolers 1602

Appendix A Alternative Heating (Stoves and Fireplace Inserts) 1608

A.1 Wood-Burning Stoves 1608
A.2 Organic Makeup and Characteristics of Wood 1608
A.3 Environmental Protection Agency (EPA) Regulations 1609
A.4 Creosote 1609
A.5 Design Characteristics of Wood-Burning Stoves 1609
A.6 Installation Procedures 1613
A.7 Smoke Detectors 1614
A.8 Gas Stoves 1615
A.9 Fireplace Inserts 1615

Appendix B Temperature Conversion Chart 1617

Glossary/Glosario 1619

Index 1671

PREFACE

Refrigeration & Air Conditioning Technology is designed and written for students in vocational-technical schools and colleges, community colleges, and apprenticeship programs. The content is in a format appropriate for students who are attending classes full-time while preparing for their first job, for students attending classes part-time while preparing for a career change, or for those working in the field who want to increase their knowledge and skills. Emphasis throughout the text is placed on the practical applications of the knowledge and skills technicians need to be productive in the refrigeration and air-conditioning industry. The contents of this book can be used as a study guide to prepare for the Environmental Protection Agency (EPA) mandatory technician certification examinations. It can be used in the HVAC/R field or closely related fields by students, technicians, installers, contractor employees, service personnel, and owners of businesses.

This text is also an excellent study guide for the Industry Competency Exam (ICE), the North American Technician Excellence (NATE), the HVAC Excellence, the Refrigeration Service Engineers Society (RSES), the United Association (UA) STAR certification, and the Heating, Air Conditioning, and Refrigeration Distributors International (HARDI) voluntary HVAC/R technician certification and home-study examinations.

The book is also written to correspond to the National Skill Standards for HVAC/R technicians. Previous editions of this text are often carried to the job site by technicians and used as a reference for service procedures. "Do-it-yourselfers" will find this text valuable for understanding and maintaining heating and cooling systems.

As general technology has evolved, so has the refrigeration and air-conditioning industry. A greater emphasis is placed on digital electronic controls and system efficiency. At the time of this writing, every central split cooling system manufactured in the United States today must have a Seasonal Energy Efficiency Ratio (SEER) rating of at least 13. This energy requirement was mandated by federal law as of January 23, 2006. SEER is calculated on the basis of the total amount of cooling (in Btus) the system will provide over the entire season, divided by the total number watt-hours it will consume. Higher SEER ratings reflect a more efficient cooling system. Air-conditioning and refrigeration technicians are responsible for following procedures to protect our environment, particularly with regard to the handling of refrigerants. Technician certification has become increasingly important in the industry.

Global warming has become a major environmental issue. When HVAC/R systems are working correctly and efficiently, they will greatly reduce energy consumption and greenhouse gases. Organizations like the Green Mechanical Council (GreenMech) are advocates for the HVAC/R industry and assist the industry in meeting with government, educational, industry, and labor interests to find solutions to the world's global-warming problem. GreenMech has created a scoring system designed to help engineers, contractors, and consumers know the "green value" of each mechanical installation. The "green value" encompasses the system's energy efficiency, pollution output, and sustainability. Realtors, building inspectors, builders, and planning and zoning officials will now have some knowledge about and guidance on how buildings and mechanical systems are performing. Green buildings and green mechanical systems are becoming increasingly popular in today's world as a way to curb global warming.

Energy audits have become an integral part of evaluating and assessing an existing building's energy performance. Higher efficiency standards for the energy performance of new buildings have been established. Higher levels of training and certification have been developed for HVAC/R technicians to meet the needs of more sophisticated, energy-efficient buildings and HVAC/R equipment.

TEXT DEVELOPMENT

This text was developed to provide the technical information necessary for a technician to be able to perform satisfactorily on the job. It is written at a level that most students can easily understand. Practical application of the technology is emphasized. Terms commonly used by technicians and mechanics have been used throughout to make the text easy to read and to present the material in a practical way. Many of these key terms are also defined in the glossary. This text is updated regularly in response to market needs and emerging trends. Refrigeration and air-conditioning instructors have reviewed each unit. A technical review takes place before a revision is started and also during the revision process.

Illustrations and photos are used extensively throughout the text. Full-color treatment of most photos and illustrations helps amplify the concepts presented.

No prerequisites are required for this text. It is designed to be used by beginning students, as well as by those with training and experience.

ORGANIZATION

Considerable thought and study have been devoted to the organization of this text. Difficult decisions had to be made to provide text in a format that would meet the needs of varied institutions. Instructors from different areas of the country and from various institutions were asked for their ideas regarding the organization of the instructional content.

The text is organized so that after completing the first four sections, students may concentrate on courses in refrigeration or air conditioning (heating and/or cooling). If the objective is to complete a whole program, the instruction may proceed until the sequence scheduled by the school's curriculum is completed.

NEW IN THIS EDITION

NEW AND/OR EXPANDED CONTENT HAS BEEN ADDED TO THE TEXT IN THE FOLLOWING AREAS:

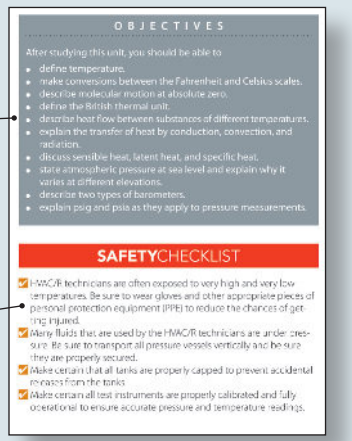
- WiFi and learning thermostats
- Thermostat applications for smart phones and other electronic hand-held devices
- Fossil-fuel furnace technologies
- Intelligent refrigeration case controllers
- Variable air volume (VAV)
- Variable refrigerant flow (VRF)
- Ultraviolet germicidal irradiation
- Natural refrigerants (hydrocarbons), their structure, boiling points, GWP, ODP, applications, charge amounts, serviceability, handling, transportation and safety
- R-22 alternatives
- System efficiencies with respect to EER, SEER, HSPF
- Supermarket refrigeration systems
- Microchannel heat exchangers
- Air-conditioning and heat pump technologies
- Ductless split systems
- Variable frequency drives
- Dry coolers
- Mechanical piping techniques
- Basic electronic theory
- Biofluels
- Blueflame burners
- Boiler setback controls
- Mixed air systems
- Psychrometrics
- Ventilation requirements
- Detailed coverage on crankcase heaters
- Detailed coverage on compressor oil pumps, partition walls, and oil check valves
- New photos on scroll compressor valve plates and other damaged valve plates
- Hydrofluoro-olefin (HFO) refrigerants
- Digital evaporator defrost and efficiency controllers
- Digital "Smart" gauges and manifolds including Bluetooth technologies
- Calculating water usage for water-cooled condensers

HOW TO USE THIS TEXT AND SUPPLEMENTARY MATERIALS

This text may be used as a classroom text, as a learning resource for an individual student, as a reference text for technicians on the job, or as a homeowner's guide. An instructor may want to present the unit objectives, briefly discuss the topics included, and assign the unit to be read. The instructor then may want to discuss the material with students. This can be followed by students completing the review questions, which can later be reviewed in class. The lecture outline provided in the *Instructor's Manual* may be utilized in this process. Lab assignments may be made at this time, followed by the students completing the lab review questions.

The instructor resource DVD may be used to access a computerized test bank for end-of-unit review questions, teaching tips, PowerPoint® presentations, and more.

FEATURES OF THE TEXT



OBJECTIVES

After studying this unit, you should be able to

- define temperature.
- make conversions between the Fahrenheit and Celsius scales.
- describe molecular motion at absolute zero.
- define the British thermal unit.
- describe heat flow between substances of different temperatures.
- explain the transfer of heat by conduction, convection, and radiation.
- discuss sensible heat, latent heat, and specific heat.
- state atmospheric pressure at sea level and explain why it varies at different elevations.
- describe two types of barometers.
- explain psig and psia as they apply to pressure measurements.

SAFETY CHECKLIST

- HVAC/R technicians are often exposed to very high and very low temperatures. Be sure to wear gloves and other appropriate pieces of personal protection equipment (PPE) to reduce the chances of getting injured.
- Many fluids that are used by the HVAC/R technicians are under pressure. Be sure to transport all pressure vessels vertically and be sure they are properly secured.
- Make certain that all tanks are properly capped to prevent accidental releases from the tanks.
- Make certain all test instruments are properly calibrated and fully operational to ensure accurate pressure and temperature readings.

Objectives

Objectives are listed at the beginning of each unit. The objective statements have been stated clearly and simply to give students direction.

Safety Checklists

A Safety Checklist is presented at the beginning of each unit, when applicable, immediately following the Objectives. This checklist emphasizes the importance of safety and is included in units where "hands-on" activities are discussed.

Safety is emphasized throughout the text. In addition to the Safety Checklist at the beginning of most units, safety precautions and techniques are highlighted throughout. It would be impossible to include a safety precaution for every conceivable circumstance that may arise, but an attempt has been made to be as thorough as possible. The overall message is to work safely whether in a school shop, laboratory, or on the job and to use common sense.

R-22 boils at about −41°F. 4R *Do not perform the following exercises—allowing refrigerant to intentionally escape into the atmosphere is against the law! We mention these examples here for illustration purposes only.* 4R

Recovery/Recycling/Reclaiming/Retrofitting

Discussions relating to recovery, recycling, reclaiming, retrofitting, or other environmental issues are highlighted in blue throughout the text. In addition, one complete unit on refrigerant management is included—Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting."

Green Awareness

As previously mentioned, global warming stemming from the uncontrolled rate of greenhouse gas emissions is a major global environmental issue. Buildings are important users of energy and materials and so are a major source of the greenhouse gases that are the by-products of energy and materials use. At the time of this writing, there are approximately 5 million commercial buildings and 125 million housing units in the United States. Surprisingly, almost every one of their mechanical systems is obsolete. Discussions relating to the green awareness movement (for example, lowering energy costs, reducing operating and maintenance costs, increasing productivity, and decreasing the amount of pollution generated) are highlighted in green throughout the text.

The correct size, layout, and installation of tubing, piping, and fittings helps to keep a refrigeration or air-conditioning system operating properly and efficiently and prevents refrigerant loss.

HVAC GOLDEN RULES

When making a service call to a business:

- Never park your truck or van in a space reserved for customers.
- Look professional and be professional.
- Before starting troubleshooting procedures, get all the information you can regarding the problem.
- Be extremely careful not to scratch tile floors or to soil carpeting with your tools or by moving equipment.
- Be sure to practice good sanitary and hygiene habits when working in a food preparation area.
- Keep your tools and equipment out of the customers' and employees' way if the equipment you are servicing is located in a normal traffic pattern.
- Be prepared with the correct tools and ensure that they are in good condition.
- Always clean up after you have finished. Try to provide a little extra service by cleaning filters, oiling motors, or providing some other service that will impress the customer.
- Always discuss the results of your service call with the owner or representative of the company. Try to persuade the owner to call if there are any questions as a

HVAC Golden Rules

Golden Rules for the refrigeration and air-conditioning technician give advice and practical hints for developing good customer relations. These "golden rules" appear in appropriate units.

PREVENTIVE MAINTENANCE FOR REFRIGERATION

PACKAGED EQUIPMENT. Packaged equipment is built and designed for minimum maintenance because the owner may be the person that takes care of it until a breakdown occurs. Most of the fan motors are permanently lubricated and will run until they quit, at which time they are replaced with new ones.

The owners should be educated to keep the condensers clean and not to stack inventory so close as to block the condenser airflow. When the unit is a reach-in cooler, the owner should be cautioned to follow the manufacturer's directions in loading the box. The load line on the inside should be observed for proper air distribution.

inspected and cleaned regularly. The technician cannot always tell when a coil is dirty by looking at the evaporator. Grease or dirt may be in the core of the coil. Routine cleaning of the evaporator once a year will usually keep the coil clean. **SAFETY PRECAUTION:** *Use only approved cleaning compounds where food is present. Turn off the power before cleaning any system. Cover the fan motors and all electrical connections when cleaning to prevent water and detergent from getting into them.*

The motors in the evaporator unit are usually sealed and permanently lubricated. If not, they should be lubricated at recommended intervals, which are often marked on the motor. Observe the fan blade for alignment and look for bearing

Preventive Maintenance

Preventive Maintenance procedures are included in many units and relate specifically to the equipment presented in that unit. Technicians can provide some routine preventive maintenance service when on other types of service calls as well as when on strictly maintenance calls. The preventive maintenance procedures provide valuable information for the new or aspiring technician and homeowner, as well as for those technicians with experience.

Diagnostic Charts

Diagnostic Charts are included at the end of many units. These charts include material on troubleshooting and diagnosis.

Problem	Possible Cause	Possible Repair
No heat—thermostat calling for heat	Open disconnect switch	Close disconnect switch.
	Open fuse or breaker	Replace fuse or reset breaker and determine why it opened.
	High-temperature fuse link open circuit	Tighten loose connection at fuse link causing heat.
	Faulty high-voltage wiring or connections	Repair or replace faulty wiring or connections.
	Control-voltage power supply off	Check control-voltage fuses and safety devices.
	Faulty control-voltage wiring or connections	Repair or replace faulty wiring or connections.
Insufficient heat	Heating element burned, open circuit	Replace heating element—check airflow.
	Portion of heaters or limits open circuit	See above.
	Low voltage	Correct voltage.

SERVICE CALL 1

A customer calls indicating that the boiler in the equipment room at a motel has hot water running out and down the drain all the time. Another service company has been performing service at the motel for the last few months. *The problem is that the water-regulating valve (boiler water feed) is out of adjustment. Water is seeping from the boiler's pressure relief valve,* **Figure 14.66**.

The technician arrives at the motel, parking alongside the building so as not to block the front door or the motel's registration parking areas. When the property manager comes into the office to greet the technician, the technician intro-

Service Technician Calls

In many units, practical examples of service technician calls are presented in a down-to-earth situational format. These are realistic service situations in which technicians may find themselves. In many instances, the solution is provided in the text, and in others the reader must decide what the best solution should be. These solutions are provided in the Instructor's Manual. The Service Technician Calls will now incorporate customer relations and technician soft skills.

SUMMARY

- Thermometers measure temperature. Four temperature scales are Fahrenheit, Celsius, Fahrenheit absolute (Rankine), and Celsius absolute (Kelvin).
- Molecules in matter are constantly moving. The higher the temperature, the faster they move.
- The British thermal unit (Btu) describes the quantity of heat in a substance. One Btu is the amount of heat necessary to raise the temperature of 1 lb of water 1°F.
- The transfer of heat by conduction is the transfer of heat from molecule to molecule.
- The transfer of heat by convection is the actual moving of heat in a fluid (vapor state or liquid state) from one place to another.
- Radiant heat is a form of energy that does not depend on matter as a medium of transfer. Solid objects absorb the energy, become heated, and transfer the heat to the air.
- Sensible heat causes a rise in temperature of a substance.
- Latent (or hidden) heat is heat added to a substance that causes a change of state and does not register on a thermometer.
- Specific heat is the amount of heat (measured in Btu) required to raise the temperature of 1 lb of a substance 1°F. Substances have different specific heats.
- Pressure is the force applied to a specific unit of area. The atmosphere around the earth has weight and therefore exerts pressure.
- Barometers measure atmospheric pressures in inches of mercury. Two of the barometers used are the mercury and the aneroid.
- Gauges have been developed to measure pressures in enclosed systems. Two common gauges used in the air-conditioning, heating, and refrigeration industry are the compound gauge and the high-pressure gauge.

REVIEW QUESTIONS

1. Temperature is defined as
   A. how hot it is.
   B. the level of heat.
   C. how cold it is.
   D. why it is hot.
2. State the standard conditions for water to boil at 212°F.
3. List four types of temperature scales.
4. Under standard conditions, water freezes at _____°C.
5. Molecular motion stops at _____°F.

Summary

The Summary appears at the end of each unit prior to the Review Questions. It can be used to review the unit and to stimulate class discussion.

Review Questions

Review Questions follow the Summary in each unit and can help to measure the student's knowledge of the unit. There are a variety of question types—multiple choice, true/false, short answer, short essay, and fill-in-the-blank.

SUPPORT MATERIALS

INSTRUCTOR'S MANUAL

This manual includes an overview of each text unit, including a summary description, a list of objectives, and important safety notes. The manual provides diagnoses for service technician calls that are not solved in the text. It also includes references to lab exercises associated with each unit. "Special Notes to Instructors" specify how to create an equipment "problem" for students to resolve during certain lab exercises. The manual also provides answers to the review questions in the text and to all questions in the *Lab Manual and Workbook* (review and lab exercises). ISBN: 978-1-305-58326-9.

LAB MANUAL AND WORKBOOK

The *Lab Manual and Workbook* includes a unit overview, key terms, and a unit review test. Each lab provides a general introduction to the lab, including objectives, text references, tools, materials, and safety precautions. The manual then provides a series of practical exercises for the student to complete in a "hands-on" lab environment, including maintenance instructions for the workstation and tools. Cross references to the "Special Notes to Instructors" in the *Instructor's Manual* allow the instructor to create a system "problem" to be solved in the lab. ISBN: 978-1-305-57870-8

INSTRUCTOR RESOURCES DVD

This educational resource creates a truly electronic classroom. It is a DVD containing tools and instructional resources that enrich the classroom and make the instructor's preparation time shorter. The elements of the instructor resource link directly to the text to provide a unified instructional system. With the instructor resource the instructor can spend time teaching, not preparing to teach. ISBN: 978-1-305-58327-6.

Features contained in the instructor resource include the following:

- Syllabus. This is the standard course syllabus for this textbook, providing a summary outline for teaching HVAC/R.
- Teaching Tips. Teaching hints form a basis for presenting concepts and material. Key points and concepts can be highlighted graphically to enhance student retention.
- Lecture Outlines. The key topics and concepts that should be covered for each unit are outlined.
- PowerPoint Presentation. These slides can be used to outline a lecture on the concepts and material. Key points and concepts are highlighted graphically to enhance student retention.
- Image Gallery. This database of key images (all in full color) taken from the text can be used in lecture presentations, as transparencies, for tests and quizzes, and with PowerPoint presentations.
- Test Bank. Over 1000 questions of varying levels of difficulty are provided in true/false, multiple-choice, fill-in-the-blank, and short-answer formats for assessing student comprehension. This versatile tool allows the instructor to manipulate the data to create original tests.

VIDEO DVD SET

A seven-DVD video set addressing over 120 topics covered in the text is available. Each DVD contains four 20-minute videos. To order the seven-DVD set, reference ISBN: 978-1-111-64451-2.

MINDTAP

MindTap is well beyond an eBook, a homework solution or digital supplement, a resource center website, a course delivery platform, or a Learning Management System. MindTap is a new personal learning experience that combines all your digital assets—readings, multimedia, activities, and assessments—into a singular learning path to improve student outcomes.

INSTRUCTOR SITE

An Instructor Companion website containing supplementary material is available. This site contains an Instructor's Manual, teaching tips, syllabus, lecture outline, an image gallery of text figures, unit presentations done in PowerPoint, and testing powered by Cognero.
Cengage Learning Testing Powered by Cognero is a flexible, online system that allows you to:

- author, edit, and manage test bank content from multiple Cengage Learning solutions
- create multiple test versions in an instant
- deliver tests from your LMS, your classroom, or wherever you want

Contact Cengage Learning or your local sales representative to obtain an instructor account. To access an Instructor Companion website from SSO Front Door:

1. Go to http://login.cengage.com and log in using the instructor e-mail address and password.
2. Enter author, title, or ISBN in the **Add a title to your bookshelf** search.
3. Click **Add to my bookshelf** to add instructor resources.
4. At the Product page, click the **Instructor Companion site** link.

DELMAR ONLINE TRAINING SIMULATION: HVAC

Delmar Online Training Simulation: HVAC is a 3D immersive simulation that offers a rich learning experience and mimics field performance. To address the critical area of Electricity, it offers a learning path from basic electrical concepts to real-world electrical troubleshooting. This innovative product includes dynamic interactive wiring diagrams in two modes: an open sand-box mode for exploration and experimentation, and a tutorial mode where the proper sequencing required for sound electrical practice is provided. Both modes are supported by an adaptive question engine. Learning electrical theory, and trying and testing sound electrical practice prepares the student for life-like, simulated exposure to faults with the HVAC equipment that follows. It also challenges learners to master diagnostic and troubleshooting skills across seven pieces of HVAC equipment found in the industry—Gas Furnace, Oil Furnace, Gas Boiler, Split Residential A/C, Commercial A/C, Heat Pumps, and Commercial Walk-in Freezers. Soft skills are also included within the simulation.

To create successful learning outcomes, Delmar Online Training Simulation: HVAC offers approximately 200 scenarios which allow students to troubleshoot and build diagnostic and critical thinking skills. Two modes within the simulation promote incremental learning: Training Mode and Challenge Mode. Training Mode has fixed scenarios to aid in familiarizing the user with the equipment, the problem needing attention, and the capabilities of the simulation. Challenge Mode has randomized scenarios within three levels: Beginner, Intermediate, and Advanced. Both modes require learners to diagnose a fault or faults and perform the repair successfully while materials and labor costs are tracked. An integrated digital badging system helps students track their progress and adds additional engagement and motivation. Simulation-based videos teach students key troubleshooting concepts as well as familiarize them with the simulation. The instructional design allows for full open engagement, so students do not have artificial guardrails leading them to a conclusion.

Combining sound instructional design with top-quality computer immersive technology, learners develop critical thinking skills and apply them to real-world customer service calls in a simulated, 3D, life-like setting. This performance simulation complements live training practice by reinforcing good habits, and even presenting scenarios that are impractical (dangerous, expensive, etc.) to create in labs or in a residence. Available for instant purchase on www.cengagebrain.com.

ABOUT THE AUTHORS

JOHN TOMCZYK

John Tomczyk received his associate's degree in refrigeration, heating, and air-conditioning technology from Ferris State University in Big Rapids, Michigan; his bachelor's degree in mechanical engineering from Michigan State University in East Lansing, Michigan; and his master's degree in education from Ferris State University.

Professor Tomczyk has worked in refrigeration, heating, and air-conditioning service and project engineering and served as a technical writing consultant in both the academic and industrial fields. His technical articles have been featured in the *Refrigeration News, Service and Contracting Journal*, and *Engineered Systems Journal*. He writes monthly for the *Air Conditioning, Heating, Refrigeration News* and is coauthor of an EPA-approved *Technician Certification Program Manual* and a Universal R-410A Safety and Retrofitting Training Manual. Professor Tomczyk also is the author of the book *Troubleshooting and Servicing Modern Air Conditioning and Refrigeration Systems,* published by ESCO Press. He also is co-owner of Delta Tee Solutions Inc., a Subchapter-S Corporation and sole owner of Technical Writing Services, LLC. Professor Tomczyk has recently retired from his professorship at Ferris State University after 29 years of service with the title of Professor Emeritus. While continuing consulting through his two companies and being a member of many HVAC/R trade organizations, he will be spending his winters in Maui, Hawaii and the remainder of the year living in the quaint beach town of Empire located in the Sleeping Bear National Lakeshore in Michigan.

EUGENE SILBERSTEIN

Over the past 30-plus years, Eugene has been involved in all aspects of the HVAC/R industry from field technician and system designer to company owner, teacher, administrator, consultant, and author. Eugene is presently an Assistant Professor and the lead faculty member in the HVAC/R program at Suffolk County Community College in Brentwood, New York. Eugene has over 20 years of teaching experience and has taught at a number of institutions in the Greater New York area.

Eugene earned his dual Bachelors Degree from The City College of New York and his Masters of Science degree from Stony Brook University, where he specialized in Energy and Environmental Systems, studying renewable and sustainable energy sources such as wind, solar, geothermal, biomass, and hydropower. He presently holds the Certified Master HVAC/R Educator (CMHE) credential from the ESCO Group and the Building Energy Assessment Professional (BEAP) credential issued by ASHRAE.

As an active member of both ASHRAE and RSES, Eugene served as the subject matter expert and wrote the production scripts for over 30 education videos directly relating to our industry. Other book credits include *Residential Construction Academy: HVAC,* 1st and 2nd Edition, *Pressure Enthalpy Without Tears* (2006), *Heat Pumps,* 1st and 2nd Edition, *and Psychrometrics Without Tears* (2014). Eugene has also written a number of articles for industry newspapers and magazines.

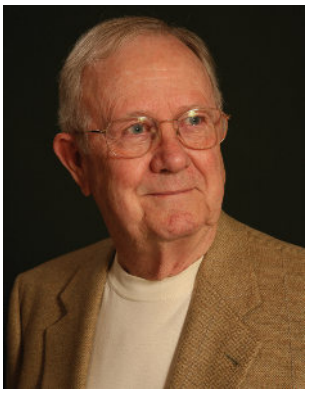
Eugene was selected as one of the top HVAC/R instructors in the country for the 2005/2006, 2006/2007, and 2007/2008 academic school years by the Air Conditioning and Refrigeration Institute (ARI), now AHRI, and the Air Conditioning, Heating and Refrigeration (ACHR) News.

BILL WHITMAN

Bill Whitman graduated from Keene State College in Keene, New Hampshire, with a bachelor's degree in industrial education. He received his master's degree in school administration from St. Michael's College in Winooski, Vermont.

After instructing drafting courses for 3 years, Mr. Whitman became the Director of Vocational Education for the Burlington Public Schools in Burlington, Vermont, a position he held for 8 years. He spent 5 years as the Associate Director of Trident Technical College in Charleston, South Carolina. Mr. Whitman was the head of the Department of Industry for Central Piedmont Community College in Charlotte, North Carolina, for 18 years.

BILL JOHNSON



Bill Johnson graduated from Southern Polytechnic with an associate's degree in gas fuel technology and refrigeration. He worked for the North Carolina's Weights and Measures Department; Coosa Valley Vocational and Technical Institute in Rome, Georgia; and the Trane Company of North Carolina. He also owned and operated an air-conditioning, heating, and refrigeration business for 10 years. He has unlimited North Carolina licenses in heating, air-conditioning, and refrigeration. Mr. Johnson taught heating, air-conditioning, and refrigeration installation, service, and design for 15 years at Central Piedmont Community College in Charlotte, North Carolina, and was instrumental in standardizing the heating, air-conditioning, and refrigeration curriculum for the state community college system. He has written a series of articles for the website of the *Air Conditioning, Heating, Refrigeration News*. These articles, called "BTU Buddy," describe service situation calls for technicians. Mr. Johnson has also authored the *BTU Buddy Notebook* along with two textbooks, *Practical Heating Technology* and *Practical Cooling Technology*, published by Cengage Learning.

ACKNOWLEDGMENTS

The authors thank the following individuals, companies, and universities for their valuable contributions to this text:

James DeVoe, Senior Acquisitions Editor, for his work with the authors and the publisher to produce a workable text that is both economical and comprehensive. His perpetual energies and insistence on the best possible product have resulted in a quality text that is usable both in schools and in the field.

John Fisher, Senior Product Manager, for his work with the authors and publisher to ensure the accuracy of the details in this text. His professional, thorough, and enthusiastic handling of the text manuscript will provide the student with a well-presented, usable product.

Kara DiCaterino, Senior Content Project Manager, for a great job of making sure all pages, artwork, and photographs are well presented and easy to follow. Her professional skills and talents are greatly appreciated.

The late **Ed Bottum, Sr.**, President of Refrigeration Research, Inc., in Brighton, Michigan, for supplying much of the history and many photographs for the timeline found in the introduction to this text. Mr. Bottum's historical collection of refrigeration items and artifacts in Brighton, Michigan, has been designated a National Historic Site by the American Society of Mechanical Engineers (ASME).

Ferris State University, Big Rapids, Michigan, for permission to use their building and HVAC/R applications laboratories to take digital photographs. These digital photographs have certainly enhanced many units in this book.

Bill Litchy, Training Materials Manager, Scotsman Ice Systems, for his valued technical consultation and professional guidance in Unit 27, "Commercial Ice Machines," in this edition. Technical literature, photographs, and illustrations from the Scotsman Company have greatly enhanced this book.

Danny Moore, Director of Technical Support, Hoshizaki America, Inc., for his technical assistance in Unit 27, "Commercial Ice Machines." His published technical articles on the topics of water and ice quality and water filtration and treatment surely enhanced the quality of this unit.

Mitch Rens, Service Publications Manager, Manitowoc Ice Inc., for his valued technical assistance and professional consultation in Unit 27, "Commercial Ice Machines." Technical literature and photographs from Manitowoc have made the unit current and applicable.

Rex Ambs, Manager of GeoFurnace Heating and Cooling, LLC, and CoEnergies, LLC, in Traverse City, Michigan, for his assistance with the enhancements to Unit 44, "Geothermal Heat Pumps." He supplied detailed technical information and digital photographs on waterless, earth-coupled, closed-loop geothermal heat pump technology.

Jim Holstine, Manager of GeoFurnace Heating and Cooling, LLC, and CoEnergies, LLC, in Traverse City, Michigan, for his technical assistance in Unit 44, "Geothermal Heat Pumps."

Dennis Weston and **Tom Kiessel**, Managers of CoEnergies, LLC, in Traverse City, Michigan, for supplying many digital photographs of waterless, earth-coupled, closed-loop geothermal heat pump systems used in Unit 44, "Geothermal Heat Pumps."

Roger McDow, Senior Instructional Lab Facilitator, Central Piedmont Community College in Charlotte, North Carolina, for assisting in the setup of the photographic sessions for all editions of this book. He organized and provided many tools and controls for photography that have provided an invaluable educational experience for students.

Tony Young, Emerson Climate Technologies, Inc., for making his company's valuable technical literature and photographs available for use in this edition.

Modine Manufacturing Company, 1500 DeKoven Ave., Racine, Wisconsin, 53403, for the use of both its technical literature and photographs of the all-aluminum Micro Channel coil technology.

Dan Mason, Danfoss Turbocore Compressors, Inc., for making his company's technical literature and photographs available for use in this edition.

Sporlan Division, Parker Hannifin Corporation, for making its technical literature and photographs available for use in this edition.

John Levey of Oilheat Associates, Inc., in Wantagh, New York, for his assistance in compiling and reviewing material for Unit 32, "Oil Heat," as well as providing new images for use in the text.

A special thanks to the family members and close relatives of the authors for their help and patience while this edition was being developed.

The contributions of the following reviewers of the fourth, fifth, and sixth edition texts are gratefully acknowledged:

George Gardianos, Lincoln Technical Institute, Mahwah, New Jersey

Raymond Norris, Central Missouri State University, Warrensburg, Missouri

Arthur Gibson, Erwin Technical Center, Tampa, Florida

Robert J. Honer, New England Institute of Technology at Palm Beach, West Palm Beach, Florida

Richard McDonald, Santa Fe Community College, Gainesville, Florida

Joe Moravek, Lee College, Baytown, Texas

Neal Broyles, Rolla Technical Institute, Rolla, Missouri

John B. Craig, Sheridan Vocational Technical Center, Hollywood, Florida

Rudy Hawkins, Kentucky Tech–Jefferson Campus, Louisville, Kentucky

Richard Dorssom, N.S. Hillyard AVTS, St. Joseph, Missouri

Robert Ortero, School of Cooperative Technical Education, New York, New York

John Sassen, Ranken Technical College, St. Louis, Missouri

Billy W. Truitt, Worcester Career and Technology Center, Newark, Maryland

George M. Cote, Erwin Technical Center

Marvin Maziarz, Niagara County Community College, Sanborn, New York

Greg Skudlarek, Minneapolis Community and Technical College, Minneapolis, Minnesota

Chris Rebecki, Baran Institute, Windsor and West Haven, Connecticut

Wayne Young, Midland College, Midland, Texas

Darren M. Jones, Meade County Area Technology Center, Brandenburg, Kentucky

Keith Fuhrman, Del Mar College West, Corpus Christi, Texas

Eugene Dickson, Indian River Community College, Fort Pierce, Florida

Mark Davis, New Castle School of Trades, Pulaski, Pennsylvania

Phil Coulter, Durham College, Skills Training Center (Whitby Campus), Whitby, Ontario, Canada

Larry W. Wyatt, Advanced Tech Institute, Virginia Beach, Virginia

Bob Kish, Belmont Technical College, St. Clairsville, Ohio

John Pendleton, Central Texas College, Killeen, Texas

Richard Wirtz, Columbus State Community College, Columbus, Ohio

Brad Richmand, ACCA, Washington, District of Columbia

Greg Perakes, Tennessee Technology Center at Murfreesboro, Murfreesboro, Tennessee

Thomas Schafer, Macomb Community College, Warren, Michigan

Larry Penar, Refrigeration Service Engineers Society (RSES), Des Plaines, Illinois

Johnnie O. Bellamy, Eastfield College Continuing Education, Mesquite, Texas

John Corbitt, Eastfield College Continuing Education, Mesquite, Texas

Dick Shaw, ACCA, Washington, D.C.

Hugh Cole, Gwinnett Technical Institute, Lawrenceville, Georgia

Norman Christopherson, San Jose City College, San Jose, **California**

Barry Burkan, Apex Technical School, New York, New York

Victor Cafarchia, El Camino College, Torrance, California

Cecil W. Clark, American Trades Institute, Dallas, Texas

Bill Litchy, Training Materials Manager, Scotsman Ice Systems, Vernon Hills, Illinois

Danny Moore, Director of Technical Support, Hoshizaki America, Peachtree City, Georgia

Lawrence D. Priest, Tidewater Community College, Virginia Beach, Virginia

Mitch Rens, Service Publications Manager, Manitowoc Ice, Inc., Manitowoc, Wisconsin

Terry M. Rogers, Midlands Technical College, West Columbia, South Carolina

Russell Smith, Athens Technical College, Athens, Georgia

The authors would like to thank the following individuals and companies for their valuable contributions to the 7th edition, 25th Anniversary Edition text:

Joseph R. Pacella, MS ISM, LEED AP, Associate Professor, Ferris State University for help in providing information on the USGBC and LEED rating systems.

John Pastorello, CEO, Refrigeration Technologies, Anaheim, CA, for supplying the technical information and digital photographs on basic and advanced leak detection in Unit 8, Leak Detection, System Evacuation, and System Cleanup.

Robert Nash, Jr., Senior Engineer, Emerson Climate Technologies, Ferris State University HVACR graduate for providing technical information and digital photographs which assisted in writing the carbon dioxide (CO_2) refrigeration system section in Unit 26.

Nick Strickland, Market Development Manager, DuPont Corporation for providing technical information on refrigerants, refrigerant blends, and their compatible oils.

Michael D. Stuart, T/IRT Level III Thermographer (Certified per ASNT Standards), Senior Product Marketing Manager, Fluke Corporation for his unselfish assistance in writing Unit 39, Residential Energy Auditing by providing many self-authored, published technical articles on residential energy auditing, and many digital photographs incorporating infrared technology which enhanced the quality of Unit 39. Special thanks to the Fluke Corporation.

Patrick Pung, Maintenance Mechanic, Selfridge Air National Guard Base, Ferris State University HVACR Technology graduate for providing technical information and digital photographs on closed-loop, slinky, geothermal heat pump systems used in enhancing Unit 44, Geothermal Heat Pump Systems.

William M. (Bill) Johnson for providing most of the proofreading and comments for the 7th edition and special 25th anniversary edition of this book.

Joe Parsons, Vice President, Earthlinked Technologies Incorporated for providing technical information and digital photographs of Direct GeoExchange heat pump systems used in the enhancement of Unit 44, Geothermal Heat Pumps.

Arn McIntyre, MS Eng., Energy Center Director at Ferris State University for his assistance in locating technical literature and contacts for writing Unit 39, Residential Energy Auditing.

Jason Mauric, Ferris State University HVACR Technology student for his assistance in photography and equipment used in writing the Residential Energy Auditing unit.

Mary Jo Gentry, Marketing Communications Manager, Richie Engineering Company–Yellow Jacket Products Division for providing many digital images of the Richie Engineering Company's tools and equipment used in the HVACR field.

Frank Spevak, Marketing and Sales Manager, and **Paul Morin**, Technical Sales Specialist, The Energy Conservatory, for providing technical assistance and digital photographs used in writing Unit 39, Residential Energy Auditing.

Jerry Ackerman, Director of Marketing and Communications, Clearwater Systems Corporation for providing technical literature and digital photographs on the latest technology in chemical-free water treatment for cooling towers used in Unit 48, Cooling Towers and Pumps.

Victor DesRoches, Marketing Coordinator, LAKOS Separators and Filtration Solutions, Fresno, CA, for providing technical literature and photographs on centrifugal particle separators which enhanced the quality of Unit 48, Cooling Towers and Pumps.

Phyllis Shaw, Marketing Communications Supervisor, Sporlan Division–Parker Hannifin Corporation for providing countless digital photographs and system schematics which can be viewed throughout this book. Quality technical literature provided has also updated and enhanced many units in this new edition and also throughout the entire book.

Fieldpiece Instruments Corporation, for providing quality digital photos of their modern HVACR tools and equipment.

Greg Sundheim, President, and **Dave Boyd**, Vice President, Appion Corporation, for providing both technical literature and quality digital photographs which have greatly enhanced Unit 8, Leak Detection, System Evacuation, and System Cleanup.

National Refrigerants, Inc., Philadelphia, PA, for their technical information on refrigerants and retrofitting refrigeration systems.

Karl Huffman, President, Hedrick Associates - Marley Cooling Towers, Grand Rapids, MI, Ferris State University HVACR Graduate for his assistance in providing technical literature and photographs on chemical-free water treatment using pulse technology for cooling towers in Unit 48, Cooling Towers and Pumps.

Paul Fauci of Slant/Fin Corporation for assistance with the artwork incorporated in the Heating Units of the text.

Laura Harris at WaterFurnace for images of the Envision NXW reverse-cycle chiller.

Thomasena Philen of Daikin AC for valuable assistance with the Variable Refrigerant Flow content.

Brian G. Good of GI Industries for high quality images and technical input on duct cleaning equipment.

Tony Quick of Air System Components, Trion Division for high quality humidifier images.

The authors would like to thank the following individuals and companies for their valuable contributions to the 8th edition text:

John Campbell, Renton Technical College, Renton, WA.

Jason Leeds, North Central Kansas Tech, Hayes, KS.

Raul Lopez, Houston Community College, Houston, TX.

Dennis Matney, Ivy Tech Community College, Indianapolis, IN.

Tim Cary, Dwyer Instruments, Inc., Michigan City, IN for high quality images of airflow measuring instruments.

Robert Thompson, Dwyer Instruments, Inc., Michigan City, IN for help with technical data regarding airflow measuring and the use of airflow measuring instrumentation.

Deborah Keny, SPX Cooling Technologies, Overland Park, KS for high quality images of cooling towers and cooling tower configurations.

Tim Snyder, Marketing Manager, The Chemours Company (Formerly DuPont), for his continued support with up-to-date refrigerant technologies, artwork, and technical support. Tim is a true friend of the authors and the industry.

David Foster, Uniweld Products, Inc., Fort Lauderdale, FL, for providing high quality images of a number of tools and pieces of test equipment for inclusion in the book. An all-around nice guy and a long-time supporter of the writing team and the industry.

Eugene Ziegler, Sales Engineer and Training Materials Manager, Sporlan, Parker Hannifin, for providing test instrumentation for inclusion in the text.

Dave Boyd, Vice President, Appion Star Performance, Englewood, CO, for providing test instrumentation for inclusion in the text. A nice guy and a great harmonica player.

John Levey, President, Oilheat Associates,Wantagh, NY for numerous high quality images and technical assistance with the Oil Heat Unit. A true gentleman and a close, personal friend.

C. Curtis Lawson, Sr. Technical Service Consultant, DuPont Refrigerants for his assistance in providing technical literature on the HVAC/R industry's newer refrigerants and refrigerant blends.

Dr. Stanley Friedman, retired Neurologist, Phoenix, Arizona for his thorough proofreading of many units in this 8th edition.

Keith Satterthwaite, Lincoln Technical Institute, Union NJ for his insight and valuable contributions to Unit 36.

AVENUE FOR FEEDBACK

The authors would appreciate feedback from students and/or instructors. They can be reached through Cengage Learning in Clifton Park, New York, or through the following e-mail addresses:

SECTION 1

THEORY OF HEAT

Units

Introduction

Unit 1 Heat, Temperature, and Pressure

Unit 2 Matter and Energy

Unit 3 Refrigeration and Refrigerants

INTRODUCTION

Refrigeration is a complex topic that covers a wide range of areas. Refrigeration relates to the cooling of substances to

- preserve and transport food products,
- produce ice,
- aid in the manufacturing of many commercial products, and
- aid in medical research.

In addition, refrigeration plays vital roles in many other industrial, commercial, and residential applications. Air-conditioning, a form of refrigeration, refers to space heating, cooling, dehumidifying, humidifying, air filtering, exhausting, ventilating, and improving overall indoor air quality for those in the occupied space.

HISTORY OF REFRIGERATION AND AIR-CONDITIONING (COOLING)

Most evidence indicates that the Chinese, as early as 1000 B.C., were the first to store ice and snow in order to cool wine and other food products. Early Greeks and Romans used underground pits, which were insulated with straw and weeds, to store ice for long periods of time. The ancient people of Egypt and India cooled liquids in porous earthen jars. These jars were set out in the dry night air, and the evaporation of the liquids seeping through the porous walls provided the cooling. Some evidence indicates that ice was even produced from the vaporization of water through the walls of these jars.

In the eighteenth and nineteenth centuries, natural ice was cut from lakes and ponds in the winter in the northern United States and stored underground for use in the warmer months. Some of this ice was packed in sawdust and transported to southern states to be used for preserving food. In the early twentieth century, it was still common in the northern states for ice to be cut from ponds and then stored in open ice houses. Sawdust insulated the ice, which was then delivered to homes and businesses.

In 1823, Michael Faraday discovered that certain gases under constant pressure will condense when they cool. In 1834, Jacob Perkins, an American, developed a closed refrigeration system using liquid expansion and then compression to produce cooling. He used ether as a refrigerant, a hand-operated compressor, a water-cooled condenser, and an evaporator in a liquid cooler. He was awarded a British patent for this system. In Great Britain during the same year, L. W. Wright produced ice by the expansion of compressed air.

TIME LINE

1800

1823 Michael Faraday discovered that certain gases under constant pressure will condense when they cool.

1834 L. W. Wright produced ice by expansion of compressed air. Jacob Perkins developed a closed refrigeration system using expansion of a liquid and compression to produce cooling. David Perkins developed a closed refrigeration system using the expansion and compression of ether.

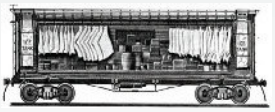
1842 John Gorrie used dripping ammonia to produce cooling.

1850

1858 Ferdinand Carré developed an ammonia mechanical refrigerator. It made blocks of ice.

1875 Raoul Pictet used sulfur dioxide as a refrigerant.

1881



Gustavus Swift was developing refrigeration railcars.

1890 Michael Cudahy improved railcar refrigeration.

In 1842, Florida physician John Gorrie placed a vessel of ammonia atop a stepladder and let the ammonia drip, which then vaporized and produced a cooling effect. This basic principle is still used in air-conditioning and refrigeration today. In 1856, Australian inventor James Harrison, an immigrant to America from Scotland, also used ammonia experimentally, but reverted to an ether compressor in equipment that had been previously constructed. In 1858, a French inventor, Ferdinand Carré, developed a mechanical refrigerator using liquid ammonia in a compression machine that produced blocks of ice. Generally, mechanical refrigeration was first designed to produce ice.

In 1875, Raoul Pictet of Switzerland first used sulfur dioxide as a refrigerant. Sulfur dioxide was not only a good refrigerant, but also served as a good lubricant for the system's compressor. This refrigerant was used frequently after 1890 and on British ships into the 1940s. Refrigeration railcars were developed by Gustavus Swift in 1881, and in 1890, Michael Cudahy had improved their design. Sulfur dioxide was also used in the Audiffren-Singrün refrigeration machine patented in 1894 by a French priest and physicist, Father Marcel Audiffren. It was originally designed to cool liquids, such as wine, for the monks.

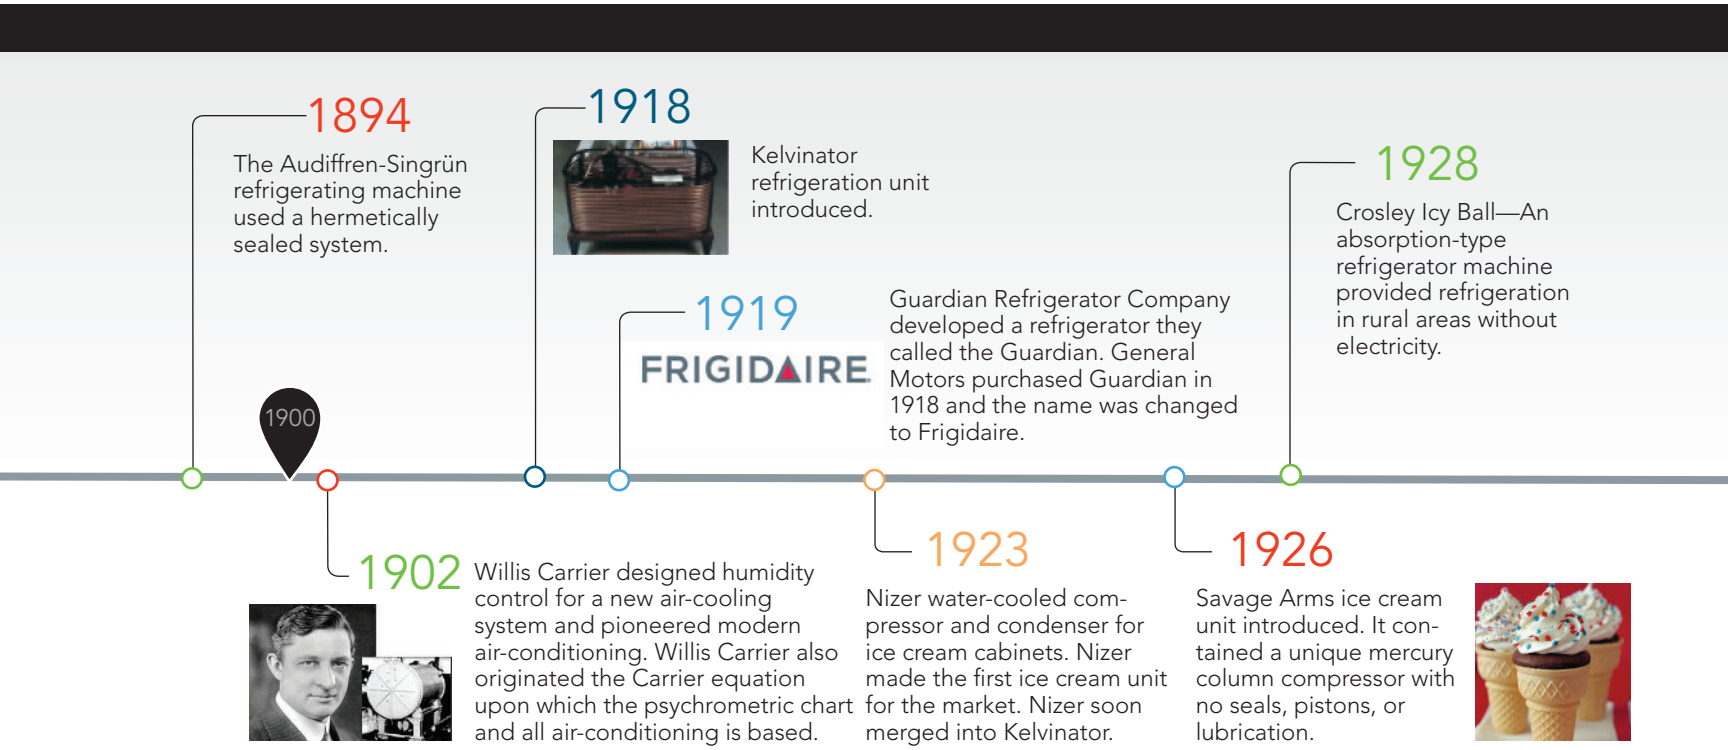
In 1902, Willis Carrier, the "father of air-conditioning," designed a humidity control to accompany a new air-cooling system. He pioneered modern air-conditioning. In 1915, he, along with other engineers, founded Carrier Engineering, now known as the Carrier Corporation.

In 1918, the Kelvinator company, originally named the Electro Automatic Refrigeration Corporation, came into being and sold the first Kelvinator household units. The refrigerator was a remote-split type in which the condensing unit was installed in the basement and connected to an evaporator in a converted icebox in the kitchen. The Guardian Refrigerator Company developed a refrigerator they called "the Guardian." General Motors purchased Guardian in 1919 and developed the refrigerator they named Frigidaire. By 1929, refrigerator sales topped 800,000. The average price fell from $600 in 1920 to $169 in 1939. By the 1930s, refrigeration was well on its way to being used extensively in American homes and commercial establishments.

In 1923, Nizer introduced a water-cooled compressor and condensing unit for ice cream cabinets, considered to be the first commercial ice cream unit. Nizer soon merged into the Kelvinator Company. In 1923–1926, units produced by Savage Arms were among the first automatically controlled commercial units. The Savage Arms compressor had no seals, no pistons, and no internal moving parts. A mercury column compressed the refrigerant gas as the entire unit rotated. The compressor was practically noiseless.

In 1928, Paul Crosley introduced an absorption-type refrigeration machine so that people could have refrigeration in rural areas where electricity was scarce. These systems, which used a mixture of ammonia and water, could lower the inside temperature to 43°F or less. Ice cubes actually could be made for a period of about 36 hours, depending on the room temperature. These machines would need periodic "recharging" by heating the system over a kerosene burner.

In 1939, the Copeland Company introduced the first successful semihermetic (Copelametic) field-serviceable



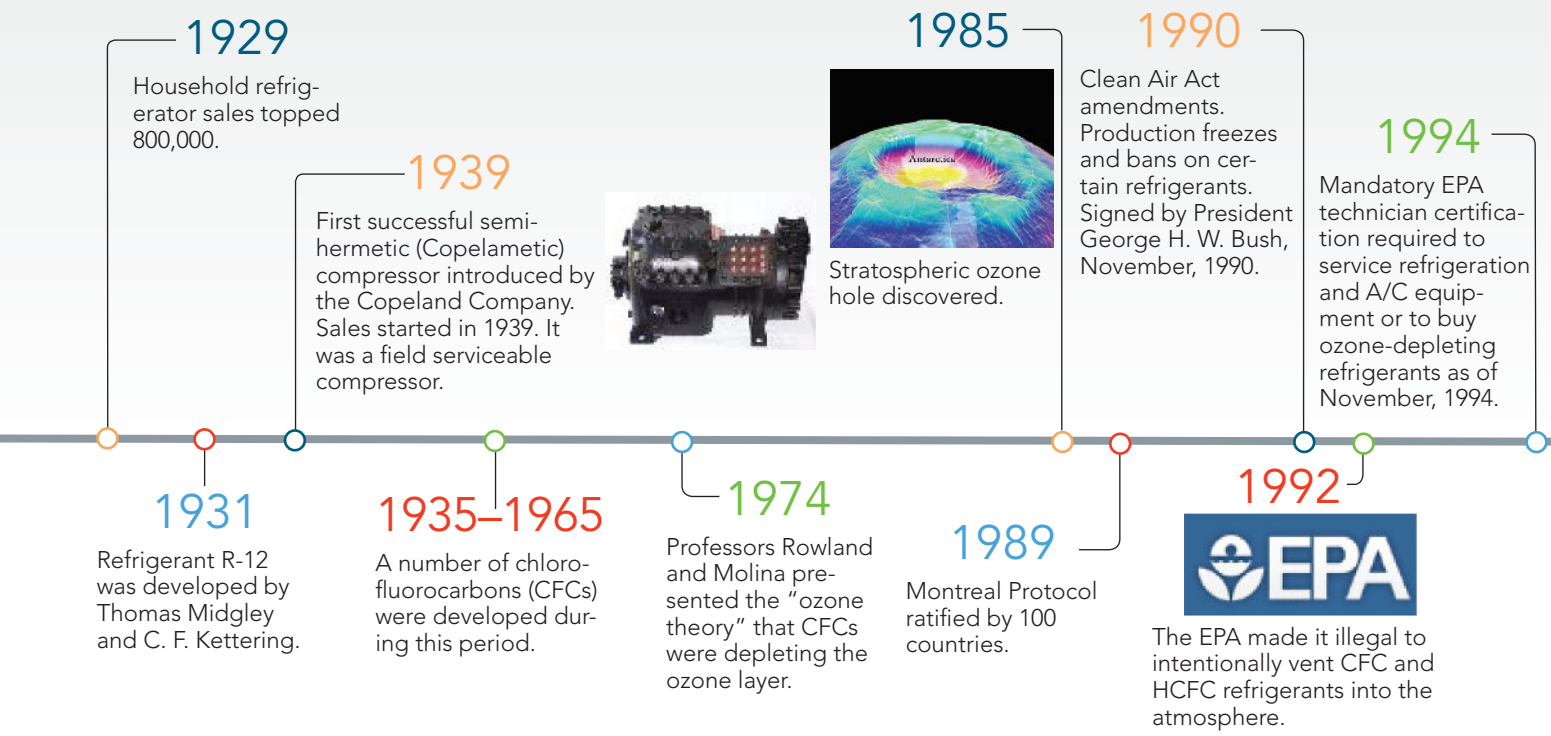
compressor. Three engineering changes made these compressors successful:

1. Cloth-insulated motor windings were replaced with Glyptal insulation.
2. Neoprene insulation replaced porcelain enamel in the electric terminals.
3. Valves were redesigned to improve efficiency.

Many different refrigerants have been developed over the years. The refrigerant R-12, a chlorofluorocarbon (CFC), was developed in 1931 by Thomas Midgley of Ethyl Corporation and C. F. Kettering of General Motors. It was produced by DuPont. In 1974, two professors from the University of California, Sherwood Rowland and Mario Molina, presented the "ozone theory." Their hypothesis was that CFC refrigerants released into the atmosphere were depleting the earth's protective ozone layer. Scientists conducted high-altitude studies and concluded that CFCs were indeed linked to ozone depletion. Representatives from the United States, Canada, and more than 30 other countries met in Montreal, Canada, in September, 1987, to try to solve the problem of released refrigerants and the effect they had on ozone depletion. This meeting produced the Montreal Protocol, which by 1989 had been ratified by 100 nations. It mandated a global freeze on the production of CFCs at 1986 levels. The Protocol also froze production of hydrochlorofluorocarbon (HCFC) refrigerants at their 1986 levels, beginning in 1992. In addition, the Protocol set a schedule of taxes on CFC refrigerants. As research on ozone depletion continues today, reassessments and updates to the Montreal Protocol also continue. At the time of this writing, the most current updates are as follows:

- 1990 (November)—President George H. W. Bush signed the Clean Air Act amendments that initiated production freezes and bans on certain refrigerants.
- 1992 (July)—The EPA made it against the law to intentionally vent CFC and HCFC refrigerants into the atmosphere.
- 1993—The EPA mandated the recycling of CFC and HCFC refrigerants.
- 1994 (November)—The EPA mandated a technician certification program deadline. Current HVAC/R technicians had to be EPA-certified by this date.
- 1995 (November)—The EPA made it against the law to intentionally vent alternative refrigerants (HFCs and all refrigerant blends) into the atmosphere.
- 1996—The EPA made it illegal to manufacture or import CFC refrigerants.
- 1996—The EPA put into place a gradual HCFC production phaseout schedule, which will totally phase out the production of HCFC refrigerants by the year 2030.

TIME LINE

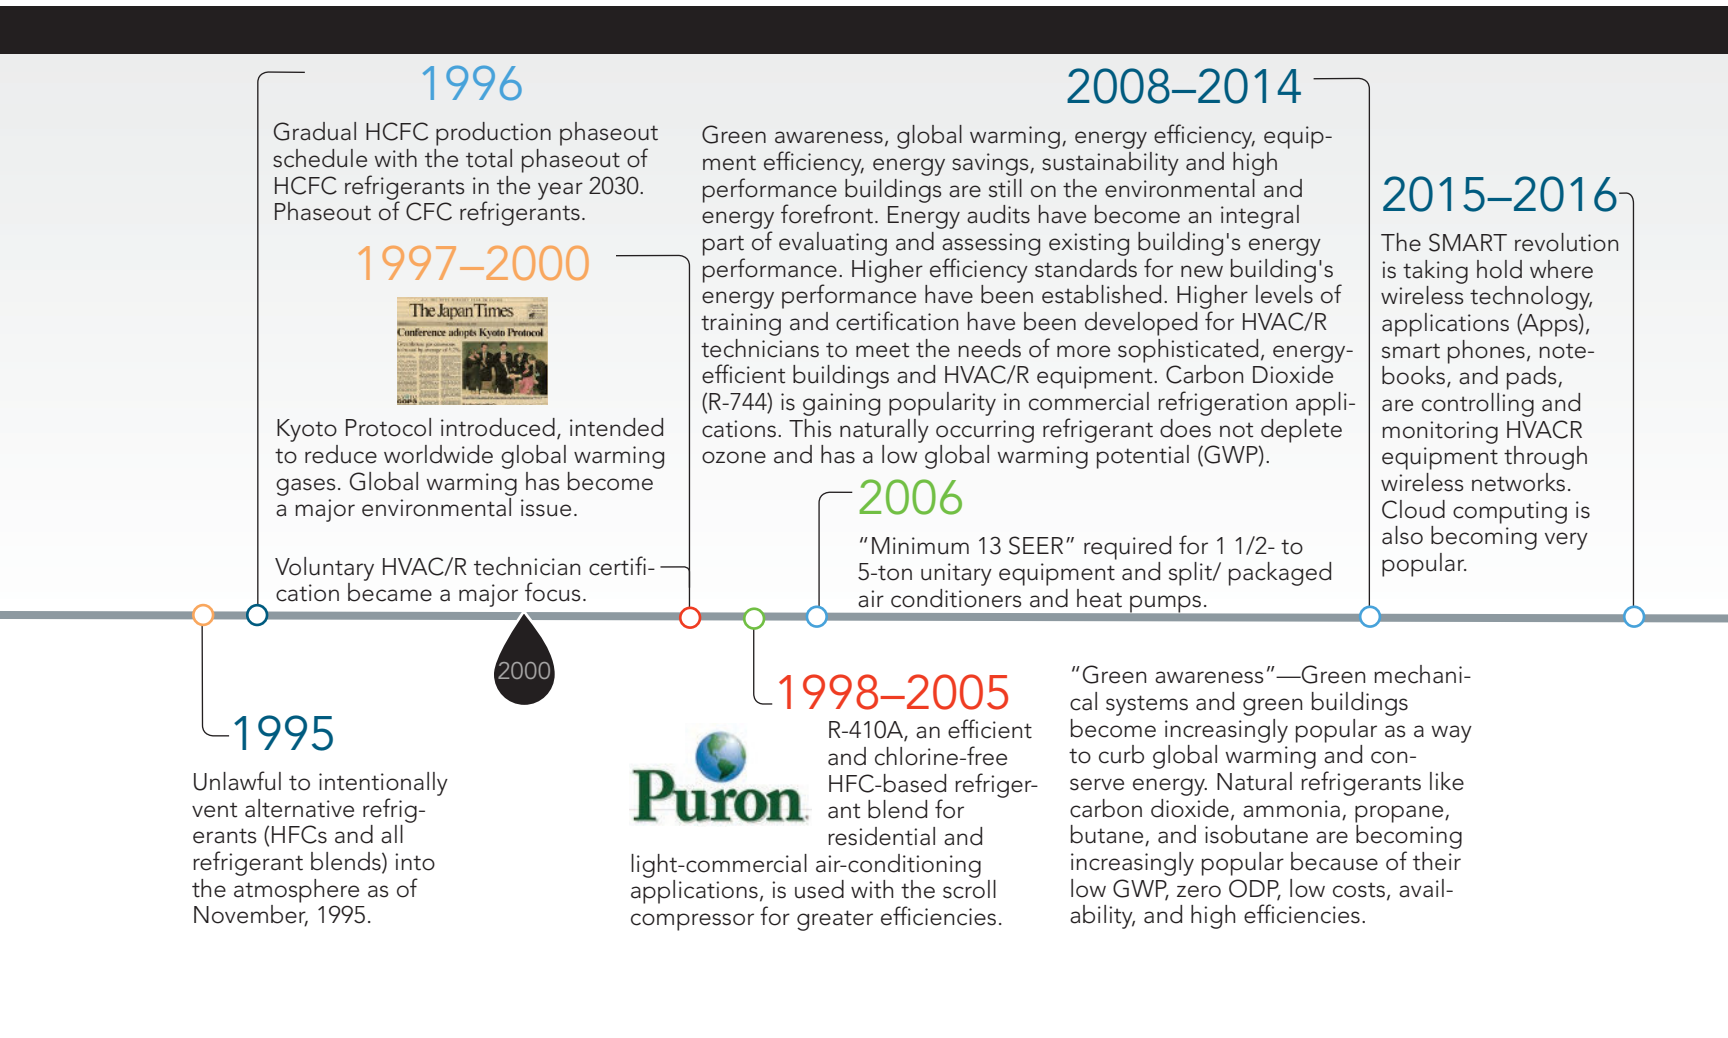


- 1998 (June)—The EPA proposed new regulations on recovery/recycling standards, equipment leak rates, and alternative refrigerants.
- 2004—35% reduction in HCFC refrigerant production.
- 2007—HCFC reduction on production was accelerated from 65% to 75% from the baseline 1989 production year.
- 2010—HCFC-22 is banned in new equipment. No production or importing of HCFC-22 and HCFC-142b, except for use in equipment manufactured before January 1, 2010.
- 2015—90% reduction in HCFC-22 production from the baseline production year of 1989. No production or importing of any HCFC, except for use in equipment manufactured before January 1, 2010.
- 2020—Total ban on HCFC-22 production. No production and no importing of R-22 and R-142b.
- 2030—Total ban on all HCFC production. No production and no importing of any HCFC.

From 1997 to 2000, voluntary HVAC/R technician certification became a major focus of the industry. From 1998 to the present, the major players in voluntary HVAC/R technician certification and home-study examinations were, and continue to be, the AC&R Safety Coalition, the Air Conditioning, Heating, and Refrigeration Institute (AHRI), the Heating, Air Conditioning, and Refrigeration Distributors International (HARDI), the Carbon Monoxide Safety Association (COSA), the Green Mechanical Council, HVAC Excellence, North American Technician Excellence (NATE), the Refrigeration Service Engineers Society (RSES), and the United Association of Journeymen and Apprentices (UA).

By 2008, global warming had become a major environmental issue. A scoring system was designed to help engineers, contractors, and consumers know the "green value" of each mechanical installation. R-410A, an efficient and chlorine-free HFC-based refrigerant blend for residential and light-commercial air-conditioning applications was developed for use with the scroll compressor for greater efficiencies. Also today, every central split cooling system manufactured in the United States must have a Seasonal Energy Efficiency Ratio (SEER) rating of at least 13. This energy requirement was mandated by federal law as of January 23, 2006. The "green value" encompasses the system's energy efficiency, pollution output, and **sustainability**. Green buildings and green mechanical systems are becoming increasingly popular in today's world as a way to curb global warming.

Green awareness, global warming, energy efficiency, energy savings, sustainability, and high-performance buildings are still at the forefront of environmental and energy concerns. Energy audits have become an integral part of evaluating and assessing the energy performance of existing buildings. Higher efficiency standards for the performance of new buildings have been established.



GREEN AWARENESS

As mentioned, global warming stemming from the uncontrolled rate of greenhouse gas emissions is a major global environmental issue. Most of the sun's energy that reaches the earth is in the form of visible light. After passing through the atmosphere, part of this energy is absorbed by the earth's surface and is converted into heat energy. The earth, warmed by the sun, radiates heat energy back into the atmosphere toward space. Naturally occurring gases and lower atmospheric pollutants such as CFCs, HCFCs, HFCs, carbon dioxide, carbon monoxide, water vapor, and many other chemicals absorb, reflect, and/or refract the earth's infrared radiation and prevent it from escaping the lower atmosphere. Carbon dioxide, mainly from the burning of fossil fuels, is a major contributor to global-warming. The gases in the atmosphere slow the earth's heat loss, making the earth's surface warmer than it would be if heat energy had passed unobstructed through the atmosphere into space. The warmer earth's surface then radiates more heat until a balance is established between incoming and outgoing energy. This warming process is called **global warming** or the **greenhouse effect**. Humans are chiefly responsible for producing many of the greenhouse gases that are causing environmental problems.

Over 70% of the earth's fresh water supply is either in ice cap or glacier form. Scientists are concerned that these ice caps or glaciers will melt if the average earth temperature rises too much, thereby increasing ocean water levels. The scientific consensus is that we must limit the rise in global temperatures to less than 3.6°F (2°C) above preindustrial levels to avoid disastrous impacts. An increase of 2°C will likely displace millions of people from their homes due to rising water levels. Food production will decline, rivers will become too warm to support marine life, coral reefs will die, snow packs will decrease and threaten water supplies, weather will become unpredictable and extreme, and many plant and animal species will die and become extinct.

Nineteen of the hottest 20 years on record have occurred in the past 20 years [this information updated from multiple sources, including http://www.climate.gov/news-features/videos/2014-global-temperature-recap]. Atmospheric carbon dioxide levels are now at their highest. Half of the world's oil is gone and other natural resources are dwindling. The average American uses 142 gallons of water per day, and in some regions of the country, water supplies are drying up. Because of this, slowing, and possibly stopping or even reversing, the growth rate of greenhouse gas emissions has become a global effort.

Buildings are the major source of demand for energy and materials, and they are also the major source of greenhouse gases that are attributed to the by-products of energy use and materials. At the time of this writing, there are over 5 million commercial buildings and over 132 million housing units in the United States. Surprisingly, almost every one of their mechanical systems is obsolete. The global-warming scares, the rising price of fuels, the scarcity of clean water, and the ever-growing waste stream demand improvements in our homes and businesses today. Trained contractors, with the help of the government, installers, builders, manufacturers, and educators, must renovate and improve the efficiency of these buildings and mechanical systems.

In the United States, buildings account for approximately

- 36% of total energy used,
- 65% of electrical consumption,
- 30% of greenhouse gas emissions,
- 30% of raw materials used,
- 30% of waste output (136 millions tons annually), and
- 12% of potable water consumption.

Organizations like the Green Mechanical Council (GreenMech) and the United States Green Building Council (USGBC) are setting goals for the use of fewer fossil fuels in existing and new buildings. Some of these goals are listed here:

- All new buildings, developments, and major renovation projects must be designed to use one-half of the fossil-fuel energy they would typically consume.
- The fossil-fuel reduction standard for all new buildings must be increased to
  - 70% in 2015,
  - 80% in 2020, and
  - 90% in 2025.
- By 2030, new buildings must be carbon-neutral, which means that they cannot use any greenhouse-gas-emitting fossil-fuel energy to operate.
- Joint efforts must be made to change existing building standards and codes to reflect these targets.

Builders can accomplish these goals by choosing proper siting, building forms, glass properties and locations, and materials and by incorporating natural heating, cooling, ventilating, and lighting strategies. Renewable energy sources such as solar, wind, biomass, and other carbon-free methods can operate equipment within the building.

Leadership in Energy and Environmental Design (LEED) is a voluntary internationally recognized green building certification system for developing high-performance, sustainable buildings, which is referred to as the LEED Green Building Rating System. It was established by the USGBC in 1999 and is widely recognized as a third-party verification system and guideline for measuring what constitutes a green building. It was enhanced in 2009 and is currently operating under Version 3 of the rating system. All of the information for LEED ratings is available at http://www.usgbc.org/. Version 4 of the LEED program was scheduled to be put into effect in July 2015 and, at the time of this writing, the implementation of the new version is on schedule.

The USGBC membership, which is composed of every sector of the building industry and consists of over 9,000

organizations, developed and continues to refine LEED. LEED promotes expertise in green building by offering project certification, professional accreditation, and training. LEED emphasizes state-of-the-art strategies for sustainable site development, water savings, energy efficiency, material selection, and indoor environmental quality. According to the United Nations World Commission on Environment and Development, a **sustainable design** "meets the needs of the present without compromising the ability of future generations to meet their own needs." Companies looking to utilize **green** technologies or incorporate sustainable design into their buildings and facilities, are concerned with six areas:

- Optimizing site location
- Optimizing energy use
- Protecting and conserving water
- Using environmentally preferable products
- Enhancing indoor environmental quality
- Optimizing operational and maintenance practices

There are nine possible LEED rating categories, and each is assigned individual points for reaching accreditation. Listed here are the nine categories (separate rating systems) and possible points per categories.

Category	Points Possible
New Construction	110
Existing Buildings (Operation & Maintenance)	92
Commercial Interiors	110
Core & Shell	110
Schools	110
Retail	110
Healthcare	110
Homes	136
Neighborhood Development	110

Points are awarded in each category depending on how well the building meets the category's requirements. For example, the following information is taken from the New Construction (NC) LEED Rating System. Keep in mind that each system has different point-generation possibilities. The LEED NC system requires that a building earn a minimum of 40 points to meet minimum requirements out of a possible 110 points. There are four levels of certification according to the point system:

Certified	40–49
Silver	50–59
Gold	60–79
Platinum	80–110

A LEED NC certified building means that it has achieved at least a minimum standard as judged in the following seven categories prior to any points being awarded toward a LEED rating.

Category	Points Possible
Sustainable Sites	26
Water Efficiency	10
Energy & Atmosphere	35
Materials & Resources	14
Indoor Environmental Quality	15
Innovation & Design Process	6
Regional Priority Credits	4
	110

The Energy & Atmosphere category has a possible 35 points, with potentially 33 of them directly linked to HVAC systems. This category for New Construction (NC) addresses such items as the facility's basic consumption of energy, its optimization of energy consumption, system commissioning and refrigerant management, and use of on-site renewable energy. Optimizing building facilities' performance can equate to a possible 19 out of 35 points. These points would equate to installing an HVAC system that improves efficiency by 48% for new construction or 44% for existing HVAC systems and constitute a large portion of the possible points, which provides opportunities in building renovation.

The Indoor Environmental Quality category has a possible 15 points, with potentially 7 of them directly linked to HVAC systems. This category has multiple possibilities: HVAC systems can affect outdoor air-delivery monitoring of facility ventilation, minimum air changes in buildings for removing harmful volatile organic compounds (VOCs), electronic thermal control systems, and thermal comfort design and verification.

In summary, the purpose of LEED is to provide a third-party certification process using nationally developed and accepted minimum standards for the construction industry. It affects the design, construction, and operation phases of high-performance "green" buildings. LEED systems take into account other ways of increasing efficiencies, such as water conservation, **heat island** reduction in urban areas, incentives for use of locally manufactured materials, site preparation, and maintenance as well as the HVAC efficiencies listed above. To receive a LEED rating, the facility must be built by a team, some of whose members are LEED accredited professionals. LEED-rated projects have a higher cost than similar, non-LEED projects because the enhancements required to increase efficiencies and the certification and documentation required cost more. Many European nations have made LEED-type systems mandatory for all buildings and have instituted existing-building rating systems that monitor yearly energy consumption of all utilities in these buildings. The higher a building's energy usage or "energy utilization index" above a minimum consumption, the higher amount of penalty tax the building owner must pay. This provides an incentive for improving the building's energy footprint.

The green awareness movement isn't just a temporary "buzzword" that will fade away with time. It is one that will be rapidly gaining momentum in the coming years. If contractors

want to remain competitive, they must obtain the necessary training with regard to green building and LEED certification.

An alternative to LEED certification is the Green Globes® program, which is offered by the Green Building Initiative. The Green Globes program operates on a 1,000-point scale and certifications range from one to four Green Globes, with four Green Globes being their highest possible rating. Both the LEED and Green Globes programs are nationally accepted.

HISTORY OF HOME AND COMMERCIAL HEATING

Human beings' first exposure to fire was probably when lightning or another natural occurrence, such as a volcanic eruption, ignited forests or grasslands. After overcoming the fear of fire, early humans found that placing a controlled fire in a cave or other shelter could create a more comfortable living environment. Fire was often carried from one place to another. Smoke was always a problem, however, and methods needed to be developed for venting it outside. Native Americans, for example, learned in later years to vent smoke through holes at the peak of their tepees, and some of these vents were constructed with a vane that could be adjusted to prevent downdrafts. The fireplaces common in Europe and North America were vented through chimneys.

Early stoves were found to be more efficient than fireplaces. These early stoves were constructed of a type of firebrick, ceramic materials, or iron. In the mid-eighteenth century, a jacket for the stove and a duct system were developed. The stove could then be located at the lowest place in a structure, and the heated air in the jacket around the stove would rise through a duct system and grates into the living area. This was the beginning of the development of circulating warm-air heating systems.

Boilers that heated water were also developed, and this water was circulated through pipes in duct systems. The water heated the air around the pipes, and the heated air passed into the rooms to be heated. Radiators were then developed. The heated water circulated by convection through the pipes to the radiators, and heat was passed into the room by radiation. These early systems were forerunners of modern hydronic heating systems.

Steam heat became a popular heating option at the beginning of the nineteenth century and coal was the fuel of choice for boilers. Coal was desirable because it burned hot and lasted a long time. But coal was not inexpensive and the coal dust that was ever-present resulted in health, primarily breathing, problems for many people. In the late 1920s, the oil burner was invented and was a very attractive alternative to coal. Oil was less expensive and cleaner than coal and nobody had to keep feeding coal to keep the fire burning.

Oil remained popular, and inexpensive, until the Arab oil embargo of 1973 and the Iranian Revolution in 1979. Oil prices spiked and people had to wait in lines, sometimes for hours, to get their ration of fuel for their cars. As a result, many people switched to natural gas, comprised primarily of methane. Natural gas boilers began to replace the old oil boilers, just as oil had replaced coal.

After the price shocks of the 1970s, oil prices stayed low for most of the 1980s and 1990s, with occasional moderate peaks. Oil prices then rose steadily from the period between September 11, 2001 and 2009, and continue to fluctuate today.

Today, commercial and residential heating needs are being met in a number of ways that include traditional hot water and steam, but new, more efficient technologies are becoming more attractive. These include radiant heating, radiant cooling, and geothermal heat pump systems.

CAREER OPPORTUNITIES

The HVAC/R industry is rapidly changing due to advancements in technology being spurred on by the need for increased energy efficiencies. The career opportunities available in HVAC/R for those who have acquired formal technical training coupled with field experience are unlimited. Schools that provide excellent technical training in the field are becoming easier to identify through HVAC/R program accreditation. As new equipment becomes more technically challenging and the existing workforce continues to age, the employment positions available will continue to outnumber applicants for the foreseeable future. This shortfall in available, competent HVAC/R service technicians is being addressed through the cooperative efforts of educational institutions, labor unions, employers, and manufacturers. Many organizations offer apprenticeship opportunities that can lead to high-income positions. Manufacturers are also teaming up with select educational institutions across North America to help develop the next generation of HVAC/R technicians.

Many newer buildings are constructed so tightly that the quality of the air must be controlled by specialized equipment. The conditions of the air must also be carefully controlled in areas that perform manufacturing processes. Heating and air-conditioning systems control the temperature, humidity, and total air quality in residential, commercial, industrial, and other types of buildings. Refrigeration systems are used to store and transport food, medicine, and other perishable items. Refrigeration and air-conditioning technicians design, sell, install, or maintain these systems. Many contractors and service companies specialize in commercial refrigeration. The installation and service technicians employed by these companies install and service refrigeration equipment in supermarkets, restaurants, hotels/motels, flower shops, and many other types of retail and wholesale commercial businesses.

Other contractors and service companies may specialize in air-conditioning. Many specialize in residential-only or commercial-only installation and service; others may install and service both residential and commercial equipment up to a specific size. Air-conditioning may include cooling, heating, humidifying,

dehumidifying, ventilating, exhausting, and air cleaning. Heating equipment may rely on fossils fuels, such as natural gas, liquefied petroleum, or oil, or may be configured as electric-based or heat pump systems. The type and number of installations will vary from one part of the country to another, depending on the climate and availability of the heat source. The heating equipment may be either a furnace (which heats air) or a boiler (which heats water). The boiler heats water and pumps it to the space to be heated, where one of many types of heat exchangers transfers the heat to the air.

Technicians may specialize in installation or service of equipment, or they may be involved with both. Other technicians may design installations or work in the sales area. Sales representatives may be in the field selling equipment to contractors, businesses, or homeowners; others may work in wholesale supply stores. Still other technicians may represent manufacturers, selling equipment to wholesalers and large contractors.

Many opportunities exist for technicians to be employed in the industry or by companies owning large buildings. Technicians may be responsible for the operation of air-conditioning equipment, or they may be involved in the service of this equipment. Opportunities also exist for employment in servicing household refrigeration and room air conditioners, which would include refrigerators, freezers, and window or through-the-wall air conditioners. Opportunities are also available for employment in a field often called transport refrigeration. This includes servicing refrigeration equipment on trucks or on large containers hauled by trucks and ships.

Most modern houses and other buildings are constructed to keep outside air from entering, except through planned ventilation. Consequently, the same air is circulated through the building many times. The quality of this air may eventually cause a health problem for people spending many hours in the building. This indoor air quality (IAQ) presents another opportunity for employment in the air-conditioning field. Technicians clean filters and ducts, take air measurements, check ventilation systems, and perform other tasks to help ensure healthy air quality. Other technicians work for manufacturers of air-conditioning equipment. These technicians may be employed to assist in equipment design, in the manufacturing process, or as equipment salespersons.

Following is a list of many career opportunities in the HVAC/R field:

- Field service technician
- Service manager
- Field supervisor
- Field installer
- Journeyman
- Project manager
- Job foreman
- Application engineer
- Controls technician
- Draftsperson
- Contractor
- Lab technician
- Inspector
- Facilities technician
- Instructor
- Educational administrator

- New product developer
- Research engineer
- Estimator

TECHNICIAN CERTIFICATION PROGRAMS

HISTORY

Even though mandatory technician certification programs are in place today, the EPA originally did not consider them as its lead option. As a matter of fact, the EPA initially thought private incentives would ensure that technicians were properly trained in refrigerant recycling and recovery. The EPA also stated that it would play an important role through a voluntary technician certification program by recognizing those who provide and participate in voluntary technician training programs that meet certain minimum standards. The EPA also thought that a mandatory certification program would be an administrative burden. The EPA then requested public comments on a mandatory versus voluntary technician certification program. More than 18,000 comments were in favor of a mandatory program, and only 142 were in favor of a voluntary program. Most of the 18,000 in favor of the mandatory certification program were major trade organizations and technicians themselves. Manufacturers of recovery and recycling equipment, along with environmental organizations, also supported mandatory certification. They believed it would increase compliance with venting, recovery, and recycling laws and the general safe handling of refrigerants. The following were reasons given by those favoring mandatory technician certification:

- Improve refrigerant leak detection techniques
- Promote awareness of problems relating to venting, recovery, and recycling of refrigerants
- Improve productivity and cost savings through proper maintenance practices
- Ensure environmentally safe service practices
- Gain more consumer trust
- Receive more liability protection
- Ensure that equipment is properly maintained
- Educate technicians on how to effectively contain and conserve refrigerants
- Create uniform and enforceable laws
- Foster more fair competition in the regulated community

With these comments in mind, the EPA decided that mandatory technician certification would increase fairness by ensuring that all technicians were complying with today's rules. The EPA

also said that a mandatory certification program would enhance the EPA's ability to enforce the rules by providing a tool to use against intentional noncompliance: the ability to revoke the technician's certification. The EPA then created a mandatory technician certification program that mandated all technicians to be certified effective November 14, 1994.

All technicians must pass an examination administered by an approved EPA testing organization in the private sector in order to purchase refrigerant and to work on equipment that contains refrigerant. This mandatory certification applies to individuals who work as installers, contractor employees, in-house service personnel, and anyone else who installs, maintains, or repairs equipment that might reasonably have the opportunity to release CFCs or HCFCs into the atmosphere. The EPA created three separate technician certification types:

- Small appliances
- High- and very high pressure appliances
- Low-pressure appliances

Persons who successfully pass a *core of questions* on stratospheric ozone protection and legislation and also pass one of the three certifications are certified in that category. If all three certifications are passed, a person will be *universally* certified. To date, the EPA is not requiring recertification. However, it will be the technicians' responsibility to keep up to date on new technologies and governmental rule changes. By creating types of certification, the EPA allowed technicians to be tested on information concerning equipment and service practices that the technicians primarily service and maintain.

Although training programs are beneficial, participation in a training program is not required currently. To create price-competitive training programs, training programs requested by technicians will be administered by the private sector. Many national educational and trade organizations—such as the AC&R Safety Coalition, the Air Conditioning, Heating and Refrigeration Institute (AHRI), the Air Conditioning Contractors of America (ACCA), the Heating, Air Conditioning, and Refrigeration Distributors International (HARDI), the Carbon Monoxide Safety Association (COSA), the Educational Standards Corporation (ESCO), the Environmental Protection Agency (EPA), Ferris State University (FSU), the Green Mechanical Council (GreenMech), HVAC Excellence, North American Technician Excellence (NATE), the Refrigeration Service Engineers Society (RSES), and the United Association of Journeymen and Apprentices (UA)—have developed training and/or testing programs. These programs are specifically intended to help technicians comply with the July 1, 1992, refrigerant venting law. Unit 9 of this text, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting," gives more detailed information on the EPA's mandatory technician certification program, including details on the specific types of certification tests and specifications. For a complete list of EPA-approved certifying organizations, contact the EPA hotline at 1-800-296-1996.

CERTIFICATION PROGRAMS

Technician certification programs can be divided into two categories:

- Mandatory technician certification programs
- Voluntary technician certification programs

Mandatory technician certification programs are covered in the preceding paragraphs and in Unit 9. Voluntary technician certification programs are becoming popular because they are industry-led and are much more comprehensive in nature when compared to mandatory certification programs. They give technicians an educational opportunity from the beginning to the end of their careers. These programs allow technicians to become recognized for their level of expertise and also allow them to achieve higher levels of competence. Their diverse nature allows almost every aspect of the industry to be covered. Voluntary certification testing is based on the courses taken for each level, with an outline and roadmap on what material will be covered on the test and where to find it. An example of a voluntary certification is the ESCO Group's R-410A Safety and Certification test, which evaluates a candidate's knowledge of the special considerations that must be taken into account when working on systems that contain this refrigerant.

WHY TECHNICIANS SHOULD BECOME CERTIFIED

As mentioned, mandatory technician certification allows the technician to purchase ozone-depleting refrigerants legally and work on equipment that contains refrigerant. Some advantages of having both mandatory and voluntary technician certifications are:

- Customers tend to ask for certified technicians because of their reliability and good workmanship.
- Equipment manufacturers develop faith in certified technicians and have a sense of well-being when they know the job has been accomplished by a certified technician.
- Higher standards are set on the job by certified technicians, giving them more respect, recognition, trust, higher pay, and a higher quality of life in the long run.
- Employers would rather hire a certified technician, because they know certified technicians care more about their reputation, customer relations, and overall professionalism.
- Certification gives the technician a status symbol for other technicians to work up to.
- Certified technicians have proven technical proficiencies with measured capabilities.

PROGRAMMATIC ACCREDITATION

Accreditation has gained popularity in the last decade for secondary and postsecondary HVAC/R programs. Program accreditation involves an independent, nongovernmental,

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

nonindustry, third-party review of an educational program. Three leading accreditation agencies are

- HVAC Excellence,
- the Partnership for Air Conditioning, Heating, and Refrigeration Accreditation (PAHRA), and
- the National Center for Construction Education and Research.

The process validates that the established standards of excellence for HVAC/R educational programs are met. These standards are designed to ensure that our future workforce receives the quality of training required to provide the skills necessary for success in the HVAC/R industry. The Department of Education in its Code of Federal Regulations, Title 34, sets guidelines and defines criteria for who can be an accredited body but does not do any accrediting itself.

The standards require a thorough examination of the programs:

- Mission
- Curriculum
- Plans of instruction
- Finances and funds
- Administrative responsibilities
- Equipment and tools
- Facilities
- Instructor's qualifications

Programmatic accreditation provides an HVAC/R program with an opportunity to recognize both its strengths and weaknesses. Some of the benefits of programmatic accreditation include the following:

- Enhanced student confidence in the quality of the program
- Assurance and confidence of employers that student graduates are properly trained
- Enhanced student placement and employer satisfaction
- Acceptability of transfer credits for students
- Self-evaluation of faculty and staff
- Enhanced articulation agreements with other HVAC/R programs and institutions
- Assistance in acquiring federal, state, and private funding
- Creation of self-improvement goals

NATIONAL SKILL STANDARDS

The National Skill Standards (NSS), as interpreted by the Vocational-Technical Education Consortium of States (VTECS) for Heating, Air Conditioning, and Refrigeration Technicians, were funded by the U.S. Department of Education from 1992 to 1998 as part of twenty-two projects from the National Skill Standards Board. The NSS were created by a joint effort of committees composed of heating, air-conditioning, and refrigeration industry professionals. These skill standards not only help technicians identify the skills and knowledge needed for their occupation but also assess their weaknesses and/or needs for additional training.

Skill standards are often described as workplace behaviors, technical skills, and the general body of knowledge required of technicians to be successful, productive, and competitive in today's workforce. As HVAC/R manufacturers increase the efficiency and sophistication of their equipment, technicians require additional, updated information as well as a sound technical skills base to maintain, install, and service this equipment. The increased number of environmental regulations concerning more energy-efficient and environmentally friendly HVAC/R equipment have also created a new knowledge and skills base for technicians to learn and use on their jobs. Although it is difficult to provide all users of this text with information on the vast array of issues covered in the NSS, the authors have made every effort to do so. We hope both private and public institutions as well as the industry will use our comprehensive book to provide both students and workers with the competencies needed for successful employment and advancement in the ever-changing and growing technical HVAC/R field.

The NSS are divided into three main areas with subdivisions as follows:

CORE KNOWLEDGE

- Communications
- Mathematics
- Science

OCCUPATIONAL-SPECIFIC SKILLS

- Core skills
- Occupational-specific skills

WORKPLACE BEHAVIORS

- Ethics
- Environment
- Communications
- Professionalism
- Problem solving

The *core skills* consist of:

- Safety and environment
- Electrical principles
- Electric motors
- Controls
- Refrigeration principles and practices
- Heating principles and practices
- Air-conditioning principles and practices
- Piping principles and practices

The *occupational-specific skills* consist of:

- Residential and light-commercial heating
- Residential and light-commercial air-conditioning
- Residential and light-commercial heat pumps
- Commercial conditioned-air systems
- Commercial refrigeration

For more detailed information on the NSS, go to https://www.federalregister.gov/agencies/national-skill-standards-board.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

CUSTOMER RELATIONS AND TECHNICIAN SOFT SKILLS

Customer relations are extremely important to a service business and consequently to a service technician. Without customers there will be no business and no income. The technician is a major factor in acquiring and keeping customers. This is true whether work is performed at a residence, an office, a restaurant, or a store, or whether the technician is an inside or outside salesperson for a distributor or contractor. The HVAC/R business and technician are dependent on the customers. All technicians should be concerned with the quality of their work because customers have the right to insist on quality. If they have had a previous unsatisfactory experience, customers may have some doubt as to whether they will get the quality service for which they are paying. As professionals, technicians should strive to provide the best workmanship possible. Quality work will prove beneficial to the technician, to the company, and to the consumer. Customers depend on the technician for their comfort and air quality at home and at the office.

FIRST IMPRESSIONS

The impression the technician makes on the customer is very important, and the first impression is the most important. The first impression begins with the technician arriving on time. Most customers feel that their time is valuable. If the technician is going to be delayed, the customer should be called and given an explanation. An appointment should be scheduled for either later that day or another time convenient for the customer. The customer affected by a delay should be given priority in scheduling a makeup appointment. If the service call is an emergency, all efforts should be made to arrive as soon as possible.

When arriving, do not park in or block the customer's driveway unless necessary. If carrying equipment or having to make several trips to the vehicle, ask permission to park in the driveway. The customer may suggest another location. Ensure that the service vehicle is kept in a neat, clean, and orderly manner. This will help to make a good impression and provide better working conditions for the technician.

Remember the customer's name and use it frequently, preferably with Ms., Mrs., or Mr. Sir or Ma'am may also be used when appropriate. Always make eye contact with the customer and avoid talking to the ground or to a clipboard. Always wear clean clothes. If a company-issued shirt and pants are available, wear them. A name patch bearing your name and the company's name and logo also makes a good first impression. Politely ask the customer how you can help. When meeting a customer, be prepared to shake hands. In many cases, it may be appropriate to let the customer initiate the handshake. Your handshake should be firm and accompanied with a smile. A handshake that is too limp may give the impression of weakness; one that is too strong may indicate an overbearing type of person. Not all people like to shake hands. After ringing the doorbell, always maintain a distance from the door. This gives customers comfortable spacing between them and you. Make sure the customer has invited you in before making a move towards the door. Politely introduce yourself by name and then introduce the company you work for. Hand the customer your business card and then tell the customer the reason for your visit. Be friendly and always have a smile. Make sure you have a pen or pencil to write down any concerns or complicated issues the customer may have. Politely answer any questions asked by the customer. Listed below is a summary of what makes a good first impression:

- Arrive on time.
- Do not park in or block the customer's driveway unless you have permission.
- Keep your service vehicle in a neat, clean, and orderly manner.
- Remember the customer's name.
- Be prepared to shake hands.
- Always make eye contact with the customer.
- Always introduce yourself and your business.
- Tell the customer the reason for your visit.
- Hand the customer your business card.
- Always wear clean clothing.
- Wear a name tag and company logo.
- Be polite to the customer.
- Give the customer a comfortable space once at the door.
- Never enter the house until invited.

APPEARANCE

Another major factor in first impressions and maintaining good customer relations is appearance. It is almost impossible to get a second chance to make a good first impression. As a serviceman moves from one service call to another throughout the day, dirt and grime may start to accumulate on clothing. For this reason, it is important to always keep a spare pair of work pants and shirt in the service truck. Work shoes may need to be wiped clean between service calls to keep them presentable also. Appearance includes the following:

Hair—Brushed or combed, neatly trimmed. Male technicians should be clean-shaven or have a neatly trimmed beard or mustache. Female technicians with longer hair may wish to contain it in a ponytail or pinned back in some fashion.

Clothing—Neat and clean. For most uniforms, ensure that the shirttail is tucked in. A clean and neat uniform will help to make the appropriate impression. If you have an ID badge, wear it in plain sight. Make certain that your clothes are pressed to give that professional appearance.

Personal hygiene—Cleanliness is important. Hands should be washed and clean. A shower before going to bed or before going to work should be a regular habit. Your appearance and personal hygiene are major indicators of your personality and the quality of work you offer.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

First impressions are so important that a service technician does not want to ruin a relationship with a customer because of poor appearance. Dirty shoes can be wiped down with a moist towel or rag if necessary. Some companies require that their service personnel put on plastic booties that cover their work boots when they enter the customer's house. Make sure the uniform you are wearing fits. A uniform that is too tight or too loose can make the service technician look uncared for. Long-sleeved shirts should be worn to protect the your arms. Long pants instead of shorts should also be worn to protect the legs and give a neat and tidy appearance. Any tattoos should be covered up by the shirt or pants. Earrings and finger rings should not be worn to work for safety reasons. Even though earrings and tattoos are in style for many younger people, they often give older customers a wrong or negative impression. Always follow the company's policy pertaining to tattoos and earrings shown and/or worn on the job. Also, once finished with your work, make sure the job site is cleaned up.

After arriving at the customer's address take a minute or two to get organized. You may have a clipboard with material to organize and review. Think about what you are going to say and do when meeting the customer. Do not flip a cigarette butt to the ground outside the truck or on the way to the house or other location. There should be no smoking while making a service call. After arriving at the house but before entering, put on your shoe covers. Do not use the customer's phone for personal calls, and do not use the customer's bathroom.

Listed next is a summary of major factors for good customer relations as they pertain to the technician's appearance:

- Make sure hair is brushed or combed neatly, mustache or beards are trimmed, and long hair is contained in a ponytail or pinned up neatly.
- Uniforms and other clothing should be neat, clean, and tucked in.
- A spare, clean uniform should be carried in the service truck.
- Always wipe down work shoes with a clean towel or rag.
- An identification badge should be worn.
- Shower daily and always have clean hands and face.
- Make sure your uniform fits. Never wear a too loose or too tight uniform.
- Take off ear and hand rings while at work.
- Wear long-sleeved shirts and long pants while working.
- Hide any tattoos with shirt or pants if possible.
- Clean up a job site once finished.

COMMUNICATION SKILLS

The technician must be able to describe the service that can be provided; however, the technician must not monopolize the conversation. A big part of communicating is listening. Most people like to be listened to and the more you listen to the customer about the problems involved with the system, the easier it will be to diagnose. Courtesy and a show of respect for the customer should be evident at all times. The training and high skill level of the technician should also be evident as a result of the conversation and the ability to answer and ask questions. Telling people how capable and skilled you are is often a turnoff. Remember to smile often. Ask pertinent questions and do not interrupt when the customer is answering. Never say anything to discredit a competing business.

Never make customers feel stupid because they do not understand a technical topic you are talking about. A service technician should avoid using too many technical terms or concepts. Try to communicate to the customer in everyday language that they can understand. Always ask the customer their account of the problem before starting any work. Politely ask questions to try to expedite your solving the problem. If possible, make customers think that they are part of the solution. Always make sure all of the customer's questions are answered before starting any work. Clearly and concisely explain what work will have to be done and why it has to be done. If the problem has to do with the way the HVAC/R system is being operated, politely show the customer the proper way the system should be operated. If there are any choices or options on how to operate the equipment, explain the advantages and disadvantages of each option and why each option is important.

In summary, good communication skills consist of

- describing the service that can be provided,
- never monopolizing the conversation,
- being a good listener,
- being courteous and showing respect for the customer,
- never bragging about your training or skills,
- asking the customer pertinent questions,
- never interrupting customers when they are answering your questions or simply talking,
- never making a customer feel stupid about any technical topic,
- using everyday language the customer can understand,
- asking customers for their account of the problem,
- making customers feel that they helped with finding the solution to the problem,
- answering all of the customer's questions before starting any work,
- clearly and concisely explaining what work has to be done and why it has to be done,
- politely showing the customer the proper way to operate any HVAC/R systems, and
- politely explaining any options for system operations and the advantages or disadvantages of each option.

CONFLICTS AND ARGUMENTS

Conflicts and arguments with customers should be avoided at all costs. When you are dealing with an angry customer, you are dealing with an emotional customer. Listen until the customer is finished before replying. A complaint may be an opportunity to solve a problem. The customer should feel

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

assured that the technician is competent and that the work will be done properly and in a timely manner. Never be critical of a customer, even in a joking manner. People hate to be criticized. It is very important to be friendly.

Even when angry, most customers are good individuals. They may have had a bad experience or may be disappointed, frustrated, and upset. Angry customers may have reviewed what they want to say and will not feel right until they have said it to a willing listener. Be sympathetic, listen carefully, and try to determine why the customer is so upset. Do not take it personally. Do not reply until the customer is definitely finished with the complaint, and then try to concentrate on the solution. Ask the customer what you as the technician can do to help resolve the problem. If you can resolve the problem, do it. If you must report it to your supervisor, let customers know that you will do this right away and will get back to them immediately if possible. After listening carefully to the customer and resolving any complaint to the extent possible, you should be ready to start the troubleshooting process.

One of the best ways to handle an angry customer is to try to calm the customer down by taking on the responsibility yourself. Apologize and assure the customer that the problem will be fixed as soon as possible. Accept the responsibility and try to find answers to the customer's questions.

If you are on a service call with a co-worker, never argue in front of the customer with that co-worker. If you and a co-worker disagree on a topic, discuss the problem outside or in private, and then approach the customer together with a unified front. Arguing in front of a customer with a co-worker ruins the customer's confidence, trust, and credibility in both workers and their company. Even if you and your co-worker never come to an agreement, pretend that you have and tell the customer that you are looking at two possibilities for solving the problem and want to test both. No matter how the customer replies or what is said to you, never take the comments personally and cause a conflict. Always maintain your professionalism. Tell customers that they are valued and you will do your best to try and resolve the problem. Let them know that you, your co-worker, and the company value their business. You may even have to admit in some situations that the company's excellent track record in customer service may have fallen short this time.

Below is a summary of how to handle conflicts and arguments:

- Listen to customers and let them finish talking before replying.
- The customer must feel that the technician is competent.
- Never be critical of a customer, even in a joking manner.
- Be sympathetic, listen carefully, and try to determine why the customer is so upset.
- Do not take anything the customer says personally, and always avoid a conflict.
- Ask what you can do to resolve the problem.
- Try to calm the customer down by accepting the responsibility yourself, and try to find an answer to the customer's questions.
- Never argue with a co-worker in front of a customer.
- Always maintain your professionalism.
- Let customers know that they are valued and you and your company value their business.

THE SERVICE CALL

After arriving and introducing yourself, it is important to ask as many questions as needed to have a clear understanding of the problem. These questions will help to assure the customer that you are capable of solving the problem. During the service procedure you may need to talk with the customer to explain what you have found and to indicate the parts needed and possibly state the approximate costs if they may be higher than expected. If you must leave the job for any reason, tell the customer the reason and when you will return. You may need to go for parts or to another job emergency, but the customer needs to be informed. An informed customer is less likely to become angry or to complain. Keep the customer informed of all unusual circumstances. Double-check all your work. Clean the work site when finished and protect the customer's property from damage.

After the service work is completed, tell the customer what you found wrong, indicate that it has been corrected, and demonstrate when possible by turning the unit on while explaining how the problem was corrected. Customers deserve to know what they are paying for. All discussions should be in terms the customer will understand. Before leaving, give billing information to the customer. This should include a description of the work done and the costs.

Listed next is a summary of how the technician should handle a service call:

- Politely introduce yourself.
- Politely ask questions of the customer to make sure you clearly understand the problem.
- Politely explain to the customer the problems found, parts needed, and the approximate cost of fixing the problem.
- If temporarily leaving the job site, inform the customer of a return time and a reason for leaving.
- Inform the customer of any unusual circumstances.
- Double-check your work.
- Clean the work site when finished.
- Protect the customer's property from damage.
- Explain to the customer how the problem was corrected.
- Before leaving, give billing information to the customer, including a work description and the costs.

THE TECHNICIAN AS A SALESPERSON

A good technician is also a good salesperson. All options to resolve a problem should be presented in an honest and fair

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

manner. Most customers are honest about why they are calling your company. It makes no sense for them to lie, because your time is their money. The faster you can fix the problem, the less money it will cost them in most cases. A service technician should never lie about a service problem or the price of fixing the problem. Even though customers may be disappointed with the truth, if they find out the service technician has lied about the problem, respect will be lost and satisfaction will not be gained. A customer will never be satisfied with a lie. An HVAC/R company will not be around very long if it is not truthful and ethical. With the truth, a customer always knows where he stands. Even though the truth may hurt at first because it is not what the customer wants to hear, it is a temporary situation. Provide estimates and work orders in writing. A customer is buying not only service or equipment but also a solution to a problem. The customer may be offered an option not necessarily required but should not be "talked into it." The sale and installation of a new system is not always the best option for a customer. If a customer feels that he or she was talked into something that was not needed, there is a good chance that the transaction will end the relationship between the customer and the company. A company may have written recommendations for guiding the technician in presenting options. For instance if a unit is "x" years old and the repair will cost "x" amount, a recommendation to replace the unit or system may be appropriate.

In summary, what makes a technician a good salesperson is the following:

- Present all problem-solving options honestly and fairly.
- Provide estimates and work orders in writing.
- Never talk the customer into something that is not needed.
- Written company guidelines should be followed by the technician in presenting service or installation options.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

UNIT 1

HEAT, TEMPERATURE, AND PRESSURE

OBJECTIVES

After studying this unit, you should be able to

- define temperature.
- make conversions between the Fahrenheit and Celsius scales.
- describe molecular motion at absolute zero.
- define the British thermal unit.
- describe heat flow between substances of different temperatures.
- explain the transfer of heat by conduction, convection, and radiation.
- discuss sensible heat, latent heat, and specific heat.
- state atmospheric pressure at sea level and explain why it varies at different elevations.
- describe two types of barometers.
- explain psig and psia as they apply to pressure measurements.

SAFETYCHECKLIST

- ✅ HVAC/R technicians are often exposed to very high and very low temperatures. Be sure to wear gloves and other appropriate pieces of personal protection equipment (PPE) to reduce the chances of getting injured.
- ✅ Many fluids that are used by the HVAC/R technicians are under pressure. Be sure to transport all pressure vessels vertically and be sure they are properly secured.
- ✅ Make certain that all tanks are properly capped to prevent accidental releases from the tanks.
- ✅ Make certain all test instruments are properly calibrated and fully operational to ensure accurate pressure and temperature readings.

1.1 HEAT, TEMPERATURE, AND PRESSURE

The term **heat** can be applied to events in our lives that refer to our comfort, food, weather, and many other things. How does *cold* figure in? Cold is defined simply as the absence of heat. We say, "It is hot outside" or "The coffee is hot; the ice cream is cold." In the HVAC/R industry we must truly understand what heat is and how heat energy moves from one substance to another as well as between the molecules of a single substance. We use the words *hot* and *cold* as relative terms. When we need to be more specific, we often refer to **temperature**. If you are asked how hot it is outside, your answer will likely be along the lines of "It's 85 degrees outside."

In our industry, accurate temperature readings are very important because it is based on these temperature readings that we make decisions regarding system operation. Therefore, it is important to use high-quality thermometers to take these readings, **Figure 1.1**. It should be noted that the terms *heat* and *temperature* are not the same and cannot be used interchangeably. The following pages provide more details regarding heat and temperature.

Another term that must be understood is **pressure**. We use the term **atmospheric pressure** when we refer to weather conditions. We also refer to pressure when we talk about the air in the tires of bicycles and cars. Information regarding the pressures inside air-conditioning and refrigeration systems is very important to the HVAC/R technician. System operating pressures, along with various temperature readings, provide valuable information to the technician that is used to properly evaluate and troubleshoot heating and cooling equipment. System pressures are obtained by using a refrigeration gauge manifold, **Figure 1.2**.

The terms *heat*, *pressure*, and *temperature* will be a part of nearly all conversations relating to the HVAC/R industry, so it's very important to understand them. The sections that follow provide more insight into these concepts and how they relate to each other.

Figure 1.1 Thermocouple thermometer used to take accurate temperature readings in heating, air-conditioning, and refrigeration systems.

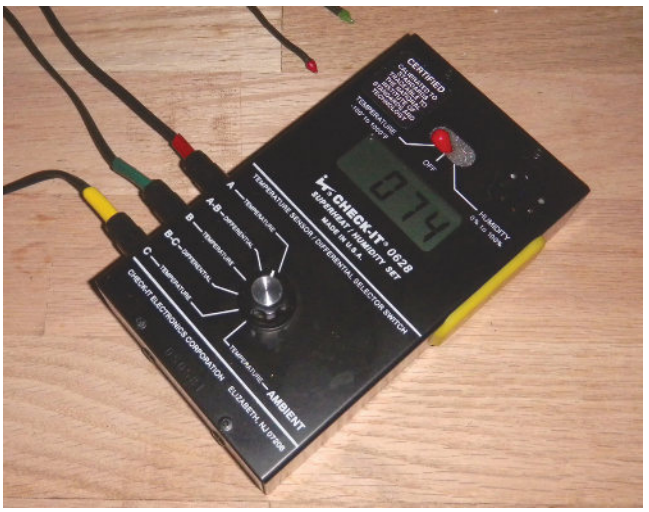

Photo by Eugene Silberstein

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 1.2 Pressure gauge used to measure the system operating pressures in air-conditioning and refrigeration equipment.

Photo by Eugene Silberstein

1.2 TEMPERATURE

Temperature can be thought of as a description of the level of heat and also may be referred to as **heat intensity**. Heat level and heat intensity should not be confused with the amount of heat, or heat content. As a substance receives more heat, its molecular motion, and therefore its temperature, increases.

Most people know that the freezing point of water is 32 degrees Fahrenheit (32°F) and that the boiling point is 212 degrees Fahrenheit (212°F), **Figure 1.3**. These points are commonly indicated on a thermometer, which is an instrument that measures temperature.

We must clarify the statements that water boils at 212°F and freezes at 32°F. These temperatures are accurate when standard atmospheric conditions exist. For example, in Denver, Colorado, which is about 5,600 miles above sea level, water boils at about 203°F. At the top of Mt. Everest, which is about 31,000 feet above sea level, water boils at about 167°F. Standard conditions occur at sea level with the barometer reading 29.92 in. Hg (14.696 psia); this topic is covered in detail later in this unit as part of the discussion of pressure. It is important to understand the concept of standard conditions because these are the conditions that will be applied to actual practice later in this book.

Heat theory states that the lowest attainable temperature is −460°F. This is the temperature at which all molecular motion stops and the temperature at which there is no heat present. This temperature is referred to as absolute zero. This is a theoretical temperature because molecular motion has never been totally stopped; scientists have actually come very close, dropping the temperature in a laboratory setting to within one-millionth of a degree of absolute zero.

The Fahrenheit temperature scale is part of the English measurement system used by the United States. This measurement system is also known as the I-P, or inch-pound, system. The Celsius temperature scale is part of the International System of Units (SI) or *metric* system used by most other countries. Some important Fahrenheit and Celsius equivalent temperatures are provided in **Figure 1.4**. A more detailed conversion chart can be found in Appendix B of this book.

Figure 1.3 The water in the container increases in temperature because the molecules move faster as heat is applied. When the water temperature reaches 212°F, boiling will occur. The bubbles in the water are small steam cells that, because they are lighter than water, rise to the top.

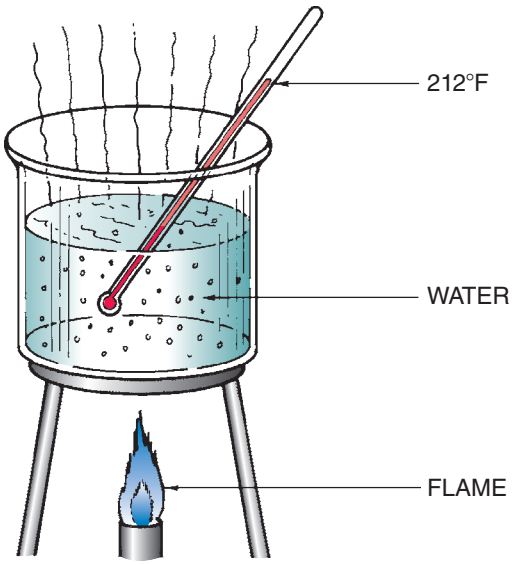

Figure 1.4 Relationship between Fahrenheit and Celsius temperatures.

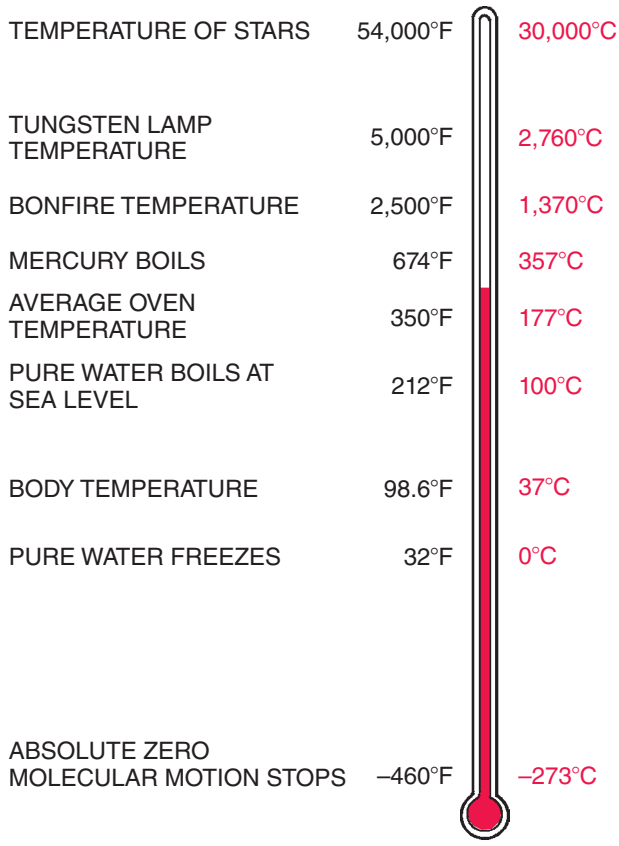


Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

If we have a Celsius temperature that we want to convert to a Fahrenheit temperature, we can use the following formula:

$$°F = (1.8 \times °C) + 32°$$

For example, if we had a Celsius temperature of 20°C, we can determine the equivalent Fahrenheit temperature by plugging the Celsius value into the formula to get:

$$°F = (1.8 \times °C) + 32°$$
$$°F = (1.8 \times 20°C) + 32°$$
$$°F = 36° + 32°$$
$$°F = 68°$$
$$\text{So, } 20°C = 68°F$$

If we have a Fahrenheit temperature that we want to convert to a Celsius temperature, we can use the following formula:

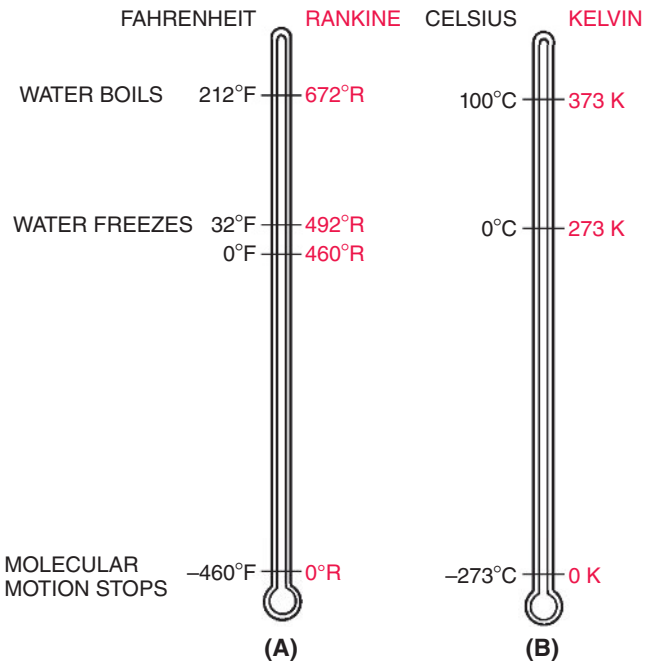
$$°C = (°F - 32°) \div 1.8$$

For example, if we had a Fahrenheit temperature of 50°F, we can determine the equivalent Celsius temperature by plugging the Fahrenheit value into the formula to get:

$$°C = (°F - 32°) \div 1.8$$
$$°C = (50°F - 32°) \div 1.8$$
$$°C = 18° \div 1.8$$
$$°C = 10°$$
$$\text{So, } 50°F = 10°C$$

Up to this point, temperature has been expressed in everyday terms. It is equally important in the HVAC/R industry to refer to temperature in engineering and scientific terms. Performance ratings of equipment are established using **absolute** temperatures. Performance ratings allow for easy comparison among equipment produced by different manufacturers. The Fahrenheit absolute scale is called the **Rankine** scale (named for its inventor, W. J. M. Rankine), and the Celsius absolute scale is known as the **Kelvin** scale (named for the scientist Lord Kelvin). Absolute temperature scales begin where molecular motion starts; and use 0 as the starting point. For instance, 0 on the Fahrenheit absolute scale is called absolute zero or 0° Rankine (0°R). Similarly, 0 on the Celsius absolute scale is called absolute zero or 0 Kelvin (0°K), **Figure 1.5**. The Fahrenheit/Celsius and the Rankine/Kelvin scales are used interchangeably to describe equipment and fundamentals of this industry.

Figure 1.5 (A) A Fahrenheit and Rankine thermometer. (B) A Celsius and Kelvin thermometer.



1.3 INTRODUCTION TO HEAT

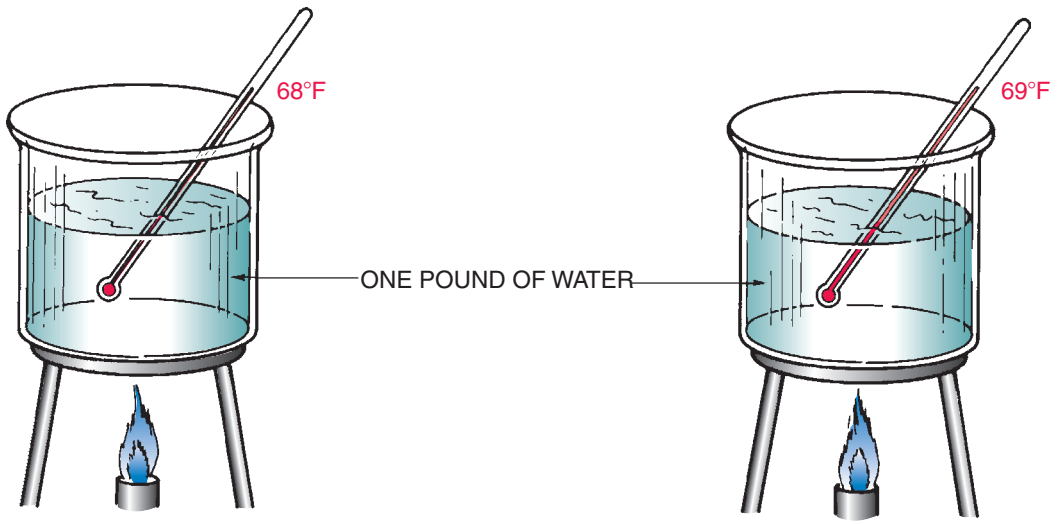
The laws of thermodynamics can help us to understand what heat is all about. The first law of thermodynamics states that energy can be neither created nor destroyed, but can be converted from one form to another. This means that most of the heat the world experiences is not being continuously created but is being converted from other forms of energy, like fossil fuels (gas and oil). This heat can also be accounted for when it is transferred from one substance to another.

Temperature describes the level of heat with reference to absolute zero, which is the temperature at which there is no heat present in a substance and all molecular motion has stopped. The term used to describe the quantity of heat or heat content is known as the **British thermal unit (Btu)**, which indicates how much heat energy is contained in a substance. The rate of heat transfer can be determined by considering the time it takes to transfer a certain amount of heat energy. Air-conditioning and heating equipment is rated in Btu/h, where the "h" represents "hour." An air-conditioning system that is rated at 24,000 Btu/h has the capacity to remove 24,000 Btu of heat energy from the structure every hour.

The Btu is defined as the amount of heat required to raise the temperature of 1 pound (lb) of water 1°F. For example, when 1 lb of water (about 1 pint) is heated from 68°F to 69°F, 1 Btu of heat energy is absorbed into the water, **Figure 1.6**. When a temperature difference exists between two substances, heat transfer will occur. The next three sections in this unit discuss the three types of heat transfer, namely, conduction, convection, and radiation. Temperature difference is the driving force behind heat transfer. The greater the temperature difference, the greater the heat transfer rate. Heat flows naturally from a warmer substance to a cooler substance. Rapidly moving molecules in the warmer substance give up some of their energy to the slower-moving molecules in the cooler

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 1.6 One British thermal unit (Btu) of heat energy is required to raise the temperature of 1 lb (pound) of water from 68°F to 69°F.



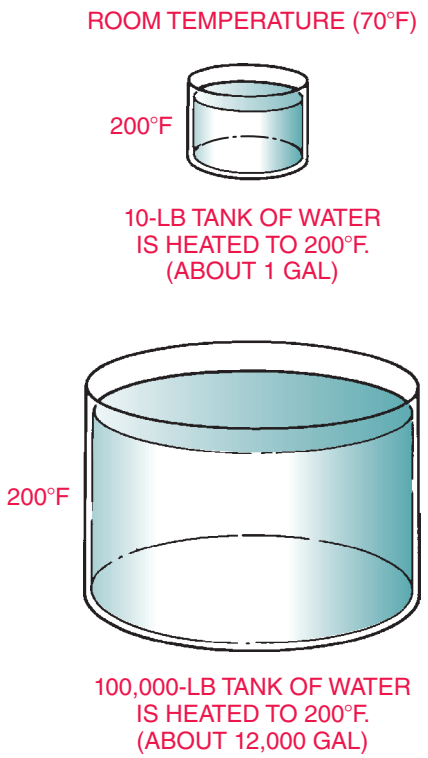
substance. The warmer substance cools because the molecules have slowed. The cooler substance becomes warmer because the molecules are moving faster. So, the next time you pour warm soda into a glass filled with ice, remember that the ice isn't making the soda cold, the soda is making the ice hot!

The following example illustrates the difference in the quantity of heat compared with the level of heat. One tank of water weighing 10 lb (slightly more than 1 gallon [gal]) is heated to a temperature level of 200°F. A second tank of water weighing 100,000 lb (slightly more than 12,000 gal) is also heated to 200°F. The 10-lb tank will cool to room temperature much faster than the 100,000-lb tank because even though the temperature of the water in both tanks is the same, there is much more heat contained in the larger tank, **Figure 1.7**.

A comparison using water may be helpful in differentiating between the heat intensity level and the quantity of heat. A 200-ft-deep well would not contain nearly as much water as a large lake with a water depth of 25 ft. The depth of water (in feet) tells us the level of water, but it in no way expresses the quantity (gallons) of water.

In practical terms, each piece of heating equipment is rated according to the amount of heat it will produce in a given time period. If the equipment had no such rating, it would be difficult for a buyer to intelligently choose the correct appliance. The rating of a gas or oil furnace used to heat a home is permanently printed on a nameplate. Either furnace would be rated in Btu per hour, which is a *rate* at which heat energy is transferred into the structure. For now, it is sufficient to say that if a 75,000-Btu/h furnace is needed to heat a house on the coldest day, one should choose a furnace rated at 75,000 Btu/h. If a smaller furnace is chosen, the house will begin to get cold any time the heat loss of the house exceeds the furnace output in Btu/h.

Figure 1.7 The smaller tank will cool to room temperature first because it contains a smaller quantity of heat, even though its temperature or heat intensity level is higher.



To describe the absence of heat, the term *cold* is often used. Because all heat is a positive value in relation to no heat, cold is not a true value; it is really an expression of comparison. When a person says it is cold outside, the term

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

is being used to express a relationship to the normal expected temperature for the time of year or to the inside temperature. Cold has no numerical value and is used by most people as a basis of comparison. Cold is sometimes referred to as a "level of heat absence."

1.4 CONDUCTION

Heat transfer by **conduction** can be explained as the energy actually traveling from one molecule to another. As a molecule moves faster, it causes the nearby molecules to do the same. For example, if one end of a copper rod is placed in a flame, in a short time the other end will get too hot to handle. The heat travels up the rod from molecule to molecule, **Figure 1.8**. Heat transfer by conduction is used in many applications. For example, heat is transferred by conduction from the hot electric burner on the cookstove to the pan or pot resting on it.

Heat does not conduct at the same rate in all materials. Copper, for instance, conducts heat at a different rate than iron. Glass is a very poor conductor of heat. Touching a wooden fence post or another piece of wood on a cold morning does not give the same sensation as touching a car fender or another piece of steel. The steel feels much colder. Actually, the steel is not colder; it just conducts heat out of the hand faster, **Figure 1.9**.

The different rates at which various materials conduct heat have an interesting similarity to the conduction of electricity. As a rule, substances that are poor conductors of heat are also poor conductors of electricity. For instance, copper is one of the best conductors of electricity and heat, and glass is one of the poorest conductors of both. Glass is actually used as an insulator in some electrical applications.

Figure 1.8 The copper rod is held in the flame only for a short time before heat is felt at the far end.

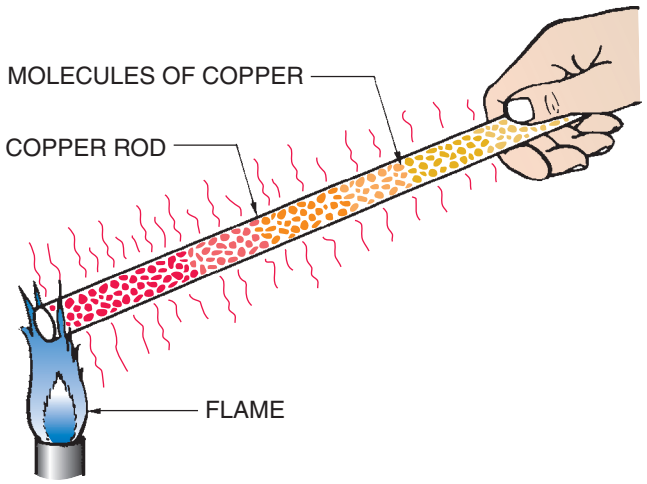


Figure 1.9 The car fender and the fence post are actually the same temperature, but the fender feels colder because the metal conducts heat away from the hand faster than the wooden fence post.

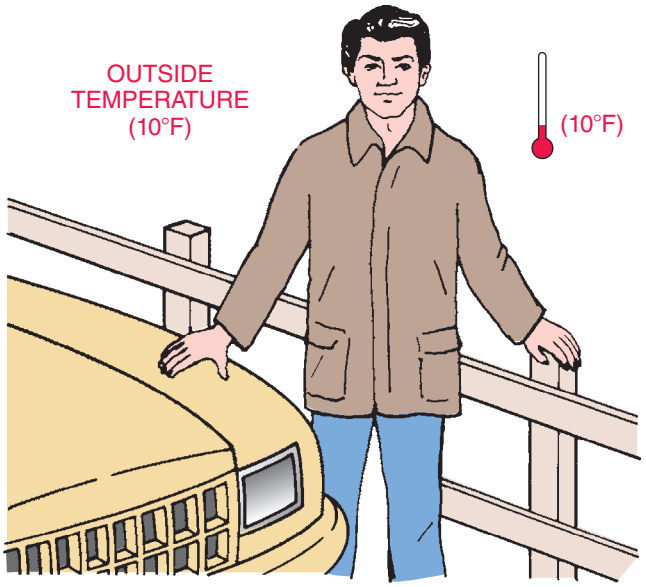

1.5 CONVECTION

Heat transfer by **convection** is used to move heat from one location to another by means of currents set up in a fluid medium. The most common fluid mediums in the heating and air-conditioning trades are air and water. Many large buildings have a central heating plant that heats water and pumps it throughout the building to the spaces to be heated. Notice the similarity of the words *convection* and *convey* ("to carry from one place to another"). Convection can be classified as either forced or natural.

A gas-fired furnace is an example of forced convection. Room air is drawn into the return of the furnace by the blower. It then passes over the furnace heat exchanger, which exchanges heat to the air from a gas flame. The air is then forced into the ductwork and distributed to the various rooms in the structure. **Figure 1.10** shows this process in which 70°F room air is entering the furnace; 130°F air is leaving; and the blower is creating the pressure difference to force the air into the various rooms. The blower provides the **forced convection**.

Another example of heat transfer by convection occurs when heated air rises naturally. This is referred to as **natural convection**. When air is heated, it expands, and the warmer air becomes less dense or lighter than the surrounding unheated air. This principle is applied in many ways in the air-conditioning industry. Sections of baseboard heaters are an example. When the air near the floor is heated, it expands and rises. This heated air is replaced by cooler air around the heater, which sets up a natural convection current in the room, **Figure 1.11**.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 1.10 Air from the room enters the blower at 70°F. The blower forces the air across the hot heat exchanger and out into the structure at 130°F.

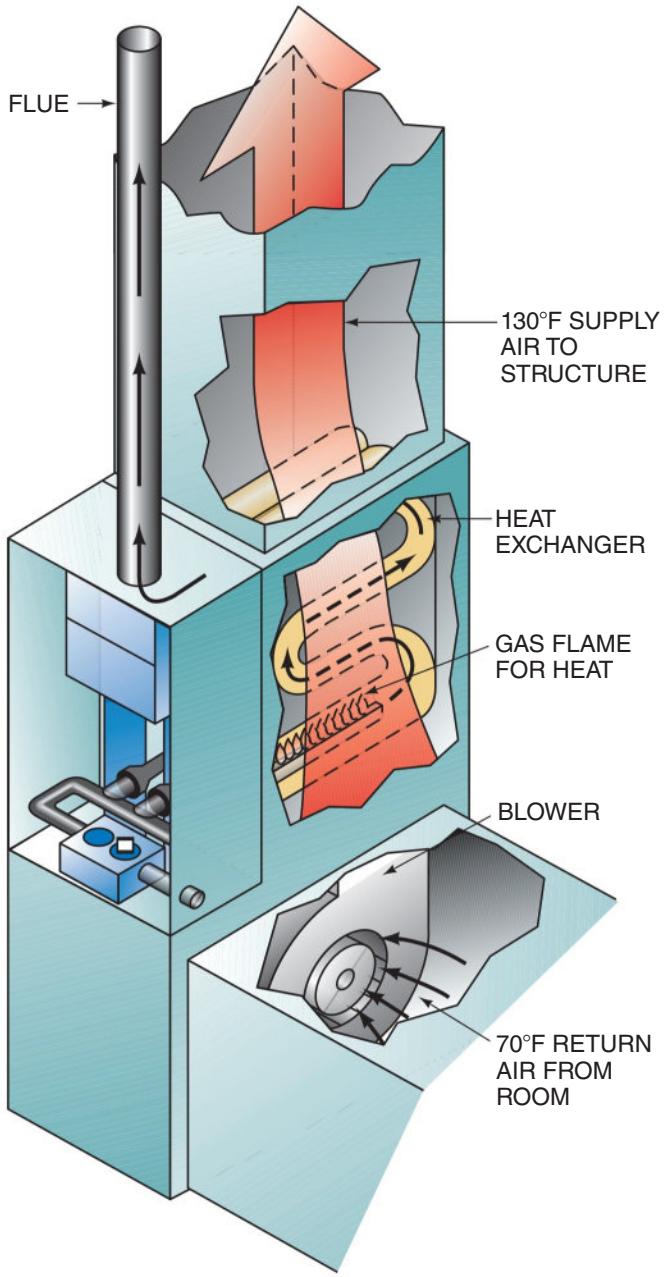

Figure 1.11 Natural convection occurs when heated air rises and cool air takes its place.

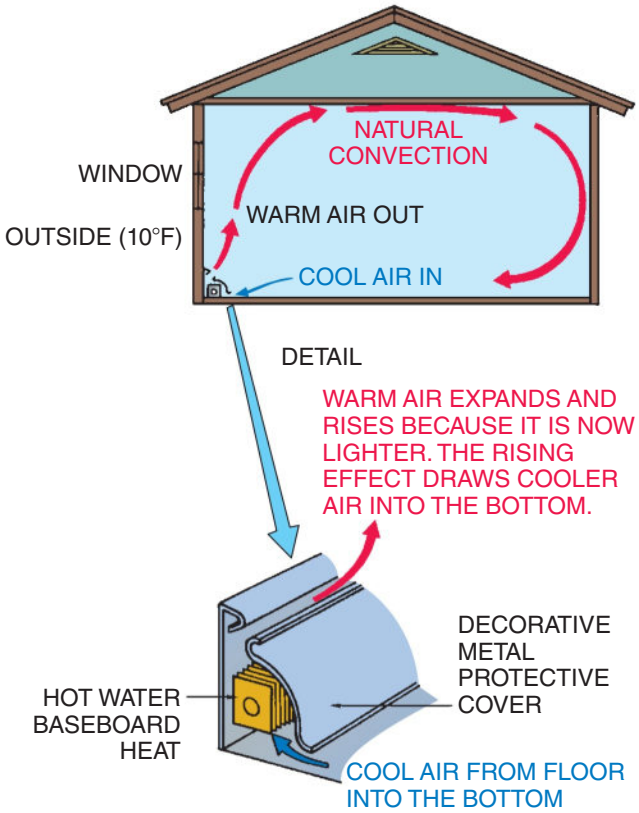


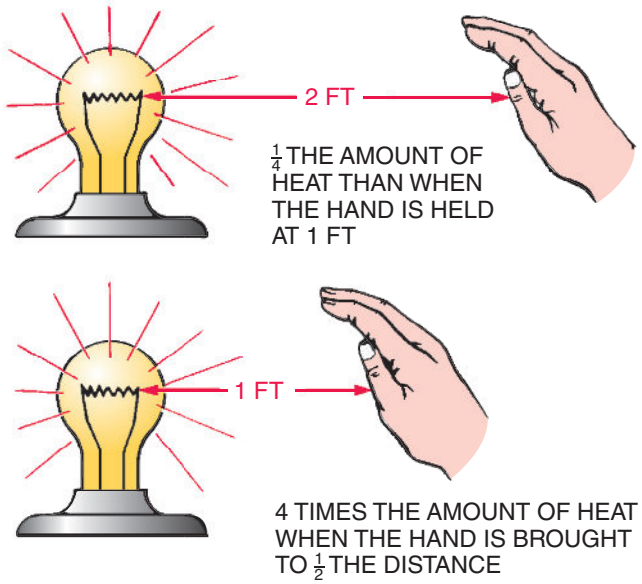
1.6 RADIATION

Heat transfer by **radiation** can best be explained by using the sun as an example of the heat source. The sun is approximately 93 million miles from earth's surface, yet we can feel its intensity. Heat transferred by radiation travels through space without heating the space and is absorbed by the first solid object that it encounters. Radiation is the only type of heat transfer that can travel through a vacuum, such as space, because it is not dependent on matter as a medium of heat transfer. Convection and conduction require some form of matter, like air or water, to be the transmitting medium. The earth does not experience the total heat of the sun because heat transferred by radiation diminishes by the inverse of the square of the distance traveled. In practical terms, this means that every time the distance is doubled, the heat intensity decreases by a factor of 4. If you hold your hand close to a light bulb, for example, you feel the heat's intensity, but if you move your hand twice the distance away, you feel only one-fourth of the heat intensity, **Figure 1.12**. Keep in mind that, because of the inverse-square-of-the-distance rule, radiant heat does not transfer the actual temperature or heat quantity value. If it did, the earth would be as hot as the sun.

Electric heaters that glow red hot are practical examples of radiant heat. The red-hot electric heater coil radiates heat into the room. It does not heat the air, but it warms the solid objects that the heat rays encounter. Any heater that glows has the same effect.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 1.12 The intensity of the radiant heat diminishes by the square of the distance.



1.7 SENSIBLE HEAT

Heat level or heat intensity can readily be measured when it changes the temperature of a substance (remember the example of changing 1 lb of water from 68°F to 69°F). This change in the heat level can be measured with a thermometer. When a change of temperature can be registered, we know that the level of heat or heat intensity has changed; this is called **sensible heat**.

1.8 LATENT HEAT

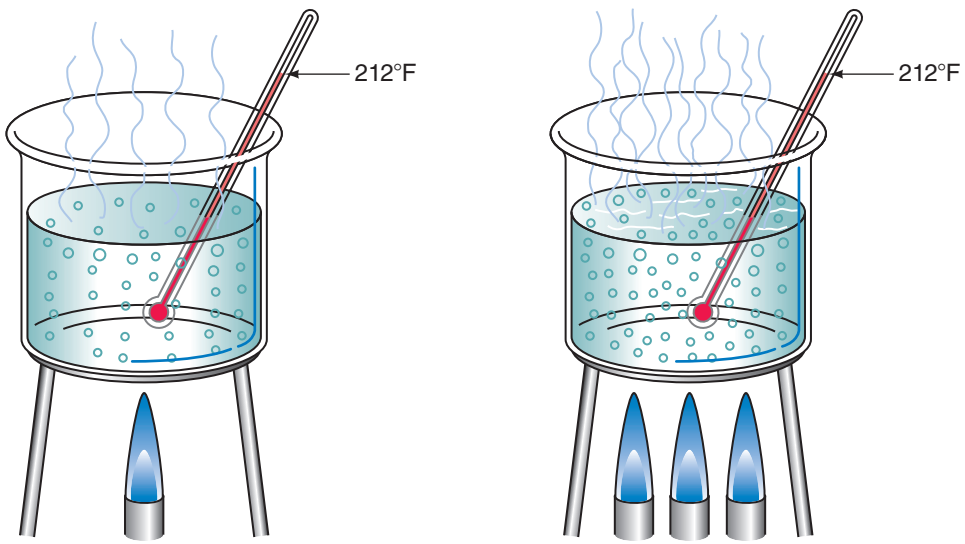
Another type of heat is called **latent** or **hidden heat**. Heat is added in this process, but no temperature rise occurs. An example is heat added to water while it is boiling in an open container. Once water is brought to the boiling point, adding more heat only makes it boil faster; it does not raise the temperature, **Figure 1.13**.

There are three other terms that are important to understand when referring to latent heat transfers: **latent heat of vaporization, latent heat of condensation**, and **latent heat of fusion**. Latent heat of vaporization is the amount of heat energy, in Btu/lb, required to change a substance into a vapor. For example, the latent heat of vaporization for water at atmospheric conditions is 970.3 Btu/lb. For ease of calculation, we often round this value to 970 Btu/lb. This means that if we have 1 lb of water at 212°F that we want to change to 1 lb of steam at 212°F, we would need to *add* 970 Btu of heat energy to the water.

Latent heat of condensation is the amount of heat energy, in Btu/lb, required to change a vapor into a liquid. This is, in effect, the opposite of latent heat of vaporization. For example, the latent heat of condensation for steam at atmospheric conditions is 970.3 Btu/lb. If we had 1 lb of steam at 212°F that we wanted to change to 1 lb of water at 212°F, we would need to *remove* 970 Btu of heat energy from the steam.

Latent heat of fusion is the amount of heat energy needed to change the state of a substance from a solid to a liquid or from a liquid to a solid. The latent heat of fusion for water is 144 Btu/lb. If we had 1 lb of ice at 32°F under atmospheric conditions, we would have to add 144 Btu of heat energy to the ice in order to melt it. If, on the other hand, we had 1 lb of

Figure 1.13 Adding three times as much heat only causes the water to boil faster. The water does not increase in temperature.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

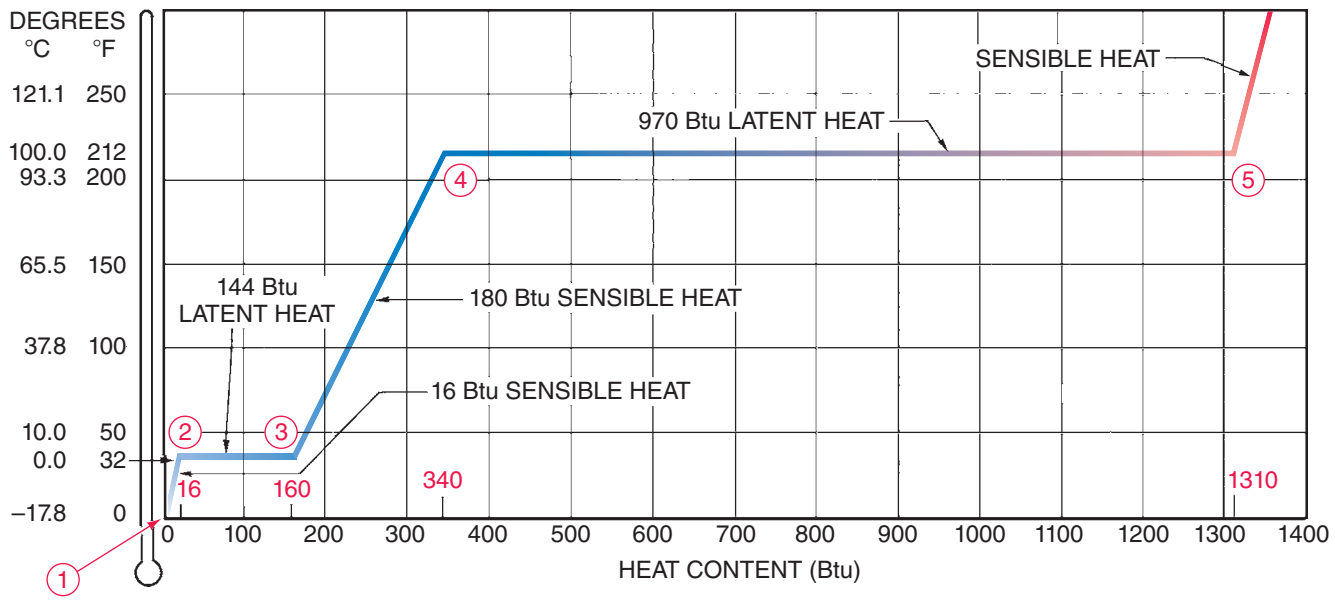
water at 32°F under atmospheric conditions, we would have to *remove* 144 Btu of heat energy from the water in order to freeze it.

The following example describes the sensible heat and latent heat characteristics of 1 lb of water at standard atmospheric pressure from 0°F through the temperature range to above the boiling point. In the chart in **Figure 1.14** notice that temperature is plotted on the left margin, and heat content is plotted along the bottom of the chart. The heat content scale on the bottom of the diagram indicates the amount of heat added during the processes being described, not the actual heat content of the substance. We can see that as heat is added, the temperature will rise except during the latent- or hidden-heat processes.

The following statements should help you to understand the chart:

1. Water is in the form of ice at point 1 where the example starts. Point 1 is *not* absolute zero. It is 0°F and is used as a starting point. Since no heat has been added to the ice at point 1, we can see that the heat content scale at that point is zero.
2. Heat added from point 1 to point 2 is sensible heat. This is a registered rise in temperature. Since it took 16 Btu of heat energy to raise the temperature of the ice from 0°F to 32°F, we can conclude that it takes only 0.5 Btu of heat energy to raise the temperature of 1 lb of ice 1°F.
3. When point 2 is reached, the ice is at its highest temperature of 32°F. This means that if more heat is added, it will be latent heat and will start to melt the ice but not raise its temperature. Adding 144 Btu of heat will change the 1 lb of ice to 1 lb of water. Removing any heat will cool the ice below 32°F.
4. When point 3 is reached, the substance is now 100% water. Adding more heat causes a rise in temperature. (This is sensible heat.) Removal of any heat at point 3 results in some of the water changing back to ice. This is described as removing latent heat because there is no change in temperature.
5. Heat added from point 3 to point 4 is sensible heat; when point 4 is reached, 180 Btu of heat will have been added from point 3. The water has been heated from 32°F to 212°F, which is a 180°F rise. Referring back to the definition of the Btu, you will see that it takes 1 Btu of heat energy to raise the temperature of 1 lb of water 1°F. So, a 180°F temperature rise will require 180 Btu of heat energy.
6. Point 4 represents the 100% saturated liquid point. The water is saturated with heat to the point that the addition of any more heat will cause the water to boil and start changing to a vapor (steam). If any heat is removed from the water at this point, it will simply cool to a temperature that is lower than 212°F. Adding 970 Btu makes the 1 lb of liquid boil to point 5 and become a vapor.
7. Point 5 represents the 100% saturated vapor point. The water is now in the vapor state. Heat removed would be latent heat and would change some of the vapor back to

Figure 1.14 The heat/temperature graph for 1 lb of water at atmospheric pressure explains how water responds to heat. An increase in sensible heat causes a rise in temperature. An increase in latent heat causes a change of state, for example, from solid ice to liquid water.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

a liquid. This is called *condensing the vapor.* Any heat added at point 5 is sensible heat; it raises the vapor temperature above the boiling point, which is called *superheating*. Any water vapor with a temperature above the boiling point of 212°F is superheated vapor. The concept of superheat will be important in future studies. Note that in the vapor state it takes only 0.5 Btu to heat the water vapor (steam) 1°F, the same as when water was in the ice (solid) state. **SAFETY PRECAUTION:** *When examining these principles in practice, be careful because the water and steam are well above body temperature, and you could be seriously burned.*•

1.9 SPECIFIC HEAT

We now realize that different substances respond differently to heat. When 1 Btu of heat energy is added to 1 lb of water, it changes the temperature 1°F. This holds true only for water; other heated substances have different values. For instance, we noted that adding 0.5 Btu of heat energy to either ice or steam (water vapor) caused a 1°F rise per pound while in these states. Ice and steam heated, or increased their temperatures, at twice the rate of water. Adding 1 Btu would cause a 2°F rise. This difference in heat rise is known as **specific heat**.

Specific heat is the amount of heat necessary to raise the temperature of 1 lb of a substance 1°F. Every substance has a different specific heat. Note that the specific heat of water is 1 Btu/lb/°F. See **Figure 1.15** for the specific heat of some other substances.

1.10 SIZING HEATING EQUIPMENT

Specific heat is significant because the amount of heat required to change the temperatures of different substances is used to size equipment. Recall the example of the house and furnace earlier in this unit. The following example shows how this would be applied in practice. A manufacturing company may need to buy a piece of heating equipment to heat steel before it can be machined. The steel may be stored outside in the cold at 0°F and need preheating before machining. The desired metal temperature for the machining is 70°F. How much heat must be added to the steel if the plant wants to machine 1000 lb/h?

The steel is coming into the plant at a fixed rate of 1000 lb/h, and heat has to be added at a steady rate to stay ahead of production. **Figure 1.15** gives a specific heat of 0.116 Btu/lb/°F for steel. This means that 0.116 Btu of heat energy must be added to 1 lb of steel to raise its temperature 1°F.

$$Q = \text{Weight} \times \text{Specific Heat} \times \text{Temperature Difference}$$

where Q = quantity of heat needed. Substituting in the formula, we get:

$$Q = 1000 \text{ lb/h} \times 0.116 \text{ Btu/lb/°F} \times 70\text{°F}$$
$$Q = 8120 \text{ Btu/h required to heat the steel for machining.}$$

The previous example has some known values and an unknown value to be found. The known information is used to find the unknown value with the help of the formula. The formula can be used when adding heat or removing heat and is often used in heat-load calculations for sizing both heating and cooling equipment.

Figure 1.15 The specific heat table shows how much heat is required to raise the temperature of several different substances 1°F.

SUBSTANCE	SPECIFIC HEAT Btu/lb/°F	SUBSTANCE	SPECIFIC HEAT Btu/lb/°F
Air	0.24 (Average)	Ice	0.504
Aluminum	0.214	Iron	0.129
Ammonia	0.525	Kerosene	0.50
Beef, lean	0.77	Lead	0.031
Beets	0.90	Marble	0.21
Building Brick	0.20	Porcelain	0.18
Concrete	0.156	Pork, fresh	0.68
Copper	0.092	Seawater	0.94
Cucumbers	0.97	Shrimp	0.83
Eggs	0.76	Spinach	0.94
Fish	0.76	Steam	0.5
Flour	0.38	Steel	0.116
Gold	0.0312	Water	1.00

1.11 PRESSURE

Pressure is defined as force per unit of area. This is normally expressed in pounds per square inch (psi). Simply stated, when a 1-lb weight rests on an area of 1 square inch (1 in^2), the pressure exerted downward is 1 psi. Similarly, when a 100-lb weight rests on a 1-in^2 area, 100 psi of pressure is exerted, **Figure 1.16**. If the 100-lb weight rested on a surface that was 100 in^2, the pressure exerted would be 1 psi.

When you swim under the surface of the water, you feel a pressure pushing inward on your body. This pressure is the result of the weight of the water and is very real. You would feel a different sensation when flying in an airplane without a pressurized cabin. Your body would be subjected to less pressure instead of more, yet you would still feel uncomfortable. It is easy to understand why the discomfort under water exists, the weight of the water pushes in. In the airplane, the situation is just the reverse. There is less pressure high in the air than down on the ground. The pressure is greater inside your body and is pushing out.

Water weighs 62.4 pounds per cubic foot (lb/ft^3). A cubic foot (7.48 gal) exerts a downward pressure of 62.4 lb/ft^2 when in actual cube shape, **Figure 1.17**. How much weight is then resting on 1 in^2? The answer is simply calculated. The bottom of the cube has an area of 144 in^2 (12 in. × 12 in.) sharing the weight. Each square inch has a total pressure of 0.433 lb (62.4 ÷ 144) resting on it. Thus, the pressure at the bottom of the cube is 0.433 psi, **Figure 1.18**.

A volume of 1 ft^3 is equivalent to 1728 in^3 (12 inches × 12 inches × 12 inches = 1728 in^3), so the dimensions of the container can be changed as long as the volume remains the same. If the same 1 ft^3 of water had the shape shown in **Figure 1.19** (24 inches × 24 inches × 3 inches = 1728 in^3), the pressure at the bottom would be different. The area at the bottom would be 576 in^2, since the base is 24 in. by 24 in.

Figure 1.16 Both weights are resting on a 1-square-inch (1-in^2) surface. One weight exerts a pressure of 1 psi; the other a pressure of 100 psi.

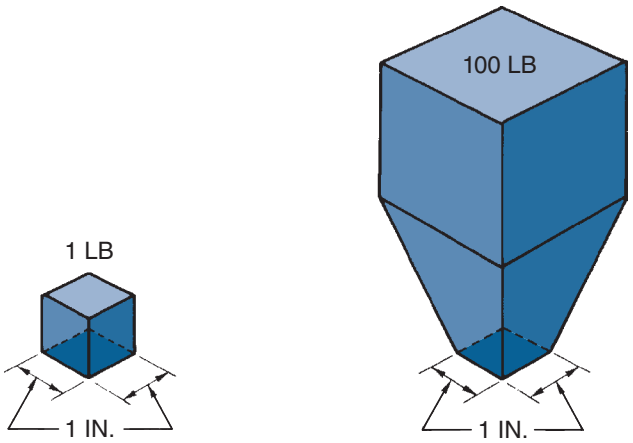

Figure 1.17 One cubic foot (1 ft^3) of water (7.48 gal) exerts pressure outward and downward. 1 ft^3 of water weighs 62.4 lb spread over 1 ft^2.

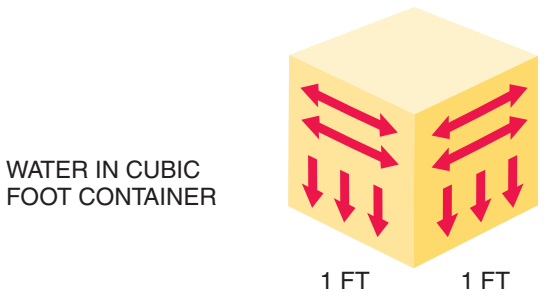

Figure 1.18 One cubic foot (1 ft^3) of water exerts a downward pressure of 62.4 lb/ft^2 on the bottom surface area of a cube.

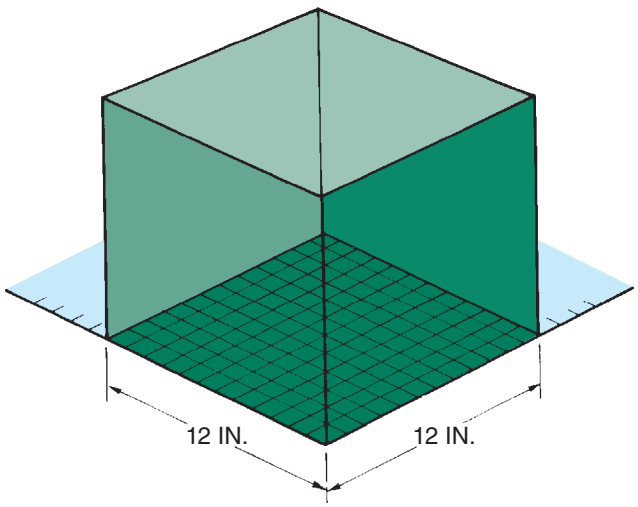

Figure 1.19 If the bottom surface is 4 ft^2, or 576 in^2, the downward pressure is 0.108 psi.

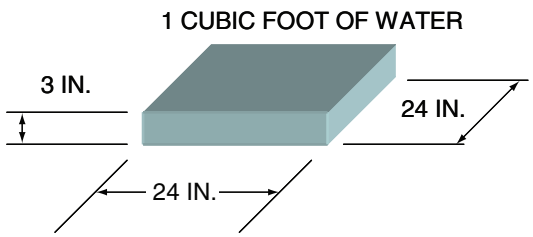

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(24 in. × 24 in. = 576 in²). The resulting pressure would then be only 0.108 psi (62.4 ÷ 576). As the base gets larger, the pressure it exerts in the downward direction gets lower. Have you ever seen someone walking across the snow wearing snowshoes? The purpose of the snowshoes is to increase the size of the base to lower the pressure pushing down. This reduces the chance of sinking into the snow.

1.12 ATMOSPHERIC PRESSURE

The sensation of being underwater and feeling the pressure of the water is familiar to many people. The earth's atmosphere is like an ocean of air that has weight and exerts pressure. The earth's surface can be thought of as being at the bottom of this ocean of air. Different locations are at different depths. For instance, there are sea-level locations such as Miami, Florida, or mountainous locations such as Denver, Colorado. The atmospheric pressures at these two locations are different. For now, we will assume that we live at the bottom of this ocean of air. The atmosphere that we live in has weight just as water does, but not as much. Actually earth's atmosphere exerts a weight or pressure of 14.696 psi at sea level. This is known as a **standard condition**.

Atmospheric pressure can be measured with an instrument called a **barometer**, which is a glass tube about 36 in. long that is closed on one end and filled with mercury. It is then inserted open-side-down into a puddle of mercury and held upright. The mercury will try to run down into the puddle, but it will not all run out. This is because the atmosphere is pushing down on the puddle, and a vacuum is formed in the top of the tube. At sea level the mercury in the tube will fall to 29.92 in. when the surrounding atmospheric temperature is 70°F, **Figure 1.20**. This is a standard that is used for comparison in engineering and scientific work. If the barometer is taken up higher, such as on a mountain, the mercury column will start to fall. It will fall about 1 in./1000 ft of altitude. When the barometer is at standard conditions and the mercury drops, the weather forecaster will talk about a low-pressure system; this means the weather is going to change. Listening closely to weather reports will make these terms more meaningful.

If the barometer is placed inside a closed jar and the atmosphere evacuated, the mercury column falls to the level of the puddle at the bottom, **Figure 1.21**. When the atmosphere is allowed back into the jar, the mercury again rises because a vacuum exists above the mercury column in the tube.

The mercury in the column has weight and counteracts the atmospheric pressure of 14.696 psi at standard conditions. A pressure of 14.696 psi, then, is equal to the weight of a column of mercury (Hg) 29.92 in. high. The expression "inches of mercury" thus becomes an expression of pressure and can be converted to pounds per square inch. The conversion factor is 1 psi = 2.036 in. Hg (29.92 ÷ 14.696); 2.036 is often rounded off to 2 (30 in. Hg ÷ 15 psi).

Another type of barometer is the **aneroid** barometer. This is a more practical instrument to transport. Atmospheric pressure has to be measured in many places, so instruments other than the mercury barometer had to be developed for field use, **Figure 1.22**.

Figure 1.20 Mercury (Hg) barometer.

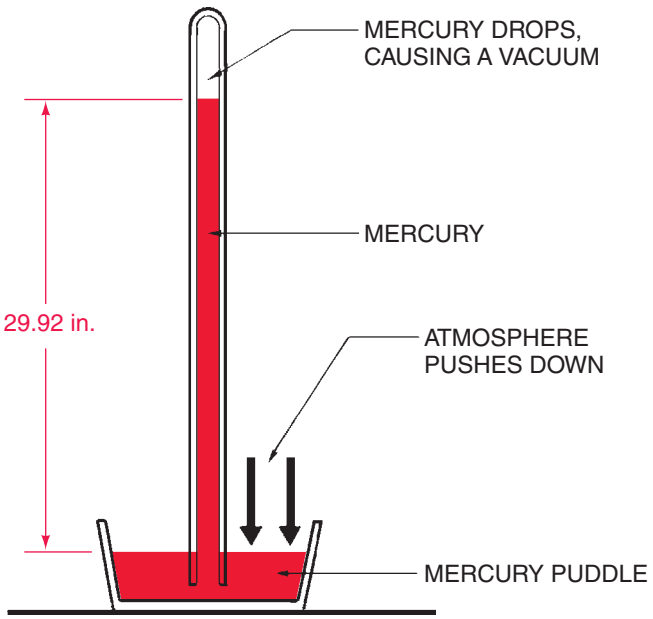

Figure 1.21 When the mercury barometer is placed in a closed glass jar (known as a bell jar) and the atmosphere is removed from the jar, the column of mercury drops to the level of the puddle in the dish.

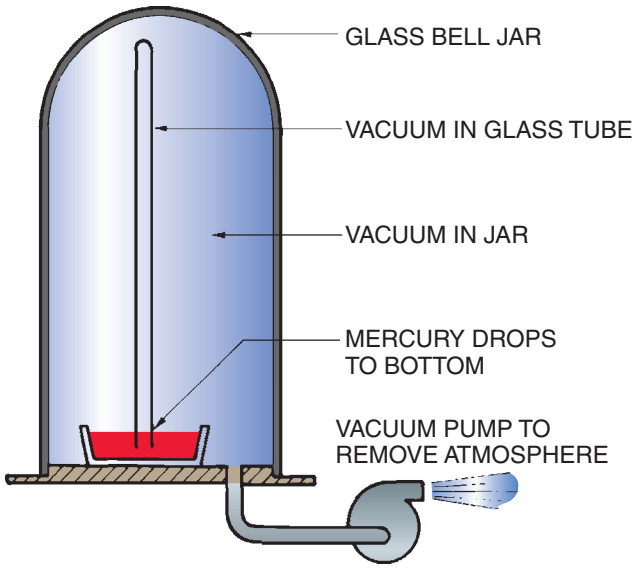

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 1.22 The aneroid barometer uses a closed bellows that expands and contracts with atmospheric pressure changes.

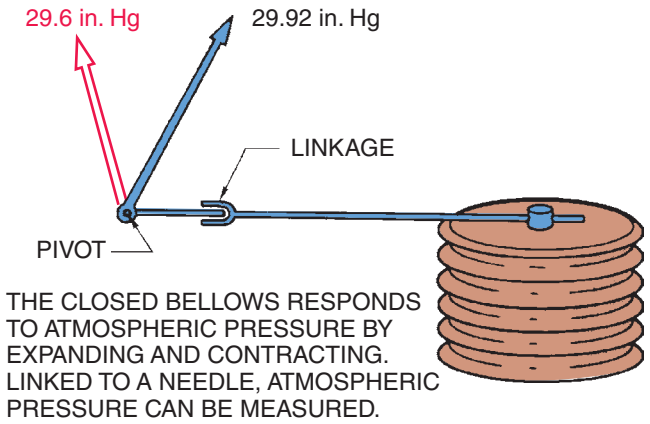

Figure 1.24 The gauge on the left, called a *compound gauge*, reads pressures above and below atmospheric pressure. The gauge on the right, called the *high-pressure (high-side) gauge*, will read up to 500 psi.

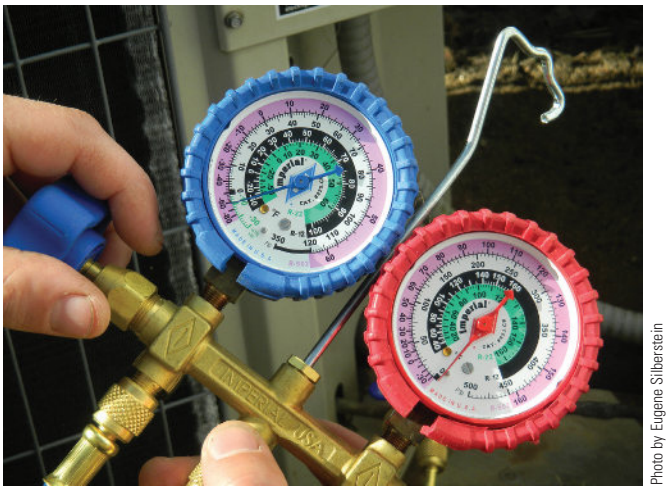

Photo by Eugene Silberstein

1.13 PRESSURE GAUGES

Measuring pressures in a closed system requires a different method—the **Bourdon tube**, **Figure 1.23**. The Bourdon tube is linked to a needle and can measure pressures above and below atmospheric pressure. A common tool used in the refrigeration industry to take readings in the field or shop is a combination of a low-pressure gauge (called the **low-side gauge**) and a high-pressure gauge (called the **high-side gauge**), **Figure 1.24**. The gauge on the left reads pressures above and below atmospheric pressure and is called a **compound gauge**. The gauge on the right will read up to 500 psi and is called the **high-pressure (high-side) gauge**.

SAFETY PRECAUTION: *Working with temperatures that are above or below body temperature can cause skin and flesh damage. Proper protection, such as gloves and safety glasses,* **must be used.** *Pressures that are above or below the atmosphere's pressure can cause bodily injury. A vacuum can cause a blood blister on the skin. Pressure above atmospheric can pierce the skin or inflict damage when blowing air lifts small objects like filings.*•

These gauges read 0 psi when opened to the atmosphere. If they do not, then they should be calibrated to 0 psi. The gauges are designed to read psig (pounds-per-square-inch gauge pressure). Atmospheric pressure is used as the starting

Figure 1.23 (A) The Bourdon tube is made of a thin substance such as brass. It is closed on one end, and the other end is fastened to the pressure being checked. When pressure increases, the tube tends to straighten out. When attached to a needle linkage, pressure changes are indicated. (B) An actual Bourdon tube.

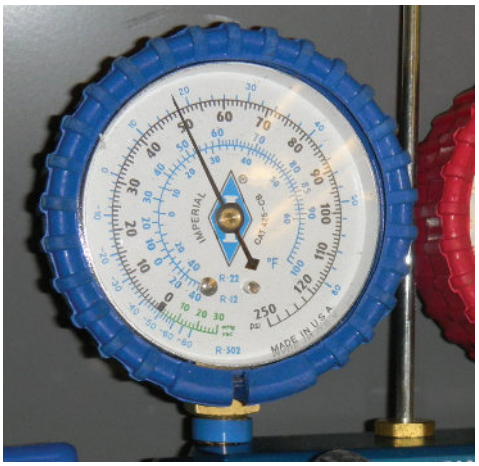
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 1.25 This gauge reads 50 psig. To convert this gauge reading to psia, add 15 psi (atmospheric pressure) to 50 psig to get 65 psia.



or reference point. If you want to know what the absolute pressure is, you must add the atmospheric pressure to the gauge reading. For example, to convert a gauge reading of 50 psig to absolute pressure, you must add the atmospheric pressure of 14.696 psi to the gauge reading. Let us round off 14.696 to 15 for this example. Then 50 psig + 15 = 65 psia (pounds per square inch absolute), **Figure 1.25**. New generation gauges are of the digital variety, **Figure 1-26**.

Figure 1.26 Digital gauges. The compound gauge on the left reads pressures above and below atmospheric pressure. The high-pressure gauge on the right will read pressures up to 800 psi. The center gauge is a vacuum gauge, which is used for system evacuation (see Unit 8, "Leak Detection, System Evacuation, and System Cleanup," for more on this topic).

Gauges provided by Appion Inc. Photo by Eugene Silberstein

SUMMARY

- Thermometers measure temperature. Four temperature scales are Fahrenheit, Celsius, Fahrenheit absolute (Rankine), and Celsius absolute (Kelvin).
- Molecules in matter are constantly moving. The higher the temperature, the faster they move.
- The British thermal unit (Btu) describes the quantity of heat in a substance. One Btu is the amount of heat necessary to raise the temperature of 1 lb of water 1°F.
- The transfer of heat by conduction is the transfer of heat from molecule to molecule.
- The transfer of heat by convection is the actual moving of heat in a fluid (vapor state or liquid state) from one place to another.
- Radiant heat is a form of energy that does not depend on matter as a medium of transfer. Solid objects absorb the energy, become heated, and transfer the heat to the air.
- Sensible heat causes a rise in temperature of a substance.
- Latent (or hidden) heat is heat added to a substance that causes a change of state and does not register on a thermometer.
- Specific heat is the amount of heat (measured in Btu) required to raise the temperature of 1 lb of a substance 1°F. Substances have different specific heats.
- Pressure is the force applied to a specific unit of area. The atmosphere around the earth has weight and therefore exerts pressure.
- Barometers measure atmospheric pressures in inches of mercury. Two of the barometers used are the mercury and the aneroid.
- Gauges have been developed to measure pressures in enclosed systems. Two common gauges used in the air-conditioning, heating, and refrigeration industry are the compound gauge and the high-pressure gauge.

REVIEW QUESTIONS

1. Temperature is defined as
   A. how hot it is.
   B. the level of heat.
   C. how cold it is.
   D. why it is hot.
2. State the standard conditions for water to boil at 212°F.
3. List four types of temperature scales.
4. Under standard conditions, water freezes at _____°C.
5. Molecular motion stops at _____°F.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

6. One British thermal unit will raise the temperature of _____ lb of water _____°F.
7. In which direction does heat flow?
   A. From a cold substance to a cold substance
   B. Up
   C. Down
   D. From a warm substance to a cold substance
8. Describe heat transfer by conduction.
9. An increase in sensible heat causes
   A. a higher thermometer reading.
   B. a lower thermometer reading.
   C. no change of the thermometer reading.
   D. ice to melt.
10. Latent heat causes
    A. a higher thermometer reading.
    B. temperature to rise.
    C. a change of state.
    D. temperature to fall.
11. Describe how heat is transferred by convection.
12. Describe how heat is transferred by radiation.
13. Specific heat is the amount of heat necessary to raise the temperature of 1 lb of a _____ 1°F.
14. Atmospheric pressure at sea level under standard conditions is _____ inches of mercury (Hg) or _____ pounds per square inch absolute (psia).
15. To change from psig to psia, you must add _____ to psig.
16. Convert 80°F to Celsius.
17. Convert 22°C to Fahrenheit.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

MATTER AND ENERGY

OBJECTIVES

After studying this unit, you should be able to

- define matter.
- list the three states in which matter is commonly found.
- define density.
- discuss Boyle's law.
- state Charles' law.
- discuss Dalton's law as it relates to the pressure of different gases.
- define specific gravity and specific volume.
- state two forms of energy important to the HVAC/R industry.
- describe work and state the formula used to determine the amount of work done by performing a given task.
- define horsepower.
- convert horsepower to watts.
- convert watt-hours to British thermal units.

SAFETYCHECKLIST

- ✔ Power-consuming devices have the potential to cause injury. Be sure to de-energize all pumps, motors and other electrical devices before working on them.
- ✔ When measuring pressures, be sure that your test instruments are fully operational and properly calibrated to avoid possible injury.

2.1 MATTER

Matter is commonly defined as a substance that occupies space and has mass. The weight of a substance is the combined effects of the substance's mass and the force of gravity pulling down on it, where Weight = Mass × Gravity. Matter is made up of atoms. Atoms are often described as the smallest amount of a substance and may combine to form molecules. Atoms of one substance may combine chemically with those of another to form a new substance. These new substances are referred to as **compounds**. The molecules formed cannot be broken down any further without changing the chemical nature of the compound. Matter exists in three states: **solids**, **liquids**, and **gases**. The heat content as well as the pressure exerted on matter determine its state. For instance, water is made up of molecules containing atoms of hydrogen and oxygen. Two atoms of hydrogen and one atom of oxygen are in each molecule of water, **Figure 2.1**. The chemical formula for water is H_2O.

Water in the solid state is known as ice. It exerts all of its force downward—it has weight. The molecules of the water are highly attracted to each other, **Figure 2.2**. When the water is heated above the freezing point, it begins to change to a liquid state. The molecular activity is higher, and the water molecules have less attraction for each other. Water in the liquid state exerts a pressure outward and downward. Because water pressure is proportional to its depth, water seeks a level surface where its pressure equals that of the atmosphere above it, **Figure 2.3**. Water heated above the liquid state, 212°F at standard conditions, becomes a vapor. In the vapor state, the molecules have even less attraction

Figure 2.1 A water molecule is formed when two hydrogen atoms bond with one oxygen atom.

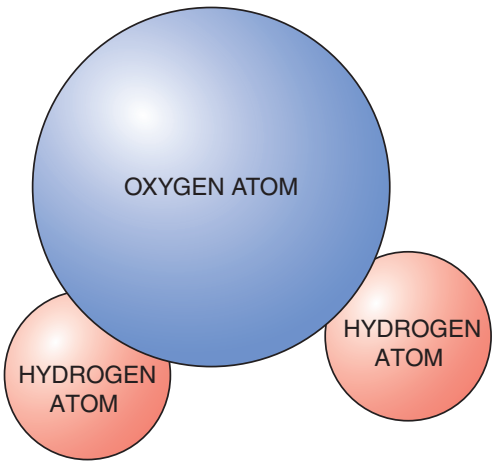


Figure 2.2 Solids exert all their pressure downward. The molecules of solid water have a great attraction for each other and hold together.

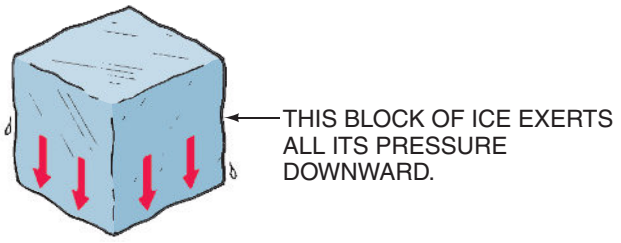

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 2.3 The water in the container exerts pressure outward and downward. The outward pressure is what makes water seek its own level. The water molecules still have a small amount of adhesion to each other. The pressure is proportional to the depth.

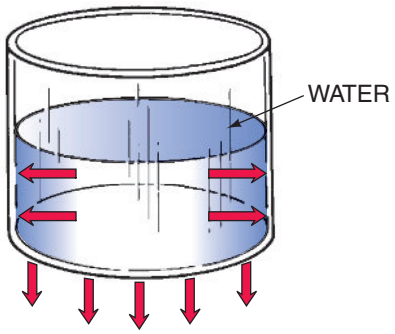

Figure 2.4 Gas molecules travel at random. When a container with a small amount of gas pressure is opened, the gas molecules seem to repel each other and fly out.

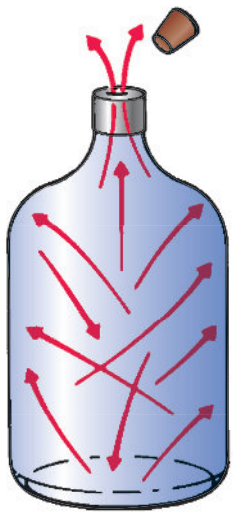


for each other. The vapor exerts pressure evenly in all directions, **Figure 2.4**.

The study of matter leads to the study of other terms that help to understand how different substances compare to each other.

2.2 MASS AND WEIGHT

Mass is the property of matter that responds to gravitational attraction. **Weight** is the force that matter (solid, liquid, or gas) applies to a supporting surface when it is at rest. Weight is not a property of matter but is dependent on the gravitational attraction. The stronger the force of gravity, the more an object will weigh. The earth has stronger gravitational attraction forces than the moon. This is why objects weigh more on the earth than on the moon. All solid matter has mass. A liquid such as water is said to have mass. The air in the atmosphere has weight and mass.

Figure 2.5 Table of density and specific gravity.

SUBSTANCE	DENSITY LB/FT^3	SPECIFIC GRAVITY
ALUMINUM	171	2.74
BRASS (RED)	548	8.78
COPPER	556	8.91
GOLD	1208	19.36
ICE @ 32°F	57.5	0.92
TUNGSTEN	1210	19.39
WATER	62.4	1
MARBLE	162	2.596

2.3 DENSITY

The **density** of a substance describes its mass-to-volume relationship. The mass contained in a particular volume is the density of that substance. Sometimes it is advantageous to compare different substances according to weight per unit volume or pounds per cubic foot. Water, for example, has a density of 62.4 lb/ft^3. Wood floats on water because the density (weight per volume) of wood is less than the density of water. In other words, it weighs less per cubic foot. Iron, on the other hand, sinks because it is more dense than water. **Figure 2.5** lists some typical densities. Using Figure 2.5 as a guide, can you figure out why ice floats on water?

2.4 SPECIFIC GRAVITY

Specific gravity is a unitless number because it is the density of a substance divided by the density of water. Water is simply used as the standard comparison. The density of water is 62.4 lb/ft^3. So, the specific gravity of water is 62.4 lb/ft^3 ÷ 62.4 lb/ft^3 = 1. Notice that the units cancel because of the division. The density of red brass is 548 lb/ft^3. Its specific gravity is then 548 lb/ft^3 ÷ 62.4 lb/ft^3 = 8.78. Figure 2.5 lists some typical specific gravities of substances. Note that a substance with a specific gravity greater than 1 will sink in water, and a substance with a specific gravity less than 1 will float on water.

2.5 SPECIFIC VOLUME

Specific volume indicates the volume that each pound of a gas occupies. The measurement requires that there must be only 1 lb of the gas. The units are ft^3/lb, which differs from the units for total volume, which are simply ft^3. One pound of clean, dry air has a total volume of 13.33 ft^3 at standard atmospheric conditions. Its specific volume would then be 13.33 ft^3/lb. As air is heated it becomes lighter and its specific volume increases. As air is cooled, its specific volume

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

decreases. Hydrogen has a specific volume of 179 ft^3/lb under the same conditions. Because more cubic feet of hydrogen exist per pound, it has a higher specific volume, thus it is lighter than air. Although both are gases, the hydrogen has a tendency to rise when mixed with air. Natural gas is explosive when mixed with air, but it is lighter than air and has a tendency to rise like hydrogen. Propane gas is another frequently used heating gas; it has to be treated differently than natural gas because it is heavier than air. Propane has a tendency to fall and collect in low places and poses a potential danger from ignition.

Specific volume and density are considered inverses of one another. This means that specific volume = 1 ÷ density and that density = 1 ÷ specific volume. If one knows the specific volume of a substance, its density can be calculated and vice versa. For example, the specific volume of dry air is 13.33 ft^3/lb. Its density would then be 1 ÷ 13.33 ft^3/lb = 0.075 lb/ft^3. Notice that even the units are inverses of each other. Substances with high specific volumes are said to have low densities. Also, substances with high densities have low specific volumes. Since density and specific volumes are inverses of each other, multiplying the density of a substance by its specific volume will always yield a product of 1.

The specific volume of air is a factor in determining the fan or blower horsepower needed in air-conditioning work. As an example, a low specific volume of air requires a blower motor with higher horsepower, and a high specific volume of air can utilize a blower motor with a lower horsepower rating. The specific volumes of various pumped gases is valuable information that enables the engineer to choose the size of the compressor or vapor pump to do a particular job. The specific volumes for vapors vary according to the pressure the vapor is under. As the pressure of the gas increases, the specific volume of the gas decreases and its density increases. As the pressure of the gas decreases, the specific volume of the gas increases and its density decreases.

2.6 GAS LAWS

It is necessary to have a working knowledge of gases and how they respond to pressure and temperature changes. Many years ago, several scientists made significant discoveries about these properties. A simple explanation of some of the gas laws they developed may help you understand the reaction of gases and the pressure/temperature/volume relationships in various parts of a refrigeration system. Whenever using pressure or temperature in an equation like the gas laws, one has to use the absolute scales of pressure (psia) and temperature (Rankine or Kelvin), or the solutions to these equations will be meaningless. Absolute scales use zero as their starting point, because zero is where molecular motion actually begins.

BOYLE'S LAW

In the early 1600s, Robert Boyle, a citizen of Ireland, developed what has come to be known as **Boyle's law**. He discovered that when pressure is applied to a volume of air that is contained, the volume of air becomes smaller and the pressure greater. Boyle's law states that *the volume of a gas varies inversely with the absolute pressure, provided the temperature remains constant*. For example, if a cylinder with a piston at the bottom and closed at the top were filled with air and the piston moved halfway up the cylinder, the pressure of the air would double, **Figure 2.6**. That part of the law pertaining to the temperature remaining constant keeps Boyle's law from being used in practical situations. This is because when a gas is compressed some heat is transferred to the gas from the mechanical compression, and when gas is expanded heat is given up. However, this law, when combined with another, becomes practical to use.

The formula for Boyle's law is as follows:

$$P_1 \times V_1 = P_2 \times V_2$$

where P_1 = original absolute pressure
V_1 = original volume
P_2 = new pressure
V_2 = new volume

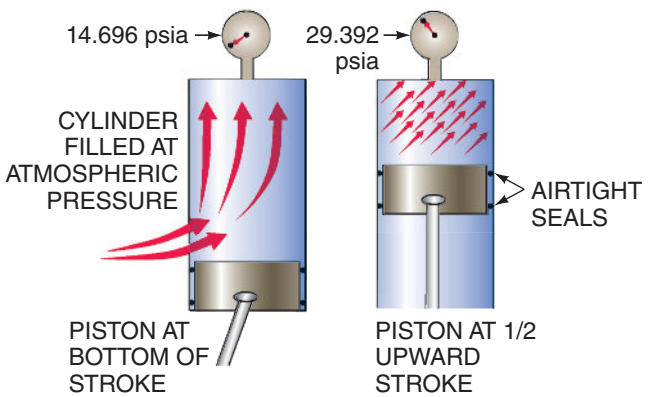
For example, if the original pressure was 40 psia and the original volume was 30 in^3, what would the new volume be if the pressure were increased to 50 psia? We are determining the new volume. The formula would have to be rearranged so we could find the new volume.

$$V_2 = \frac{P_1 \times V_1}{P_2}$$

$$V_2 = \frac{40 \text{ psia} \times 30 \text{ in}^3}{50 \text{ psia}}$$

$$V_2 = 24 \text{ in}^3$$

Figure 2.6 Absolute pressure in a cylinder doubles when the volume is reduced by half.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

CHARLES' LAW

In the 1800s, a French scientist named Jacques Charles made discoveries regarding the effect of temperature on gases. **Charles' law** states that *at a constant pressure, the volume of a gas varies directly as to the absolute temperature, and at a constant volume, the pressure of a gas varies directly with the absolute temperature.* Stated in a different form: When a gas is heated and if it is free to expand, it will do so, and the volume will vary directly as to the absolute temperature; if a gas is confined in a container that will not expand and it is heated, the pressure will vary directly with the absolute temperature.

This law can also be stated with formulas. Two formulas are needed because one part of the law pertains to pressure and temperature and the other part to volume and temperature.

This formula pertains to volume and temperature:

$$\frac{V_1}{T_1} = \frac{V_2}{T_2}$$

where V_1 = original volume
V_2 = new volume
T_1 = original temperature
T_2 = new temperature

If 2000 ft³ of air is passed through a gas-fired furnace and heated from 75°F room temperature to 130°F, what is the volume of the air leaving the heating unit? See **Figure 2.7**.

$V_1 = 2000\ \text{ft}^3$
$T_1 = 75°\text{F} + 460°\text{R} = 535°\text{R (absolute)}$
$V_2 = \text{unknown}$
$T_2 = 130°\text{F} + 460°\text{R} = 590°\text{ R (absolute)}$

We must mathematically rearrange the formula so that the unknown is alone on one side of the equation.

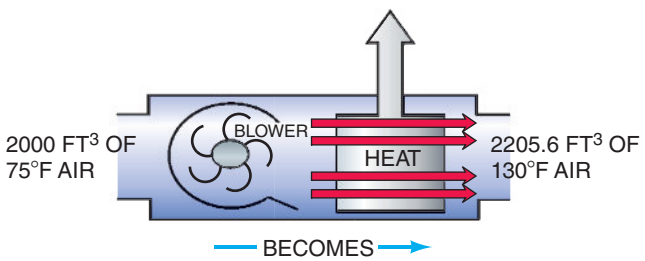
$$V_2 = \frac{V_1 \times T_2}{T_1}$$

$$V_2 = \frac{2000\ \text{ft}^3 \times 590°\text{R}}{535°\text{R}}$$

$$V_2 = 2205.6\ \text{ft}^3$$

This result shows that the air expanded when heated.

Figure 2.7 Air expands when heated.



The following formula pertains to pressure and temperature:

$$\frac{P_1}{T_1} = \frac{P_2}{T_2}$$

where P_1 = original pressure
T_1 = original temperature
P_2 = new pressure
T_2 = new temperature

If a large natural gas tank holding 500,000 ft³ of gas is stored at 70°F in the spring and the temperature rises to 95°F in the summer, what would the pressure be if the original pressure was 25 psig in the spring?

$P_1 = 25\ \text{psig} + 14.696\ \text{(atmospheric pressure)}$
or 39.696 psia
$T_1 = 70°\text{F} + 460°\text{R or } 530°\text{R (absolute)}$
$P_2 = \text{unknown}$
$T_2 = 95°\text{F} + 460°\text{R or } 555°\text{R (absolute)}$

Again, the formula must be rearranged so that the unknown is on one side of the equation by itself.

$$P_2 = \frac{P_1 \times T_2}{T_1}$$

$$P_2 = \frac{39.696\ \text{psia} \times 555°\text{R}}{530°\text{R}}$$

$$P_2 = 41.57\ \text{psia} - 14.696 = 26.87\ \text{psig}$$

GENERAL LAW OF PERFECT GAS

A general gas law, often called the general law of perfect gas, is a combination of Boyle's and Charles' laws. This combination law is more practical because it includes temperature, pressure, and volume.

The formula for this law can be stated as follows:

$$\frac{P_1 \times V_1}{T_1} = \frac{P_2 \times V_2}{T_2}$$

where P_1 = original pressure
V_1 = original volume
T_1 = original temperature
P_2 = new pressure
V_2 = new volume
T_2 = new temperature

For example, 20 ft³ of gas is being stored in a container at 100°F and a pressure of 50 psig. This container is connected by pipe to one that will hold 30 ft³, for a total volume of 50 ft³, and the gas is allowed to equalize between the two

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

containers. The temperature of the gas is lowered to 80°F. What is the pressure in the combined containers?

P_1 = 50 psig + 14.696 (atmospheric pressure) or 64.696 psia
V_1 = 20 ft³
T_1 = 100°F + 460°R = 560°R
P_2 = unknown
V_2 = 50 ft³
T_2 = 80°F + 460°R or 540°R

The formula is mathematically rearranged to solve for the unknown P_2.

$$P_2 = \frac{P_1 \times V_1 \times T_2}{T_1 \times V_2}$$

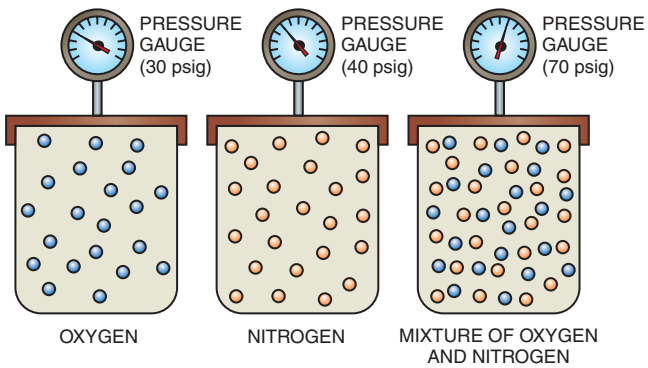
$$P_2 = \frac{64.696 \text{ psia} \times 20 \text{ ft}^3 \times 540°\text{R}}{560°\text{R} \times 50 \text{ ft}^3}$$

P_2 = 24.95 psia − 14.696 (Atmospheric pressure)
= 10.26 psig

DALTON'S LAW

John Dalton, an English mathematics professor, made the discovery in the early 1800s that the atmosphere is made up of several different gases. He found that each gas created its own pressure and that the total pressure was the sum of these individual pressures. Officially called Dalton's Law of Partial Pressures, **Dalton's law** states that *the total pressure of a confined mixture of non-reacting (inert) gases is the sum of the pressures of each of the gases in the mixture*. For example, if one cubic foot of nitrogen and one cubic foot of oxygen are placed in a closed one cubic foot container, the pressure on the container will be the total pressure of the nitrogen as if it were in the container by itself added to the oxygen pressure in the container by itself, **Figure 2.8**.

Figure 2.8 Dalton's law of partial pressures. The total pressure is the sum of the individual pressures of each gas.

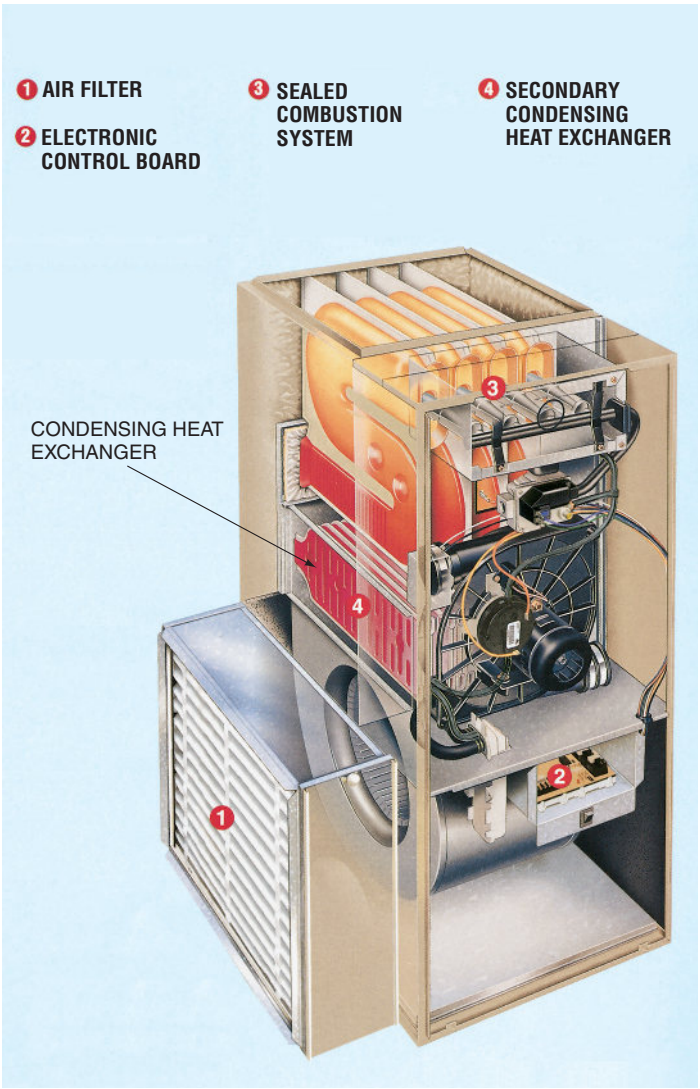


2.7 ENERGY

Using energy properly to operate equipment is a major goal of the HVAC/R industry. Energy in the form of electricity drives the motors; heat energy from the fossil fuels of natural gas, oil, and coal heats homes and industry. What is this energy and how is it used?

The only new energy we get is from the sun heating the earth. Most of the energy we use is converted to usable heat from something already here (e.g., fossil fuels). This conversion from fuel to heat can be direct or indirect. An example of direct conversion is a gas furnace, which converts the gas to usable heat by combustion. The gas is burned in a combustion chamber, and heat from combustion is transferred to circulated air by conduction through the thin steel walls of the furnace's heat exchanger. The heated air is then distributed throughout the heated space, **Figure 2.9**.

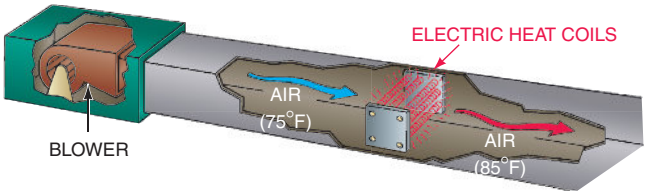
Figure 2.9 A high-efficiency furnace with burners on top of the heat exchanger.



Source: Bryant Heating and Cooling Systems

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 2.10 An electric heat airstream.



An example of indirect conversion is a fossil-fuel power plant. Gas may be used in the power plant to produce the steam that turns a steam turbine generator to produce electricity. The electricity is then distributed by the local power company and consumed locally as electric heat, **Figure 2.10**.

2.8 CONSERVATION OF ENERGY

The preceding sections in this unit lead to the **law of conservation of energy**. This law states that *energy is neither created nor destroyed but can be converted from one form to another.* It can thus be said that all energy can be accounted for.

Most of the energy we use is a result of the sun's support of plant growth for millions of years. Fossil fuels come from decayed vegetable and animal matter covered by earth and rock during changes in the earth's surface. This decayed matter is in various states, such as gas, oil, or coal, depending on the conditions it was subjected to in the past, **Figure 2.11**. The energy stored in fossil fuels is called chemical energy because a chemical reaction is needed to release the energy.

Figure 2.11 Gas and oil deposits settle into depressions.

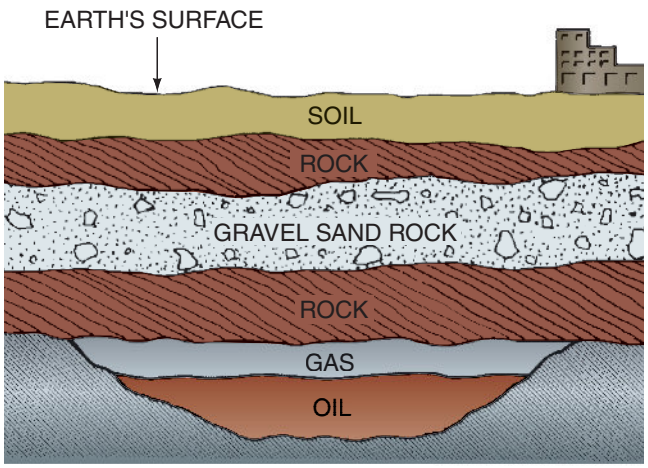


Figure 2.12 (A) If two substances of different temperatures are moved close to each other, heat from the substance with the higher temperature will flow to the one with the lower temperature. (B) Heat energy is still available at these low temperatures and will transfer from the warmer substance to the colder substance.

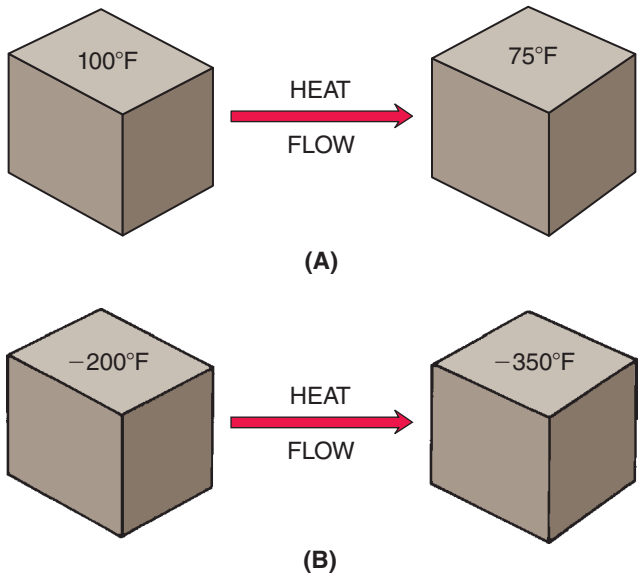


2.9 ENERGY CONTAINED IN HEAT

Temperature is a measure of the degree of heat or the heat intensity, but not necessarily the amount of heat. Heat is a form of energy because of the motion of molecules. To be specific, heat is thermal energy. If two substances of different temperatures are moved close to each other, heat energy from the substance with the higher temperature will flow to the one with the lower temperature, **Figure 2.12(A)**. Because molecular motion does not stop until −460°F, energy is still available in a substance even at very low temperatures. In **Figure 2.12(B)** a substance at −200°F is placed next to a substance at −350°F. As we discussed earlier, heat travels from hot to cold, so heat travels from the warmer −200°F substance to the colder −350°F substance.

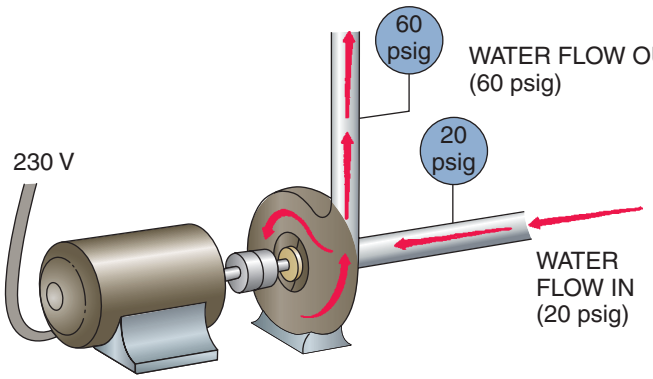
Most of the heat energy used in homes and industry is provided from fossil fuels, but some comes from electrical energy. As shown in Figure 2.10, electron flow in high-resistance wire causes the wire to become hot, thus heating the air. A moving airstream is then passed over the heated wire, allowing heat to be transferred to the air by conduction and moved to the heated space by forced convection (the blower).

2.10 ENERGY IN MAGNETISM

Magnetism is another method of converting electron flow to usable energy. Electron flow is used to generate magnetic fields that are, in turn, used to turn motors. The motors turn

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 2.13 Electrical energy used in an electric motor is converted to work to boost water pressure to force circulation.



the fans, pumps, and compressors that ultimately move air, water, and refrigerant. In **Figure 2.13** an electric motor turns a water pump to boost the water pressure from 20 to 60 psig. This takes energy. The energy in this example is purchased from the power company.

The preceding examples serve only as an introduction to the concepts of chemical energy, heat energy, and electrical energy. Each subject will be covered in detail later. For now, it is important to realize that any system furnishing heating or cooling uses energy.

2.11 PURCHASE OF ENERGY

Energy must be transferred from one owner to another and accounted for. This energy is purchased as a fossil fuel or as electric power. Energy purchased as a fossil fuel is normally purchased by the unit. Natural gas is an example. Natural gas flows through a meter that measures how many cubic feet have passed during some time span, such as a month. Fuel oil is normally sold by the gallon, coal by the ton. Electrical energy is sold by the kilowatt-hour or kWh. The amount of heat each of these units contains is known, so a known amount of heat is purchased. Natural gas, for instance, has a heat content of about 1000 Btu/ft^3; the heat content of fuel oil #2 is about 139,000 Btu/gallon. There are numerous types of coal available and the heat content can range from 14 million Btu/ton up to over 26 million Btu/ton.

2.12 ENERGY USED AS WORK

Energy purchased from electrical utilities is known as electric power. **Power** is the rate of doing work. **Work** can be explained as a force moving an object in the direction of the force; it is expressed in units called foot-pounds, or ft-lb. It is expressed by this formula:

$$\text{Work} = \text{Force} \times \text{Distance}$$

Force is expressed in pounds, and distance is expressed in feet. For instance, when a 150-lb man climbs a flight of stairs 100 ft high (about the height of a 10-story building), he performs work. But how much? The amount of work in this example is equivalent to the amount of work necessary to lift this man the same height. We can calculate the work by using the preceding formula.

$$\text{Work} = 150 \text{ lb} \times 100 \text{ ft}$$
$$= 15{,}000 \text{ ft-lb}$$

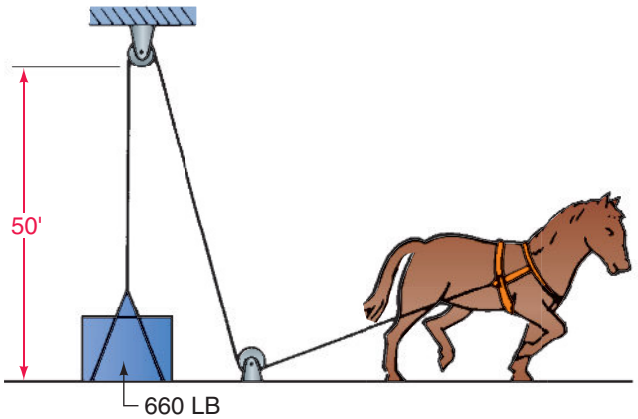
Notice that no time frame has been considered. This example can be accomplished by a healthy man in a few minutes. But if the task were to be accomplished by a machine such as an elevator, more information would be necessary. Do we want to take seconds, minutes, or hours to do the job? The faster the job is to be accomplished, the more power is required.

2.13 POWER

Power is the rate of doing work. An expression of power is **horsepower (hp)**. Many years ago it was determined that an average horse could lift the equivalent of 33,000 lb to a height of 1 ft in 1 min, which is the same as 33,000 ft-lb/min, or 1 hp. This describes a rate of doing work because the time factor has been added. Keep in mind that lifting 330 lb to a height of 100 ft in 1 min or lifting 660 lb to a height of 50 ft in 1 min will require the same amount of power. As a point of reference, the blower motor in the average furnace can be rated at 1/2 hp. See **Figure 2.14** for a visual representation of 1 horsepower.

When the horsepower is compared with the man climbing the stairs, the man would have to climb the 100 ft in less than 30 sec to equal 1 hp. That makes the task seem even harder. A 1/2-hp motor could lift the man 100 ft in about 1 min if only the man were lifted. The reason is that 15,000 ft-lb of work is required. (Remember that 33,000 ft-lb of work in 1 min equals 1 hp.)

Figure 2.14 When a horse can lift 660 lb to a height of 50 ft in 1 min, it has done the equivalent of 33,000 ft-lb of work in 1 min, or 1 hp.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Our purpose in discussing these topics is to help you understand how to use power effectively and to understand how power companies determine their methods of charging money for power.

2.14 ELECTRICAL POWER—THE WATT

The unit of measurement for electrical power is the **watt (W)**. This is the unit used by power companies. When you get your energy bill, you pay for kilowatt hours (kWh), which is the cost for using 1000 watts of power for one hour. When converted to electrical energy, 746 watts = 1 horsepower (1 hp).

Fossil-fuel energy can be compared with electrical energy, and one form of energy can be converted to the other. There must be some basis, however, for conversion to make the comparison. The examples we use to illustrate this will not take efficiencies for the various fuels into account. Efficiencies of fossil fuels will be discussed in the corresponding Units of this text.

Some examples of conversions follow:

1. **Converting electric heat rated in kilowatts (kW) to the equivalent gas or oil heat rated in Btu/h.** Suppose that we want to know the capacity in Btu/h for a 20-kW electric heater (a kilowatt is 1000 watts).

$$1 \text{ kW} = 3413 \text{ Btu/h}$$
$$20 \text{ kW} \times 3413 \text{ Btu/kWh} = 68{,}260 \text{ Btu/h of heat energy}$$

2. **Converting Btu/h to kW.** Suppose that a gas or oil furnace has an output capacity of 100,000 Btu/h. Since 3413 Btu/h = 1 kW, we have

$$100{,}000 \text{ Btu/h} \div 3413 \text{ Btu/h/kW} = 29.3 \text{ kW}$$

3. In other words, a 29.3-kW electric heating system would be required to replace the 100,000-Btu/h furnace.

Contact your local utility company for rate comparisons between different fuels. **SAFETY PRECAUTION:** *Any device that consumes power, such as an electric motor or gas furnace, is potentially dangerous. These devices should only be handled or adjusted by experienced people.*•

SUMMARY

- Matter takes up space, has mass, and can be in the form of a solid, a liquid, or a gas.
- The weight of a substance at rest on the earth is proportional to its mass.
- Density is the weight of a substance per cubic foot.
- Specific gravity is the property used to compare the density of various substances.
- Specific volume is the amount of space a pound of a vapor or a gas will occupy.
- Boyle's law states that the volume of a gas varies inversely with the absolute pressure, provided the temperature remains constant.
- Charles' law states that at a constant pressure, the volume of a gas varies directly as to the absolute temperature, and at a constant volume the pressure of a gas varies directly with the absolute temperature.
- Dalton's law states that the total pressure of a confined mixture of non-reactive gases is the sum of the pressures of each of the gases in the mixture.
- Electrical energy and heat energy are two forms of energy used in the HVAC/R industry.
- Fossil fuels are purchased by the unit. Natural gas is metered by the cubic foot; oil is purchased by the gallon; and coal is purchased by the ton. Electricity is purchased from the electric utility company by the kilowatt-hour (kWh).
- Work is the amount of force necessary to move an object: Work = Force × Distance.
- One horsepower is the equivalent of lifting 33,000 lb to a height of 1 ft in 1 min, or some combination totaling the same.
- Watts are a measurement of electrical power. One horsepower equals 746 W.
- 3.413 Btu/h = 1 W; 1 kW (1000 W) = 3413 Btu/h.

REVIEW QUESTIONS

1. Matter is a substance that occupies space and has
   A. color.
   B. texture.
   C. temperature.
   D. mass.
2. What are the three states in which matter is commonly found?
3. _____ is the term used for water when it is in the solid state.
4. In what direction does a solid exert force?
5. In what direction does a liquid exert force?
6. Vapor exerts pressure in what direction?
   A. Outward
   B. Upward
   C. Downward
   D. All of the above
7. Define density.
8. Define specific gravity.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

9. Describe specific volume.
10. Why does an object weigh less on the moon than on earth?
11. The density of tungsten is 1210 lb/ft^3. What would be its specific volume?
12. The specific volume of red brass is 0.001865 ft^3/lb. What would be its density?
13. Aluminum has a density of 171 lb/ft^3. What would be its specific gravity?
14. Four pounds of a gas occupy 10 ft^3. What would be its density and specific gravity?
15. Why is information regarding the specific volume of gases important to the designer of air-conditioning, heating, and refrigeration equipment?
16. Whose law states that the volume of a gas varies inversely with the absolute pressure, as long as the temperature remains constant?
    A. Charles'
    B. Boyle's
    C. Newton's
    D. Dalton's
17. At a constant pressure, how does a volume of gas vary with respect to the absolute temperature?
18. Describe Dalton's law as it relates to a confined mixture of non-reactive gases.
19. What are the two types of energy most frequently used or considered in this industry?
20. How were fossil fuels formed?
21. _____ is the time rate of doing work.
22. State the formula for determining the amount of work accomplished in a particular task.
23. If an air-conditioning compressor weighing 300 lb had to be lifted 4 ft to be mounted on a base, how much work, in ft-lb, must be done?
24. Describe horsepower and list the three quantities needed to determine horsepower.
25. How many watts of electrical energy are equal to 1 hp?
26. How many Btu of heat can be produced by 4 kWh of electricity?
27. How many Btu/h would be produced in a 12-kW electric heater?
28. What unit of energy does the power company charge the consumer for?
29. If 3000 ft^3 of air is crossing an evaporator coil and is cooled from 75°F to 55°F, what would be the volume of air, in ft^3, exiting the evaporator coil?
30. A gas is compressed inside a compressor's cylinder. When the piston is at its bottom dead center, the gas is initially at 10 psig, 65°F, and 10.5 in^3. After compression and when the piston is at top dead center, the gas is 180°F and occupies 1.5 in^3. What would be the new pressure of the gas in psig?

UNIT 3

REFRIGERATION AND REFRIGERANTS

OBJECTIVES

After studying this unit, you should be able to

- discuss applications for high-, medium-, and low-temperature refrigeration.
- describe the term *ton of refrigeration.*
- describe the basic refrigeration cycle.
- explain the relationship between pressure and the boiling point of water or other liquids.
- describe the function of the evaporator or cooling coil.
- explain the purpose of the compressor.
- list the compressors normally used in residential and light commercial buildings.
- discuss the function of the condensing coil.
- state the purpose of the metering device.
- list four characteristics to consider when choosing a refrigerant for a system.
- list the designated colors for refrigerant cylinders for various types of refrigerants.
- discuss different refrigerants and their applications.
- describe how refrigerants can be stored or processed while refrigeration systems are being serviced.
- plot a refrigeration cycle for refrigerants (R-22, R-134a, and R-502) on a pressure/enthalpy diagram.
- plot a refrigeration cycle on a pressure/enthalpy diagram for refrigerant blends R-404A and R-410A.
- plot a refrigeration cycle on a pressure/enthalpy diagram for a refrigerant blend (R-407C) that has a noticeable temperature glide.

SAFETYCHECKLIST

- ☑ Areas in which there is the potential for refrigerant leaks should be properly ventilated.
- ☑ Extra precautions should be taken to ensure that no refrigerant leaks occur near an open flame.
- ☑ Refrigerants are stored in pressurized containers and should be handled with care. Goggles with side shields and gloves should be worn when checking pressures and when transferring refrigerants from the container to a system or from the system to an approved container.

3.1 INTRODUCTION TO REFRIGERATION

This unit is an introduction to refrigeration and refrigerants. The term *refrigeration* is used here to include both the cooling process for preserving food and comfort cooling (air-conditioning).

Preserving food is one of the most valuable uses of refrigeration. The rate of food spoilage gets slower as molecular motion slows, which retards the growth of bacteria that causes food to spoil. Below the frozen hard point, which for most foods is considered to be 0°F, food-spoiling bacteria stop growing. The food temperature range between 35°F and 45°F is known in the industry as medium temperature; below 0°F is considered low temperature. These ranges are used to describe many types of refrigeration equipment and applications. Refrigeration systems that operate to produce warmer temperatures are referred to as high-temperature refrigeration systems. Comfort cooling systems, commonly referred to as air-conditioning systems, are used, for example, to cool our homes and commercial spaces and are classified as high-temperature refrigeration systems.

For many years dairy products and other perishables were stored in the coldest room in the house, the basement, the well, or a spring. In the South, temperatures as low as 55°F could be maintained in the summer with underground water, which would extend the time that some foods could be kept. In the North, and to some extent in the South, ice was placed in "ice boxes" in kitchens. The ice melted when it absorbed heat from the food in the box, cooling the food, **Figure 3.1.**

In the early 1900s, ice was manufactured by mechanical refrigeration and sold to people with ice boxes, but still only the wealthy could afford it. Also in the early 1900s, some companies manufactured a household refrigerator. Like all new items, it took a while to become popular. Now, most houses have a refrigerator with a freezing compartment. Modern refrigerators have become state-of-the-art appliances—and some models even include automatic beverage and ice dispensers, built-in television screens, and connections to the World Wide Web.

Frozen food was just beginning to become popular about the time World War II began. Because most people

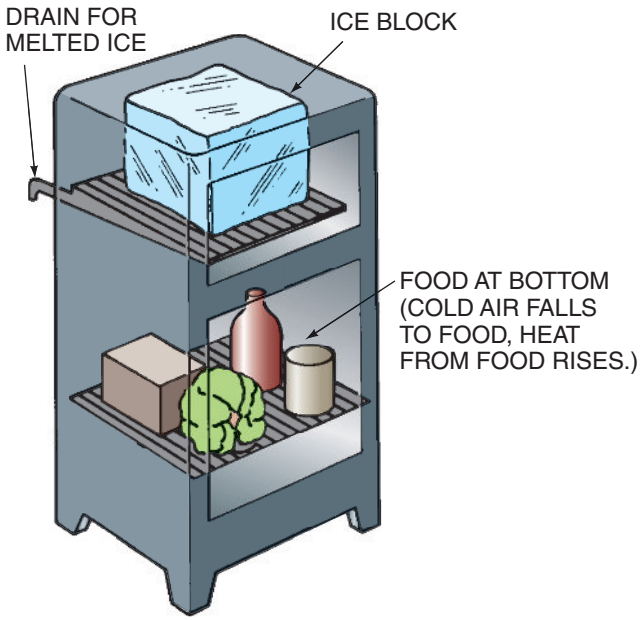
Figure 3.1 Ice boxes were made of wood at first, then metal. The boxes were insulated with cork. If a cooling unit were placed where the ice was located, this would constitute a refrigerator.



did not have a freezer at this time, centralized frozen food lockers were established so that a family could have its own locker. Food that is frozen fresh is appealing because it stays fresh for a longer period of time. Refrigerated and frozen foods are so common now that most people take them for granted.

3.2 REFRIGERATION

Refrigeration is the process of removing heat from a place where it is not wanted and transferring that heat to a place where it makes little or no difference. In the average household, the room temperature from summer to winter is normally between 70°F and 90°F. The temperature inside the refrigerator fresh food section should be about 35°F. Heat flows naturally from a warm level to a cold level. Therefore, heat in the room is trying to flow into the refrigerator; it does so through the insulated walls, the door when it is opened, and warm food placed in the refrigerator, **Figure 3.2**, **Figure 3.3**, and **Figure 3.4**. For this reason, to increase the efficiency of the unit, it is always best to allow food to cool down to room temperature before placing it in the refrigerator.

3.3 RATING REFRIGERATION EQUIPMENT

Refrigeration equipment must have a capacity rating system so that equipment made by different manufacturers

Figure 3.2 The colder air falls out of the refrigerator because it is heavier than the warmer air located outside. The cooler air is replaced with warmer air at the top. This is referred to as heat leakage.

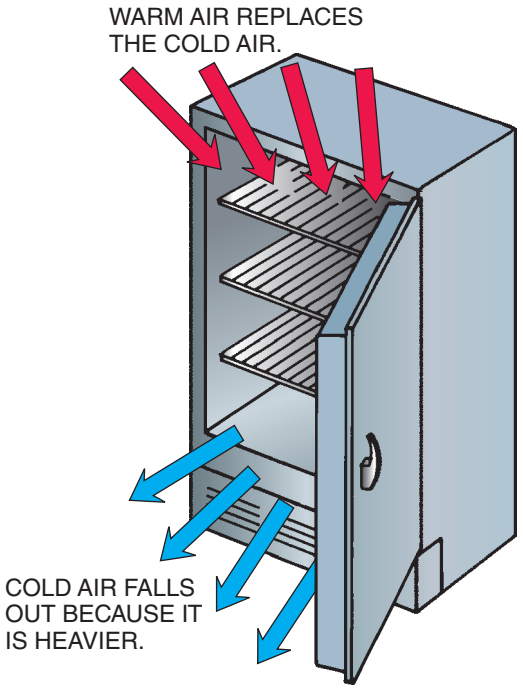


Figure 3.3 Heat transfers through the walls into the box by conduction. The walls have insulation, but this does not stop the heat leakage completely.

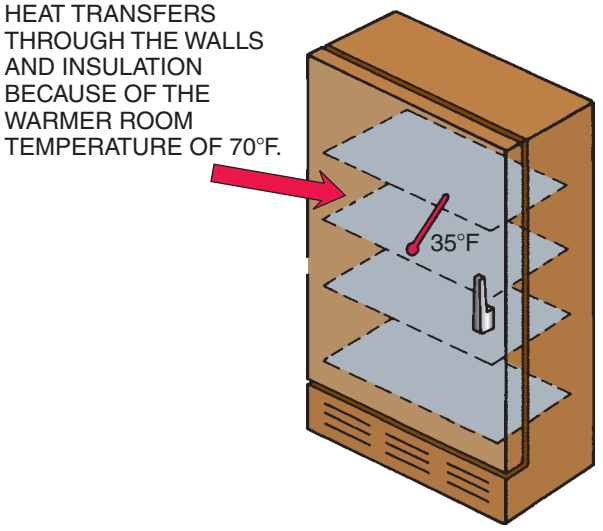
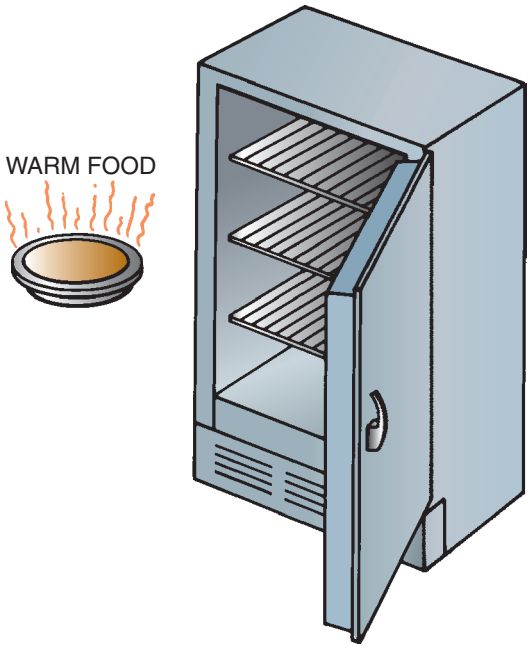


and different models can be compared. The method for rating refrigeration equipment capacity goes back to the days of using ice as the source for removing heat. It takes 144 Btu of heat energy to melt 1 lb of ice at 32°F. This same figure is also used in the capacity rating of refrigeration equipment.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.4 Warm food that is placed in the refrigerator adds heat to the refrigerator and is also considered heat leakage. This added heat has to be removed or the temperature inside the refrigerator will rise.

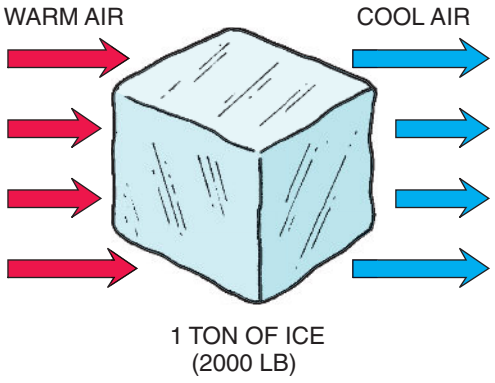


The term for this capacity rating is the *ton*. **One ton of refrigeration** is the amount of heat required to melt 1 ton of ice in a 24-hour period. Previously, we saw that it takes 144 Btu of heat to melt 1 lb of ice. It would then take 2000 times that much heat to melt a ton of ice (2000 lb = 1 ton):

$$144 \text{ Btu/lb} \times 2000 \text{ lb} = 288{,}000 \text{ Btu}$$

When this is accomplished in a 24-hour period, it is known as 1 ton of refrigeration. The same rules apply when removing heat from a substance. For example, an air conditioner that has a 1-ton capacity will remove 288,000 Btu/24 h, or 12,000 Btu/h (288,000 ÷ 24 = 12,000), or 200 Btu/min (12,000 ÷ 60 = 200), **Figure 3.5**.

Figure 3.5 Ice requires 144 Btu/lb to melt. Melting 1 ton of ice requires 288,000 Btu (2000 lb × 144 Btu/lb = 288,000 Btu).



3.4 THE REFRIGERATION PROCESS

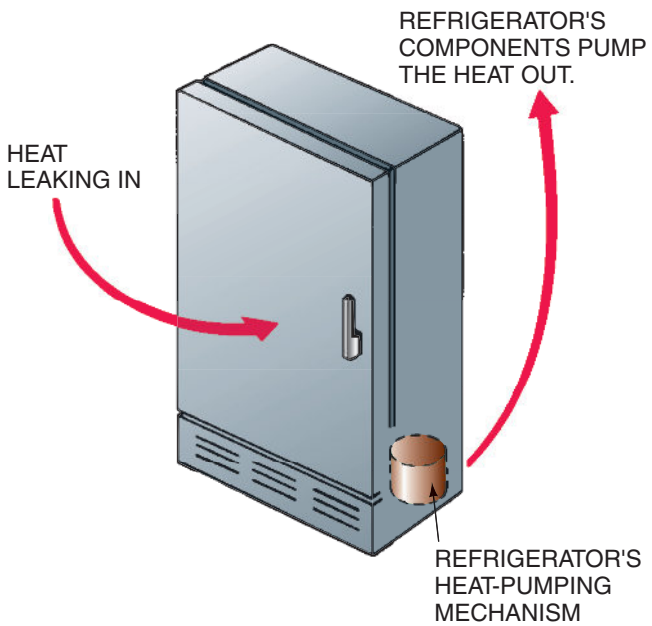
The components of the refrigerator have to pump the heat up the temperature scale from the 35°F or 0°F refrigeration compartments to the 70°F room, **Figure 3.6**. Heat leaking into the refrigerator raises the air temperature inside but does not normally raise the temperature of the food an appreciable amount. If it did, the food would spoil. When the temperature inside the refrigerator rises to a predetermined level, the refrigeration system comes on and pumps the heat out.

The process of pumping heat out of the refrigerator could be compared to pumping water from a valley to the top of a hill. It takes just as much energy to pump water up the hill as it does to carry it. A water pump with a motor accomplishes the work. If, for instance, a gasoline engine were driving the pump, the gasoline would be burned and converted to work energy. An electric motor uses electric power as work energy, **Figure 3.7**. Refrigeration is the process of moving heat from an area of lower temperature into an area or medium of higher temperature. This takes energy that must be purchased.

The following example uses a residential window air-conditioning system to explain the basics of refrigeration. Residential air-conditioning, whether a window unit or a central system, is considered to be high-temperature refrigeration and is used for comfort cooling.

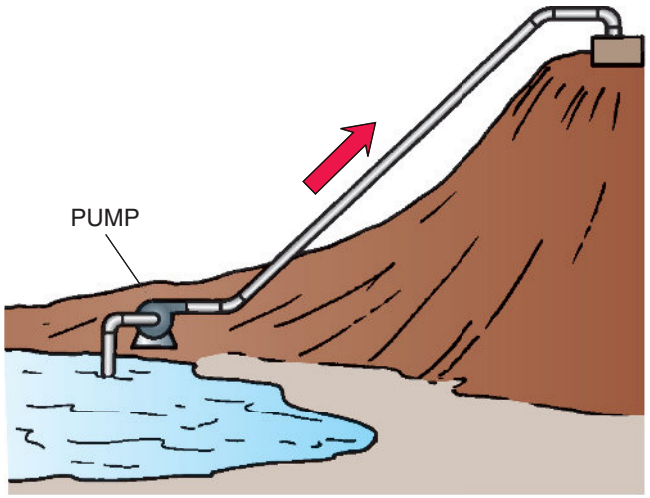
The refrigeration concepts utilized in the residential air conditioner are the same as those in the household refrigerator. The air conditioner pumps the heat from inside the house

Figure 3.6 Heat that leaks into the refrigerator from any source must be removed by the refrigerator's heat-pumping mechanism. The heat has to be pumped from the cool, 35°F interior of the refrigerator to the warmer, 70°F air in the room in which the refrigerator is located.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.7 Power is required to pump water uphill. The same is true for pumping heat up the temperature scale from a 35°F box temperature to a 70°F room temperature.



to the outside of the house, just as the household refrigerator pumps heat from the refrigerator into the kitchen. In addition, just as heat leaks into the refrigerated compartments in the refrigerator, heat leaks into the house and must be removed. The heat is transferred outside by the air-conditioning system.

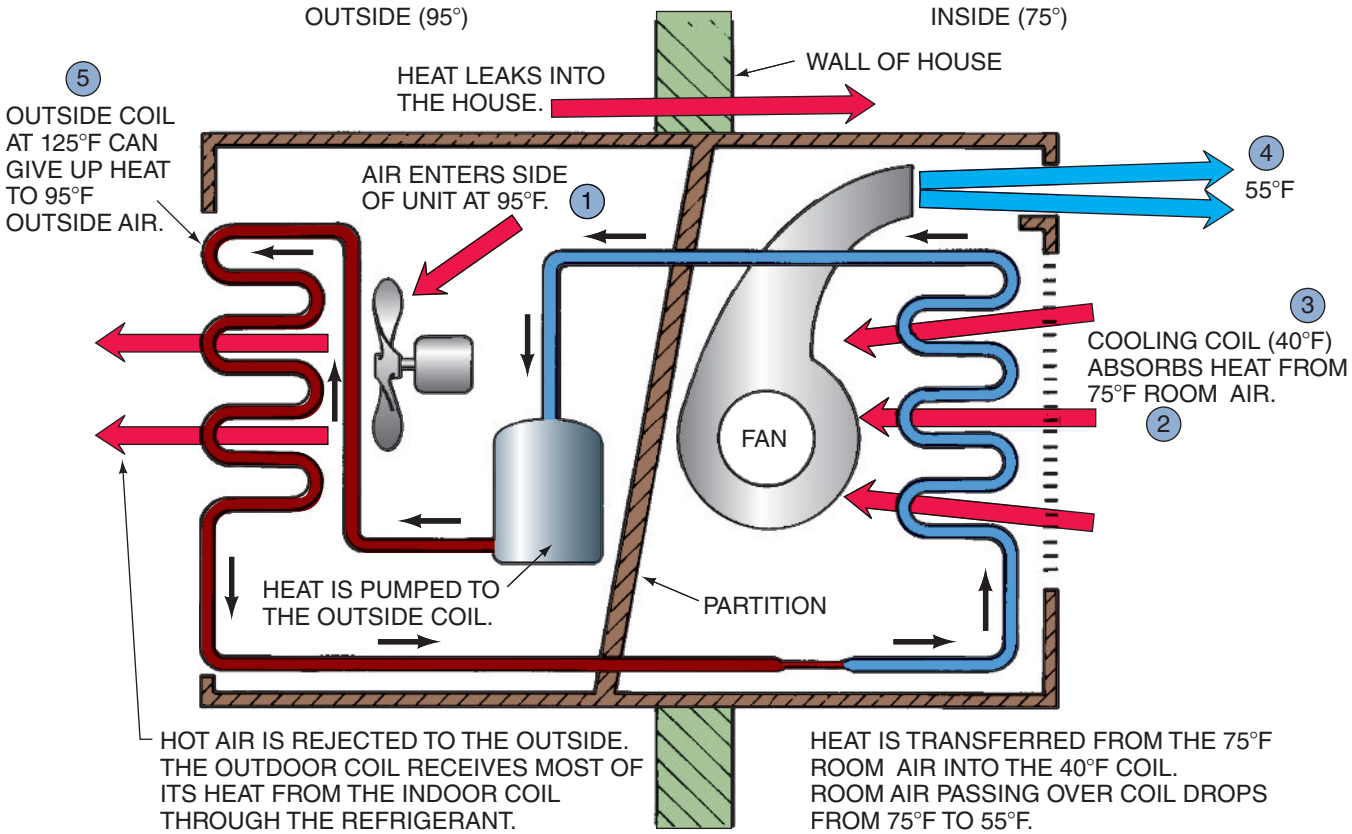
The cold air in the house is recirculated air. Room air at approximately 75°F goes into the air-conditioning unit, and air at approximately 55°F comes out. This is the same air with some of the heat removed, **Figure 3.8**.

Figure 3.8 and the following statements illustrate this concept and are also guidelines to some of the design data used throughout the air-conditioning field.

1. The outside design temperature is 95°F.
2. The inside design temperature is 75°F.
3. The design cooling coil temperature is 40°F. This coil transfers heat from the room into the refrigeration system. Notice that with a 75°F room temperature and a 40°F cooling coil temperature, heat will transfer from the room air into the refrigerant in the coil.
4. The heat transfer makes the air leaving the coil and entering the fan about 55°F. The air exits the fan also at 55°F.
5. The outside coil temperature is 125°F. The coil transfers heat from the system to the outside air. Notice that when the outside air temperature is 95°F and the coil temperature is 125°F, heat will be transferred from the system to the outside air.

Careful examination of **Figure 3.8** shows that heat from the house is transferred into the refrigeration system through the inside coil and transferred to the outside air from the

Figure 3.8 A window air-conditioning unit.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

refrigeration system through the outside coil. The air-conditioning system is actually pumping the heat out of the house. The system capacity must be large enough to pump the heat out of the house faster than it is leaking back in so that the occupants will not become uncomfortable.

3.5 TEMPERATURE AND PRESSURE RELATIONSHIP

To understand the refrigeration process, we must go back to **Figure 1.15** (heat/temperature graph), where water was changed to steam. Water boils at 212°F at 29.92 in. Hg pressure. This suggests that water has other boiling points. The next statement is one of the most important in this text. You may wish to memorize it. ***The boiling point of water can be changed and controlled by controlling the vapor pressure above the water.*** Understanding this concept is necessary because water is used as the heat transfer medium. The next few paragraphs are important for understanding refrigeration.

The **temperature/pressure relationship** correlates the vapor pressure and the boiling point of water and is the basis for controlling a system's temperatures. So if we are able to control the pressures in a refrigeration or air-conditioning system, we will be able to control the temperatures that the system will maintain.

Pure water boils at 212°F at sea level when the barometric pressure is at the standard value of 29.92 in. Hg. This condition exerts an atmospheric pressure of 14.696 psia (0 psig) on the water's surface. This reference point is on the last line of the table in **Figure 3.9**. Also see **Figure 3.10**, showing the container of water boiling at sea level at atmospheric pressure. When this same pan of water is taken to a mountaintop, the boiling point changes, **Figure 3.11**, because the thinner atmosphere causes a reduction in pressure (about 1 in. Hg/1000 ft). In Denver, Colorado, for example, which is about 5000 ft above sea level, the atmospheric pressure is approximately 25 in. Hg. Water boils at 203.4°F at that pressure. This makes cooking foods such as potatoes and dried beans more difficult because they now need more time to cook. But by placing the food in a closed container that can be pressurized, such as a pressure cooker, and allowing the pressure to go up to about 15 psi above atmosphere (or 30 psia), the boiling point can be raised to 250°F, **Figure 3.12**.

Studying the water temperature/pressure table reveals that whenever the pressure is increased, the boiling point increases, and that whenever the pressure is reduced, the boiling point is reduced. If water were boiled at a temperature low enough to absorb heat out of a room, we could have comfort cooling (air-conditioning).

Suppose we place a thermometer in a pan of pure water at room temperature (70°F), put the pan inside a bell jar with a barometer, and start the vacuum pump. When the pressure in the jar reaches the pressure that corresponds to the boiling point of water at 70°F, the water will start to boil and vaporize. This point is 0.739 in. Hg (0.363 psia). (**Figure 3.13** illustrates the container in the bell jar; the data can be found in the table in Figure 3.9.)

Notice, in Figure 3.9, that the temperatures are listed in the left-hand column and the pressures are found in the body of the chart, hence the name temperature/pressure

Figure 3.9 The boiling point of water. The temperature at which water will boil at a specified pressure can be found on the temperature/pressure chart for water.

WATER TEMPERATURE	ABSOLUTE PRESSURE

Figure 3.10 Water boils at 212°F when the atmospheric pressure is 29.92 in. Hg.

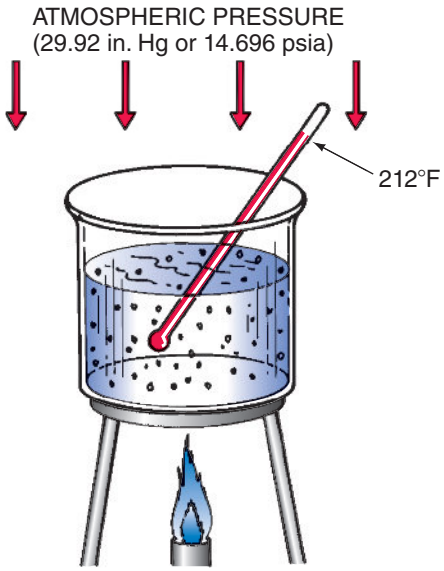

Figure 3.11 Water boils at 203°F when the atmospheric pressure is 24.92 in. Hg.

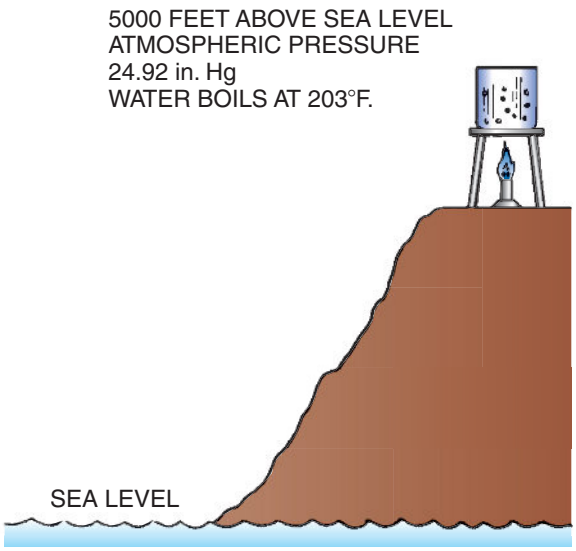

chart (or table). Sometimes, however, the information is presented differently. On some charts, the pressures are located in the left-hand column and the temperatures are found in the body of the chart. These charts or tables are referred to as pressure/temperature charts. Although the information is the same, the way that it is presented is different. Make certain that you know which type of chart you are using—or inaccurate calculations and system conclusions may result.

If we were to lower the pressure in the bell jar to correspond to a temperature of 40°F, this new pressure of 0.248 in. Hg (0.122 psia) will cause the water to boil at 40°F. The water is not hot even though it is boiling.

Figure 3.12 The water in a pressure cooker boils at 250°F. As heat is added, the water boils to make vapor. Since the vapor cannot escape, the vapor pressure rises to 15 psig. The water boils at a temperature higher than 212°F because the pressure in the vessel has risen to a level above atmospheric pressure.

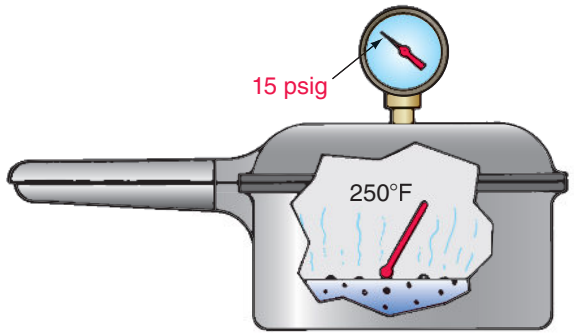

Figure 3.13 The pressure in the bell jar is reduced to 0.739 in. Hg. The boiling temperature of the water is reduced to 70°F because the pressure is 0.739 in. Hg (0.363 psia).

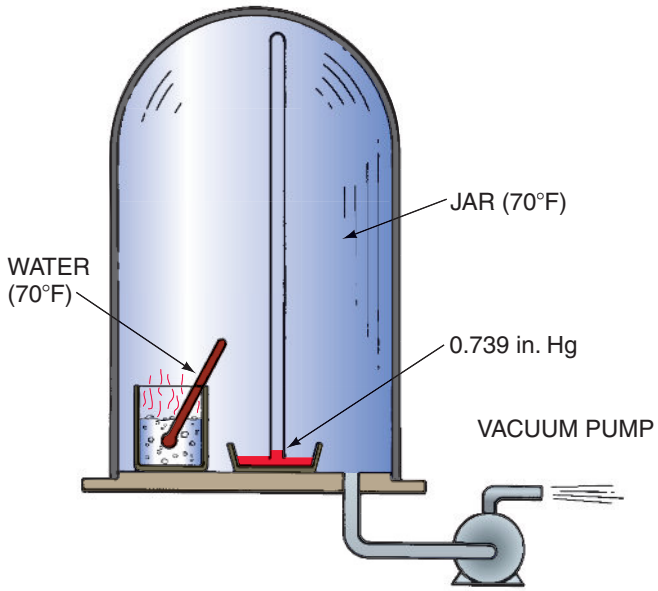


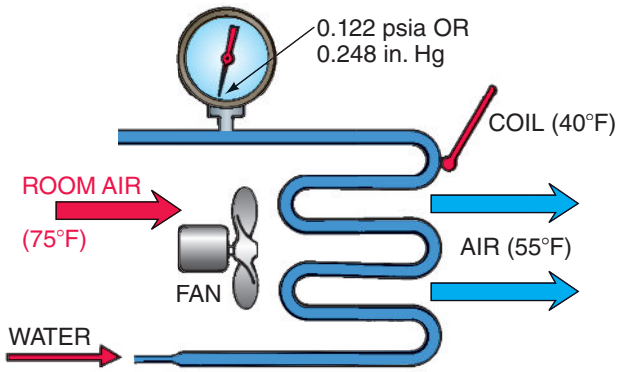
The thermometer in the pan indicates this. If we opened the jar to the atmosphere, we would find the water to be cold. Also, the pressure in the jar would rise and the boiling process would stop.

Now let us circulate this water boiling at 40°F through a cooling coil. If room air were passed over it, it would absorb heat from the room air. Because this air is giving up heat to the coil, the air leaving the coil is cold. **Figure 3.14** illustrates the cooling coil.

When water is used in this way, it is called a *refrigerant*. A **refrigerant** is a substance that can be changed readily to a vapor by boiling it and then changed to a liquid by condensing it. The refrigerant must be able to make this change repeatedly without altering its characteristics. Water is not normally used as a refrigerant in small applications for

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.14 The water is boiling at 40°F because the pressure is 0.122 psia, or 0.248 in. Hg. The room air is 75°F and gives up heat to the 40°F coil.



reasons that will be discussed later. We used it in this example because most people are familiar with its characteristics.

To explore how a real refrigeration system works, we will use refrigerant-22 (R-22) in the following examples because it is commonly used in residential air-conditioning. See **Figure 3.15** for the temperature/pressure relationship chart for several refrigerants, including R-22. This chart is like that for water but uses different temperature and pressure levels. Take a moment to become familiar with the chart; observe that temperature is in the left column, expressed in °F, and pressure is to the right, expressed in psig. Find 40°F in the left column, read to the right, and notice that the gauge reading is 68.5 psig for R-22. What does this mean in usable terms? It means that when R-22 liquid is at a vapor pressure of 68.5 psig, it will boil at a temperature of 40°F. When air is passed over the coil, it will cool just as in the example with water.

The pressure and temperature of a refrigerant will correspond when both liquid and vapor are present under two conditions:

1. When the change of state (boiling or condensing) is occurring, and
2. When the refrigerant is at equilibrium (i.e., no heat is added or removed).

In both conditions 1 and 2, the refrigerant is said to be **saturated**. When a refrigerant is saturated, both liquid and vapor can exist simultaneously. When they do, both the liquid and the vapor will have the same saturation temperature. **NOTE:** *The same temperature for the liquid and vapor is not true of some of the newer blended refrigerants that have a temperature glide. Temperature glide will be covered in Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting".* • The saturation temperature depends on the pressure of the liquid/vapor mixture, called the **saturation pressure.** The higher the pressure, the higher the saturation temperature of the liquid and vapor mixture. The lower the pressure, the lower the saturation temperature.

Suppose that a cylinder of R-22 is allowed to sit in a room until it reaches the room temperature of 75°F. It will then be in equilibrium because no outside forces are acting on it. The cylinder and its partial liquid, partial vapor contents will now be at the room temperature of 75°F. The temperature and pressure chart indicates a pressure of 132 psig, Figure 3.15. The temperature/pressure chart is also referred to as a saturation chart because it contains saturation temperatures for different saturation pressures.

Suppose that the same cylinder of R-22 is moved into a walk-in cooler and allowed to reach the room temperature of 35°F and attain equilibrium. The cylinder will then reach a new pressure of 61.5 psig because while it is cooling off to 35°F, the vapor inside the cylinder is reacting to the cooling effect by partially condensing; therefore, the pressure drops.

If we move the cylinder (now at 35°F) back into the warmer room (75°F) and allow it to warm up, the liquid inside it reacts to the warming effect by boiling slightly and creating vapor. Thus, the pressure gradually increases to 132 psig, which corresponds to 75°F.

If we move the cylinder (now at 75°F) into a room at 100°F, the liquid again responds to the temperature change by slightly boiling and creating more vapor. As the liquid boils and makes vapor, the pressure steadily increases (according to the temperature/pressure chart) until it corresponds to the liquid temperature. This continues until the contents of the cylinder reach the pressure, 196 psig, corresponding to 100°F, **Figure 3.16**, **Figure 3.17**, and **Figure 3.18**.

The vapor that was generated because of the increase in temperature is referred to as **vapor pressure**. Vapor pressure is the pressure exerted on a saturated liquid. Any time saturated vapor and liquid are together, vapor pressure is generated. Vapor pressure acts equally in all directions, and this action is what the pressure gauge reads on a refrigeration or air-conditioning system. As the temperature of the liquid/vapor mixture increases, vapor pressure increases. As the temperature of the liquid/vapor mixture decreases, vapor pressure decreases.

Further study of the temperature/pressure chart shows that when the pressure is lowered to atmospheric pressure, R-22 boils at about −41°F. 4R *Do not perform the following exercises—allowing refrigerant to intentionally escape into the atmosphere is against the law! We mention these examples here for illustration purposes only.* 4R

If the valve on the cylinder of R-22 were opened slowly and the vapor allowed to escape into the atmosphere, the loss of vapor pressure would cause the liquid remaining in the cylinder to boil and drop in temperature. Whenever any liquid boils, heat is absorbed in the process, which causes a cooling effect. The heat in this case came from the R-22 liquid in the cylinder. Soon the pressure in the cylinder would be down to atmospheric pressure, and the cylinder would frost over and become −41°F. (We are assuming that the vapor valve at the top of the R-22 cylinder is large enough to allow the R-22 vapor to escape freely. This way, the vapor will leave the cylinder at the same rate the R-22 liquid is boiling in the cylinder.)

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.15 This chart shows the temperature/pressure relationship in in. Hg vacuum, or psig. Pressures for R-404A and R-410A are average liquid and vapor pressures.

VACUUM (in. Hg) – RED FIGURES
GAUGE PRESSURE (psig) – BOLD FIGURES

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.16 The cylinder of R-22 is left in a 75°F room until it and its contents are at room temperature. The cylinder contains a partial liquid, partial vapor mixture. When both reach room temperature, they are in equilibrium and no further temperature changes will occur. At this time, the cylinder pressure, 132 psig, will correspond to the ambient, or surrounding, temperature of 75°F. The liquid and vapor refrigerant are said to be saturated at 75°F.

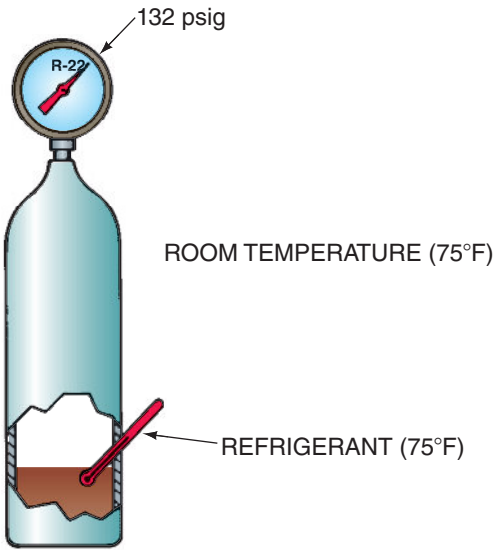

Figure 3.17 The cylinder of R-22 is moved into a 35°F walk-in cooler and left until the cylinder and its contents are at the same temperature as the cooler. As the refrigerant in the cylinder cools, some of the vapor will condense into a liquid, reducing the vapor pressure in the cylinder. Once the partial liquid, partial vapor mixture reaches the cooler temperature of 35°F, they are in equilibrium and no further temperature changes will occur. At this time, the cylinder pressure, 61.5 psig, will correspond to the cooler temperature of 35°F. The liquid and vapor refrigerant are now saturated at 35°F.

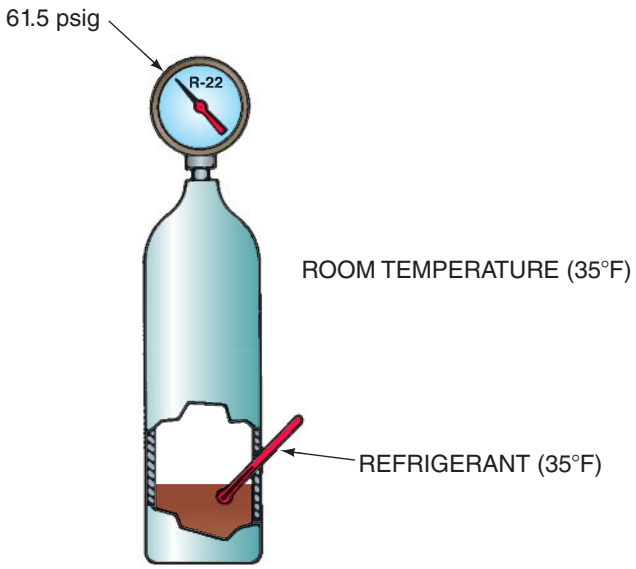

Figure 3.18 The cylinder of R-22 is moved to a 100°F room and allowed to reach the equilibrium point of 100°F and 196 psig. The rise in pressure is due to the fact that at the higher temperature, some of the liquid refrigerant vaporizes. This causes the vapor pressure to increase. The liquid and vapor are still saturated but are now at a higher saturation temperature.

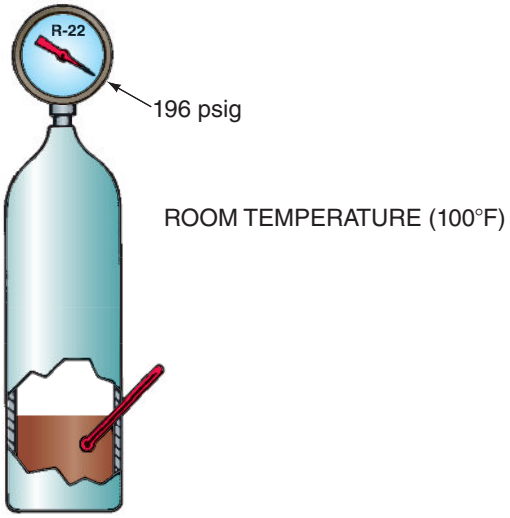

Figure 3.19 When the gauge hose is attached to the valve on the liquid line of an R-22 cylinder and liquid is allowed to trickle out of it and into the cup, the liquid will collect in the cup. The liquid R-22 will continue to boil at a temperature of −41°F until all the liquid has vaporized. 4R *Do not perform this experiment because it is illegal to intentionally vent or release refrigerants into the atmosphere.* 4R

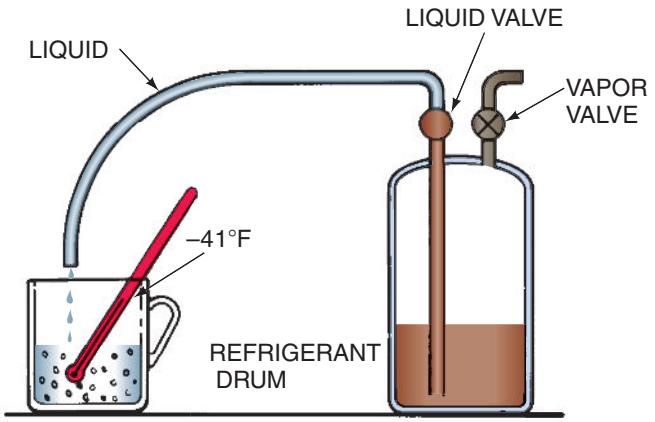
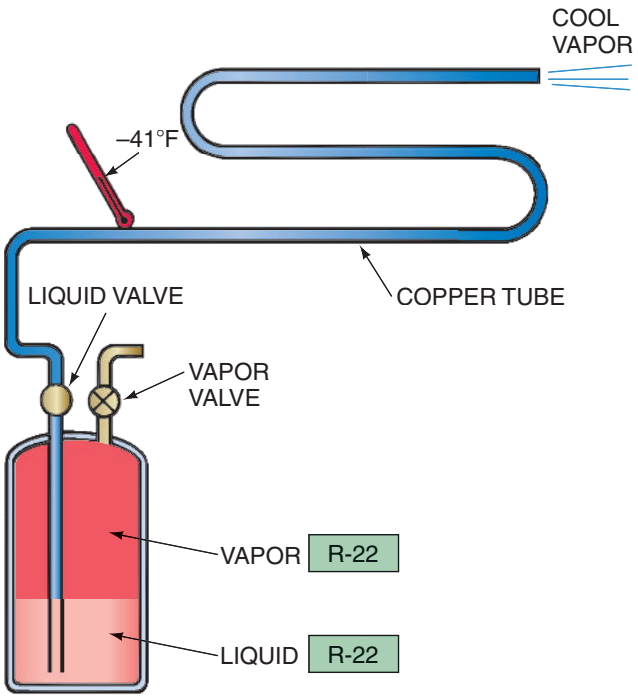


Now, let's say that we took one end of a gauge hose and connected it to the liquid port of a refrigerant (R-22) cylinder and we directed the other end to a cup. If the liquid valve were opened very slowly, liquid refrigerant would flow from the cylinder, through the gauge hose, and into the cup. The liquid refrigerant would accumulate in the cup and you might notice the liquid boiling. If a thermometer were placed in the cup of boiling refrigerant, it would register a reading of −41°F, **Figure 3.19**. You can double-check these numbers by looking up the saturation temperature for R-22 at 0 psig on the temperature/pressure chart. 4R *Again, do not perform the preceding experiments.* 4R

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.20 When the tubing is attached to the valve on the liquid line of an R-22 cylinder and liquid is allowed to trickle into the tubing, the liquid will boil at a temperature of −41°F at atmospheric pressure. 4R *Do not perform this experiment as it is illegal to intentionally vent or release refrigerants to the atmosphere.* 4R



A crude but effective demonstration has been used in the past to show how air can be cooled. 4R *Do not perform this experiment because intentionally venting refrigerant into the atmosphere is illegal.* 4R

A long piece of copper tubing is fastened to the liquid tap on the refrigerant cylinder, and liquid refrigerant is allowed to trickle into the tube while air passes over it. The tube has a temperature of −41°F, corresponding to atmospheric pressure, because the refrigerant is escaping out of the end of the tube at atmospheric pressure. If the tube were coiled up and placed in an airstream, it would cool the air, **Figure 3.20**.

3.6 REFRIGERATION COMPONENTS

By adding some components to a refrigeration system, temperature/pressure problems can be eliminated. The four major components that make up mechanical refrigeration systems are the following:

1. The evaporator
2. The compressor
3. The condenser
4. The refrigerant metering device

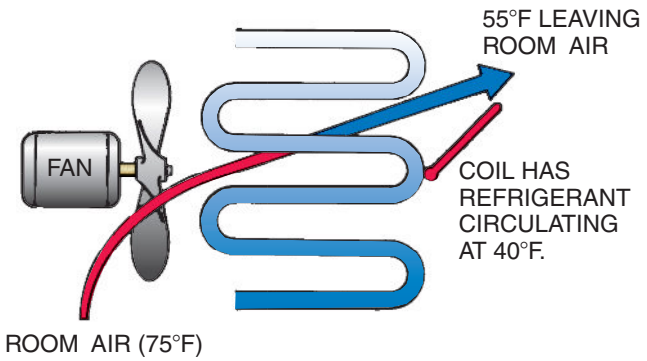
3.7 THE EVAPORATOR

The **evaporator** absorbs heat into the system. When the refrigerant is boiled at a lower temperature than that of the substance to be cooled, it absorbs heat from the substance. The boiling temperature of 40°F was chosen in the previous air-conditioning examples because it is the design temperature normally used for air-conditioning systems. The reason is that the ideal room temperature is close to 75°F, which readily gives up heat to a 40°F coil. The 40°F temperature is also well above the freezing point of the coil. See **Figure 3.21** for the coil-to-air relationships.

The evaporator can be thought of as a "heat sponge." Just as a dry kitchen sponge absorbs liquid from a spill because the water content of the sponge is low, the evaporator is able to absorb heat because the temperature of the coil is lower than the temperature of the medium being cooled. Continuing our analogy, the sponge will stop absorbing liquid if it becomes completely soaked. This is why we have to squeeze the sponge to remove the absorbed water. Looking back at our evaporator, if we just keep adding heat to the coil, its temperature will rise and the amount of heat it can absorb will drop. So, the heat that is absorbed into the evaporator must be removed later on to allow the system to continue to operate.

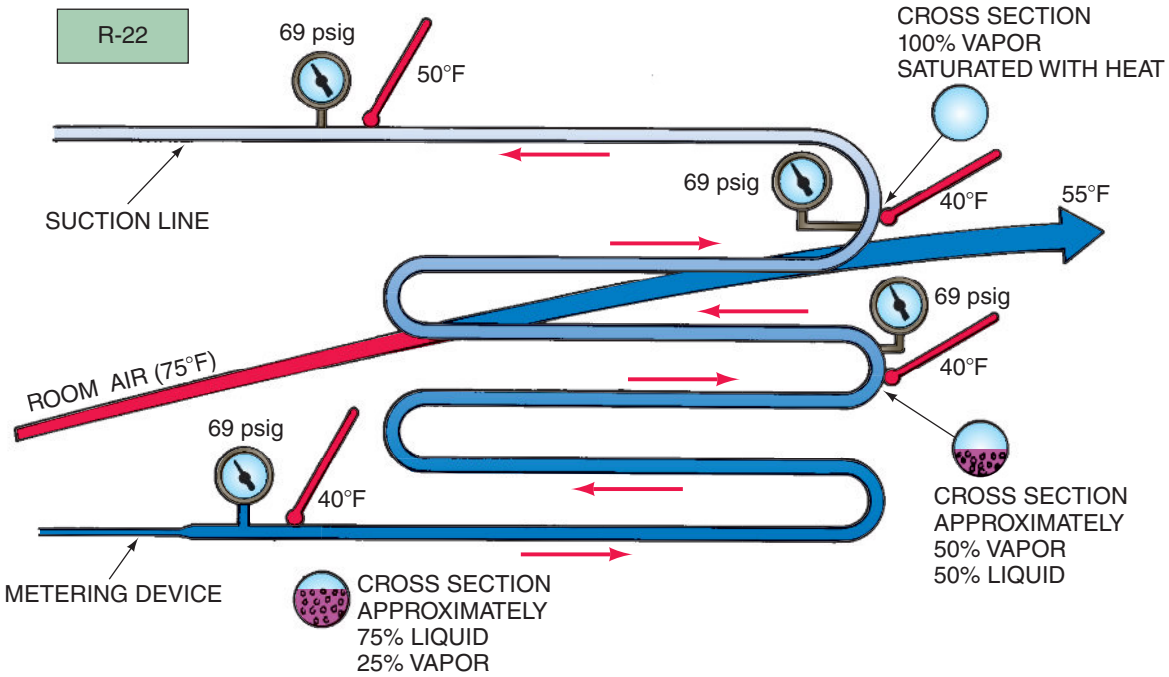
Let us see what happens as the R-22 refrigerant passes through the evaporator coil. The refrigerant enters the coil from the bottom as a mixture of about 75% liquid and 25% vapor. These percentages can change because they are system- and application-dependent (a topic for later discussion). Evaporators are usually fed from the bottom to help ensure that no liquid leaves the top without first boiling off to a vapor. If they were fed from the top, liquid could quickly drop by its own weight to the bottom before it is completely boiled off to a vapor. This protects the compressor from any liquid refrigerant. In addition, vapor is less dense than liquid and as the liquid refrigerant boils, the vapor has a tendency to rise. Since the refrigerant enters the coil from the bottom and leaves from the top, the direction of refrigerant flow is from the bottom to the top, the same direction as the direction of the rising vapor. If the refrigerant entered

Figure 3.21 The evaporator is operated at 40°F to be able to absorb heat from the 75°F air.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.22 The evaporator absorbs heat into the refrigeration system by boiling the refrigerant at a temperature that is lower than the temperature of the room air passing over it. The 75°F room air readily gives up heat to the 40°F evaporator by conduction.



the evaporator from the top and left through the bottom, the direction of flow would be opposite to that of the rising vapor, which would cause the refrigerant to slow down.

The mixture is tumbling and boiling as it flows through the tubes, with the liquid being turned to vapor all along the coil because heat is being added to the coil from the air, **Figure 3.22**. About halfway up the coil, the mixture becomes more vapor than liquid. The purpose of the evaporator is to boil all of the liquid into a vapor just before the end of the coil. This occurs approximately 90% of the way through the coil, leaving pure vapor. At the point where the last droplet of liquid vaporizes, we have what is called a saturated vapor. This is the point where the vapor would start to condense if heat were removed from it or become superheated if any heat were added to it. *When a vapor is superheated, it no longer corresponds to a temperature/pressure relationship. Because no liquid remains to boil off to vapor, no more vapor pressure can be generated when heat is added. The vapor will now take on sensible heat when heated, and its temperature will rise, but the pressure will remain unchanged.* Superheat is considered insurance for the compressor because it ensures that no liquid leaves the evaporator and enters the compressor. When there is superheat, there is no liquid.

To summarize, the three main functions of the evaporator are to

1. absorb heat from the medium being cooled.
2. allow the heat to boil off the liquid refrigerant to a vapor in its tubing bundle.
3. allow the heat to superheat the refrigerant vapor in its tubing bundle.

Figure 3.23 A typical refrigeration evaporator.

Evaporators have many design configurations. But for now just remember that they absorb the heat into the system from the substance to be cooled. The substance may be solid, liquid, or gas, and the evaporator has to be designed to fit the condition. See **Figure 3.23** for a typical evaporator. Once absorbed into the system, the heat is now contained in the refrigerant and is drawn into the compressor through the suction line. The suction line simply connects the evaporator to the compressor and provides a path for refrigerant vapor to travel, **Figure 3.24**. The suction line typically passes through unrefrigerated spaces, and the surrounding air temperature is much higher than the temperature of the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.24 The suction line connects the outlet of the evaporator to the inlet of the compressor.

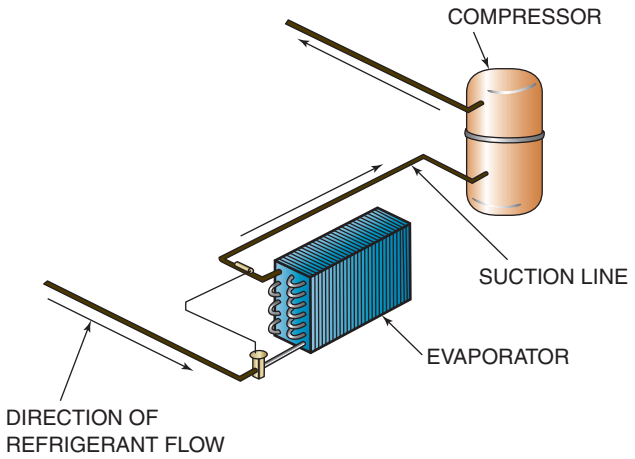

Figure 3.25 Suction lines should be well insulated to increase system efficiency and capacity and to prevent sweating.

refrigerant line. Heat from the surrounding air can, therefore, be readily absorbed into the refrigeration system, making the system work much harder than needed. For this reason, the suction line is insulated, **Figure 3.25**. A well-insulated suction line helps the system operate as efficiently as possible and the insulation prevents the suction line from reaching the dew point temperature and sweating.

3.8 THE COMPRESSOR

The compressor is the heart of the refrigeration system. It pumps heat through the system in the form of heat-laden refrigerant. A compressor can be considered a **vapor pump**. It reduces the pressure on the low-pressure side of the system, which includes the evaporator, and increases the pressure on the high-pressure side of the system. This pressure difference is what causes the refrigerant to flow. All compressors in refrigeration systems perform this function by compressing the vapor refrigerant, which can be accomplished in several ways with different types of compressors. The most common compressors used in residential and light commercial air-conditioning and refrigeration are the **reciprocating**, the **rotary**, and the **scroll**.

The reciprocating compressor uses a piston in a cylinder to compress the refrigerant, **Figure 3.26**. Valves, usually reed or flapper valves, ensure that the refrigerant flows in the correct direction, **Figure 3.27**. This type of compressor, known as a positive displacement compressor, increases the pressure of the refrigerant by physically decreasing the volume of the

Figure 3.26 The crankshaft converts the circular, rotating motion of the motor to the reciprocating, or back-and-forth, motion of the piston.

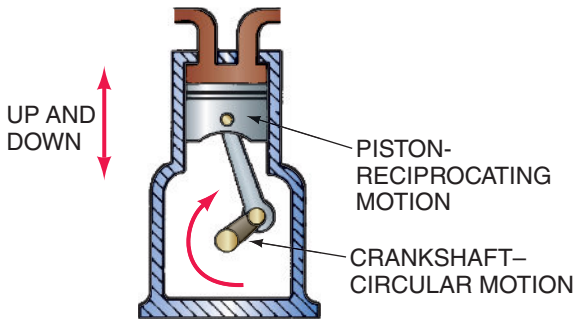

Figure 3.27 Flapper valves and compressor components.

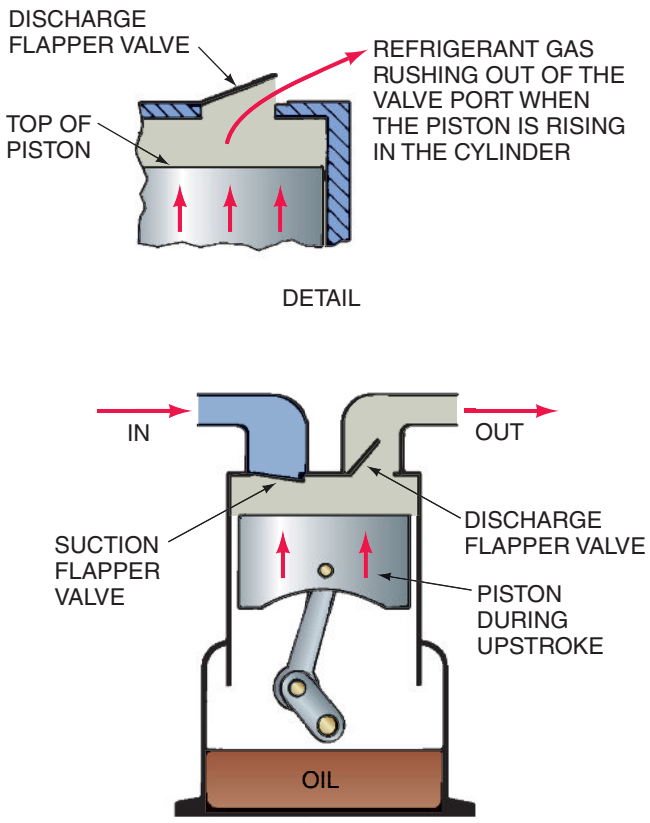

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

container that is holding the refrigerant. In the case of the reciprocating compressor, the volume is decreased as the piston moves up in the cylinder. When the cylinder is filled with vapor, it must be emptied as the compressor turns, or damage will occur. For many years, it was the most commonly used compressor for systems of up to 100 hp. Newer and more efficient compressor designs are now being used.

The rotary compressor is also a positive displacement compressor but are usually very small compared with reciprocating compressors of the same capacity. They are typically used for applications in the small equipment range, such as window air conditioners, household refrigerators, and some residential air-conditioning systems. Rotary compressors are extremely efficient and have few moving parts, **Figure 3.28.** They use a rotating drumlike piston that squeezes the refrigerant vapor out the discharge port.

The scroll compressor is one of the latest compressors to be developed and has an entirely different working mechanism. It has a stationary part that looks like a coil spring, and a moving part that matches and meshes with the stationary part, **Figure 3.29**. The movable part orbits inside the stationary part and squeezes the vapor from the low-pressure side to the high-pressure side of the system between the movable and stationary parts. Several stages of compression are taking place in the scroll at the same time, making it a very smooth running compressor with few moving parts. The scroll is sealed on the bottom and top by the rubbing action and at the tip with a tip seal. These sealing surfaces prevent refrigerant from the high-pressure side from pushing back to the low-pressure side while the compressor is running. The scroll compressor is

Figure 3.28 A rotary compressor with motion in one direction and no backstroke.

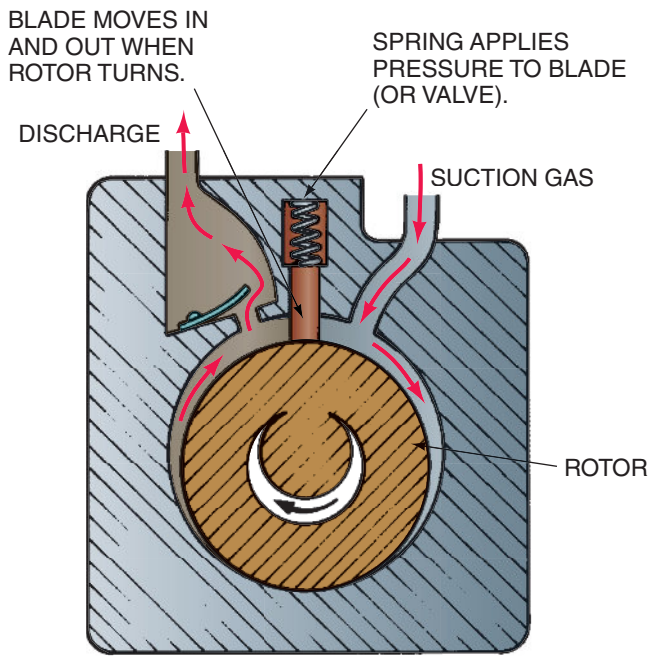

Figure 3.29 An illustration of the operation of a scroll compressor mechanism.

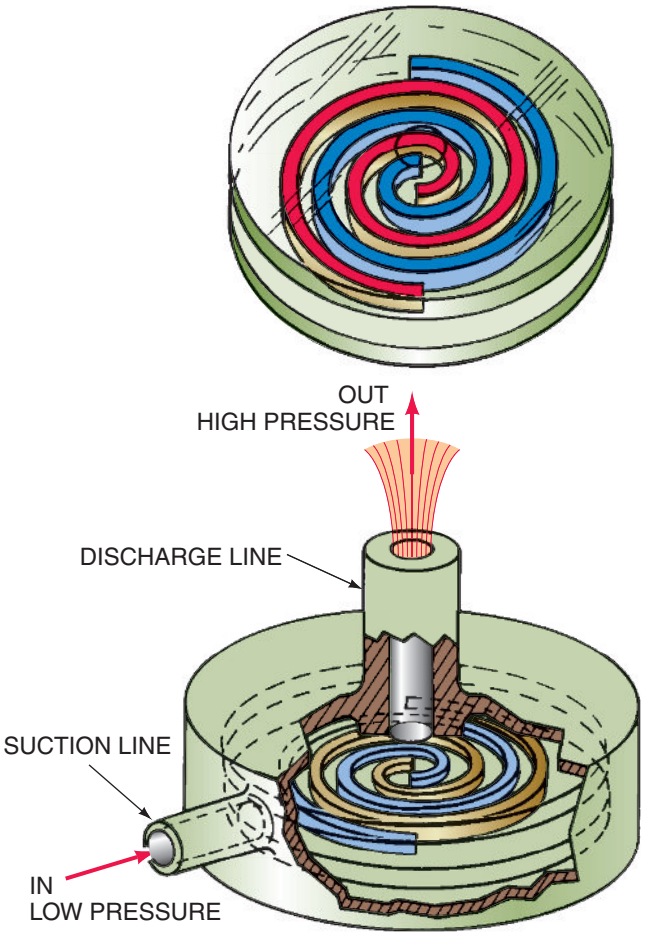


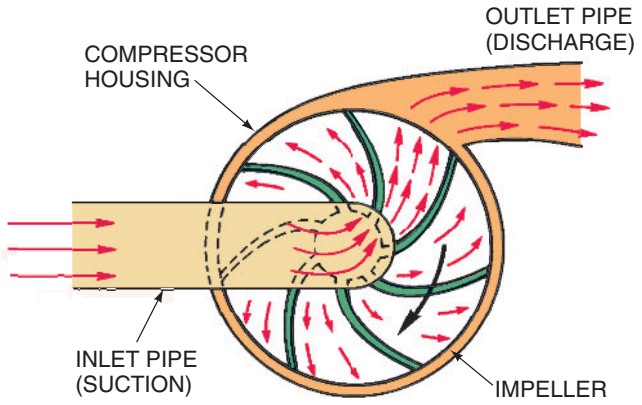
a positive displacement compressor until too much pressure differential builds up; then the scrolls are capable of moving apart, allowing high-pressure refrigerant to blow back through the compressor, preventing overload. The capability to move the mating scrolls apart makes the mechanism more forgiving if a little liquid refrigerant enters the compressor's inlet, because compressor damage is less likely to occur.

Recent advances in computer-aided manufacturing techniques have increased the popularity of the scroll compressor in air-conditioning and high-, medium-, and low-temperature refrigeration applications. The capacity of the scroll compressor can be controlled by the size and the wall height of the orbiting and stationary (spiral) scrolls.

Large commercial systems use other types of compressors because they must move much more refrigerant vapor through the system. The centrifugal compressor is used in large air-conditioning systems. It is much like a large fan and is not positive displacement, **Figure 3.30.** The centrifugal compressor is referred to as a **kinetic displacement compressor**. These compressors increase the kinetic energy of the refrigerant vapor with a high-speed fan and then convert this energy to a higher pressure. This technology is also used in jet engines.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.30 An illustration of the operation of a centrifugal compressor mechanism.



The screw compressor is another positive displacement compressor and is used in larger air-conditioning and refrigeration applications. This compressor is made up of two nesting "screws," **Figure 3.31**. A space between the screws gets smaller and smaller as the refrigerant moves from one end to the other. The vapor refrigerant enters the compressor at the point where the screw spacing is the widest. As the refrigerant flows between these rotating screws, the volume is reduced and the pressure of the vapor increases. The screw compressor is popular for use in low-temperature refrigeration applications.

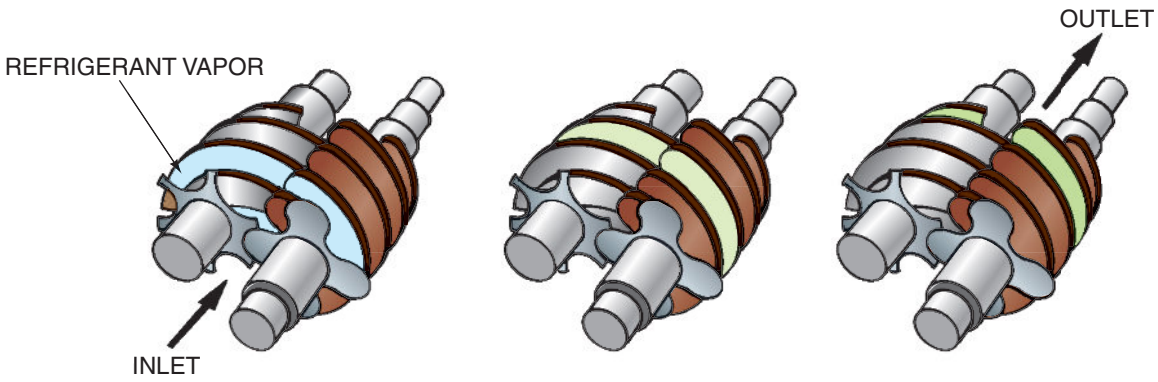
The important thing to remember is that a compressor performs the same function no matter what type it is. For now it can be thought of as a component that increases the pressure in the system and moves the vapor refrigerant from the low-pressure side to the high-pressure side into the condenser.

3.9 THE CONDENSER

The **condenser** rejects both sensible (measurable) and latent (hidden) heat from the refrigeration system. This heat can come from what the evaporator has absorbed, any heat of compression or mechanical friction generated in the compression stroke, motor-winding heat, and any heat absorbed by superheating the refrigerant in the suction line before it enters the compressor.

The condenser receives the hot gas after it leaves the compressor through the short pipe, called the hot gas line, between the compressor and the condenser, **Figure 3.32.** This line is also referred to as the **discharge line**. The hot gas is forced into the top of the condenser coil by the compressor. The discharge gas from the compressor is a high-pressure, high-temperature, superheated vapor. The temperature of the hot gas from the compressor can be in the 200°F range and will change depending on the surrounding temperatures and the system application. The refrigerant at the outlet of the compressor *does not* follow a temperature/pressure relationship. This is because the refrigerant is 100% vapor and superheated. The high-side pressure reading of 278 psig in **Figure 3.33** corresponds to the 125°F condenser saturation temperature, which is the temperature at which the refrigerant will begin to condense from a vapor into a liquid. The vapor pressure of 278 psig read by the high-side gauge is actually coming from the condenser. This vapor pressure is often referred to as head pressure, high-side pressure, discharge pressure, or condensing pressure in the HVAC/R industry. The 200°F gas temperature coming out of the compressor is superheated by 75°F (200°F − 125°F) and, again, cannot have a temperature/pressure relationship.

Figure 3.31 An illustration of the internal working mechanism of a screw compressor.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.32 The discharge line connects the outlet of the compressor to the inlet of the condenser.

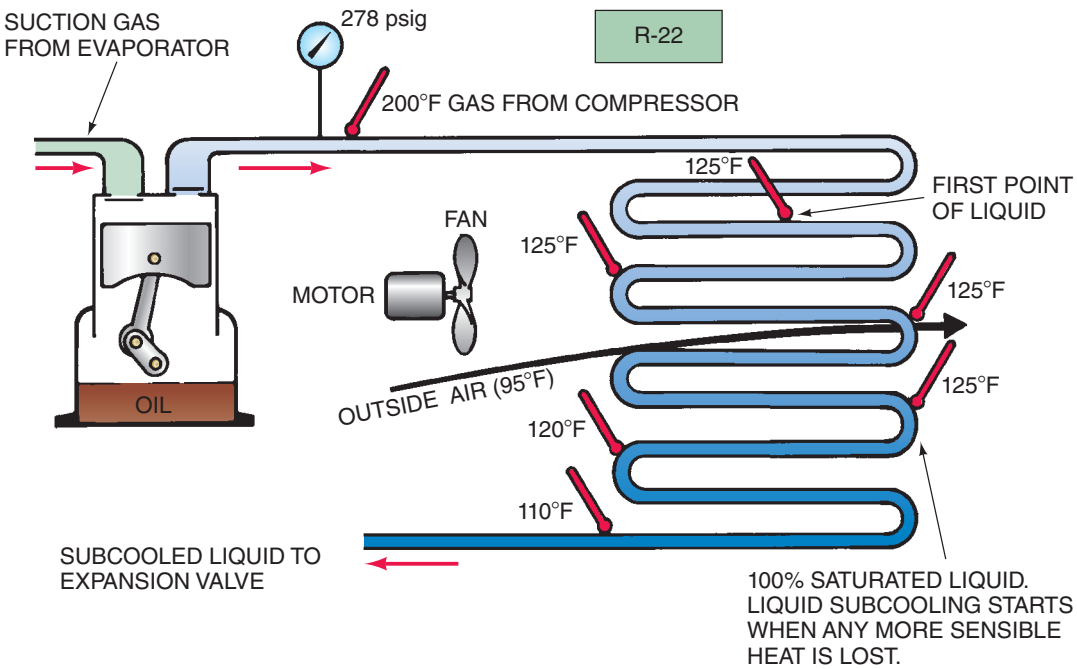
Courtesy Ferris State University.

Therefore, the hot vapor must first cool, or desuperheat, 75° before it can begin to condense.

The gas leaving the compressor, flowing through the discharge line, and entering the condenser is so hot compared with the surrounding air that a heat exchange between the hot gas and the surrounding air begins to occur immediately. The air being passed over the condenser is 95°F, compared to the near 200°F gas entering the condenser. As the gas moves through the condenser, it begins to give up sensible heat to the surrounding air, which causes a drop in gas temperature. The gas keeps cooling off, or **desuperheating**, until it reaches the condensing temperature of 125°F, when the change of state begins to occur. The change of state begins slowly at first with small amounts of vapor changing to liquid and gets faster as the vapor-liquid mixture moves through the condenser. This change from vapor to liquid happens at the condensing saturation temperature and pressure of 125°F and 278 psig, respectively. This is a latent heat process, meaning that even though heat in Btu is being rejected from the refrigerant, the temperature is staying constant at 125°F. **NOTE:** *This process of constant temperature occurring during the change of state does not occur for some of the newer, blended refrigerants that have a temperature glide.*

When the condensing refrigerant gets about 90% of the way through the condenser, the refrigerant in the pipe becomes pure saturated liquid. If any more heat is removed from the 100% saturated liquid, it will go through a sensible-heat rejection process because no more vapor is left to condense. This causes the liquid to drop below the condensing saturation temperature of 125°F. Liquid cooler than the condensing saturation temperature is called **subcooled** liquid, **Figure 3.33.**

Figure 3.33 Subcooled liquid at the outlet of the condenser.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Three important things may happen to the refrigerant in the condenser:

1. The hot gas from the compressor is desuperheated from the hot discharge temperature to the condensing temperature. Remember, the condensing temperature determines the head pressure. This is sensible heat transfer.
2. The refrigerant is condensed from a vapor to a liquid. This is latent heat transfer.
3. The liquid refrigerant temperature may then be lowered below the condensing temperature, or subcooled. The refrigerant can usually be subcooled to between 10°F and 20°F below the condensing temperature, but is system-dependent, Figure 3.33. This is a sensible heat transfer.

Many types of condensing devices are available. The condenser is the component that rejects the heat from the refrigeration system and is specifically designed to eject a solid, liquid, or gas. Very often, the condenser and the compressor are incorporated into a single piece of equipment called a *condensing unit*. **Figure 3.34** shows some typical condensing units.

Incorporating both of these components into a single unit makes system installation an easier task. The suction line carries low-pressure, low-temperature, superheated vapor to the condensing unit, and the liquid line carries high-pressure, high-temperature subcooled liquid from the condensing unit to the metering device.

3.10 THE REFRIGERANT METERING DEVICE

The warm subcooled liquid is now moving down the liquid line in the direction of the **metering device**. The liquid temperature is about 110°F and may still give up some heat to the surroundings before reaching the metering device. This line may be routed under a house or through a wall where it may easily reach a new temperature of about 105°F. Any heat given off to the surroundings is helpful because it came from within the system and will help improve system capacity and efficiency. It also brings the subcooled liquid temperature closer to the evaporator's saturation temperature, which also increases system capacity.

One type of metering device is a simple fixed-size (**fixed-bore**) type known as an **orifice**, which is a small restriction of a fixed size in the liquid line, **Figure 3.35**. This device holds back the full flow of refrigerant and is one of the dividing points between the high-pressure and the low-pressure sides of the system. Only pure liquid must enter it. The pipe leading to the orifice may be the size of a pencil, and the precision-drilled hole in the orifice may be the size of a very fine sewing needle. As you can see from the figure, the liquid flow is greatly restricted here. In an R-22 system, the liquid refrigerant entering the orifice is at a pressure of 278 psig; the refrigerant leaving the orifice is a *mixture* of about 75% liquid and 25% vapor at a new pressure of 70 psig and a new temperature of 41°F, **Figure 3.35**. Two questions usually arise about this fact:

1. Why did approximately 25% of the liquid change to a gas?
2. How did the mixture of 100% pure liquid go from about 105°F to 41°F in such a short space?

Figure 3.35 A fixed-bore (orifice) metering device on an R-22 system.

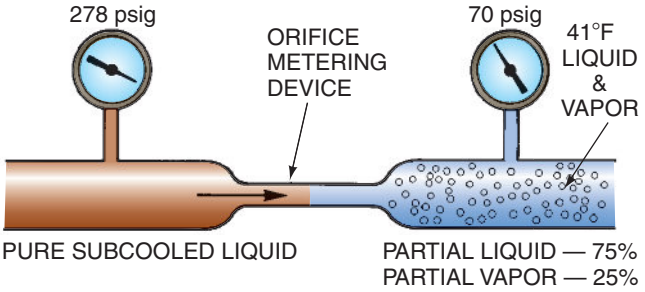

Figure 3.36 A person squeezing the end of a garden hose.

These questions can be answered by using the analogy of a garden hose under pressure—the water coming out feels cooler, **Figure 3.36.** The water actually *is* cooler because some of it evaporates and turns to mist. Evaporation removes heat from the rest of the water and cools it down. When the high-pressure subcooled refrigerant passes through the orifice, it does the same thing as the water in the hose: Its pressure changes (278 psig to 70 psig) and some of the refrigerant flashes to a vapor (called *flash gas*). At this point, the refrigerant is a saturated mixture of liquid and vapor at 70 psig. Since the refrigerant is saturated, it follows the temperature/pressure relationship for that refrigerant—hence, the 41°F refrigerant temperature at the outlet of the metering device. In addition, the evaporating refrigerant further cools the liquid refrigerant that remains as the refrigerant flows through the metering device. This quick drop in pressure in the metering device lowers the boiling point or saturation temperature of the liquid leaving the metering device. Flash gas at the exit of the metering device is considered a loss to the system's capacity because less liquid is now available to boil to vapor in the evaporator when cooling the refrigerated space. Because of this, flash gas should be kept to a minimum.

3.11 MATCHING REFRIGERATION SYSTEMS AND COMPONENTS

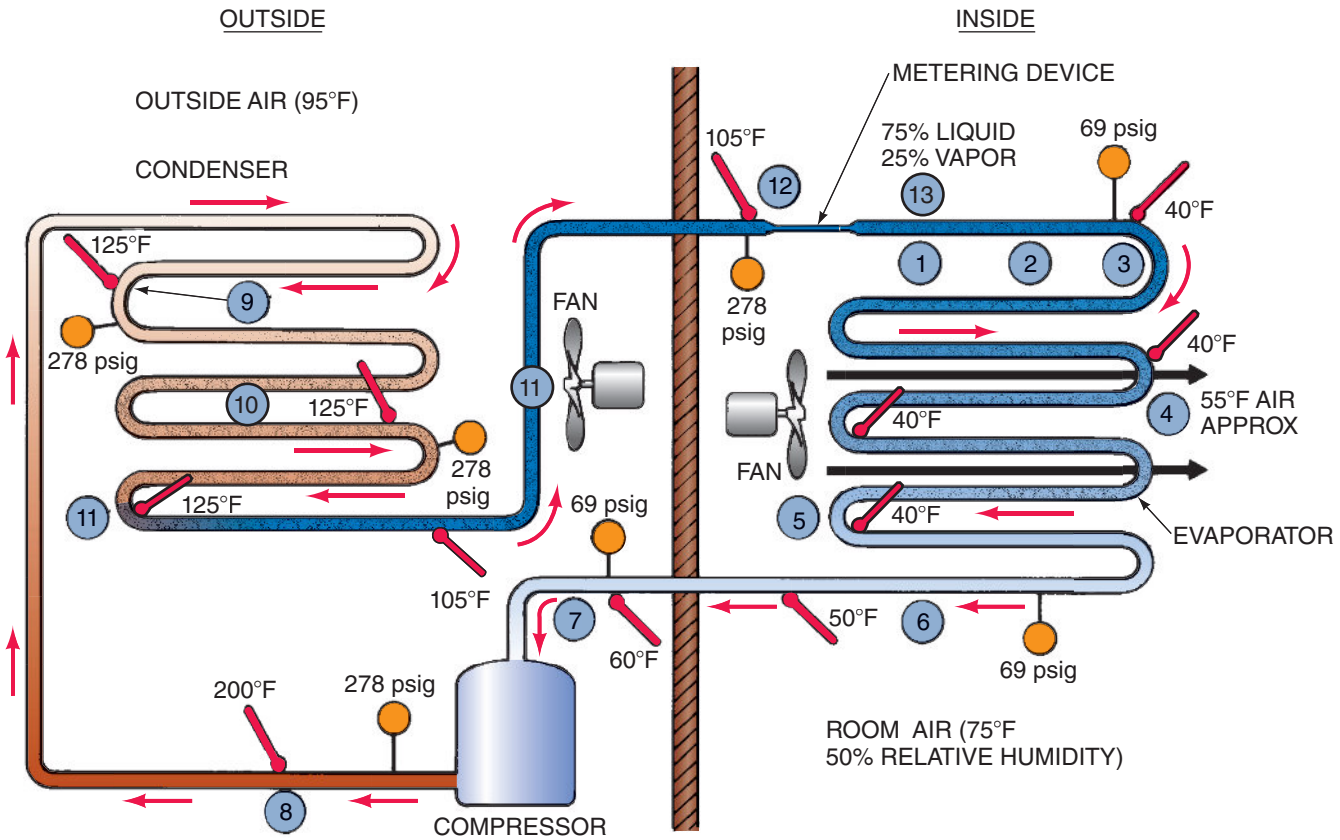
We have described the basic components of the mechanical, vapor-compression refrigeration system according to function. These components must be properly matched for each specific application. For instance, a low-temperature compressor cannot be used in a high-temperature application because of the pumping characteristics of the compressor. Some equipment can be mixed and matched successfully by using the manufacturer's data, but only someone with considerable knowledge and experience should do so. What follows is a description of a matched system correctly working at design conditions. Later we will explain malfunctions and adverse operating conditions.

A typical home air-conditioning system operating at a design temperature of 75°F inside temperature has a relative humidity (moisture content of the conditioned room air) of 50%. The air in the house gives up heat to the refrigerant. The indoor coil is also responsible for removing some of the moisture from the air to keep the humidity at an acceptable level. This is known as **dehumidifying**.

Moisture removal requires considerable energy. Approximately the same amount (970 Btu) of latent heat removal is required to condense a pound of water vapor from the air as to condense a pound of steam. All air-conditioning systems must have a method for dealing with this moisture after it has turned to a liquid. Some units drip, some drain the liquid into plumbing waste drains, some use a slinger ring on the condenser fan, and some use the liquid at the outdoor coil to help the system capacity by evaporating it at the condenser. Remember that part of the system is inside the house and part of the system is outside the house. The numbers in the following description correspond to the circled numbers in **Figure 3.38**.

1. A mixture of 75% liquid and 25% vapor leaves the metering device and enters the evaporator.
2. The mixture is saturated R-22 at a pressure of 69 psig, which corresponds to a 40°F boiling point. It is important to remember that *the pressure is 69 psig because the evaporating refrigerant is boiling at 40°F.*
3. The mixture tumbles through the tube in the evaporator with the liquid evaporating from the 75°F heat and humidity load of the inside air as it moves along.

Figure 3.38 A typical R-22 air-conditioning system showing temperatures and airflow. Red indicates warm/hot refrigerant; blue indicates cool/cold refrigerant.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

4. When the mixture is about halfway through the coil, the refrigerant is composed of about 50% liquid and 50% vapor and is still at the same temperature and pressure because a change of state is taking place. Remember that this is a latent heat transfer.
5. The refrigerant is now 100% vapor. In other words, it has reached the 100% *saturation* point of the vapor.

   Recall the example using the saturated water table; at various points the water was saturated with heat. That is, if any heat is removed at that point, some of the vapor changes back to a liquid; if any heat is added, the temperature of the vapor rises. This rise in temperature of the vapor makes it a *superheated* vapor. (Superheat is sensible heat.) At point 5, the saturated vapor is still at 40°F and still able to absorb more heat from the 75°F room air.
6. The pure vapor that now exists is normally superheated about 10°F above the saturation temperature. Examine the line in **Figure 3.38** at this point to see that the temperature is about 50°F. **NOTE:** *To arrive at the correct superheat reading, take the following steps:*
   - *A. Note the suction pressure or evaporating pressure reading from the suction, or low-side, gauge: 69 psig.*
   - *B. Convert the suction pressure reading to suction or evaporating temperature using the temperature/pressure chart for R-22: 40°F.*
   - *C. Use a suitable thermometer to record the actual temperature of the suction line at the outlet of the evaporator: 50°F.*
   - *D. Subtract the saturated suction temperature from the actual suction line temperature: 50°F − 40°F = 10°F of superheat.* •

   The vapor is said to be heat laden because it contains the heat removed from the room air. The heat was absorbed into the vaporizing refrigerant that boiled off to vapor as it traveled through the evaporator. The vapor superheats another 10°F and is now 60°F as it travels down the suction line to the compressor. The superheat that is picked up only in the evaporator is referred to as *evaporator superheat*; the total superheat that is picked up in the evaporator and the suction line is referred to as *system superheat*. To calculate the system superheat, we measure the suction line temperature (from item C, above) close to the compressor's inlet instead of at the outlet of the evaporator. In this example, the evaporator superheat is 10°F (50°F − 40°F) and the system superheat is 20°F (60°F − 40°F). System superheat is often referred to as *compressor* superheat.
7. The vapor is drawn into the compressor by its pumping action, which creates a low-pressure suction. When the vapor left the evaporator, its temperature was about 50°F with 10°F of superheat above the saturated boiling temperature of 40°F. As the vapor moves along toward the compressor, it is contained in the suction line, which is usually copper and should be insulated to keep it from drawing heat into the system from the surroundings and to prevent it from sweating. However, it still picks up some heat. Because the suction line carries vapor, any heat that it picks up will quickly raise the temperature. Remember that it does not take much sensible heat to raise the temperature of a vapor. Depending on the length of the line and the quality of the insulation, the suction line temperature may be 60°F at the compressor inlet.
8. Highly superheated gas leaves the compressor through the *hot gas line* on the high-pressure side of the system. This line normally is very short because the condenser is usually close to the compressor. On a hot day the hot gas line may be close to 200°F with a pressure of 278 psig. Because the saturated temperature corresponding to 278 psig is 125°F, the hot gas line has about 75°F (200°F − 125°F) of superheat that must be removed before condensing can occur. Because the line is so hot and a vapor is present, the line will give up heat readily to the surroundings. The surrounding air temperature is 95°F.
9. The superheat has been removed and the refrigerant has cooled down to the 125°F condensing temperature. Point 9 is the point in the system where the desuperheating vapor has just cooled to a temperature of 125°F; this is referred to as a 100% saturated vapor point. If any heat is taken away or rejected, liquid will start to form. As more heat is rejected, the remaining saturated vapor will continue to condense to saturated liquid at the condensing temperature of 125°F. Now notice that the coil temperature is corresponding to the high-side pressure of 278 psig and 125°F. The high-pressure reading of 278 psig is due to the refrigerant condensing at 125°F. In fact, 278 psig is the *vapor pressure* that the vapor is exerting on the liquid while it is condensing. Remember, it is vapor pressure that the gauge reads.
10. The conditions for condensing are determined by the efficiency of the condenser. In this example we use a standard condenser, which has a condensing temperature about 30°F higher than the surrounding air used to absorb heat from the condenser. In this example, 95°F outside air is absorbing the heat, so 95°F + 30°F = 125°F condensing temperature. Some condensers will condense at 25°F above the surrounding air temperature; these are high-efficiency condensers and the high-pressure side of the system will be operating at a lower pressure. Condensing temperatures and pressures are also dependent on the heat load given to the condenser to reject. The higher the heat load, the higher will be the condensing temperature and the corresponding pressure. It can also be concluded that as the outside temperature rises, the operating pressure on the high side

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

of the system will also rise. For example, if the outside ambient (surrounding) temperature rises to 105°F, the condenser saturation temperature on our sample system would rise to about 135°F.

11. The refrigerant is now 100% liquid at the saturated temperature of 125°F. As the liquid continues along the coil, the air continues to cool the liquid to below the actual condensing temperature. The liquid may go as much as 20°F below the condensing temperature of 125°F before it reaches the metering device. Any liquid at a temperature below the condensing temperature of 125°F is called *subcooled* liquid. In this example, the liquid is cooled to 105°F before it reaches the metering device. The liquid now has 20°F (125°F − 105°F) of subcooling.
12. The liquid refrigerant reaches the metering device through a pipe, usually copper, from the condenser. This liquid line is often field installed and not insulated. Since the temperature of the liquid line is warmer than the temperature of the surrounding air, keeping the liquid line uninsulated allows some additional heat to be rejected by the refrigerant into the surrounding air, which helps increase the operating efficiency of the system. Since the liquid line may be long, and depending on the distance between the condenser and the metering device, the amount of additional heat being rejected may be significant. Heat given up here is leaving the system, and that is good. The refrigerant entering the metering device may be as much as 20°F cooler than the condensing temperature of 125°F, so the liquid line entering the metering device may be 105°F.
13. The refrigerant entering the metering device is 100% subcooled liquid. In the short length of the metering device's orifice (a pinhole about the size of a small sewing needle), the subcooled liquid is changed to a mixture of about 75% saturated liquid and 25% saturated vapor. The ratio of liquid to vapor leaving the metering device depends on both the system and the application. The 25% vapor, known as flash gas, is used to cool the remaining 75% of the liquid down to 40°F, the boiling temperature of the evaporator. The cooling performed by flash gas is a system loss because it cools the liquid temperature down to the 40°F evaporating temperature. The cooling is therefore wasted because it is not performed in the evaporator to lower the temperature of the inside air and remove humidity. The only way to minimize flash gas is to get the temperature of the subcooled liquid entering the metering device closer to the evaporating temperature.

The refrigerant has now completed one cycle and is ready to go around again. It should be evident that a refrigerant does the same thing over and over, changing from a liquid to a vapor in the evaporator and back to a liquid in the condenser. The expansion device meters the flow to the evaporator, and the compressor pumps the refrigerant out of the evaporator.

The following list briefly summarizes the refrigeration cycle:

1. The evaporator absorbs heat into the system.
2. The compressor pumps the heat-laden vapor.
3. The condenser rejects heat from the system.
4. The expansion device meters the flow of refrigerant.

3.12 REFRIGERANTS

Previously, we have used water and R-22 as examples of refrigerants. Although many products have the characteristics of a refrigerant, we will cover only a few here. Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting," provides more detailed information.

The following four refrigerants either can no longer be manufactured or have phaseout dates in the near future:

R-12—Used primarily in medium- and high-temperature refrigeration applications. Manufacturing and importing banned as of January 1, 1996.

R-22—Used primarily in residential, commercial, and industrial air-conditioning applications and in some commercial and industrial refrigeration. R-22 was phased out in new equipment in 2010, and total production will be phased out in 2020.

R-500—Used primarily in older air-conditioning applications and some commercial refrigeration. Manufacturing and importing banned as of January 1, 1996.

R-502—Used primarily in low-temperature refrigeration applications. Manufacturing and importing banned as of January 1, 1996. It is an **azeotropic** refrigerant blend that has negligible **temperature glide** and behaves like a **pure compound**.

The following are some of the more popular refrigerants, even though some of them may be replaced in the near future with lower GWP refrigerants. Note: At the time of this writing, the Environmental Protection Agency (EPA) has proposed rules for refrigerant substitutes. The rules involve a change in the listing status for certain refrigerant substitutes under the Significant New Alternatives Policy Program (SNAP). Some of the refrigerants and refrigerant blends listed below may be affected when this proposed rule becomes mandatory. Many refrigerants and refrigerant blends that have high global warming potentials (GWPs) will no longer be allow to be used even as retrofit refrigerants. These refrigerants and blends will still be listed as follows because they exist in HVACR equipment from past installations and retrofits. It is important that service technicians understand what these refrigerants and blends consist of for service purposes. It is

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

the service technician's responsibility to keep abreast with the most recent laws and rules concerning refrigerants use and service:

R-134a—Properties very similar to R-12. Used primarily in medium- and high-temperature refrigeration applications, refrigerators and freezers, and automotive air-conditioning. It is a replacement for R-12 but not a direct one because retrofitting is required. The ester-based lubricants used with R-134a are not compatible with the oils typically used in R-12 systems.

R-402A—A near-azeotropic interim HCFC-based refrigerant retrofit blend of R-125, R-290, and R-22 for low- and medium-temperature commercial refrigeration applications. Replaces R-502.

R-404A—R-404A has slightly higher working pressures than R-502. A **near-azeotropic** refrigerant blend with a small temperature glide. Eliminated from new supermarket refrigeration systems, remote condensing units, and some stand-alone equipment because of its high GWP. Some new lower-GWP refrigerants, such as R-448A, R-449A, R-450A, and R-513A, all have less than half the GWP of the candidates they are replacing.

R-407A—A retrofit refrigerant blend for R-22 in medium- and low-temperature commercial refrigeration applications. It is not recommended for air conditioning applications.

R-407C—Similar properties to R-22. It is replacing R-22 in residential and commercial air-conditioning applications. It can be used as a retrofit refrigerant for R-22. A near-azeotropic refrigerant blend, R-407C, like R-134a, operates with ester-based lubricants that are not compatible with the oils typically used in R-22 systems. R-407C is a great choice when the condensing unit of a system must be replaced, as most of the refrigeration oil is contained in the compressor. R-407C can also be used in-medium temperature refrigeration systems.

R-408A—A near-azeotropic interim HCFC based refrigerant retrofit blend of R-125, R-143a, and R-22 for low- and medium-temperature commercial refrigeration applications. Replaces R-502.

R-410A—A near-azeotropic refrigerant blend replacing R-22 in residential and commercial air-conditioning applications. It has much higher operating pressures than R-22 and special safety concerns. R-410A has a very small temperature glide and is not recommended as a retrofit refrigerant. **SAFETY PRECAUTION:** *Never add R-410A to a system that was manufactured for use with R-22. R-22 system components are typically not manufactured to accept the higher operating pressures that are present in R-410A systems. For example, the shells of R-410A compressors are manufactured with thicker steel than are the shells of R-22 compressors.*•

R-417A—A near-azeotropic retrofit refrigerant blend for R-22 direct expansion air-conditioning systems. It is best suited to replace R-22 in smaller split air-conditioning systems. It is an efficient and cost effective, non-ozone depleting HFC-based refrigerant blend. It is compatible with mineral oil, alkylbenzene, and polyol ester lubricants. It has lower discharge temperatures and pressures than R-22.

R-438A—A near-azeotropic refrigerant blend for use as a retrofit refrigerant for R-22 with minimum system change. R-438A is a blend of five different refrigerants. It can be used for retrofitting R-22 direct expansion air-conditioning (high-temperature) applications and medium- and low-temperature refrigeration applications. It has a small percentage of hydrocarbons in its blend to help in oil return. This makes it compatible with mineral oils. R-438A is nonflammable and has an ASHRAE safety group classification of A1. Its ozone depletion potential (ODP) is zero. The evaporator and condenser temperature glide is typically in the 6–7°F temperature range. It is not recommended for flooded evaporators or systems with centrifugal compressors.

R-422A—A near-azeotropic retrofit refrigerant blend for R-502 and R-502 service blends in commercial refrigeration applications. Consists of R-125, R-134a, and R-600a.

R-422B—A near-azeotropic retrofit refrigerant blend for R-22 in air-conditioning.

R-422C—A near-azeotropic retrofit refrigerant blend for R-502 and R-502 service blends in commercial refrigeration applications.

R-422D—A near-azeotropic refrigerant retrofit blend for R-22 in commercial refrigeration applications.

R-427A—A near-azeotropic refrigerant retrofit blend for R-22 in air-conditioning and commercial refrigeration, but preferred for commercial refrigeration applications.

R-507—A replacement for R-502 in low- and medium-temperature refrigeration applications. R-507 is an azeotropic mixture of R-125 and R-143a. Has slightly higher pressures and capacity than R-404A.

R-507A—An azeotropic mixture of R-125 and R-143a. It has a higher efficiency than R-404A and also a higher efficiency than low-temperature R-22. Polyol ester lubricant must be used with R-507A. Eliminated from new supermarket refrigeration systems, remote condensing units, and some stand-alone equipment because of its high GWP.

Some futuristic refrigerants with lower GWPs include:

HFO-1234yf—A low GWP replacement for R-134a intended for use in mobile air-conditioning (MAC) systems in the automotive industry. It is currently being used in this application today in some MAC systems.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

HFO-1234-ze—Intended to replace R-410A in residential and light commercial air-conditioning and heat pump applications while offering a 75% reduction in GWP. It also offers excellent energy efficiency, is cost effective, and can be used in existing equipment design with minimal changes. HFO-1234ze also has significant advantages over R-32, which has medium GWPs and high discharge temperatures. High discharge temperatures can affect system performance and durability in hot climates. Also, oil changes may be needed with R-32.

Hydrofluoro-olefin (HFO) refrigerants are widely recognized as the next generation of refrigerants because of their environmental friendliness, cost-effectiveness, and great energy efficiencies. Refer to Unit 9, "Refrigerant and Oil Chemistry and Management," for more information on hydrofluoro-olefin (HFO) and hydrocarbon (HC) refrigerants. 4R *As we will see later in this unit, the choice of refrigerant is becoming more important because of environmental issues. For many years, it was thought that the common refrigerants were perfectly safe to use. New discoveries have shown that some of the common refrigerants—R-12, R-500, R-502, and R-22—are causing damage to the ozone layer in the stratosphere, 7 to 30 miles above earth's surface. Refrigerants are also being blamed for global warming effects.* 4R

3.13 REFRIGERANTS MUST BE SAFE

To protect people from sickness or injury, even death, if the refrigerant should escape from its system a refrigerant must be safe. For instance, using ammonia for the air-conditioning system in a public place could be a disaster even though from many standpoints ammonia is an efficient refrigerant. Modern refrigerants are nontoxic, and equipment is designed to use a minimum amount of refrigerant to accomplish its job. A household refrigerator or window air conditioner, for example, normally uses less than 2 lb of refrigerant, yet for years almost 1 lb of refrigerant was used as the propellant in a 16-oz aerosol can of hair spray. **SAFETY PRECAUTION:** *Because refrigerants are heavier than air, proper ventilation is important. Avoid open flame when a refrigerant is present. When refrigeration equipment or cylinders are located in a room with an open gas flame, such as a pilot light on a gas water heater or furnace, the equipment must be kept leak free. If the refrigerant escapes and gets to the flame, the flame will sometimes burn an off-blue or blue-green, which means it is giving off a toxic and corrosive gas that will deteriorate any steel in the vicinity, burn the eyes and nose, and severely hamper the breathing of anyone in the room.*

3.14 REFRIGERANTS MUST BE DETECTABLE

A good refrigerant must be readily detectable. For detecting some large leaks, the first thing to do is to listen for the hiss of escaping refrigerant, **Figure 3.39(A)**. In some cases, some leaks may be so small they cannot be heard by the human ear. However, many leaks can be found by listening. There is an ultrasonic leak-detecting device on the market that detects leaks by sound, **Figure 3.39(B)**. This leak detector enables the

Figure 3.39 Common methods used for leak detection. (A) Listening for audible leaks. (B) Ultrasonic leak detector. (C) Soap-bubble solution. (D) Soap-bubble solution causing bubbles to form when a leak is present. (E) Halide torch. (F) The flame on the halide leak detector turns green when a leak is present. (G) Electronic leak detector. (H)

technician to hear the sound of the fluid moving through the piping circuit toward the location of the leak. The pitch of the emitted sound changes as the sensor is brought closer and closer to the leak.

Soap bubbles are a practical and yet simple leak detector. Many service technicians use commercially prepared products that will blow large elastic-type bubbles at the point of the leak, **Figures 3.39**(C) and (D). These products are valuable when the technician knows a leak is in a certain area. Soap-bubble solution can be applied with a brush to the tubing joint to see exactly where the leak is. When refrigerant lines are below freezing temperature, a small amount of antifreeze can be added to the bubble solution. At times, a piece of equipment can be submerged in water to watch for bubbles, which is effective when applicable.

The halide leak detector, **Figure 3.39**(E), is used to detect acetylene or propane gas leaks. It operates on the principle that when the refrigerant is exposed to an open flame in the presence of glowing copper, the flame will change color, **Figure 3.39**(F). The halide leak detector should be used in well-ventilated areas, because the resulting blue or green flame indicates that toxic gas is being produced. Although the amounts produced can be very small, the gas is an irritant—corrosive as well as toxic.

The electronic leak detector in **Figure 3.39**(G) is battery operated, is small enough to be easily carried, and has a flexible probe. The refrigerant charge specifications for

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

some residential air-conditioning equipment call for half-ounce accuracy. The electronic leak detectors are capable of detecting leak rates down to a quarter of an ounce per year.

Another detection system uses a high-intensity ultraviolet lamp, **Figure 3.39(H)**. An additive induced into the refrigerant system will show as a bright yellow-green glow under the ultraviolet lamp at the source of the leak. After repairing the leak and wiping the area clean with a general-purpose cleaner, the area can be reinspected—the additive remains in the system. Should a new leak be suspected at a later date, it will still show as a yellow-green color under the ultraviolet light. This system will detect leaks as small as a quarter of an ounce per year.

3.15 THE BOILING POINT OF THE REFRIGERANT

The boiling point of a refrigerant should be low at atmospheric pressure so that low temperatures may be obtained without going into a vacuum. For example, R-502 can be boiled as low as −50°F before the boiling pressure goes into a vacuum, whereas R-12 can be boiled only as low as −21°F before it goes into a vacuum. Water would have to be boiled at 29.67 in. Hg vacuum just to boil at 40°F.

NOTE: *When using the compound gauge below atmospheric pressure, the scale reads in reverse of the inches of mercury absolute scale. The gauge starts at atmospheric pressure and counts down to a perfect vacuum, called inches of mercury vacuum. When possible, design engineers avoid using refrigerants that boil below 0 psig. This is one reason why R-502 was a good choice for a low-temperature system. When a system operates in a vacuum and a leak occurs, the atmosphere is pulled inside the system instead of the refrigerant leaking out of the system.*

3.16 PUMPING CHARACTERISTICS

Pumping characteristics have to do with how much refrigerant vapor is pumped per amount of work accomplished. Water was disqualified as a practical refrigerant for small equipment partly for this reason. One pound of water at 40°F has a vapor volume of 2445 ft3 compared to about 0.6 ft3 for R-22. As we will see later on, system capacity is directly related to the number of pounds of refrigerant that are circulated through the system per unit of time. This is expressed in units called pounds per minute, or lb/min. Since the vapor volume of 40°F water is so high, the compressor would have to move 2445 ft3 of vapor to move a single pound. Thus, the compressor would have to be very large for a water system. Modern refrigerants meet all of these requirements better than any of the older types. **Figure 3.40** presents the temperature/pressure chart for the refrigerants we have discussed.

3.17 POPULAR REFRIGERANTS AND THEIR IMPORTANT CHARACTERISTICS

The American National Standards Institute (ANSI) and the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) are responsible for naming refrigerants and identifying their characteristics. **Figure 3.41** on page 60 is an organized list of some of the more popular refrigerants and their characteristics. For more detailed information on refrigerants, refer to Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting." 4R *As mentioned earlier, environmental issues like ozone depletion and global warming have forced manufacturing phaseout dates for many refrigerants. However, these refrigerants can still be used if recovered or recycled, or if they are in an operating refrigeration or air-conditioning system. Environmental issues and phaseout dates have made many refrigerants very expensive due to the heavy taxes imposed, and so alternative (environmentally friendly) refrigerants have entered the market. It is now illegal to intentionally vent any refrigerant into the atmosphere. Stiff fines of up to $32,500 and/or imprisonment can follow. Because of this, mandatory technician certification programs have educated HVAC/R personnel on environmental issues, alternative refrigerants, and legislation issues.* 4R

3.18 REFRIGERANT CYLINDER COLOR CODES

Each type of refrigerant is contained in a cylinder or drum that has a designated color. Following are the colors for some of the most frequently used refrigerants:

R-407B	Cream	R-114	Dark blue
R-407C	Chocolate	R-500	Yellow
R-410A	Rose	R-502	Orchid
R-11	Orange	R-717	Silver
R-12	White	R-409A	Tan
R-22	Green	R-123	Light gray-blue
R-113	Purple	R-401A	Coral red
R-134a	Light blue	R-401B	Mustard yellow
R-401C	Aqua	R-404A	Orange
R-402A	Light brown	R-406A	Light gray-green
R-402B	Green-brown	R-407A	Bright green

Some equipment manufacturers color-code their compressors to indicate the type of refrigerant used in the system. **Figure 3.42** shows refrigerant containers for some newer refrigerants.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.40 This chart shows the temperature/pressure relationship in in. Hg vacuum, or psig. Pressures for R-404A and R-410A are an average liquid and vapor pressure.

3.19 RECOVERY, RECYCLING, OR RECLAIMING OF REFRIGERANTS

4R It is mandatory for technicians to recover and sometimes recycle refrigerants during installation and servicing operations to help reduce emissions of chlorofluorocarbons (CFCs), hydrochlorofluorocarbons (HCFCs), and hydrofluorocarbons (HFCs) to the atmosphere. Examples of recovery equipment are shown in ***Figure 3.43****. Many larger systems can be fitted with receivers or dump tanks into which the refrigerant can be pumped and stored while the system is serviced. However, in smaller-capacity systems it is not often feasible to provide these components. Recovery units or other storage devices may be necessary. Most recovery and/or recycling units that have been developed to date vary in technology and capabilities, so manufacturers' instructions must be followed carefully when using this equipment. Unit 9 , "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting," includes a detailed description of the recovery, recycling, and reclaiming of refrigerants. 4R*

3.20 PLOTTING THE REFRIGERANT CYCLE

A graphic picture of the refrigerant cycle may be plotted on a pressure/enthalpy diagram. Pressure is plotted on the left-hand side of the diagram and enthalpy on the bottom of the diagram, **Figure 3.44**. **Enthalpy** describes how much heat a substance contains with respect to an accepted reference point. Quite often, people refer to enthalpy as total heat, but this is not absolutely accurate because it refers to the heat content above the selected reference point. Refer to **Figure 1.15**, the heat/temperature graph for water. We used 0°F as the starting point of heat for water, knowing that you can really remove more heat from the water (ice) and lower the temperature below 0°F. We described the process as the amount of heat added starting at 0°F. This heat is called enthalpy. The pressure/enthalpy diagram is a similar diagram, available for all refrigerants and sometimes referred to as a p-e (pressure/enthalpy) or p-h (pressure/heat) chart. Since different refrigerants have different characteristics, properties, and temperature/pressure relationships, the pressure/enthalpy chart for each refrigerant is different. The pressure/enthalpy chart is used to plot the complete refrigeration cycle as a continuous loop.

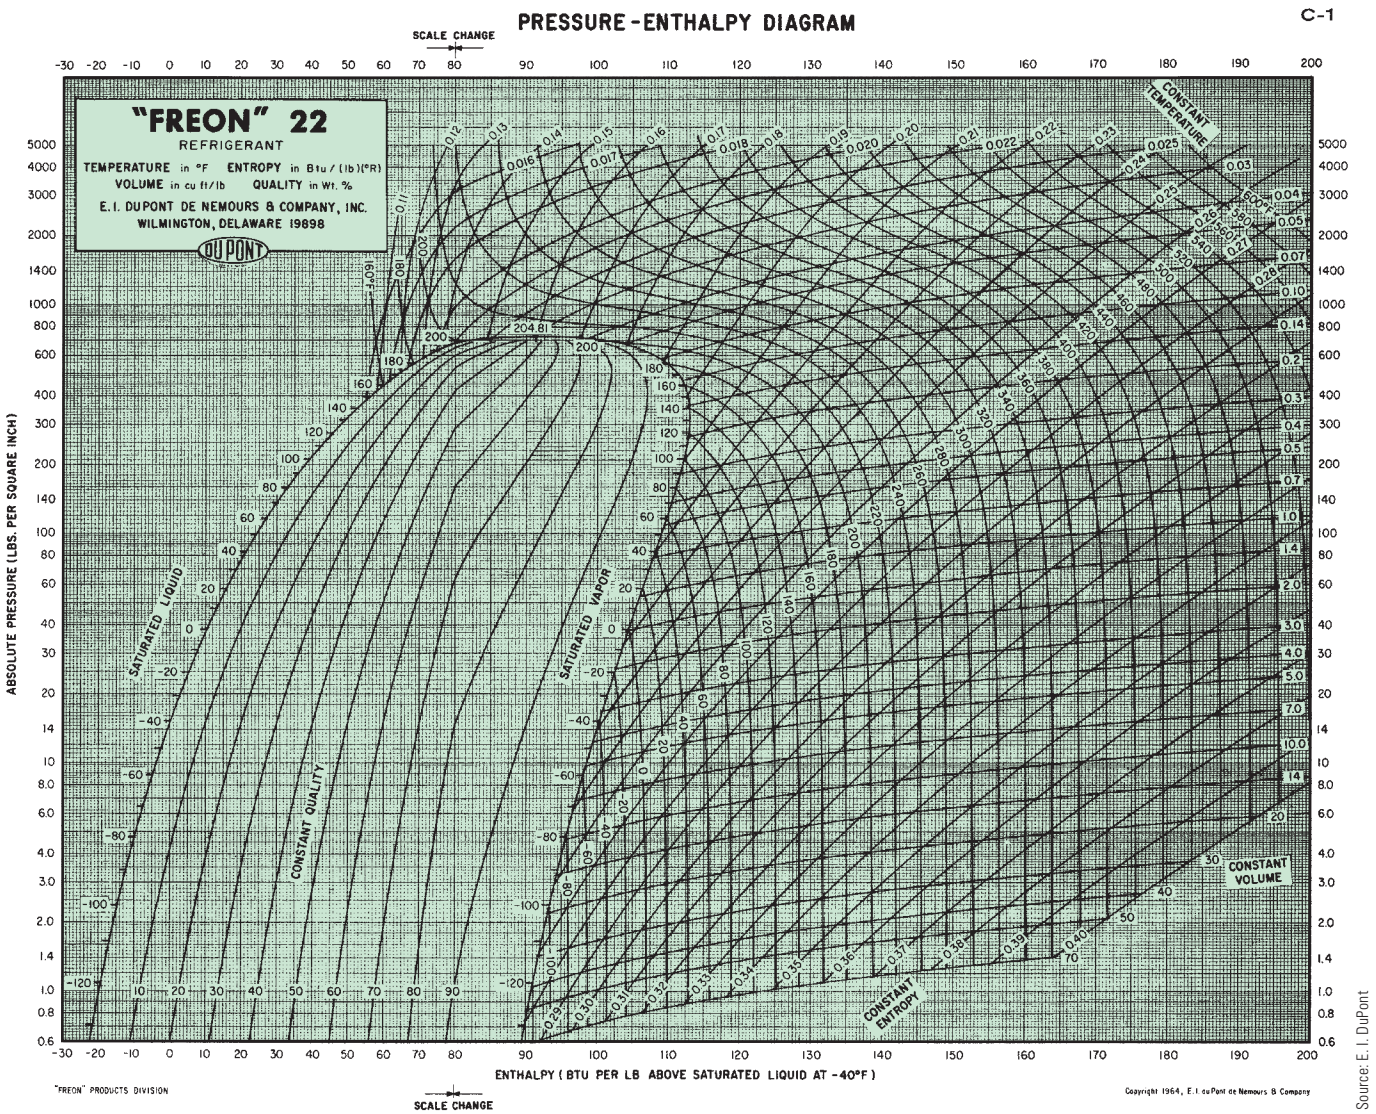
The selected reference point for measuring the heat content in a refrigerant is −40°F. The pressure/enthalpy chart in **Figure 3.45** shows that the enthalpy, or heat content, in Btu/lb (along the bottom of the chart) has a value of 0 Btu/lb when the refrigerant is a saturated liquid at −40°F. The heat content for temperature readings below −40°F saturated liquid are indicated as being negative. As we move from left to right on the chart, the heat content per pound of refrigerant increases. As we move from right to left, the heat content per pound of refrigerant decreases.

As you inspect the pressure/enthalpy chart in **Figure 3.44**, you will notice that there is a horseshoe-shaped curve toward the center of the chart. This curve is called the *saturation curve* and contains the same information that is contained on the temperature/pressure chart discussed earlier. The only difference is that the pressures on the pressure/enthalpy chart are expressed in absolute pressures, psia, instead of gauge pressures, psig.

Any time a plot falls on, or under, this curve, the refrigerant is saturated and will have a corresponding temperature and pressure relationship. There are two saturation curves. The one on the left is the saturated liquid curve. If heat is

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.44 The pressure/enthalpy chart relates system operating pressure and temperatures to the heat content of the refrigerant in Btu/lb.

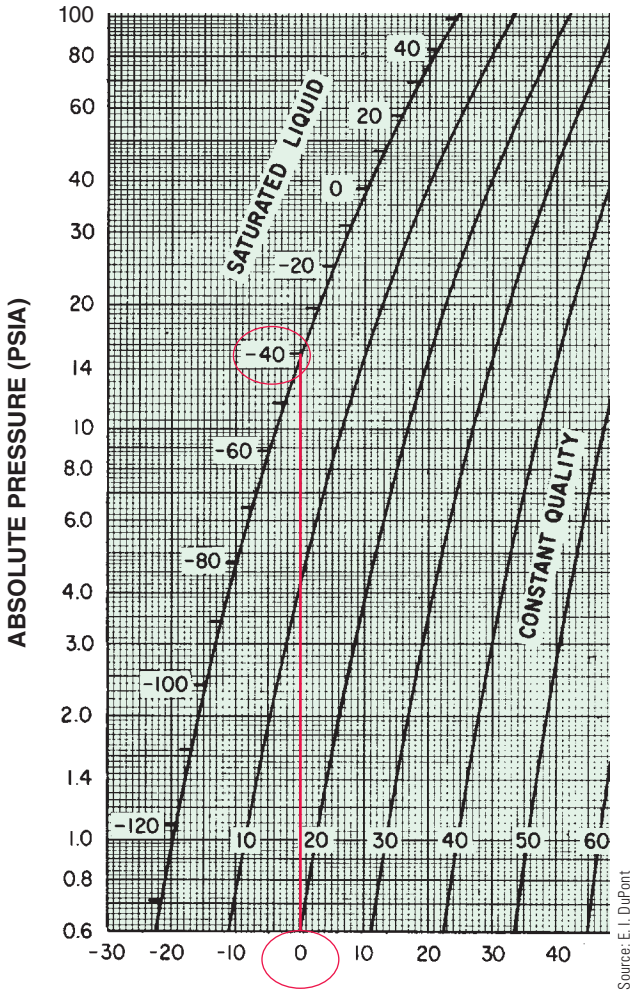


added, the refrigerant will start changing state to a vapor; if heat is removed, the liquid will be subcooled. The right-hand curve is the saturated vapor curve. If heat is added, the vapor will superheat; if heat is removed, the vapor will start changing state to a liquid. Notice that the saturated liquid and vapor curves touch at the top. This is called the **critical temperature** or **critical pressure**. Above this point, the refrigerant will not condense. It is a vapor regardless of how much pressure is applied.

The area between the saturated liquid and saturated vapor curve, inside the horseshoe-shaped curve, is where the change of state occurs. Any time a plot falls between the saturation curves, the refrigerant is in the partial liquid, partial vapor state. The slanted, near-vertical lines between the saturated liquid and saturated vapor lines are the constant quality lines and describe the ratio of vapor to liquid in the mixture between the saturation points. There are nine of these lines under the saturation curve, each of which represents 10%. The saturated liquid line on the left side of the curve represents 0% vapor and 100% liquid, while the saturated vapor line on the right side of the saturation curve represents 100% vapor and 0% liquid. The nine constant quality lines that are located under the saturation curve are labeled, from left to right, 10 through 90. These numbers represent the percentage of quality. *Percentage of quality* means percentage of vapor. This means that if a point falls on the 20% constant quality line, it would be 20% vapor and 80% liquid. If the plot is closer to the saturated liquid curve, there is more liquid than vapor. If the plot is closer to the saturated vapor curve, there is more vapor than liquid. For example, let's find a point on the chart at 40°F (on the saturated liquid curve) and 30 Btu/lb (along the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.45 The reference point used for measuring heat content is saturated liquid at 240°F.



bottom), **Figure 3.46**. This point is inside the horseshoe-shaped curve, and the refrigerant is 90% liquid and 10% vapor. **Figure 3.47** summarizes in skeletal form the important regions, points, and lines of the pressure/enthalpy diagram. For practical reasons, we will use only a few of these skeletal forms for illustrating the functions of the refrigeration cycle.

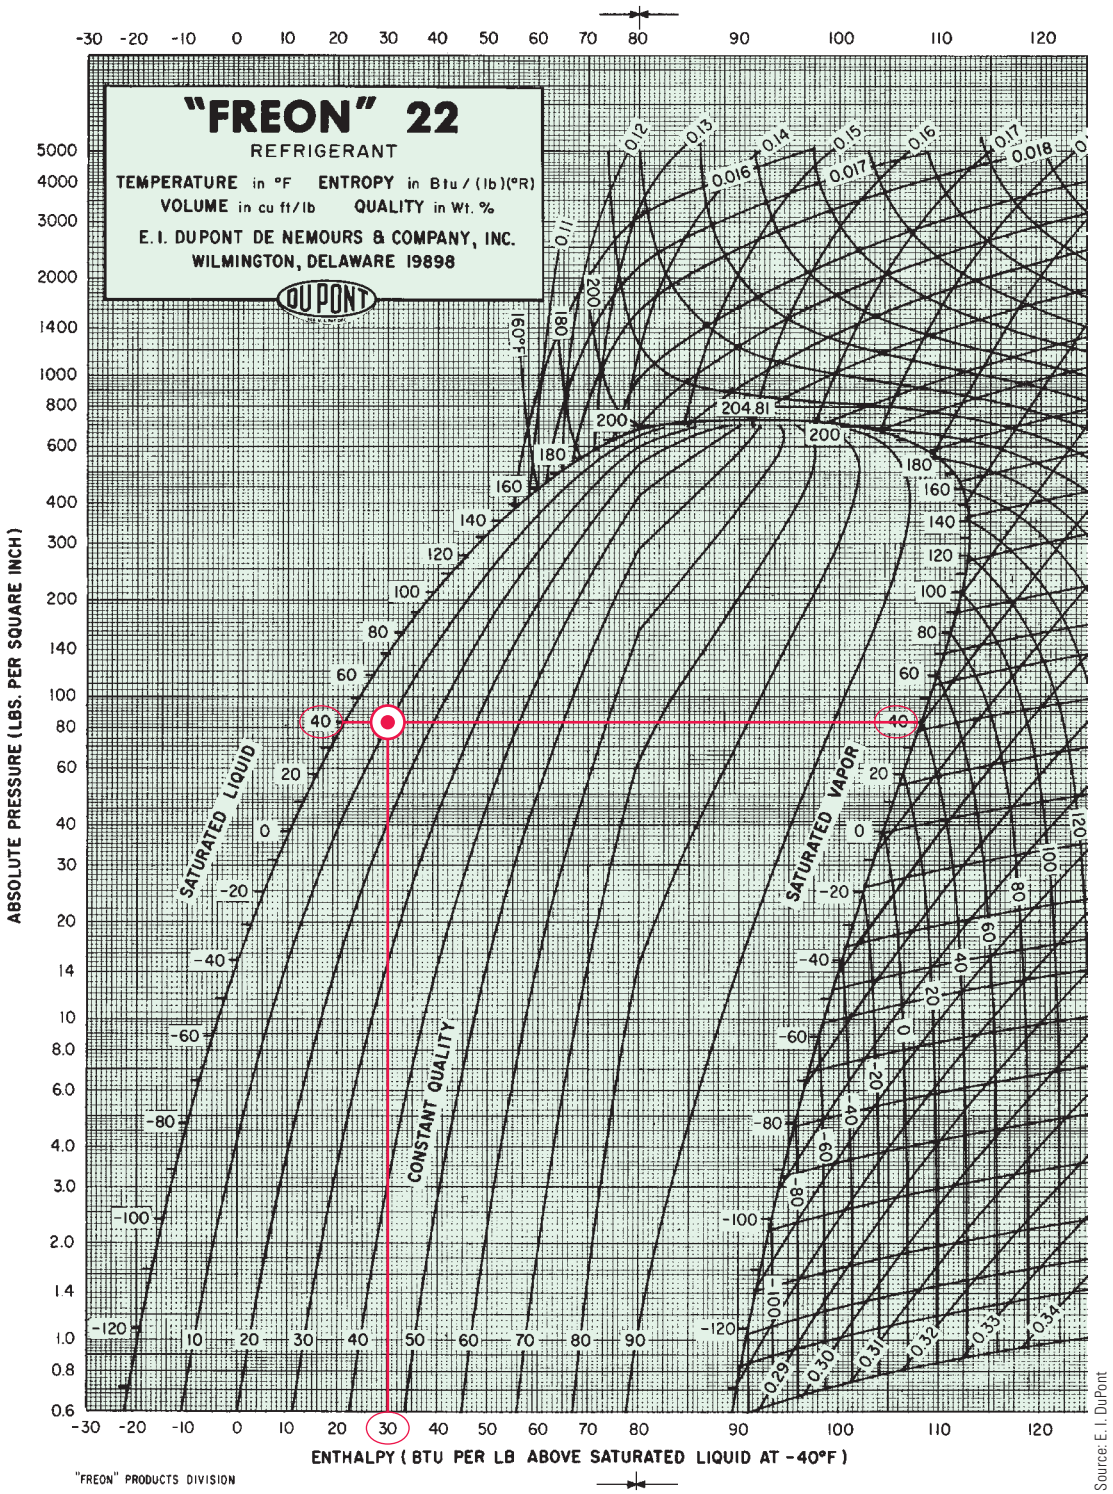
A refrigeration cycle is plotted in **Figure 3.48**. The system to be plotted is an air-conditioning system using R-22. The system is operating at 130°F condensing temperature (296.8 psig or 311.5 psia discharge pressure) and at an evaporating temperature of 40°F (68.5 psig or 83.2 psia suction pressure). The cycle plotted has no subcooling, and 10°F of superheat is absorbed as the refrigerant leaves the evaporator with another 10°F of superheat absorbed by the refrigerant in the suction line as it returns to the compressor. The compressor is air-cooled, and the suction gas enters the suction valve adjacent to the cylinders. Assume that the hot gas line is very short and its heat of rejection is negligible.

The following eight steps summarize the basic refrigeration cycle (refer to **Figure 3.48**):

1. Refrigerant R-22 enters the expansion device as a saturated liquid at 311.5 psia (296 psig) and 130°F, point A. The heat content is 49 Btu/lb entering the expansion valve and 49 Btu/lb leaving the expansion valve. **Figure 3.48** shows the metering device represented by a vertical line. It can therefore be concluded that even though the temperature and pressure of the refrigerant drops as it flows through the metering device, the heat content of the refrigerant remains the same. It is important that heat content (Btu/lb) is not confused with temperature. Note that the temperature of the liquid refrigerant before the valve is 130°F, and the temperature leaving the valve is 40°F. The temperature drop can be accounted for by observing that we have 100% liquid entering the valve and about 70% liquid leaving the valve. About 30% of the liquid has changed to a vapor (flash gas). During the process of evaporating, heat is absorbed from the remaining liquid, lowering its temperature to 40°F. Remember, flash gas does not contribute to the net refrigeration effect. The **net refrigeration effect (NRE)** is expressed in Btu/lb and is the quantity of heat that each pound of refrigerant absorbs from the refrigerated space to produce useful cooling.
2. Flash gas occurs because the refrigerant entering the evaporator from the metering device (130°F) must be cooled to the evaporating temperature (40°F) before the remaining liquid can evaporate in the evaporator and produce useful cooling as part of the net refrigeration effect. The heat needed to flash the liquid came from the liquid itself and not from the conditioned space. No enthalpy is gained or lost in this process, which further explains why the expansion line from point A to point B happened at a constant enthalpy. This expansion process is called *adiabatic expansion* because it happened at a constant enthalpy. Adiabatic processes, by definition, result in temperature and pressure changes with no change in heat content.
3. Usable refrigeration starts at point B where the refrigerant has a heat content of 49 Btu/lb. As heat is added to the refrigerant in the evaporator, the refrigerant gradually changes state to a vapor. Notice that as we move toward the right from point B in a horizontal line, the pressure remains unchanged but the heat content increases. The source of this increase in enthalpy is the heat content in the air being cooled by the evaporator. All liquid has changed to a vapor when it reaches the saturated vapor curve, and a small amount of heat is added to the refrigerant in the form of superheat (10°F). When the refrigerant leaves the evaporator at point C, it contains about 110 Btu/lb. This is a net refrigeration effect of 61 Btu/lb (110 Btu/lb − 49 Btu/lb = 61 Btu/lb) of refrigerant circulated. The net refrigeration effect,

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.46 The quality of saturated R-22 at 40°F and with a heat content of 30 Btu/lb is 10% vapor and 90% liquid.



NRE, is the same as usable refrigeration, the heat actually extracted from the conditioned space. About 10 more Btu/lb are absorbed into the suction line before reaching the compressor inlet at point D. This is not usable refrigeration because the heat does not come from the conditioned space, but is heat that must be pumped by the compressor and rejected by the condenser.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

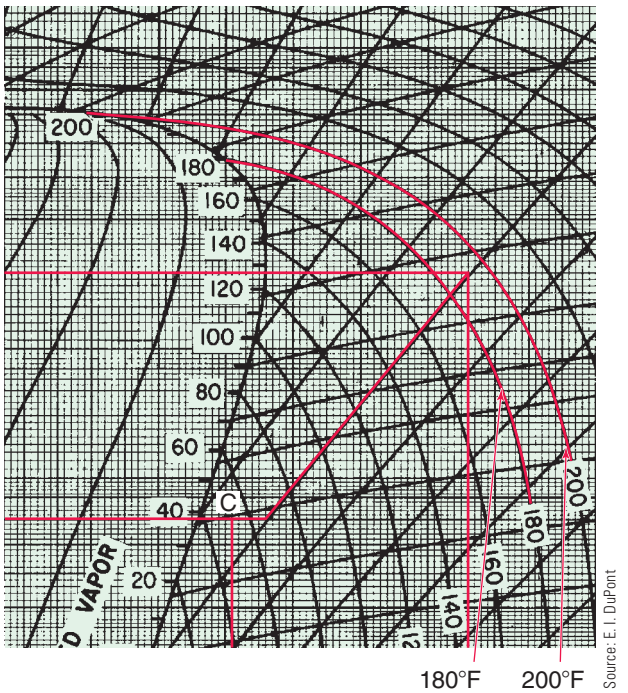
4. The refrigerant enters the compressor at point D and leaves the compressor at point E. No heat has been added in the compressor except heat of compression, because the compressor is air-cooled. Some of the heat of compression will conduct to the head of the compressor and be rejected to the surroundings. The refrigerant enters the compressor cylinder from the suction line. (A fully hermetic compressor with a suction-cooled motor would not plot out just like this. We have no way of knowing how much heat is added by the motor, so we do not know what the temperature of the suction gas entering the compressor cylinder would be for a suction-cooled motor. Manufacturers obtain their own figures for this using internal thermometers during testing.) Notice that the line that represents the compressor is sloped up and to the right. This indicates that both the heat content and the pressure of the refrigerant are increasing.
5. The line that represents the compressor is drawn parallel to another set of lines on the chart that are referred to as lines of constant **entropy**, **Figure 3.47**. Entropy, in our case, represents the compression process and the relationship among the system characteristics of heat content, absolute pressure, and absolute temperature. These lines of constant entropy indicate that during the compression process, the changes in pressure and temperature are predictable. The units of constant entropy are Btu/lb/°R, where °R is an absolute temperature (as mentioned in Unit 1 "Heat, Temperature, and Pressure").
6. The refrigerant leaves the compressor at point E and contains about 127 Btu/lb. At point E, the refrigerant is now at the outlet of the compressor and traveling in the discharge line toward the condenser. This condenser must reject 78 Btu/lb (127 Btu/lb − 49 Btu/lb = 78 Btu/lb), called the *heat of rejection*. Remember that the condenser must reject all of the heat that is absorbed in the evaporator and suction line as well as the heat generated and concentrated in the compressor during the compression process. Therefore, the heat of rejection is also referred to as the *total heat of rejection*, THOR, because the condenser must reject all of the heat introduced to the system.
7. At point E we can also determine the temperature at the outlet of the compressor. We can do this by looking at the position of the point with respect to the lines of constant temperature, which are the downward-sloped, curved lines on the right-hand side of the saturation curve, **Figure 3.49**. The temperature of the discharge gas is about 190°F (see the constant temperature lines for temperature of superheated gas). When the hot gas leaves the compressor, it contains the maximum amount of heat that must be rejected by the condenser.
8. The refrigerant enters the condenser at point E as a highly superheated gas. The refrigerant condensing temperature is 130°F and the hot gas leaving the compressor is 190°F, so it contains 60°F (190°F − 130°F = 60°F) of superheat. The condenser will first reduce the superheat down to the condensing temperature, which falls on the saturated vapor line. (This process is, once again, referred to as desuperheating.) Then, the condenser will condense the refrigerant to a liquid at 130°F for reentering the expansion device at point A, the saturated liquid line, for another trip around the cycle.

Figure 3.49 The compressor discharge temperature can be found by locating point E and its relation to the constant temperature lines. The compressor discharge temperature shown here is 190°F.



The refrigerant cycle in the previous example can be improved by removing some heat from the condensed liquid by subcooling it. This can be seen in **Figure 3.50**, a scaled-up diagram. The same conditions are used in this figure as in **Figure 3.48**, except the liquid is subcooled 20°F (from 130°F condensing temperature to 110°F liquid). The system then has a net refrigeration effect of 68 Btu/lb instead of 61 Btu/lb. This is an increase in capacity of about 11%. Notice that the liquid leaving the expansion valve is only about 23% vapor instead of the 30% vapor in the first example. Also notice that the heat content at the outlet of the metering device is 42 Btu/lb, so the NRE of 68 Btu/lb was determined by subtracting the heat content of 42 Btu/lb at the inlet of the evaporator from the heat content of 110 Btu/lb at the outlet of the evaporator (110 Btu/lb − 42 Btu/lb = 68 Btu/lb). This is a gain in capacity. Less capacity is lost to flash gas, because the subcooled liquid temperature at 110°F is now a bit closer to the evaporator temperature of 40°F.

Other conditions may be plotted on the pressure/enthalpy diagram. For example, suppose the head pressure

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.50 Adding subcooling increases the net refrigeration effect of the system.

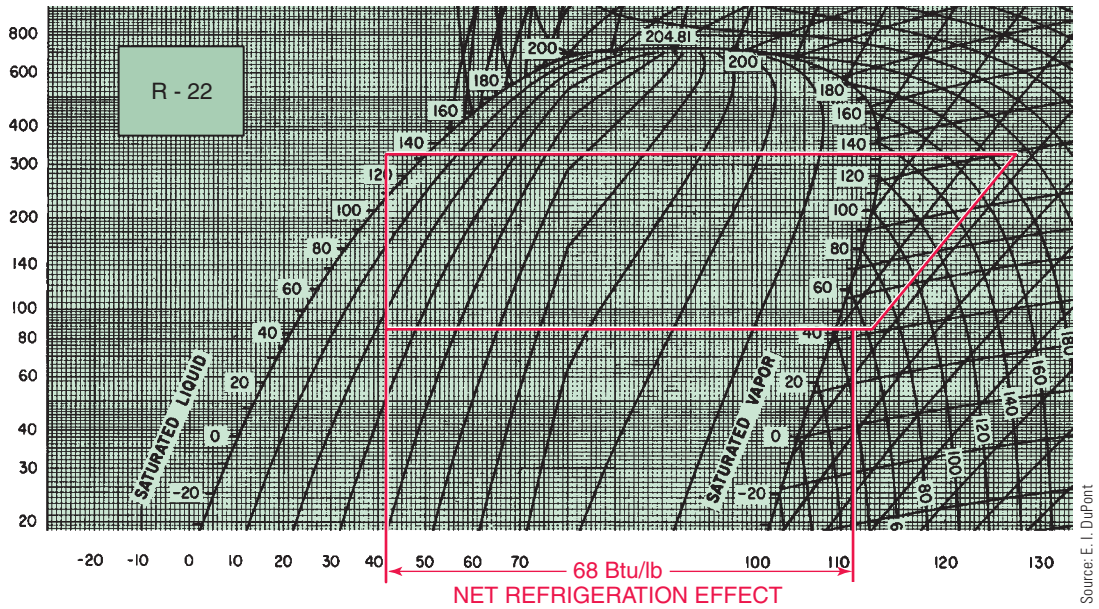


Figure 3.51 A rise in system head pressure will result in a reduction of system capacity.

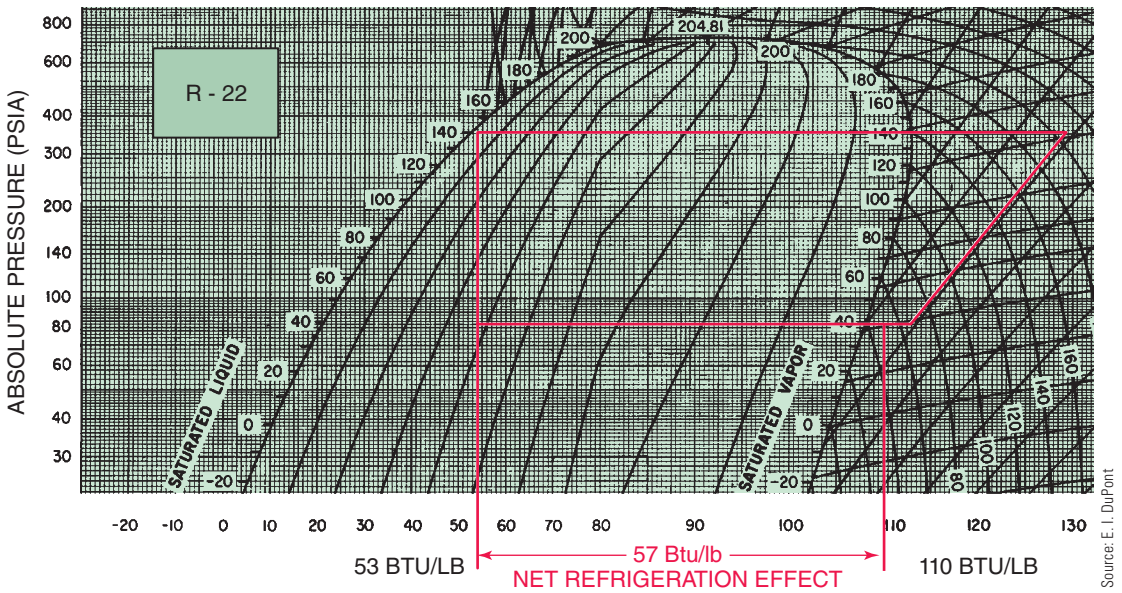
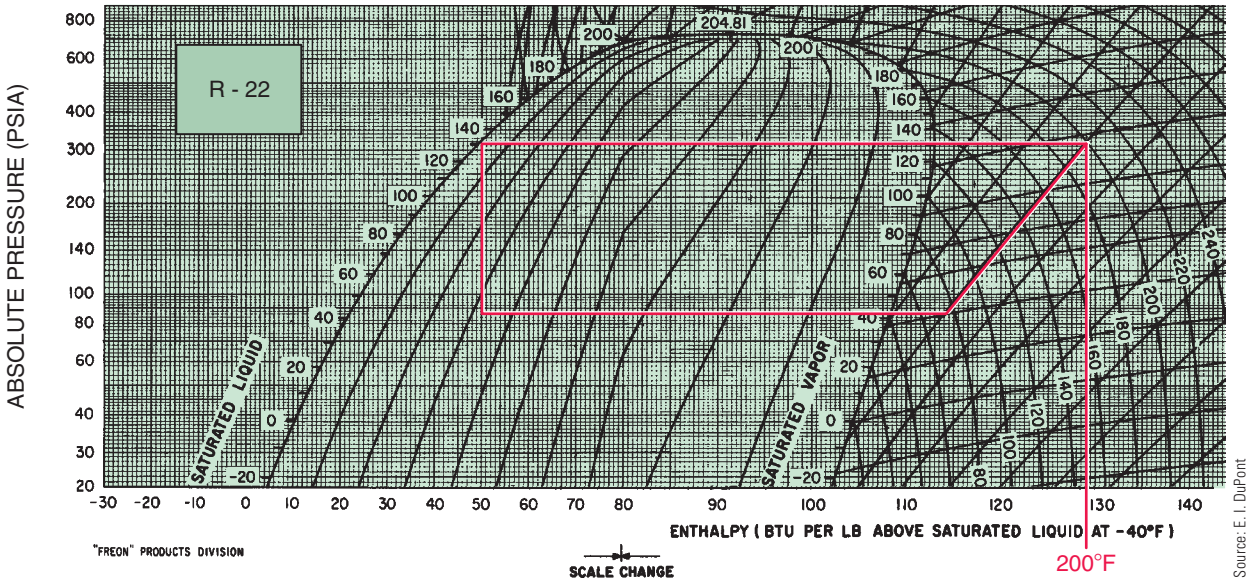


is raised due to a dirty condenser, **Figure 3.51**. Using the first example, **Figure 3.48**, and raising the condensing temperature to 140°F (337.2 psig or 351.9 psia), we see the percentage of liquid leaving the expansion valve to be about 64% (36% flash gas) with a heat content of 53 Btu/lb. Using the same heat content leaving the evaporator, 110 Btu/lb, we have a net refrigeration effect of 57 Btu/lb. This is a net reduction in refrigeration effect of about 7% from the original example, which contained 49 Btu/lb at the same point. This shows the importance of keeping condensers clean.

Figure 3.52 shows how increased superheat affects the first system in **Figure 3.48**. The suction line has not been insulated and absorbs heat. The suction gas may leave the evaporator at 50°F and rise to 75°F before entering the compressor. Notice the high discharge temperature (about 200°F). This is approaching the temperature that will cause oil to break down and form acids in the system. Most compressors must not exceed 225°F. The compressor must pump more refrigerant to accomplish the same refrigeration effect, and the condenser must reject more heat.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.52 An increase in superheat results in an increase in compressor discharge temperature.



Before its manufacturing phase-out date in 1996, R-12 used to be a popular medium-temperature application refrigerant. Environmental issues have caused manufacturers to explore some different refrigerants to replace R-12, namely, R-134a and the newer refrigerant blends. R-134a has a zero ozone depletion potential but has oil compatibility problems and cannot be easily retrofitted into existing R-12 systems. R-134a also suffers in capacity when used in low-temperature applications. (Environmental issues will be covered in Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting.")

The following sequence shows how R-22 performs in a typical medium-temperature application. Follow the description in **Figure 3.53**. **Figure 3.54** is a system diagram of the same system.

1. Refrigerant enters the expansion valve at point A at 100°F, subcooled 15°F from the condensing temperature of 115°F.
2. The refrigerant leaves the expansion valve at point B at 28% vapor and 72% liquid with a heat content of 38 Btu/lb. It then travels through the evaporator.
3. The refrigerant leaves the evaporator at point C in the vapor state with 10° of superheat, a heat content of 108 Btu/lb, and a net refrigeration effect of 70 Btu/lb.
4. Refrigerant vapor enters the compressor at point D at 57°F, containing 37° of superheat. The heat content at the inlet of the compressor, point D, is 113 Btu/lb.
5. The vapor refrigerant is compressed on the line from D to E and leaves the compressor at point E at a temperature of about 180°F. As the condensing temperature of the application becomes higher, the temperature rises. At some point, the designer must decide either to use a different refrigerant or change the application.
6. The heat content at the outlet of the compressor, point E, is 136 Btu/lb. Since the refrigerant entered the compressor with a heat content of 113 Btu/lb, the amount of heat added to the refrigerant during the compression process is 23 Btu/lb (136 Btu/lb − 113 Btu/lb). This is referred to as the *heat of compression* (HOC) for the compressor.
7. An additional 5 Btu/lb was added to the refrigerant in the suction line (113 Btu/lb − 108 Btu/lb). This additional heat is referred to as *suction line superheat* and has a negative effect on system performance and efficiency. The lower the suction line superheat, the higher the system efficiency.

R-134a, a replacement refrigerant for R-12, would plot out on the pressure/enthalpy chart as follows. Use **Figure 3.55** to follow this example.

1. Refrigerant enters the expansion valve at point A at 105°F, subcooled 10° from 115°F.
2. Refrigerant leaves the expansion valve at point B with a heat content of 47 Btu/lb. The quality is 33% vapor with 67% liquid. It then travels through the evaporator.
3. Vapor refrigerant leaves the evaporator at point C with a heat content of 109 Btu/lb and a net refrigeration effect of 62 Btu/lb (109 − 47 = 62).
4. The refrigerant enters the compressor at point D with a superheat of 40° and a heat content of 114 Btu/lb. The vapor is compressed along the line from D to E. *Note the lower discharge temperature of 160°F.*

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.53 An R-22 medium-temperature refrigeration system

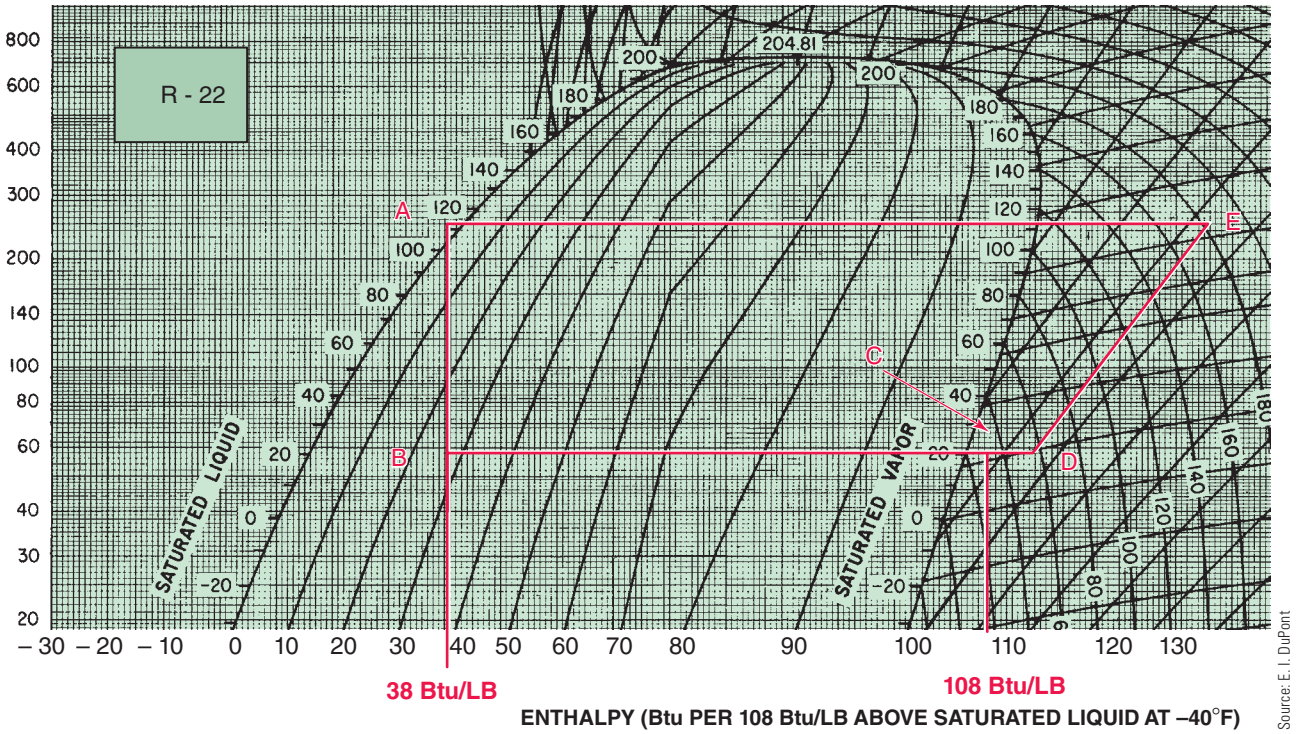


Figure 3.54 A medium-temperature refrigeration system showing operating temperatures and pressures.

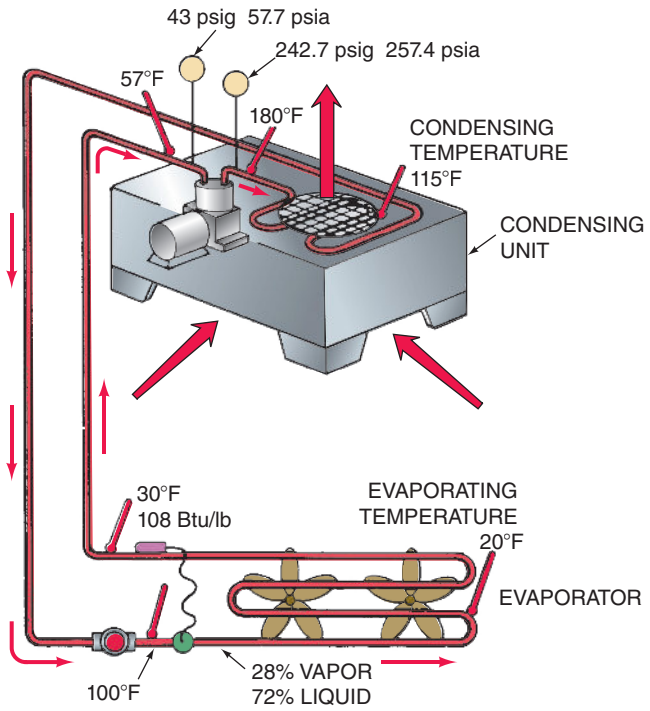


5. The refrigerant leaves the compressor at point E with a heat content of 130 Btu/lb. The HOC for this system is 16 Btu/lb.
6. The refrigerant is then desuperheated 45°F from point E to the saturated vapor line.
7. The refrigerant is now gradually condensed from the saturated vapor line to the saturated liquid line at 115°F. This is the *latent heat of condensation* being rejected.
8. The saturated liquid is now subcooled from the saturated liquid line to point A. It is subcooled 10° (115°F – 105°F) until it enters the metering device at 105°F. The process then repeats itself.

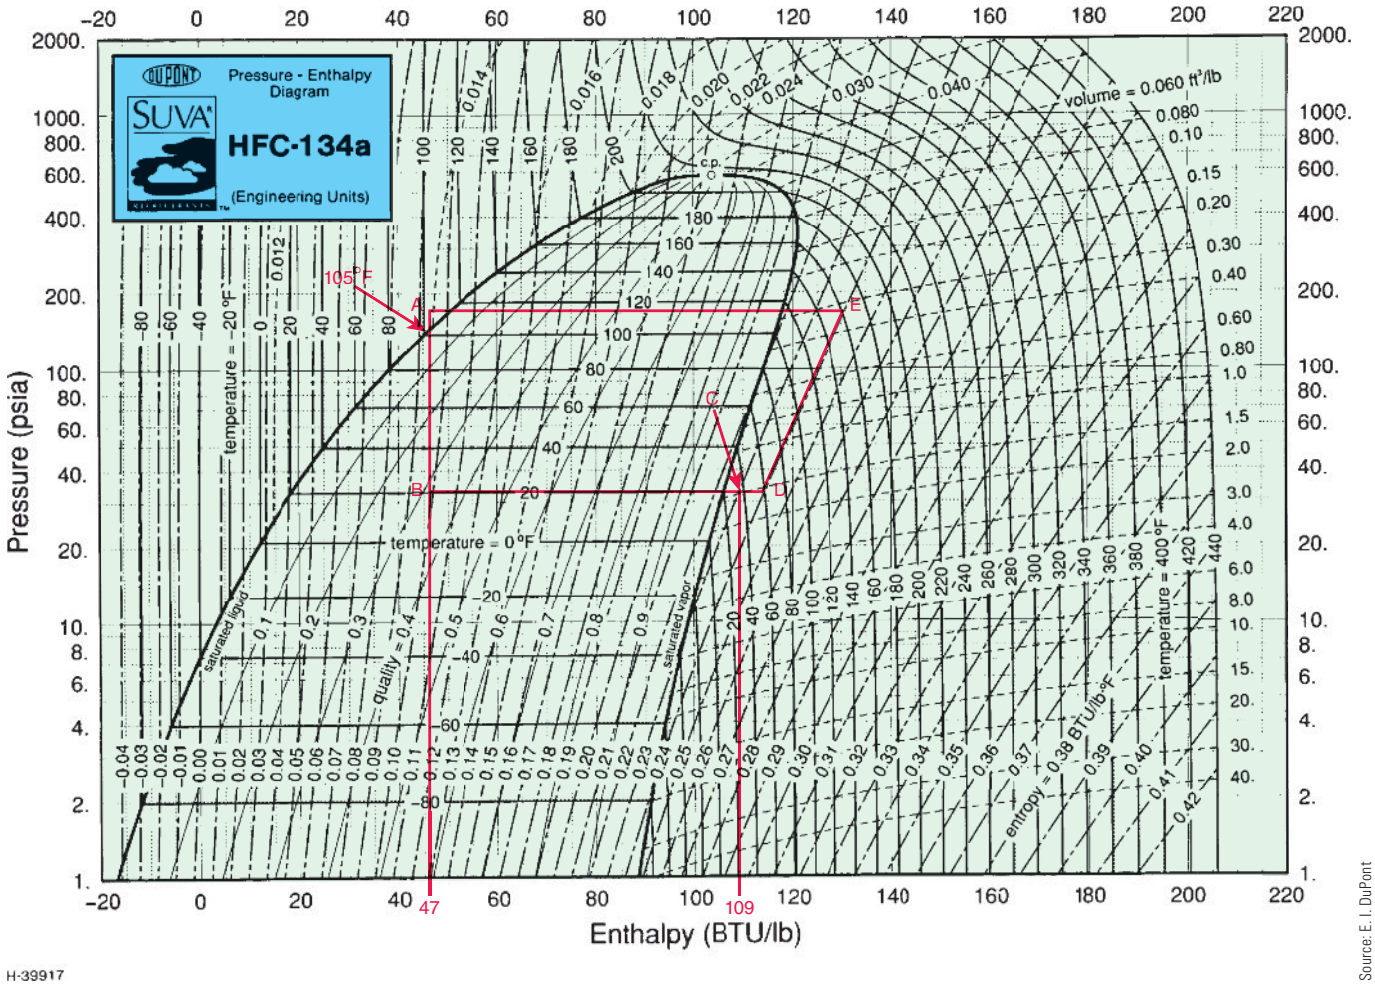
Another comparison of refrigerants may be made using low temperature as the application. Here we will see much higher discharge temperatures and see why some decisions about various refrigerants are made. We will use a condensing temperature of 115°F and an evaporator temperature of −20°F and compare R-502 to R-22.

R-502 has been used for many low-temperature applications to prevent the system from operating in a vacuum on the low-pressure side. Follow the same conditions using R-502 in **Figure 3.56.**

1. Refrigerant enters the expansion valve at 105°F, subcooled from 115°F and 48% vapor, 52% liquid. The heat content is 38 Btu/lb.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.55 An R-134a pressure/enthalpy diagram.



2. The remaining vapor is evaporated and 10° of superheat is added by the time the vapor reaches point C. The heat content rises to 78 Btu/lb, and the NRE is 40 Btu/lb.
3. The vapor enters the compressor at point D and is compressed to point E, where the vapor leaves the compressor at 160°F.
4. The refrigerant is then desuperheated, condensed, and subcooled from points E to A.
5. Notice that the suction pressure is 15.3 psig (30 psia) for R-502 while boiling at −20°F. R-502 will not go into a vacuum until the temperature is −50°F. Because of this R-502 is very good for low-temperature applications. It also has a very acceptable discharge gas temperature.

As an exercise, verify the following:

- Heat content at the inlet of the compressor is 80 Btu/lb.
- Heat content at the outlet of the compressor is 98 Btu/lb.
- Heat of compression, HOC, is 18 Btu/lb.

R-22 is being used for many low-temperature applications because R-502 has been phased out due to the CFC/ozone depletion issue. However, even R-22 will have a manufacturing phase-out date of 2020. R-22 has the problem of high discharge gas temperature. **Figure 3.57** shows a plot of the low-temperature application above using R-22. Use the following sequence:

1. The refrigerant enters the expansion valve at point A at 105°F, subcooled from 115°F, just as in the preceding problem. At the inlet of the evaporator, the refrigerant has a heat content of 40 Btu/lb. The refrigerant leaves the evaporator at point C with a heat content of 104 Btu/lb. The temperature at the outlet of the evaporator is −10°F, so the evaporator is operating with 10° of superheat. The NRE for this evaporator is 64 Btu/lb (104 Btu/lb − 40 Btu/lb).
2. The refrigerant is evaporated to a vapor at −20°F and enters the compressor at point D at a temperature of 20°F. Notice that R-22 boils at 10.1 psig at −20°F. It

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.56 An R-502 low-temperature refrigeration system.

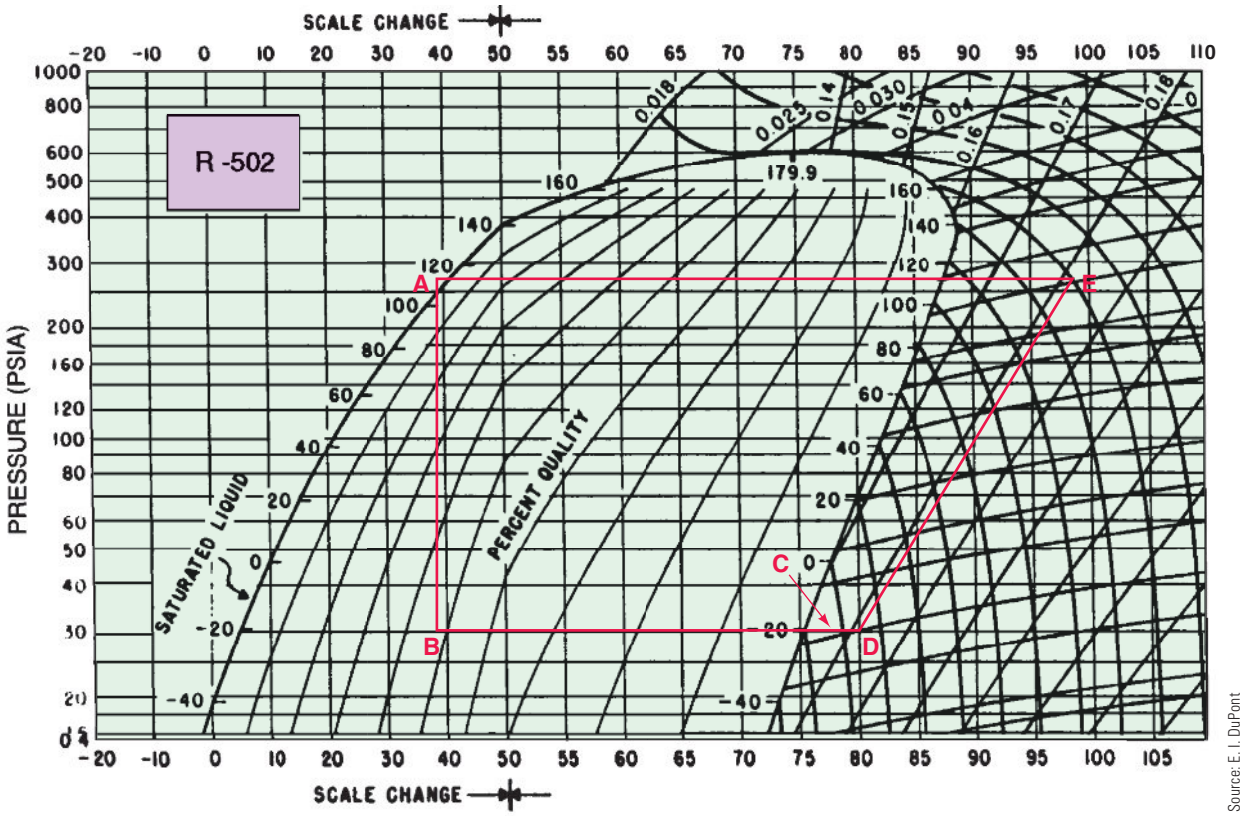


Figure 3.57 An R-22 low-temperature refrigeration system.

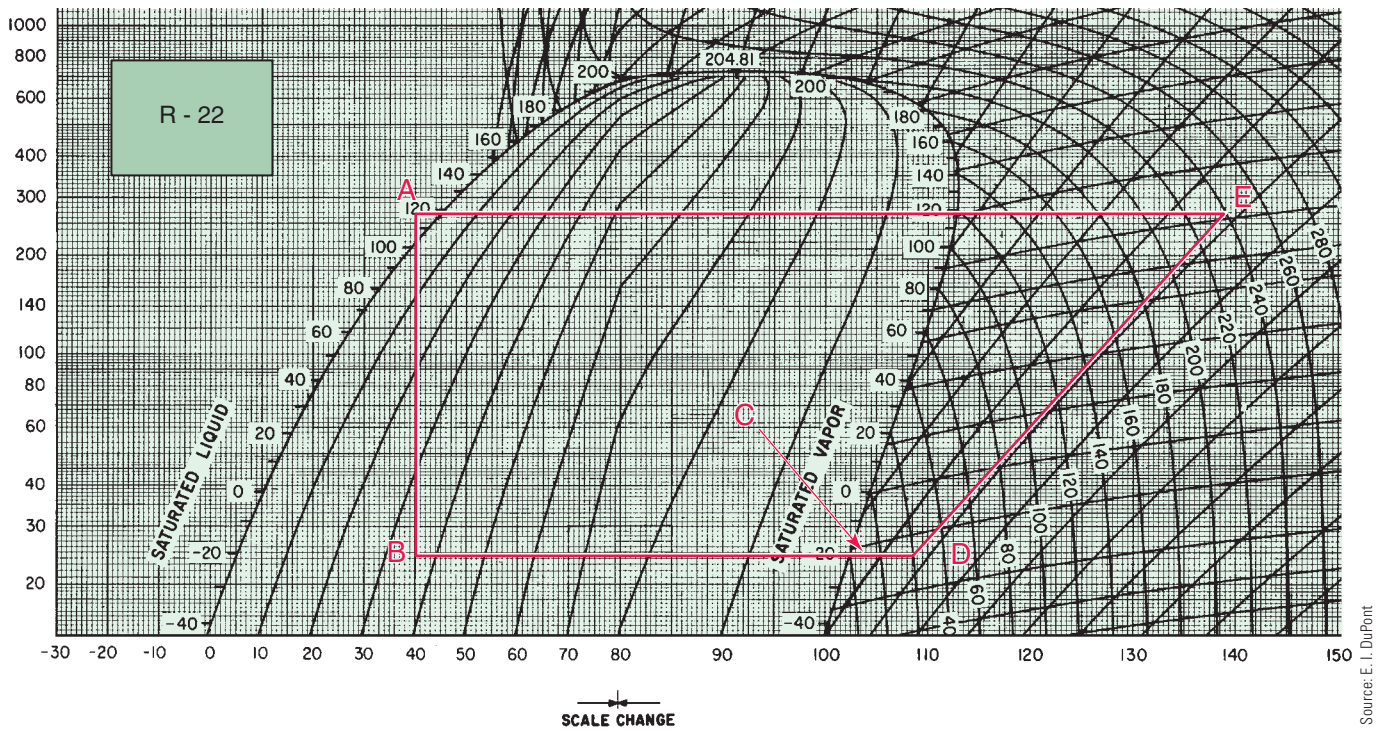


Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

is in a positive pressure. Evaporators using R-22 can be operated down to −41°F before the suction pressure goes into a vacuum. The heat content at the inlet of the compressor is 110 Btu/lb.

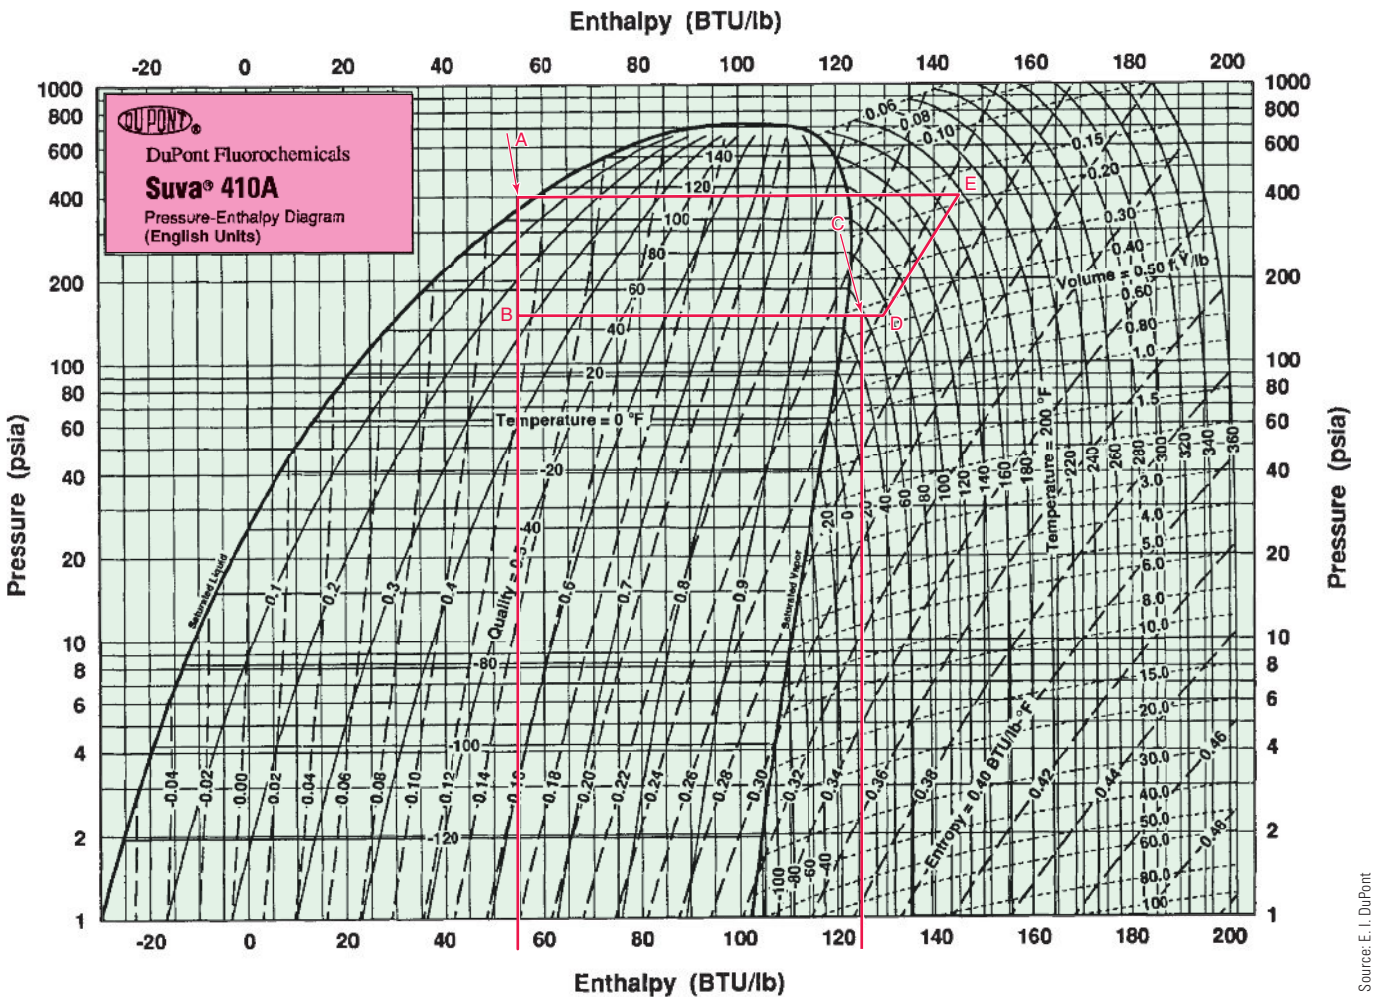
3. The vapor is compressed along line D to E, where it leaves the compressor at point E at a temperature of 240°F. Remember, R-502 had a discharge temperature of 160°F under the same conditions. R-22 is much hotter. A 240°F discharge temperature can be worked with but is close to being too high. Any increase in discharge temperature due to a dirty condenser can cause serious system problems. The heat content at the outlet of the compressor is 138 Btu/lb and the HOC is 28 Btu/lb.
4. The vapor leaves the compressor at point E, where it is desuperheated, condensed, and subcooled to point A.

As mentioned earlier in this unit, R-22 was phased out in new equipment in 2010, and total production will be phased out in 2020. A long-term replacement refrigerant for R-22 in new equipment is R-410A. **Figure 3.58** shows an air-conditioning system plotted on a pressure/enthalpy chart incorporating R-410A as the refrigerant. The system is a high-efficiency air-conditioning system operating with a 45°F (130 psig) evaporating temperature and a 115°F (390 psig) condensing temperature. Notice the higher pressures associated with R-410A compared to an R-22 system. For more detailed information on refrigerants, refer to Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting."

Follow the steps below.

1. The refrigerant enters the expansion valve at point A at 105°F, subcooled 10°F from the 115°F condensing temperature.
2. The refrigerant leaves the expansion valve at point B at 45°F (27% vapor and 73% liquid) to be totally evaporated in the evaporator. Because R-410A has such a small temperature glide (0.3°F), the temperature glide

Figure 3.58 An R-410A air-conditioning system.



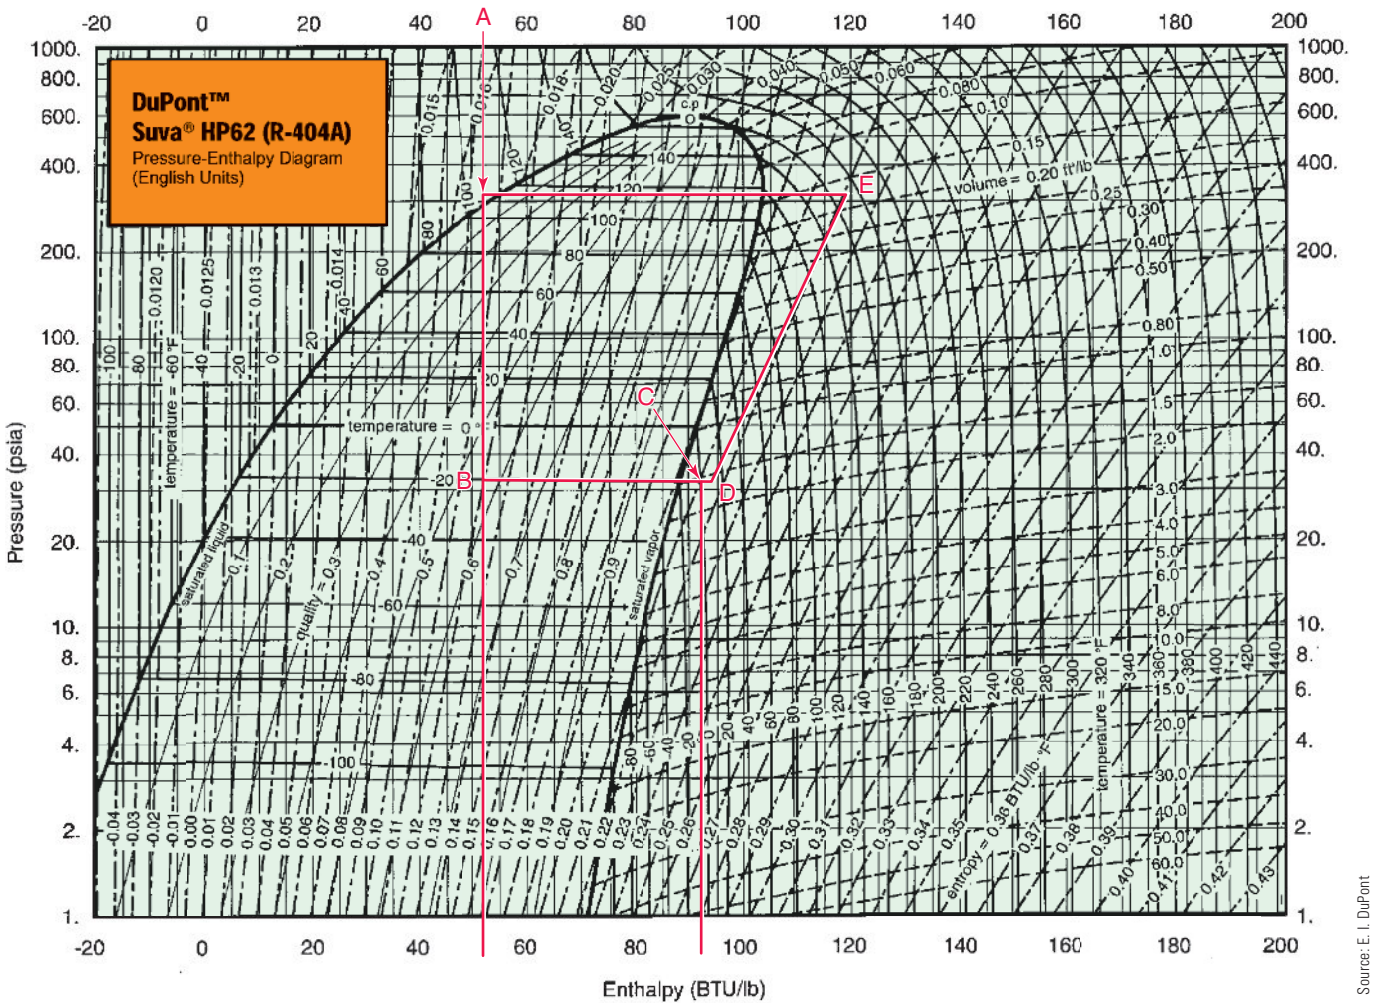
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

can be ignored in most air-conditioning applications involving pressure/temperature relationships.

3. At point C, the refrigerant leaves the evaporator as 100% vapor with 10°F of evaporator superheat and at a temperature of 55°F. The difference in enthalpy between point B and point C is the net refrigeration effect.
4. The superheated vapor now enters the compressor at point D with 30°F of total superheat and at a temperature of 75°F. The superheated vapor is now compressed to 180°F along the line to point E.
5. The superheated vapor leaves the compressor at point E. The refrigerant is now desuperheated from point E to the saturated vapor line.
6. The now saturated refrigerant is gradually condensed from the saturated vapor line to the saturated liquid line at 115°F. This is referred to as rejection of the latent heat of condensation.
7. The saturated liquid is now subcooled 10°F (115°F − 105°F) from the saturated liquid line to point A, where it enters the metering device at 105°F. The process then repeats itself.

As mentioned earlier, R-502 was used primarily in medium- and low-temperature refrigeration applications. Its manufacture was banned in 1996. R-502 is an azeotropic refrigerant blend with negligible temperature glide, and it behaves like a pure compound. R-404A is its long-term replacement refrigerant and has a slightly higher working pressure than R-502. **Figure 3.59** shows a low-temperature refrigeration system plotted on a pressure/enthalpy chart incorporating R-404A as the refrigerant. The system is a commercial freezer operating with an evaporating temperature of −20°F (16.7 psig) and a 115°F (290 psig) condensing temperature.

Figure 3.59 An R-404A low-temperature refrigeration system.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Follow the sequence below.

1. The refrigerant enters the expansion valve at point A at 105°F, subcooled 10°F from the 115°F condensing temperature.
2. The refrigerant leaves the expansion valve at point B at −20°F (55% vapor and 45% liquid) to be totally evaporated in the evaporator. At point C, the refrigerant leaves the evaporator as 100% vapor with 10°F of evaporator superheat and at a temperature of −10°F. The difference in enthalpy between point B and point C is the net refrigeration effect.
3. The superheated vapor enters the compressor at point D with 30°F of total superheat and at a temperature of 10°F. The superheated vapor is now compressed to 170°F along the line to point E.
4. The superheated vapor leaves the compressor at point E. The refrigerant is now desuperheated from point E to the saturated vapor line.
5. The now saturated refrigerant is gradually condensed from the saturated vapor line to the saturated liquid line at 115°F. This is referred to as rejection of the latent heat of condensation.
6. The saturated liquid is subcooled 10°F (115°F − 105°F) from the saturated liquid line to point A, where it enters the metering device at 105°F. The process then repeats itself.

Pressure/enthalpy diagrams are useful for establishing the various conditions around the refrigerant cycle system. They are partially constructed from properties shown in refrigerant tables. **Figure 3.60** is a page from a typical table for R-22.

Column 1 is the temperature corresponding to the pressure columns for the saturation temperature. Column 5 lists the specific volume for the saturated vapor refrigerant in cubic feet per pound. For example, at 60°F, the compressor must pump 0.46523 ft^3 of refrigerant to circulate 1 lb of refrigerant in the system. The specific volume along with the net refrigeration effect help the engineer determine the compressor's pumping capacity. The example in **Figure 3.48** using R-22 had a net refrigeration effect of 61 Btu/lb of refrigeration circulated. If a system needed to circulate enough refrigerant to absorb 36,000 Btu/h (3 tons of refrigeration), it would need to circulate 590.2 lb of refrigerant per hour (36,000 Btu/h divided by 61 Btu/lb = 590.2 lb/h). If the refrigerant entered the compressor at 60°F, the compressor must move 275 ft^3 of refrigerant per hour (590.2 lb/h × 0.46523 ft^3/lb = 275 ft^3/h). (There is a slight error in this calculation because the 0.46523 ft^3/h is for saturated refrigerant and the vapor is superheated entering the compressor. Superheat tables are available but will only complicate this calculation and the error is quite small.) Many compressors are rated in cubic feet per minute, so this compressor would need to pump 4.58 ft^3/min (275 ft^3/h ÷ 60 min/h = 4.58 ft^3/min).

The density portion of the table tells the engineer how much a particular volume of liquid refrigerant will weigh at the rated temperature. For example, 1 ft^3 of R-22 weighs 76.773 lb when the liquid temperature is 60°F. This is important for determining the weight of refrigerant in components, such as evaporators, condensers, and receivers. The enthalpy portion of the table (total heat) lists the heat content of the liquid and vapor and the amount of latent heat required to boil 1 lb of liquid to a vapor. For example, at 60°F, saturated liquid refrigerant would contain 27.172 Btu/lb compared with 0 Btu/lb at −40°F. It would require 82.54 Btu/lb to boil 1 lb of 60°F saturated liquid to a vapor. The saturated vapor would then contain 109.712 Btu/lb total heat (27.172 + 82.54 = 109.712). The entropy column is of no practical value except on the pressure/enthalpy chart, where it is used to plot the compressor discharge temperature.

These charts and tables are not normally used in the field for troubleshooting but are intended for engineers to use in designing equipment. They do, however, help the technician understand the refrigerants and the refrigerant cycle. Different refrigerants have different temperature/pressure relationships and enthalpy relationships. These all must be considered by the engineer when choosing the correct refrigerant for a particular application. A complete study of each refrigerant and how it compares to all other refrigerants is helpful, but you do not need to understand the complete picture to successfully perform in the field. A complete study and comparison is beyond the scope of this book.

3.21 PLOTTING THE REFRIGERANT CYCLE FOR BLENDS WITH NOTICEABLE TEMPERATURE GLIDE (ZEOTROPIC BLENDS)

Temperature glide occurs when the refrigerant blend has many temperatures as it evaporates or condenses at a given pressure. The pressure/enthalpy diagram for refrigerants with temperature glide differs from that for refrigerants that do not have temperature glide. **Figure 3.61** illustrates a skeletal pressure/enthalpy diagram for a refrigerant blend with temperature glide. Notice that the lines of constant temperature (isotherms) are not horizontal, but are angled downward as they travel from saturated liquid to saturated vapor. As you follow the lines of constant pressure (isobars) straight across from saturated liquid to saturated vapor, more than one isotherm will be intersected. Thus, for any one pressure (evaporating or condensing), there will be a range of associated temperatures—a temperature glide. For example, in **Figure 3.61**, for a constant pressure of 130 psia, the temperature glide is 10°F (70°F − 60°F). The isobar of 130 psia intersects both the 60°F and the 70°F isobars as it travels from saturated liquid to saturated vapor.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 3.62 illustrates an actual pressure/enthalpy diagram for refrigerant R-407C, a zeotropic refrigerant blend with very similar properties to those of R-22 in air-conditioning equipment. It is a blend of R-32, R-125, and R-134a with a fairly large temperature glide (10°F) in the ranges of air-conditioning applications. Notice the isotherms angled downward from left to right, showing temperature glide.

The terms near-azeotropic and zeotropic refrigerant blends are used in the HVACR industry because they describe temperature glide and fractionation. Azeotropic blends have negligible franctionation and temperature glide, near-azeotropic blends have some fractionation and temperature glide, while zeotropic blends have the most fractionation and temperature glide. Refer to Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting," for more in-depth information on refrigerants, refrigerant blends, temperature glide, and fractionation. Charging methods for refrigerant blends will be covered in Unit 10, "System Charging." **SAFETY PRECAUTION:** *All refrigerants that have been discussed in this text are stored in pressurized containers and should be handled with care. Consult your instructor or supervisor about the use and handling of these refrigerants. Goggles and gloves should be worn while transferring the refrigerants from the container to the system.*•

SUMMARY

- Bacterial growth that causes food spoilage slows at low temperatures.
- Refrigeration of products at temperatures above 45°F and below room temperature is considered high-temperature refrigeration.
- Refrigeration of products at temperatures between 35°F and 45°F is considered medium-temperature refrigeration.
- Refrigeration of products at temperatures from 0°F to −10°F is considered low-temperature refrigeration.
- Refrigeration is the process of removing heat from a place where it is not wanted and transferring it to a place where it makes little or no difference.
- One ton of refrigeration is the amount of heat necessary to melt 1 ton of ice in a 24-hour period. It takes 288,000 Btu to melt 1 ton of ice in a 24-hour period, or 12,000 Btu in 1 h, or 200 Btu in 1 min.
- The relationship of the vapor pressure to the boiling point temperature is called the temperature/pressure relationship.
- A compressor can be considered a vapor pump. It lowers the pressure in the evaporator to the desired temperature and increases the pressure in the condenser to a level where the vapor may be condensed to a liquid.
- Liquid refrigerant moves from the condenser to the metering device, where it again enters the evaporator.
- Refrigerants have a definite chemical makeup and are usually designated with an "R" and a number for field identification.
- A refrigerant must be safe, detectable, environmentally friendly, have a low boiling point, and have good pumping characteristics.
- Refrigerant cylinders are color-coded to indicate the type of refrigerant they contain.
- Refrigerants should be recovered or stored while a refrigeration system is being serviced, then recycled, if appropriate, or sent to a manufacturer to be reclaimed.
- Pressure/enthalpy diagrams may be used to plot refrigeration cycles.

REVIEW QUESTIONS

1. Name three reasons why ice melts in an icebox: _____, _____, _____.
2. What are the approximate temperature ranges for low-, medium-, and high-temperature refrigeration applications?
3. One ton of refrigeration is
   A. 1200 Btu.
   B. 12,000 Btu/h.
   C. 120,000 Btu.
   D. 120,000 Btu/h.
4. Describe briefly the basic refrigeration cycle.
5. What is the relationship between pressure and the boiling point of liquids?
6. What is the function of the evaporator in a refrigeration or air-conditioning system?
7. What does the compressor do in the refrigeration system?
8. Define a superheated vapor.
9. The evaporating pressure is 76 psig for R-22 and the evaporator outlet temperature is 58°F. What is the evaporator superheat for this system?
   A. 13°F
   B. 74°F
   C. 18°F
   D. 17°F

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

10. If the evaporating pressure was 76 psig for R-22 and the compressor inlet temperature was 65°F, what would be the total superheat entering the compressor?
    A. 11°F
    B. 21°F
    C. 10°F
    D. 20°F
11. Define the term *subcooled liquid*.
12. The condensing pressure is 260 psig and the condenser outlet temperature is 108°F for R-22. By how many degrees is the liquid subcooled in the condenser?
    A. 12°F
    B. 42°F
    C. 7°F
    D. 14°F
13. The condensing pressure is 260 psig and the metering device inlet temperature is 100°F for R-22. What is the total subcooling in this system?
    A. 15°F
    B. 20°F
    C. 25°F
    D. 30°F
14. What is meant by a saturated liquid and vapor?
15. What is meant by desuperheating a vapor?
16. What happens to the refrigerant in the condenser?
17. What happens to refrigerant heat in the condenser?
18. The metering device
    A. cycles the compressor.
    B. controls subcooling.
    C. stores refrigerant.
    D. meters refrigerant.
19. What is adiabatic expansion?
20. Describe flash gas, and tell how it affects system capacity.
21. Quality means _____ when referring to a refrigerant.
22. Describe the difference between a reciprocating compressor and a rotary compressor.
23. List the cylinder color codes for R-12, R-22, R-502, R-134a, R-11, R-401A, R-402B, R-410A, R-404A, and R-407C.
24. Define enthalpy.
25. Define a pure compound refrigerant, and give two examples.
26. Define net refrigeration effect as it applies to the refrigeration cycle.
27. Define heat of compression, and explain how it is computed.
28. Define flash gas, and explain how it applies to the net refrigeration effect of the refrigeration cycle.
29. Define temperature glide as it pertains to a refrigerant blend.
30. Define a zeotropic refrigerant blend, and give an example.
31. Define a near-azeotropic refrigerant blend, and give two examples.

GENERAL SAFETY PRACTICES

OBJECTIVES

After studying this unit, you should be able to

- describe proper procedures for working with pressurized systems and vessels, electrical energy, heat, cold, rotating machinery, and chemicals; for moving heavy objects; and for utilizing proper ventilation.

The heating, air-conditioning, and refrigeration technician works close to many potentially dangerous situations: liquids and gases under pressure, electrical energy, heat, cold, chemicals, rotating machinery, the moving of heavy objects, and areas needing ventilation. The job must be completed in a manner that is safe for the technician and the public.

This unit describes some general safety practices and procedures with which all technicians should be familiar. Whether in a school laboratory, a shop, a commercial service shop, or a manufacturing plant, always be familiar with the location of emergency exits and first aid and eyewash stations. When you are on the job, be aware of how you would get out of a building or particular location should an emergency occur. Know the location of first aid kits and first aid equipment. Many other more specific safety practices and tips are given in other units where they may be applicable. Always use common sense and be prepared.

All tools of the trade have limitations. The technician should make it a practice to know what these limitations are by reading the manufacturer's literature. If you have the feeling that you are going beyond the manufacturer's limitations, you probably are and should not proceed. Improper use of tools can cause property damage and personal injury.

Safety goggles are one of the most overlooked safety devices in the industry. Flying debris can cause an eye injury before a person can react, so it is good practice to wear goggles anytime the possibility of injury exists. Even when good work practices are followed, accidents do happen. It would be a good practice for every technician to take a class in cardiopulmonary resuscitation (CPR). Classes are offered by many schools and the Red Cross.

Technicians should always be professional and not play on the job; countless mistakes have been made while playing around. It may seem like fun, until someone gets hurt. Remember, you may involve someone else in the problem if you are working at their place of business or home when an accident occurs.

4.1 PRESSURE VESSELS AND PIPING

Pressure vessels and piping are part of many systems that are serviced by refrigeration and air-conditioning technicians. For example, a cylinder of R-22 in the back of an open truck with the sun shining on it may have a cylinder temperature of 110°F on a summer day. The temperature/pressure chart indicates that the pressure inside the cylinder at 110° is 226 psig. This pressure reading means that the cylinder has a pressure of 226 lb for each square inch of surface area. A large cylinder may have a total area of 1500 in^2. This gives a total inside pressure (pushing outward) of

$$1500\ in^2 \times 226\ psi = 339{,}000\ lb$$

This is equal to

$$339{,}000\ lb \div 2000\ lb/ton = 169.5\ tons$$

See **Figure 4.1**. This pressure is well contained and will be safe if the cylinder is protected. Do not drop it. **SAFETY PRECAUTION:** *Move the cylinder only while a protective cap is on it, if it is designed for one,* **Figure 4.2.** • Cylinders too large to be carried should be moved chained to a cart, **Figure 4.3**. If a refrigerant cylinder ever falls off the moving cart, the protective cap will protect the valve from breaking off and becoming a projectile. The cylinder will have a tendency to rock back and forth when it falls because of the momentum of the dense liquid contained within it. It is this rocking action that may cause the valve to break off. If the cylinder falls accidentally, the protective cap will also prevent the vaporization of all the liquid in the cylinder, which can displace the air we breathe and cause death or personal injury. The air is displaced because the refrigerant vapor is denser than the air. The protective cap must be secured.

The pressure in a cylinder can be thought of as a potential danger. It will not become dangerous unless it is allowed to escape in an uncontrolled manner. The cylinder has a relief valve at the top in the vapor space, **Figure 4.4(A)**. If the

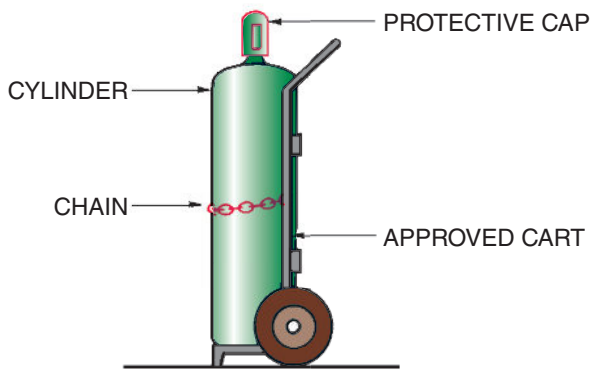
Figure 4.3 Pressurized cylinders should be chained to and moved safely on an approved cart.



pressure builds up to the relief valve setting, the valve will start relieving vapor. As the vapor pressure is relieved, the liquid in the cylinder will begin to vaporize and absorb heat from the surrounding liquid, producing a cooling effect. This will reduce the pressure in the cylinder, **Figure 4.4(B)**. Relief valve settings are set at values above the worst typical operating conditions and are typically more than 400 psig.

The refrigerant cylinder has a fusible plug made of a material with a low melting temperature. The plug will melt and blow out if the cylinder gets too hot. This prevents the cylinder from bursting and injuring personnel and property around it.

SAFETY PRECAUTION: *Refrigerant cylinders should be stored and transported in the upright position to keep the pressure relief valve in contact with the vapor space, not the liquid inside the cylinder. Some technicians may apply heat to refrigerant cylinders while charging*

a system to keep the pressure from dropping in the cylinder. This is an extremely dangerous practice. It is recommended for the above purpose that the cylinder of refrigerant be set in a container of warm water with a temperature no higher than 90°F, **Figure 4.5.**•

Figure 4.5 A refrigerant cylinder in warm water (not warmer than 90°F).

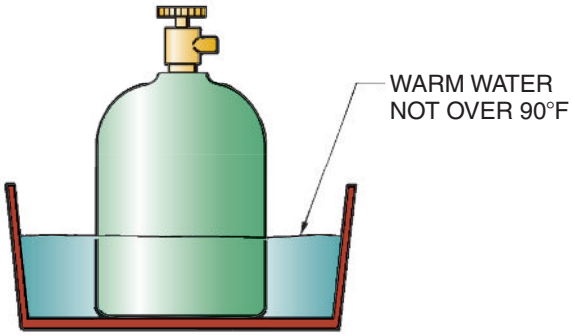

Figure 4.6 (A) Protective side-shield eye goggles. (B) Modern wraparound, tinted safety glasses.

(B)

You will be taking pressure readings of refrigeration and air-conditioning systems. Liquid R-22 boils at −41°F when it is released to the atmosphere. If you are careless and get this refrigerant on your skin or in your eyes, it will quickly cause frostbite. Keep your skin and eyes away from any liquid refrigerant. When you attach gauges and take refrigerant pressure readings or transfer refrigerant into or out of a system, wear gloves and side-shield goggles. **Figure 4.6(A)** is a photo of protective eye goggles. **SAFETY PRECAUTION:** *If a leak develops and refrigerant is escaping, the best thing to do is stand back and look for a valve with which to shut it off. Do not try to stop it with your hands.*•

Released refrigerant, and any particles that may become airborne with the blast of vapor, can harm the eyes. Wear approved goggles, which are vented to keep them from fogging over with condensation and which help keep the operator cool, **Figure 4.6(A)**. Modern wraparound, tinted safety glasses may also be worn to protect the eyes from particles and refrigerant, **Figure 4.6(B)**.

SAFETY PRECAUTION: *All cylinders into which refrigerant is transferred should be approved by the Department of Transportation as recovery cylinders.* **Figure 4.7** *shows cylinders with color codes that indicate they are approved as recovery cylinders—gray bodies with yellow tops. It is against the law to transport refrigerant in nonapproved cylinders.*•

In addition to the pressure potential inside a refrigerant cylinder, there is tremendous pressure potential inside

Figure 4.7 Color-coded refrigerant recovery cylinders. The bodies of the cylinders are gray; the tops are yellow.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

nitrogen and oxygen cylinders. They are shipped at pressures of 2500 psig and must not be moved unless the protective cap is in place. They should be chained to and moved on carts designed for the purpose, as shown previously in **Figure 4.3**. Dropping a cylinder without the protective cap may break the valve off the cylinder, and the pressure inside can propel the cylinder like a balloon full of air that is turned loose, **Figure 4.8**.

The pressure of nitrogen must also be regulated before it can be used, **Figure 4.9,** because the pressure in the cylinder is too great to be connected to a system. If a person allowed nitrogen under cylinder pressure to enter a refrigeration system, some weak point in the system could burst, which could be particularly dangerous if it were at the compressor shell. **Figure 4.9** shows nitrogen tank pressure of approximately 2200 psi being regulated down to about 130 psi. Notice the downstream safety pressure relief valve that protects the system and the operator.

Oxygen also must be regulated because of high pressure. In addition, all oxygen lines must be kept absolutely oil free. Oil residue in an oxygen regulator connection may cause an explosion, which may blow the regulator apart in your hand. **SAFETY PRECAUTION:** *Oxygen is under a great deal of pressure but should never be used as a pressure source to pressurize lines or systems. If there is oil or oil residue in the system, adding oxygen to pressurize them will lead to an explosion.*•

Oxygen is often used with acetylene. Acetylene cylinders are not under the same high pressure as nitrogen and oxygen but must be treated with the same respect because acetylene is highly explosive. A pressure-reducing regulator must be used, **Figure 4.10**. Always use an approved cart, chain the cylinder to the cart, and secure the protective cap (refer again to **Figure 4.3**). All stored cylinders must be supported so they will not fall over, and they must be separated as required by code, **Figures 4.11(A)** and **(B).**

Figure 4.8 When a cylinder valve is broken off, the cylinder becomes a projectile until pressure is exhausted.

4.2 ELECTRICAL HAZARDS

Electrical shocks and burns are ever-present hazards. It is impossible to troubleshoot all circuits with the power off, so you must learn safe methods for troubleshooting "live" circuits. As long as electricity is contained in the conductors and the device is where it is supposed to function, there is nothing to fear. When uncontrolled electrical flow occurs (e.g., if you touch two live wires), you are very likely to get hurt.

SAFETY PRECAUTION: *Electrical power should always be shut off at the distribution or entrance panel and locked out in an approved manner when installing equipment. Specific requirements furnished by the Occupational Safety and Health Administration (OSHA) give the details for working safety conditions, including electrical lockout and tag procedures. Whenever possible, the power should be shut off and locked out when servicing the equipment. Electrical panels have a place for a padlock for the purpose of lockout,* **Figure 4.12(A).** *To avoid someone turning the power on, you should keep the panel locked when you are out of sight and keep the only key with you. Emergency STOP controls can be installed in the electrical lines for added safety,* **Figure 4.12(B).**

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Do not ever think that you are good enough or smart enough to work with live electrical power when it is not necessary.•

However, at certain times tests have to be made with the power on. Extreme care should be taken when making these tests. Ensure that your hands touch only the meter probes and that your arms and the rest of your body stay clear of all electrical terminals and connections. You should know the voltage in the circuit you are checking. Make sure that the range selector on the test instrument is set properly before using it.

SAFETY PRECAUTION: *Do not stand in a wet or damp area when making these checks. Use only proper test equipment, and make sure it is in good condition. Wear heavy shoes with an insulating sole and heel. Intelligent and competent technicians take all precautions. Many areas display danger signs warning that proper eyewear and footwear is required in that area,* **Figure 4.13.**•

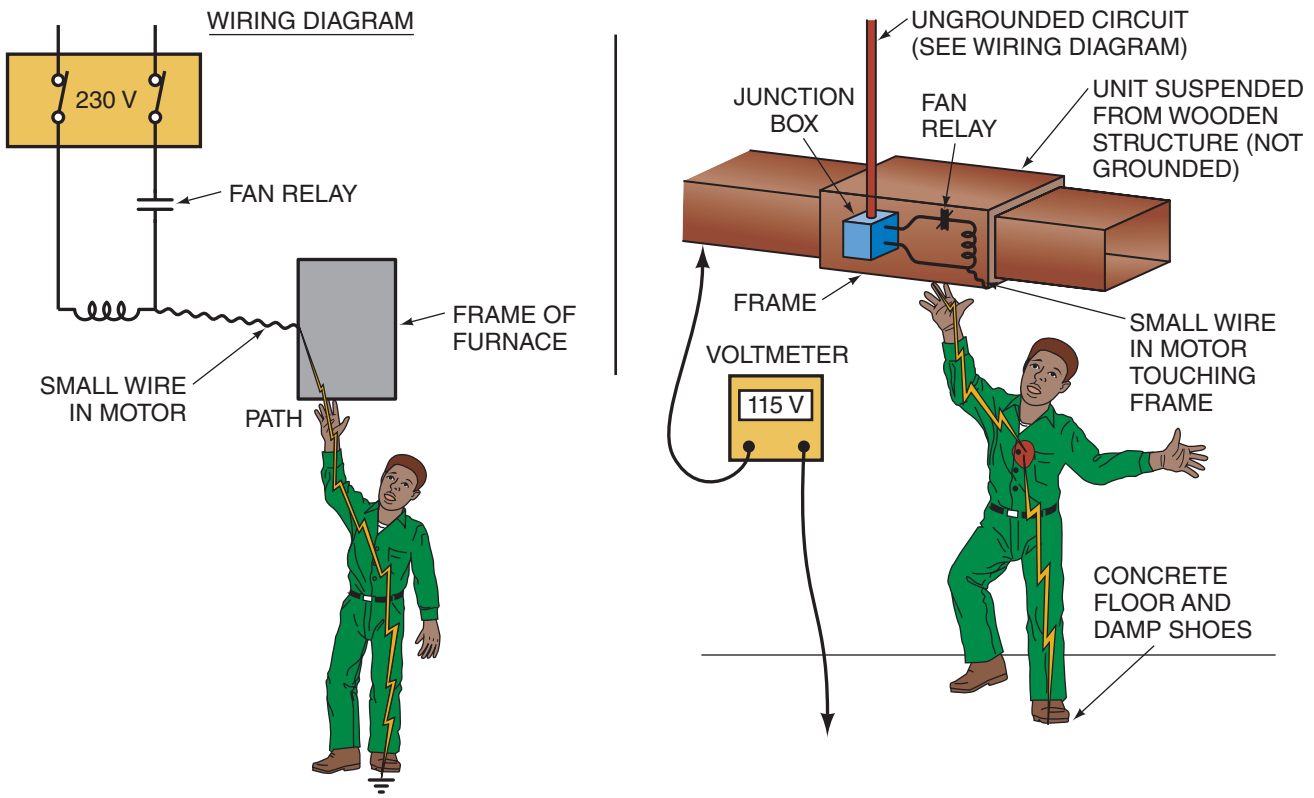
ELECTRICAL SHOCK

Electrical shock occurs when you become part of the circuit. Electricity flows through your body and can damage your heart—stop it from pumping—resulting in death if it is not restarted quickly. It is a good idea to take a first aid course that includes CPR methods for lifesaving. **SAFETY PRECAUTION:** *To prevent electrical shock, do not become a conductor between two live wires or a live (hot) wire and ground.•* The electricity must have a path to flow through. The higher the voltage that you may be working with, the greater the potential for injury. In this industry, we work with circuits that may have voltages of 460 V or up to 560 V. Always know the power supply you are working with and act accordingly. Do not let your body be the path. **Figure 4.14** is a wiring diagram showing situations in which the technician is part of a circuit.

Figure 4.13 Signage requiring safety eyewear and footwear.

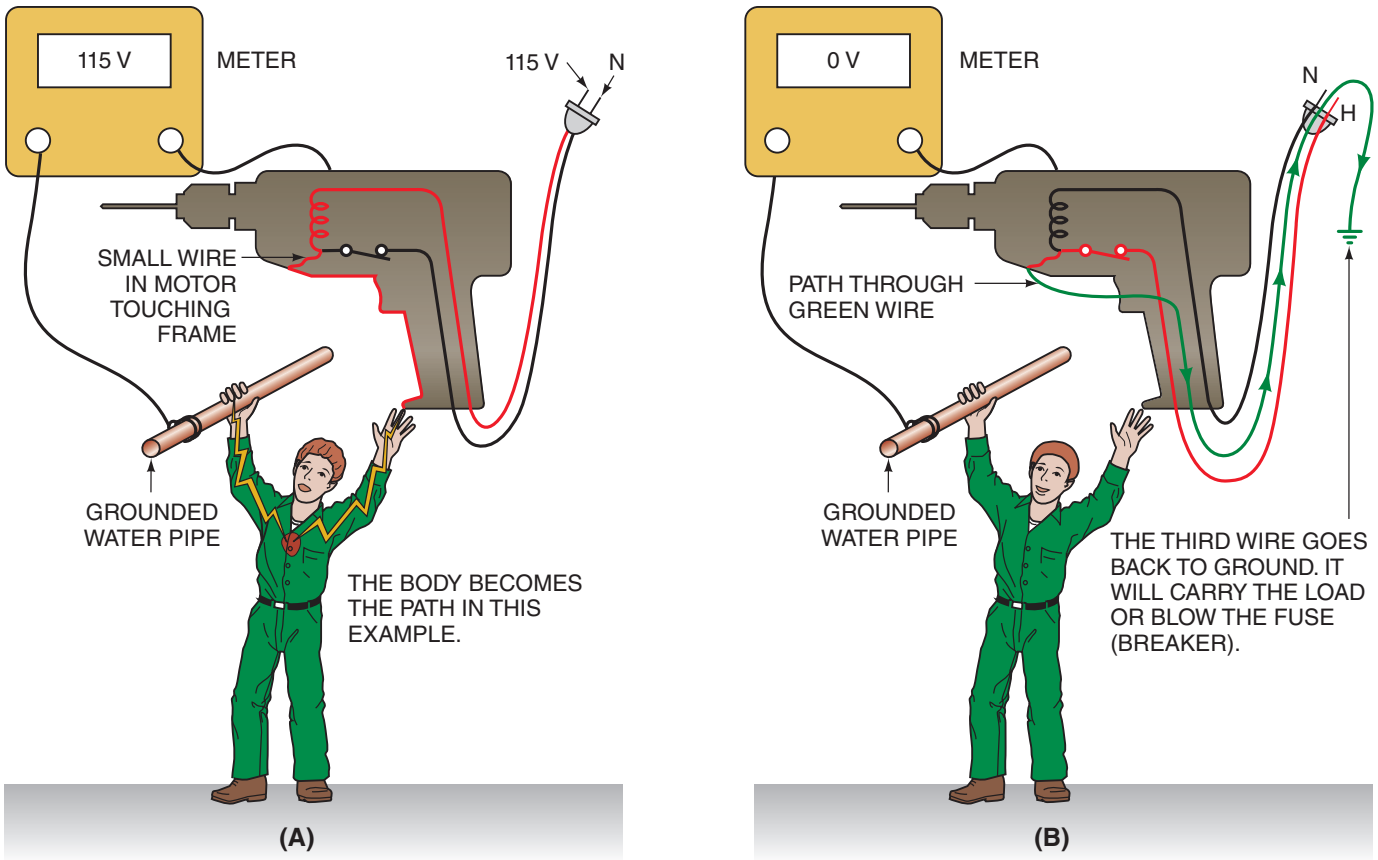
Courtesy Ferris State University. Photo by John Tomczyk

Figure 4.14 This figure shows ways that the technician can become part of the electrical circuit and receive an electrical shock.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 4.15 (A) An electrical circuit to ground from the metal frame of a drill. (B) Metal frame of a drill properly grounded.



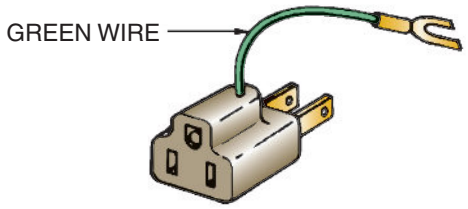
SAFETY PRECAUTION: *The technician should use only properly grounded power tools connected to properly grounded circuits.*

Caution should be used when using portable electric tools, which are handheld devices having electrical energy inside just waiting for a path to flow through. Some portable electric tools are constructed with metal frames. These should all have a grounding wire in the power cord. The grounding wire protects the operator. The tool will work without it, but it is not safe. If the motor inside the tool develops a loose connection and the frame of the tool becomes electrically hot, the third wire, rather than your body, will carry the current, and a fuse or breaker will interrupt the circuit, **Figure 4.15**.

In some instances, technicians may use the three- to two-prong adapters at job sites because the wall receptacle may have only two connections and their portable electric tool has a three-wire plug, **Figure 4.16**. The adapter has a third wire that must be connected to a ground for the circuit to give protection. If this wire is fastened under the wall plate screw and the screw terminates in an ungrounded box nailed to a wooden wall, you are not protected, **Figure 4.17**. Ensure that the third or ground wire is properly connected to a ground.

Alternatives to the older style of metal portable electric tools are the plastic-cased and the battery-operated tool. In the plastic-cased tool the motor and electrical connections are

Figure 4.16 A three- to two-prong adapter.



insulated within the tool. This is called a double-insulated tool and is considered safe, **Figure 4.18(A)**. The battery-operated tool uses rechargeable batteries and is very convenient and safe, **Figure 4.18(B)**.

The extension cord in **Figure 4.19** is plugged into a ground fault circuit interrupter (GFCI) receptacle. It is recommended for use with portable electric tools. Designed to help protect the operator from shock, they detect very small electrical leaks to ground. A small electrical current leak will cause the GFCI to open the circuit, preventing further current flow.

ELECTRICAL BURNS

Do not wear jewelry (rings and watches) while working on live electric circuits because they can cause shock and possible burns. Never use a screwdriver or other tool in an electrical panel when

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 4.17 The wire from the adapter is intended to be fastened under the screw in the duplex wall plate. However, this will provide no protection if the outlet box is not grounded.

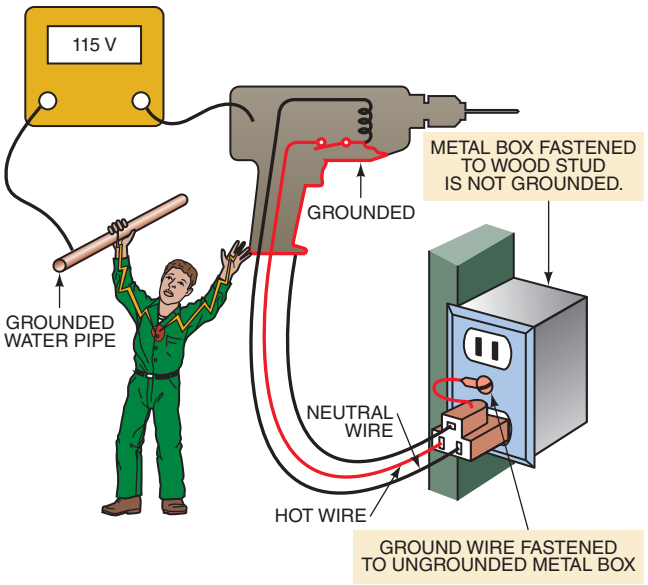


Figure 4.18 (A) A double-insulated electric drill. (B) A battery-operated electric drill.

(B)

Figure 4.19 An extension cord with a ground fault circuit interrupter receptacle.

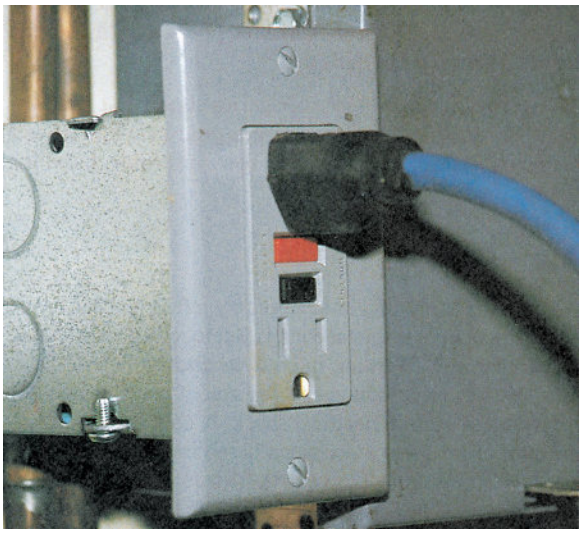

Photo by Bill Johnson

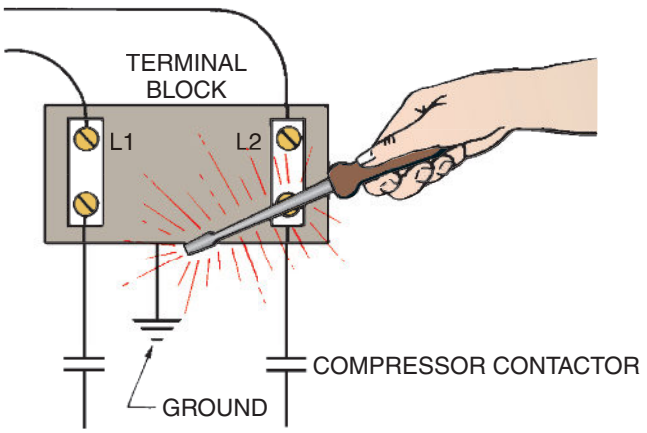
Figure 4.20 This wiring illustration shows a short circuit caused by the slip of a screwdriver.



the power is on. Electrical burns can come from an electrical arc, such as in a short circuit to ground when uncontrolled electrical energy flows. For example, if a screwdriver slipped while you were working in a panel and the blade completed a circuit to ground, the potential flow of electrical energy is tremendous. When a circuit has a resistance of 10 Ω and is operated on 120 V, it would, using Ohm's law, have a current flow of

$$I = \frac{E}{R} = \frac{120\text{V}}{10\Omega} = 12\,\text{A}$$

If this example is calculated again with less resistance, the current will be greater because the voltage is divided by a smaller number. If the resistance is lowered to 1 Ω, the current flow is then

$$I = \frac{E}{R} = \frac{120\text{V}}{1\Omega} = 120\,\text{A}$$

If the resistance is reduced to 0.1 Ω, the current flow will be 1200 A. By this time the circuit breaker will trip, but you may have already incurred burns or an electrical shock, **Figure 4.20**.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Current flow of 0.015 ampere or less through the body can prove fatal. It is a good idea to keep a first aid kit in a permanent location for any type of injury, **Figures 4.21 (A)** and **(B)**.

LADDER SAFETY

Nonconducting ladders should be used on all jobs and should be the type furnished with service trucks. Two types of nonconducting ladders are those made of wood and those made of fiberglass. Nonconducting ladders work as well as aluminum ladders; they are just heavier. They are also much safer.

Figure 4.21 (A) First aid kit mounted on a wall. (B) Contents of a general first aid kit.

Courtesy Ferris State University. Photo by John Tomczyk

(A)

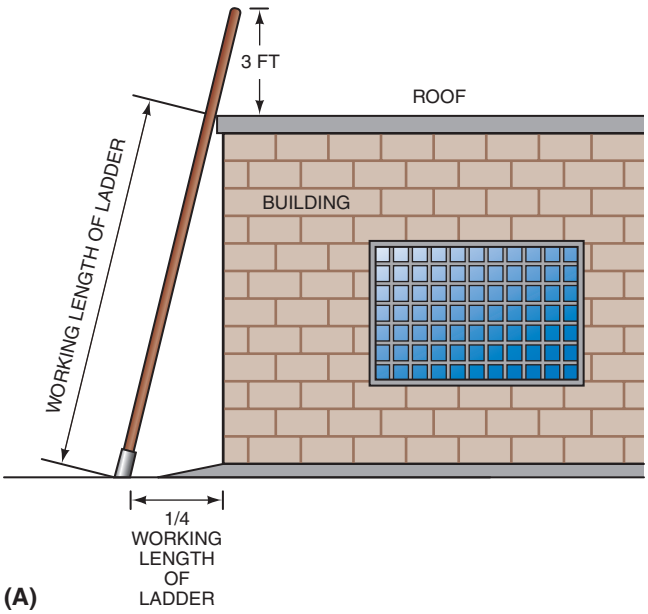
Courtesy Ferris State University. Photo by John Tomczyk

(B)

SAFETY PRECAUTION: *A technician may raise a ladder into a power line or place it against a live electrical hazard without realizing it. Chances should not be taken. When the technician is standing on a nonconducting ladder, it will provide protection from electrical shock to ground. However, it will not provide protection between two or more electrical conductors.*•

There are other ladder safety practices than those involving electricity. When a ladder is used for access to an upper landing area such as a roof, it should extend at least 3 ft above the landing surface. Also, the horizontal distance from the top support to the foot of the ladder should be approximately one-fourth the working length of the ladder, **Figure 4.22(A)**. Ensure that ladders are placed on a stable, level surface, not on slippery surfaces, and that they have slip-resistant feet. If there is any question, secure the ladder at the feet. Ladders should be used only for their designed purpose and should

Figure 4.22 (A) The side rails of a portable ladder should extend 3 ft above the upper landing surface. The angle of the ladder should be such that the horizontal space at the bottom is about one-fourth the distance of the working length of the ladder. (B) Carrying strap for carrying refrigerant cylinders on the ground or up a ladder safely.



(A)

Source: SC Products, Inc., Wilmington, DE

(B)

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

not be loaded with more weight than they were designed to hold. Use other methods for raising loads to the roof when the weight is excessive. Ladders should be maintained free of oil, grease, and any other slipping hazards.

Working from heights on rooftops or from ladders is potentially very dangerous. Rooftops have different pitches or slants. When the angle becomes steep, the technician should use a safety belt and be tied off in such a manner that a fall would be stopped. Technicians should always work in pairs when doing rooftop work or when working on a high ladder. In many cases, the ladder should be secured at the top, particularly if it is to be used for several climbs. **SAFETY PRECAUTION:** *Never use the cross-bracing on the far side of stepladders for climbing. The far side is only safe for climbing if it is provided with steps.*•

When carrying tools and equipment up a ladder, care must be taken to use the proper techniques, methods, or tools. **Figure 4.22(B)** shows a service technician transporting a refrigerant cylinder with a carrying strap. The carrying strap enables technicians to carry cylinders on the ground or up a ladder safer, easier, and quicker, saving time and money.

4.3 HEAT

The use of heat requires special care. Torches have a high concentration of heat. They are used for many things, including soldering, brazing, or welding. Many combustible materials may be in the area where soldering is required. For example, the refrigeration system in a restaurant may need repair. The upholstered restaurant furniture, grease, and other flammable materials must be treated as carefully as possible. **SAFETY PRECAUTION:** *When soldering or using concentrated heat, you should have a fire extinguisher close by, and you should know exactly where it is and how to use it,* **Figure 4.23 (A, B).**• Learn to use a fire extinguisher *before* the fire occurs. A fire extinguisher should always be included as a part of the service tools and equipment on a service truck.

Many fire extinguishers are designed for specific types of fires. Type A is for trash, wood, and paper fires. Type B is for burning liquids and Type C is for electrical equipment fires. However, some fire extinguishers are rated for all three types of fires, **Figure 4.23(B)**. Usually, these extinguishers are the dry-chemical type. Make sure you know what type of fire extinguisher you are using on a fire, or the fire can spread and serious personal injury and property damage can occur.

SAFETY PRECAUTION: *When a solder connection must be made next to combustible materials or a finished surface, use a shield of noncombustible material for insulation,* **Figure 4.24.** *A fire-resistant spray may also be used to decrease the flammability of wood if a torch must be used nearby,* **Figure 4.25.** *The spray retardant should be used with an appropriate shield.*• A shield is also often necessary when soldering within an equipment cabinet, for example, when an ice-maker compressor is changed or when a drier must be soldered in line. A shield should be used to protect any wires that may be close by.

Figure 4.23 (A) A typical fire extinguisher. (B) Fire extinguisher details showing the types of fires it should be used on.

Photo by Bill Johnson

(A)

Courtesy Ferris State University. Photo by John Tomczyk

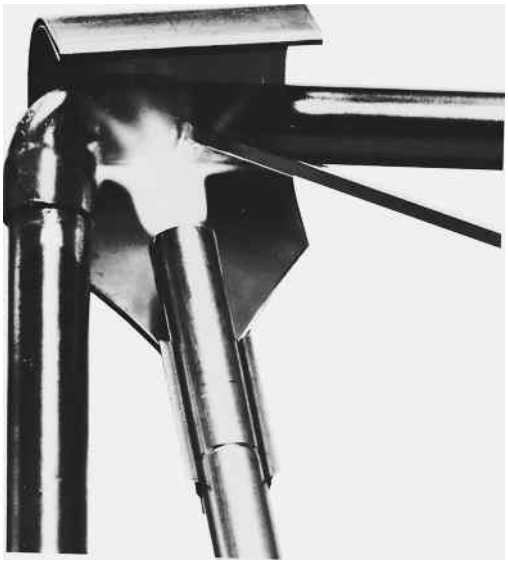
(B)

SAFETY PRECAUTION: *Never solder tubing lines that are sealed. Service valves or Schrader ports should be open before soldering is attempted. When heat from a torch is added to a sealed tubing line, a small amount of pressure will build up inside the tubing and may bubble through the hot molten solder. This will cause leaks in the solder joint.*•

SAFETY PRECAUTION: *Hot refrigerant lines, hot heat exchangers, and hot motors can burn your skin and leave a permanent scar. Care should be used while handling them.*•

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 4.24 A shield used when brazing or soldering.



Source: Thermadyne Industries, Inc.

Figure 4.25 A fire-retardant spray.

SAFETY PRECAUTION: *Working in very hot weather or in hot attics can be very hard on the body. Technicians should be aware of how their body and the bodies of those around them are reacting to the working conditions. Watch for signs of overheating, such as someone's face turning very red or someone who has stopped sweating. Get them out of the heat and cool them off. Overheating can be life-threatening; call for emergency help.*•

4.4 COLD

Cold can be as harmful as heat. Liquid refrigerant can freeze your skin or eyes instantaneously. But long exposure to cold is also harmful. Working in cold weather can cause frostbite. Wear proper clothing and waterproof boots, which also help protect against electrical shock. A cold, wet technician will not always make decisions based on logic. Make it a point to stay warm. **SAFETY PRECAUTION:** *Be aware of the windchill when working outside. The wind can quickly take the heat out of your body, and frostbite will occur. Waterproof boots not only protect your feet from water and cold but help to protect you from electrical shock hazard when you are working in wet weather. However, do not depend on these boots for protection against electrical hazards.*

Low-temperature freezers are just as cold in the middle of the summer as in the winter. Cold-weather gear must be used when working inside these freezers.• For example, an expansion valve may need changing, and you may be in the freezer for more than an hour. It is a shock to the system to step from the outside where it may be 95°F or 100°F into a room that is 0°F. If you are on call for any low-temperature applications, carry a coat and gloves and wear them in cold environments.

4.5 MECHANICAL EQUIPMENT

Rotating equipment can damage body and property. Motors that drive fans, compressors, and pumps are among the most dangerous because they have so much power. **SAFETY PRECAUTION:** *If a shirt sleeve or coat were caught in a motor drive pulley or coupling, severe injury could occur. Loose clothing should never be worn around rotating machinery,* **Figure 4.26.** *Even a small electric hand drill can wind a necktie up before the drill can be shut off.*•

SAFETY PRECAUTION: *When starting an open motor, stand well to the side of the motor drive mechanism.*• If the coupling or belt were to fly off the drive, it would fly outward in the direction of rotation of the motor. All set screws or holding

Figure 4.26 **SAFETY PRECAUTION:** *Never wear a necktie or loose clothing when using or working around rotating equipment.*•

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

mechanisms must be tight before a motor is started, even if the motor is not connected to a load. Place all wrenches away from a coupling or pulley. A wrench or nut thrown from a coupling can be a lethal projectile, **Figure 4.27**.

SAFETY PRECAUTION: *When a large motor, such as a fan motor, is coasting to a stop, do not try to stop it. If you try to stop the motor and fan by gripping the belts, the momentum of the fan and motor may pull your hand into the pulley and under the belt,* **Figure 4.28.**•

SAFETY PRECAUTION: *Never wear jewelry while working on a job that requires much movement. A ring may be caught on a nail head, or a bracelet may be caught on the tailgate of a truck as you jump down,* **Figure 4.29.**•

SAFETY PRECAUTION: *When using a grinder to sharpen tools, remove burrs, or for other reasons, always use a face shield,* **Figure 4.30.**• Most grinding stones are made for grinding ferrous metals, such as cast iron, steel, and stainless steel. However, other stones are made for nonferrous metals, such as aluminum, copper, or brass. Use the correct grinding stone for the metal you are grinding. The tool rest should be adjusted to approximately 1/16 in. from the grinding stone, **Figure 4.31**. As the stone wears down, keep the tool rest adjusted to this setting. A grinding stone must not be used on a grinder that turns faster than the stone's rated maximum revolutions per minute (rpm), as it may explode, **Figure 4.32**.

Figure 4.27 **SAFETY PRECAUTION:** *Ensure that all nuts are tight on couplings and other components.* •

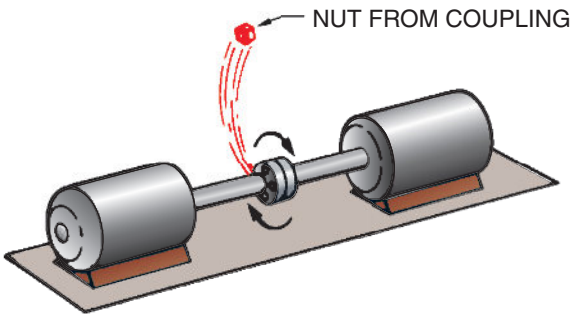


Figure 4.28 **SAFETY PRECAUTION:** *Never attempt to stop a motor or other mechanism by gripping the belt.* •

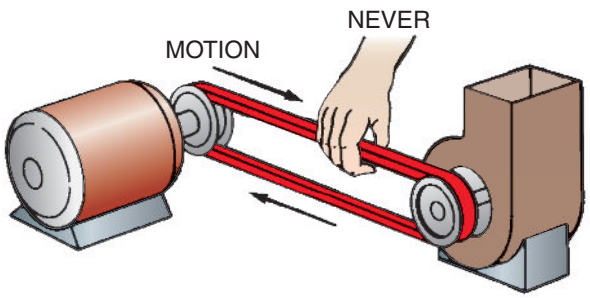

Figure 4.29 Jewelry can catch on nails or other objects and cause injury.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 4.31 Keep the tool rest on a grinder adjusted properly.

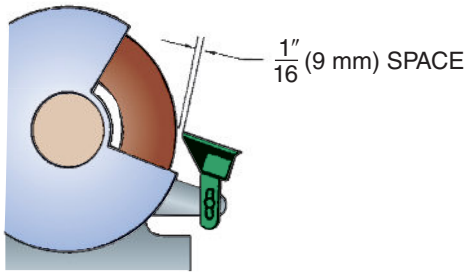

Figure 4.32 When installing a grinding stone, ensure that it is compatible with the grinder.

4.6 MOVING HEAVY OBJECTS

From time to time heavy objects must be moved. Think out the best and safest method for moving these objects; do not just use muscle power. Special tools can help you move equipment. For example, a crane or even a helicopter can be used when equipment must be installed on top of a building, **Figure 4.33**. Do not try to lift heavy equipment by yourself; get help from another person and use tools and equipment designed for that purpose. A technician without proper equipment is limited.

SAFETY PRECAUTION: *When you must lift, use your legs, not your back, and wear an approved back brace belt,* **Figure 4.34.**•
Some available tools are a pry bar, a lever truck, a refrigerator hand truck, a lift gate on a pickup truck, and a portable dolly, **Figure 4.35**.

When moving large equipment across a carpeted or tiled floor or across a gravel-coated roof, first lay down some plywood. Keep the plywood in front of the equipment as it is moved along. When equipment has a flat bottom, such as a package air conditioner, short lengths of pipe may be used to move the equipment across a solid floor, **Figure 4.36**.

Figure 4.33 A helicopter lifting air-conditioning equipment to a roof.

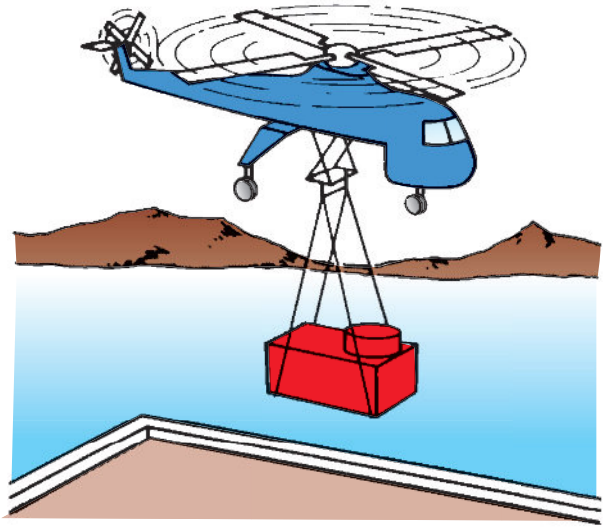

Figure 4.34 **SAFETY PRECAUTION:** *(A) Use your legs, not your back, to lift objects. Keep your back straight. (B) Use a back belt brace.* •

4.7 REFRIGERANTS IN YOUR BREATHING SPACE

Fresh refrigerant vapors and many other gases are heavier than air and can displace the oxygen in a closed space. Because of this, low-level ventilation should be used, and proper ventilation must be used at all times to avoid being overcome by lack of oxygen. Should you be in a close space and the concentration of refrigerant become too great, you may not notice it until it is too late. Your symptoms would be a dizzy feeling, and your lips may become numb. If you should feel this way, move quickly to a place with fresh air.

SAFETY PRECAUTION: *Proper ventilation should be set up in advance of starting a job. Fans may be used to push or pull fresh air into a confined space where work must be performed. Cross-ventilation can help prevent a buildup of fumes,* **Figure 4.37.**•

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(C)

Some installations require special leak detectors with alarms. These detectors sound an alarm well in advance of a harmful buildup. **Figure 4.38(A)** shows a refrigerant-specific leak detector for HCFC-123 (R-123) that will sniff out certain parts per million (ppm) of refrigerant. If the programmed ppm level is reached, the detector will sound an alarm and color-coded lights will flash. When the leak-detector alarm sounds, take proper precautions, which may require special breathing gear. Turn on the ventilation system. **Figure 4.38(B)** shows a written warning placed on an equipment room's entry door for added safety. **Figure 4.38(C)** is a refrigerant-specific leak detector for HFC-134a (R-134a) located in an equipment room that houses a certain amount of R-134a either in a working refrigeration system's receiver or in storage cylinders. **Figure 4.39(A)** shows an evacuation plan for the second floor of a building in case of a refrigerant leak, fire, or any other emergency. Building directories are

also important for human safety because they let the occupants know where main entrances, stairs, elevators, and restrooms are located. Room configurations and locations are also covered in building directories, **Figure 4.39(B).**

Refrigerant vapors that have been heated during soldering or because they have passed through an open flame (for example, when there is a leak in the presence of a fire) are dangerous. They have a strong odor, are toxic, and may cause harm. **SAFETY PRECAUTION:** *If you are soldering in a confined place, keep your head below the rising fumes and make sure that you have plenty of ventilation,* **Figure 4.40.**•

Figure 4.40 Keep your face below the heated area and ensure that the area is well ventilated.

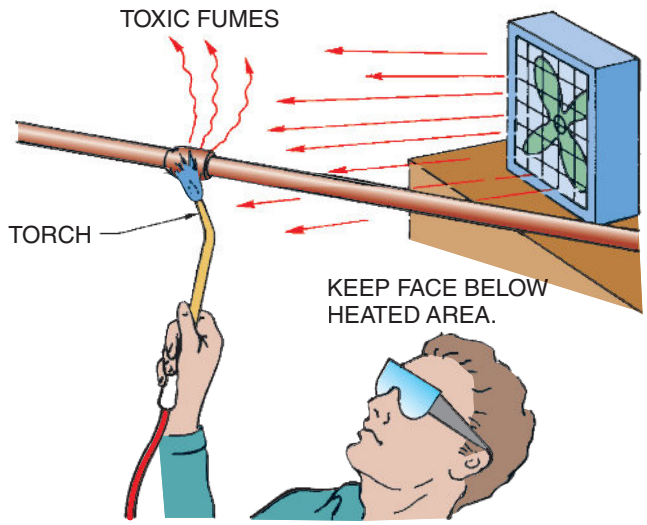

Figure 4.41 ASHRAE's Standard 34-2010 for Designation and Safety Classifications of Refrigerants.

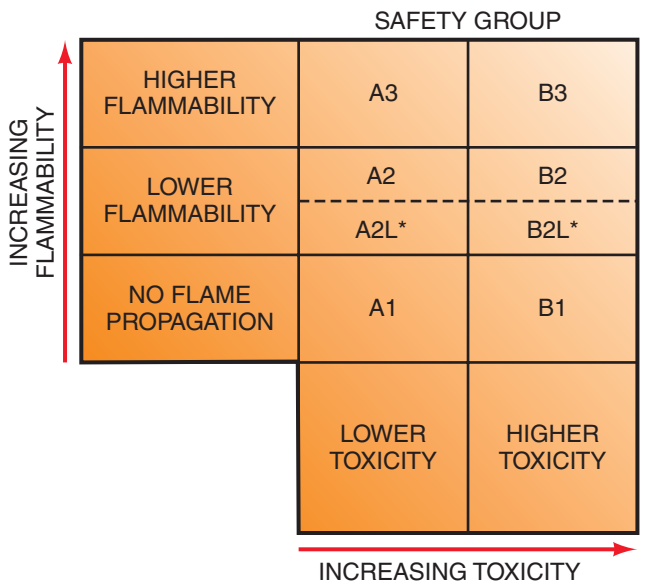

* A2L and B2L are lower flammability refrigerants with a maximum burning velocity of ≤10 cm/s (3.9 in./s).

The American National Standards Institute (ANSI) and the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) has developed Standard 34-2010 for Designation and Safety Classifications of Refrigerants. **Figure 4.41** is a matrix outlining Standard 34-2010, and the following explains its letter and number classifications.

Class A—For refrigerants where toxicity levels have not been identified at concentrations less than or equal to 400 ppm (parts per million).

Class B—For refrigerants where evidence of toxicity exists at concentrations below 400 ppm.

Class 1—For refrigerants that do not show flame propagation when tested in 65°F air at 14.7 psia.

Class 2—For refrigerants with a lower flammability limit of more than 0.00625 lb/ft^3 when tested at 70°F and 14.7 psia. They also have a heat of combustion of less than 8174 Btu/lb.

Class 3—For refrigerants with high flammability. Their lower flammability limit is less than or equal to 0.00625 lb/ft^3 when tested at 70°F and 14.7 psia. They have a heat of combustion greater than or equal to 8174 Btu/lb.

The two subclasses (A2L and B2L) apply to lower flammability refrigerants. The capital letter "L" refers to "Lower" flammability.

4.8 USING CHEMICALS

Chemicals are often used to clean equipment such as air-cooled condensers and evaporators. They are also used for water treatment. The chemicals are normally simple and mild, except for some harsh cleaning products used for water treatment. **SAFETY PRECAUTION:** *These chemicals should be handled according to the manufacturer's directions. Do not get careless. If you spill chemicals on your skin or splash them in your eyes, follow the manufacturer's directions and go to a doctor. It is a good idea to read the entire label before starting a job. It is hard to read the first aid treatment for eyes after your eyes have been damaged.*•

Refrigerant and oil from a motor burnout can be harmful. The contaminated refrigerant and oil may be hazardous to your skin, eyes, and lungs because they contain acid. **SAFETY PRECAUTION:** *Keep your distance if a line is subject to rupture or any amount of refrigerant is allowed to escape.*•

Emergency eye and body wash facilities should be readily available in order to deal with accidents involving any harmful chemicals or refrigerants. Signs directing a person to the wash facilities should be posted and clearly marked, **Figures 4.42(A)**, **(B)**, and **(C)**. Emergency call boxes can also be located throughout the building for added safety. By simply pushing the red button on the call box, the proper authority will be notified that help is needed in a specific location, **Figure 4.43.**

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

SUMMARY

- Electrical energy is present whenever you troubleshoot energized electrical circuits. Be careful. Turn off electrical power, if possible, when working on an electrical component. Lock the panel or disconnect the box, and keep the only key in your possession.
- Refrigerant-specific leak detectors that sense parts per million (ppm) of refrigerant are used in equipment rooms for safety.
- Some fire extinguishers are designed for specific types of fires, and some can be used for many types: trash, wood, paper, liquid, and electrical fires.
- Evacuation plans and building directories mounted in a conspicuous place on the building's interior walls are an important safety feature.
- Rotating equipment such as fans and pumps can be dangerous and should be treated with caution.
- When moving heavy equipment, use correct techniques, choose appropriate tools and equipment, and wear a back brace belt.
- Chemicals used for cleaning and water treatment must be handled with care.

REVIEW QUESTIONS

1. Where would a technician encounter freezing temperatures when working with liquid refrigerant?
2. Which of the following can happen to a full nitrogen cylinder when the top is broken off?
   A. Nitrogen will slowly leak out.
   B. There will be a loud bang.
   C. The tank will act like a rocket and move very fast.
   D. It will make a sound like a washing machine.
3. Why must nitrogen be used only with a regulator when it is charged into a system?
4. What can happen when oil is mixed with oxygen under pressure?
5. Trying to stop escaping liquid refrigerant with your hands will result in _____.
6. Electrical shock to the body affects the _____.
7. Electrical energy passing through the body causes two types of injury, _____ and _____.
8. How can a technician prevent burning the surroundings while soldering in a tight area?
9. What safety precautions should be taken when starting a large electric motor whose coupling is disconnected?
10. The third (green) wire on an electric drill is the _____ wire.
11. Describe how heavy equipment can be moved across a rooftop.
12. What special precautions should be taken before using chemicals to clean a condenser?
13. When a hermetic motor burns while in use, _____ are produced.
14. What refrigerant safety group classification has the highest flammability and the highest toxicity?
15. What do the letters A, B, and C mean on a fire extinguisher?

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

UNIT 5

TOOLS AND EQUIPMENT

OBJECTIVES

After studying this unit, you should be able to

- describe hand tools used by the air-conditioning, heating, and refrigeration technician.
- describe equipment used to install and service air-conditioning, heating, and refrigeration systems.
- describe equipment and tools used by residential energy auditors.

SAFETYCHECKLIST

☑ Tools and equipment should be used only for the job for which they were designed. Other use may damage the tool or equipment and may be unsafe for the technician.

Air-conditioning, heating, and refrigeration technicians must be able to properly use hand tools and specialized equipment relating to this field. Technicians must use the tools and equipment intended for the job. Using the correct tool is more efficient, saves time, and is safer. Accidents often can be prevented by using the correct tool. This unit contains a brief description of most of the general and specialized tools and equipment that technicians use in the HVAC/R field. Some are described in more detail in other units as they apply to specific tasks.

5.1 GENERAL TOOLS

HAND TOOLS

Figure 5.1 through **Figure 5.6** illustrate many general hand tools used by service technicians.

In general, it is a good idea to buy the best tools that you can afford. Good hand tools are usually more expensive and will usually last longer. For example, an inexpensive screwdriver will often have an undersized handle and will be hard to grip. Also, the bit on the end will not be made of hard, tempered steel and will deform easily. The better choice would be a screwdriver with a comfortable handle and a very hard tip, which is under great stress when the technician is working with a very tight screw. Good hand tools are usually guaranteed for replacement if they are broken during regular use.

POWER TOOLS

PORTABLE ELECTRIC DRILLS. Portable electric drills are used extensively by refrigeration and air-conditioning technicians. They are available in cord (115 V) or cordless (battery operated) models, **Figure 5.6(E)** and **Figure 5.6(F)**. If the drill has a cord and is not double-insulated, it must have a three-prong plug and be used only with a grounded receptacle. Drills that have variable speed and reversing options are recommended. Many technicians prefer the battery-operated type for its convenience and safety. Be sure that the batteries are kept charged.

Power tools are much like hand tools. Quality costs more. Many tools are made for the consumer market; the tool is used once a year for a light-duty job. A technician, however, must use these tools under all kinds of conditions—wet, dry, cold, and hot—and use them often. Inexpensive tools will begin to let you down when you need them most. You should buy the best tools you can and mark them distinctively to indicate who owns the tool. At job sites there are often several technicians working in the same area using the same types of tools. Make sure you know your own tools.

5.2 SPECIALIZED HAND TOOLS

The following tools are regularly used by technicians in the air-conditioning, heating, and refrigeration field.

DRIVERS AND WRENCHES

NUT DRIVERS. Nut drivers have a socket head and are used primarily to drive hex head screws out of panels on air-conditioning, heating, and refrigeration cabinets. They are available with hollow shafts, solid shafts, and extra long or stubby shafts, **Figure 5.7**. The hollow driver shaft allows the screw to

protrude into the shaft when it extends beyond the nut. The 1/4 and 5/16 inch nut driver is sometimes referred to as the most widely used and most common hand tool in HVAC/ work.

AIR-CONDITIONING AND REFRIGERATION REVERSIBLE RATCHET BOX WRENCHES. Ratchet box and hex wrenches, which allow the ratchet direction to be changed by pushing the lever-like button near the end of the wrench, are used with air-conditioning and refrigeration valves and fittings. Two openings on each end of the wrench allow it to be used on four sizes of valve stems or fittings, **Figure 5.8**.

FLARE NUT WRENCH. The flare nut wrench is used like a box end wrench. The opening at the end of the wrench allows it to be slipped over the tubing. The wrench can then be placed over the flare nut to tighten or loosen it, **Figure 5.9**. Adjustable wrenches should not be used because they may round off the corners of fittings made of soft brass. Do not use a pipe to extend the handle on a wrench for more leverage. Fittings can be loosened by heating or by using a penetrating oil.

Figure 5.8 Air-conditioning and refrigeration reversible ratchet (A) hex and (B) box wrenches. The offset design saves knuckles in tight places.

WIRING AND CRIMPING TOOLS

Wiring and crimping tools are available in many designs. **Figure 5.10** illustrates a combination tool for crimping solderless connectors, stripping wire, cutting wire, and cutting small bolts. The figure also illustrates an automatic wire stripper. To use this tool, insert the wire into the proper strip-die hole. The length of the strip is determined by the amount of wire extending beyond the die away from the tool. Hold

the wire in one hand and squeeze the handles with the other. Release the handles and remove the stripped wire.

INSPECTION MIRRORS

Inspection mirrors are usually available in rectangular or round shapes, with stainless steel or glass reflective surfaces that are usually mounted on ball joints that swivel 360 degrees. They come with fixed or telescoping handles, some more than 30 in. long. The mirrors are used to inspect areas or parts in components that are behind or underneath other parts, **Figure 5.11**.

(B)

Figure 5.12 A stapling tacker.

Photo by Bill Johnson

STAPLING TACKERS

Stapling tackers are used to fasten insulation and other soft materials to wood; some types may be used to secure low-voltage wiring, **Figure 5.12**.

5.3 TUBING TOOLS

The following tools are used to install tubing. Most will be described more fully in other units in the book.

TUBE CUTTER

Tube cutters are available in different sizes and styles. Standard tube cutters for small- and large-diameter tubing are shown in **Figures 5.13(A)** and **(B)**. They are also available with a ratchet-feed mechanism. The cutter opens quickly to insert the tubing and slides to the cutting position. Some models have a flare cut-off groove that reduces tube loss when removing a cracked flare. Many models also include a retractable reamer to remove inside burrs, and a filing surface to remove outside burrs. **Figure 5.14** illustrates three small tube cutters for use in tight spaces where standard cutters do not fit.

INNER–OUTER REAMERS

Inner–outer reamers use three cutters to both ream the inside and trim the outside edges of tubing, **Figure 5.15**.

FLARING TOOLS

The flaring tool has a flaring bar to hold the tubing, a slip-on yoke, and a feed screw with flaring cone and handle. Several sizes of tubing can be flared with these tools, **Figure 5.16**.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

SWAGING TOOLS

Swaging tools are available in the punch-, lever-, and die-types, **Figure 5.17**.

TUBE BENDERS

The three types of tube benders are the spring, the lever, and the gear. **Figure 5.18** shows the spring and lever tube benders. These tools are used for bending soft copper and aluminum.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

5.4 SPECIALIZED SERVICE AND INSTALLATION EQUIPMENT

GAUGES

GAUGE MANIFOLD. One of the most important of all pieces of refrigeration and air-conditioning service equipment is the **gauge manifold**. This equipment normally includes the **compound gauge** (low-pressure and vacuum), the **high-pressure gauge**, and the **manifold**, valves, and hoses. The gauge manifold may be two-valve with three hoses or four-valve with four hoses. The four-valve design has separate valves for the vacuum, low-pressure, high-pressure, and refrigerant cylinder connections, **Figure 5.23**. Some gauge manifolds and hoses are manufactured to handle the higher pressures of refrigerants like R-410A. Also, notice in **Figure 5.24(A)** that the vacuum hose is 3/8 in. in diameter, while the other hoses are 1/4 in. in diameter. The 3/8 diameter offers less restriction to flow for a faster vacuum. **Figure 5.24(B)** shows digital, wireless, Bluetooth-capable high and low side pressure gauges for remote monitoring. **Figure 5.24(C)** shows a digital, wireless, stand-alone micron vacuum gauge with Bluetooth capabilities for remote monitoring.

SAFETY PRECAUTION: *If using a refrigerant with higher pressures like R-410A, make sure the equipment for either evacuating, charging, or recovering is rated for these higher pressures. Otherwise, serious injury could occur.* •

Electronic manifolds are also available that can provide more information than those described above. The manifold in **Figure 5.25(A)** can measure system pressures and temperatures, calculate superheat and subcooling, and measure vacuum level in microns. It may also be used as a digital thermometer. **Figure 5.25(B)** is a wireless, digital, pressure/temperature gauge that provides wireless connection to a smart device so a technician can test the HVAC/R system without losing refrigerant.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(C)

No hoses or manifolds are necessary with this wireless device. **Figure 5.25**(C) is a digital manifold, which eliminates the need for manual calculations while presenting the data in an easy-to-read format on your smart device.

PROGRAMMABLE CHARGING METER OR SCALE. Programmable scales or meters will allow a technician to accurately charge refrigerant by weight. This can usually be done manually or automatically, and the amount of refrigerant to be charged into the system can be programmed. **Figure 5.26** is an example of a programmable charging meter or scale.

Figure 5.26 A programmable charging meter or scale.

Source: Robinair SPX Corporation.

DIGITAL VACUUM GAUGE. A digital vacuum gauge has an interchangeable sensor that measures to the equivalent of 10 microns of vacuum with seven different scales, **Figure 5.27**.

ELECTRONIC THERMISTOR VACUUM GAUGE. An electronic thermistor vacuum gauge measures the vacuum when a refrigeration, air-conditioning, or heat pump system is being evacuated. It can measure a vacuum as low as about 50 microns, or 0.050 mm Hg (1000 microns = 1 mm), **Figure 5.28**.

Figure 5.27 Digital vacuum gauge.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

VACUUM PUMP

Vacuum pumps designed specifically for servicing air-conditioning and refrigeration systems remove air and non-condensable gases from the system. Evacuating the system is necessary because the air and noncondensable gases take up space, contain moisture, and cause excessive pressures. **Figure 5.29** shows photos of two vacuum pumps. Vacuum pumps may be either one- or two-stage. The two-stage pump is the one most often recommended for use. It will create a lower vacuum to improve the system vacuum in situations where moisture is an issue.

REFRIGERANT RECOVERY RECYCLING STATION

It is illegal to intentionally vent refrigerant into the atmosphere. **Figures 5.30(A)** and **(B)** are photos of typical recovery/recycling and recovery-only stations. The refrigerant from a refrigerator or air-conditioning system is pumped into a cylinder or container at this station and is stored until it can be either charged back into the system if it meets the requirements or transferred to another approved container for transportation to a refrigerant reclaiming facility.

5.5 REFRIGERANT LEAK DETECTORS

HALIDE LEAK DETECTOR

A halide leak detector, **Figure 5.31,** is used to detect acetylene or propane gas refrigerant leaks. When the detector is ignited, the flame heats a copper disk. Air for combustion is drawn through the attached hose, the end of which is passed over or near fittings or other areas where a leak may be suspected. If there is

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 5.31 A halide leak detector used with acetylene.

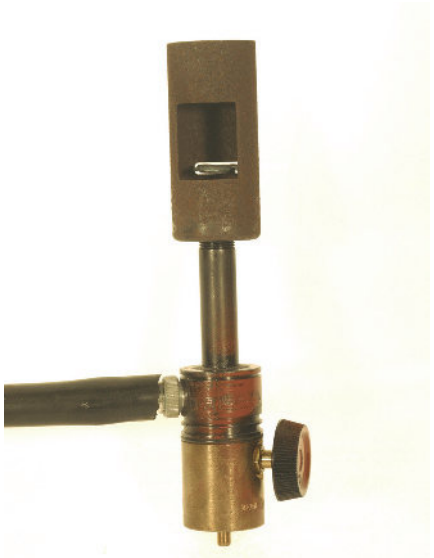

Photo by Bill Johnson

a leak, the refrigerant will be drawn into the hose and contact the copper disk. This breaks down the halogen refrigerants into other compounds and changes the color of the flame, ranging from green to purple, depending on the size of the leak.

ELECTRONIC LEAK DETECTORS

Electronic leak detectors contain an element sensitive to a particular refrigerant class. The device may be battery- or AC-powered and often has a pump to suck in the gas and air mixture. A ticking signal that increases in frequency and intensity as the probe "homes in" on the leak alerts the operator. Many also have varying sensitivity ranges that can be adjusted, **Figure 5.32**.

Many modern leak detectors are equipped with selector switches for detecting all three refrigerant types: CFC, HCFC, or HFC. HCFCs have less chlorine than CFCs, so the sensitivity of the selector switch has to be changed to detect them. HFCs do not contain chlorine but do contain fluorine. When the selector switch is set to HFC, the sensitivity of the leak detector is increased and the more elusive fluorine can be detected.

HIGH-INTENSITY ULTRAVIOLET LAMP

The ultraviolet system, **Figure 5.33**, induces an additive into the refrigerant system. The additive shows up as a bright yellow-green glow under the ultraviolet lamp at the source of the leak. The additive can remain in the system to test for a new suspected leak at a later date.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

ULTRASOUND LEAK DETECTOR

Ultrasound detectors use the sound from the escaping refrigerant to detect a leak, **Figure 5.34.**

5.6 OTHER TOOLS

THERMOMETERS

Thermometers may be simple pocket styles or infrared, electronic, and recording types. The pocket styles may be glass-stem mercury (or alcohol) thermometers or dial-indicator or digital types, **Figure 5.35.** Other thermometers are shown in **Figure 5.36(A)**, electronic; **Figure 5.36(B, C)**, infrared; and **Figure 5.37**, recording.

FIN STRAIGHTENERS

Fin straighteners are available in different styles. The different styles shown in **Figure 5.38** are capable of straightening condenser and evaporator coil fins spaced at 8, 9, 10, 12, 14, and 15 fins per inch.

HEAT GUNS

Heat guns are needed in many situations to warm refrigerant, melt ice, and do other tasks. **Figure 5.39** shows a heat gun carried by many technicians.

HERMETIC TUBING PIERCING VALVES

Piercing valves are an economical way to tap a line for charging, testing, or purging hermetically sealed units. A valve such as the one in **Figure 5.40, page 124**, is clamped to the line. Often these valves are designed so that turning the valve stem causes a sharp needle to pierce the tubing. Then the stem is backed off so that the service operations can be accomplished. These valves should be installed according to the manufacturer's directions.

Piercing valves are either the gasket- or solder-type. The gasket-type is used only for temporary system access because the gaskets will get brittle and deteriorate over time when

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

(B)

exposed to the atmosphere and high temperatures. Solder-type piercing valves are used for permanent access to a system because they do not employ gaskets.

COMPRESSOR OIL CHARGING PUMP

Figure 5.41 shows an example of a compressor oil charging pump that is used for charging refrigeration compressors with oil while they are under pressure.

SOLDERING AND WELDING EQUIPMENT

Soldering and welding equipment is available in many styles, sizes, and qualities.

A **soldering gun** is used primarily to solder electrical connections. It does not produce enough heat for soldering tubing, **Figure 5.42**.

Figure 5.43 shows a **propane gas torch** with a disposable propane gas tank. This is an easy torch to use. The flame adjusts easily and can be used for many soldering operations.

Air-acetylene units provide sufficient heat for soldering and brazing. They consist of a torch, which can be fitted with several sizes of tips, and a regulator, hoses, and an acetylene tank, **Figure 5.44**.

Oxyacetylene welding units are used in certain soldering, brazing, and welding applications. The units consist

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

of a torch, regulators, hoses, oxygen tanks, and acetylene gas tanks. When the oxygen and acetylene gases are mixed in the proper proportion, a very hot flame is produced, **Figure 5.45**.

PSYCHROMETERS

SLING PSYCHROMETER. The sling psychrometer uses the wet-bulb/dry-bulb principle to obtain relative humidity readings quickly. Two thermometers, a dry bulb and a wet bulb, are whirled together in the air. Evaporation will occur at the wick of the wet-bulb thermometer, giving it a lower temperature reading. The difference in temperature depends on the humidity in the air. The drier the air, the greater the difference in the temperature readings because the air absorbs more moisture, **Figure 5.46**. Most manufacturers include a scale so that the relative humidity can easily be determined. Before you use the psychrometer, be sure that the wick is clean and wet (with pure water, if possible).

Digital sling psychrometers are also available and will provide the same readings as the manual psychrometers. **Figure 5.47** shows two styles of digital sling psychrometers.

MOTORIZED PSYCHROMETER. A motorized psychrometer is often used when many readings are to be taken over a large area.

Figure 5.43 A propane gas torch with a disposable propane gas tank.

AIR VELOCITY MEASURING INSTRUMENTS

AIR VELOCITY. Air velocity measuring instruments, which measure air velocity in feet per minute, are necessary for balancing duct systems, checking fan and blower characteristics, and making static pressure measurements. **Figure 5.49** shows an air velocity measuring kit. The air velocity instrument can measure velocity from 50 to 10,000 ft/min. **Figure 5.50(A)** shows an instrument that incorporates a microprocessor that will take up to 250 readings across hood openings or in a duct and will display the average air velocity and temperature readings when needed. **Figure 5.50(B)** shows a modern vane anemometer with a digital readout.

AIR BALANCING METER. The air balancing meter shown in **Figure 5.51** eliminates the need for multiple readings. The meter will make readings directly from exhaust or supply grilles in ceilings, floors, or walls and give a readout in cubic feet per minute (cfm).

FLUE-GAS INDICATORS

CARBON DIOXIDE (CO_2) AND OXYGEN (O_2) INDICATORS. CO_2 and O_2 indicators are used to analyze flue gases to determine the combustion efficiency of gas or oil furnaces, **Figure 5.52**. Modern microprocessor-based flue gas analyzers are also available but for a steeper price.

CARBON MONOXIDE (CO) INDICATOR. A CO indicator is used to take flue-gas samples in natural gas furnaces to determine the percentage of CO present, **Figure 5.53**. A more modern microprocessor-based combustion analyzer can be used today with more ease and accuracy, **Figure 5.54**.

COMBUSTION ANALYZER. The combustion analyzer, **Figure 5.54(A)**, measures and displays concentrations in flue gases of oxygen (O_2), carbon monoxide (CO) (a poisonous gas), oxides of nitrogen (NO_x), and sulfur dioxide (SO_2) and

COMBUSTIBLE GAS LEAK DETECTOR. The gas leak detector has an audible alarm and provides visual leak detection by means of light-emitting diode (LED) indicators. A red LED light on the tip illuminates the search area, **Figure 5.55**.

DRAFT GAUGE. A draft gauge is used to check the pressure of the flue gas in gas and oil furnaces to ensure that the flue gases are moving up the flue at a satisfactory speed, **Figure 5.56**. The flue gas is normally at a slightly negative pressure.

ELECTRICAL MEASUREMENT DEVICES

VOLT-OHM-MILLIAMMETER (VOM). A VOM, often referred to as a multimeter, is an electrical instrument that measures voltage (volts), resistance (ohms), and current (milliamperes) and has several ranges in each mode. They are available in many types, ranges, and quality, either with a regular (analog) dial readout or a digital readout. **Figure 5.57** illustrates both the analog and digital types. If you purchase a VOM, be sure to select one with the features and ranges used by technicians in the HVAC/R field. The voltmeter is very important. Your life may depend on knowing what voltages you are working with. Be sure to get the best one you can afford and resist the temptation to buy an inexpensive VOM.

AC CLAMP-ON AMMETER. An AC clamp-on ammeter (also called clip-on, tang-type, snap-on, or other names) is a versatile instrument—some can also measure voltage or resistance or both. If you don't have a clamp-on ammeter, you must interrupt the circuit to place an ammeter in the circuit. With the clamp-on style, you simply clamp the jaws around a single conductor, **Figure 5.58**.

MEGOHMMETER. A megohmmeter is used for measuring very high resistances. The device shown in **Figure 5.59** can measure up to 4000 megohms.

5.7 MISCELLANEOUS TOOLS AND EQUIPMENT FOR SPECIALIZED NEEDS

SCHRADER CORE REMOVER AND REPLACER

Remove and replace Schrader cores without removing refrigerant charge. Schrader core removal allows for less restriction when evacuating a system allowing for a faster and deeper vacuum, **Figure 5.61**.

QUICK COUPLES, LOW LOSS FITTINGS, AND ADAPTER HOSES

Quick couples automatically trap refrigerant in the hose when disconnected, **Figure 5.62(A)**. Hoses with low loss fittings connected on their ends, **Figure 5.62(B).** An assortment of low loss adapter hoses for control of refrigerant and to minimizing refrigerant loss, **Figure 5.62(C)**.

CAPILLARY TUBE CUTTER

Cuts capillary tubes cleanly without flattening or constricting the tubing, **Figure 5.63**.

REFRIGERANT RECOVERY PLIERS

A fast and easy way to recover refrigerant before disposal of a unit, **Figure 5.64**.

SERVICE WRENCH AND ADAPTERS

Combination service wrench and hex adapter. The offset design saves knuckles in tight places, **Figure 5.65**.

HAND-HELD REFRACTOMETER

Used for retrofitting a mineral oil system with POE lubricant. Can accurately predict remaining mineral oil in the system down to one percent, **Figure 5.66**.

FAN BLADE PULLER

Used for removing propeller type fan blades, squirrel cage type blower wheels, and pulleys and sheaves, **Figure 5.67**.

REFRIGERANT TANK HEATER

Adds heat and pressure to refrigerant tanks for faster charging especially on cold days, **Figure 5.68**.

ICE BUCKET

Quickly chill a refrigerant tank and lower its pressure for faster refrigerant recovery. Causes a greater pressure difference between the tank's pressure and the system's refrigerant pressure to speed up the flow rate of the recovery process, **Figure 5.69**.

REFRIGERANT TANK TRANSPORTER STRAP

Connects to disposable and returnable refrigerant cylinders. The strap enables technicians to carry cylinders on the

ground or up ladders using both hands on the ladder for safer, easier, and quicker tank transporting, saving time and money, **Figure 5.70.**

LIQUID RESTRICTORS

Restricts refrigerant liquid for safe and fast liquid charging into the low side of a system. Recommended for near-azeotropic refrigerant blends (400 series blends), **Figure 5.71.**

FLARE CUT-OFF TOOL

A tool designed to cut off the flare only when the flare nut cannot be moved back enough for a regular cutter or saw, **Figure 5.72.**

The tools and equipment shown in **Figures 5.73** through **5.81** are used by a residential energy auditor in performing energy audits on a residential house.

A technician will use many other tools and equipment, but the ones covered in this unit are the most common.

SUMMARY

- Air-conditioning, heating, and refrigeration technicians should be familiar with commonly used hand tools and equipment.
- Technicians should use hand tools and specialized equipment properly.
- **SAFETY PRECAUTION:** *Tools and equipment should be used only for the job for which they were designed. Other use may damage the tools or equipment and may be unsafe for the technician.* •

REVIEW QUESTIONS

1. _____ and _____ are two types of screwdriver bits.
2. Five different types of wrenches are _____, _____, _____, _____, and _____.
3. Give an example of a use for a nut driver.
4. List four different types of pliers.
5. Describe two types of benders for soft tubing.
6. A wiring and crimping tool is used to
   A. crimp tubing.
   B. assemble tubing.
   C. cut and strip wire.
   D. install wire staples.
7. A flaring tool is used to
   A. cut copper tubing.
   B. flare a sheet metal joint.
   C. put a flare on the end of copper tubing.
   D. provide a yoke for bending brazing filler metal.
8. A vacuum pump is used to
   A. remove contaminants from a refrigeration system.
   B. vacuum dust before installing the refrigeration system compressor.
   C. vacuum the area before using an air-acetylene unit.
   D. prepare an area for taking a temperature reading.
9. Two types of refrigerant leak detectors are _____ and _____.
10. List the components usually associated with a gauge manifold unit.
11. List three types of thermometers.
12. For what type of soldering is a soldering gun normally used?
13. An air-acetylene unit is used for _____ and _____.
14. What is a sling psychrometer used for?
15. When are air velocity measuring instruments used?
16. Describe the purpose of CO_2 and O_2 indicators.
17. What is the purpose of a draft gauge?
18. List three electrical measurements that a VOM can make.
19. Why would a technician use an electronic charging scale?
20. Why is it necessary to recover refrigerant?

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

UNIT 6

FASTENERS

OBJECTIVES

After studying this unit, you should be able to

- identify common fasteners used with wood.
- identify common fasteners used on hollow walls.
- identify common fasteners used with sheet metal.
- write and explain a typical tapping screw dimension.
- identify typical machine screw heads.
- write and explain each part of a machine screw thread dimension.
- identify and describe fasteners used in masonry applications.
- describe hanging and securing devices for piping, tubing, and ductwork.
- describe various types of other commonly used fasteners.
- describe solderless terminals and screw-on wire connectors.

SAFETYCHECKLIST

- ☑ When staples are used to fasten a wire in place, do not hammer them too tightly as they may damage the wire.
- ☑ When using fasteners, make sure that all materials are strong enough for the purpose for which they are being used.
- ☑ Wear goggles whenever drilling holes and when cleaning out holes.
- ☑ Do not use powder-actuated systems without the proper training.
- ☑ When installing fasteners, be sure to follow all installation instructions carefully.

As an air-conditioning (heating and cooling) and refrigeration technician, you need to know about different types of fasteners and various fastening systems. Knowing about different fasteners, including their intended use as well as their limitations, will help make sure that you use the right fastener or system to securely install and mount all equipment, system components, and materials.

6.1 NAILS

Probably the most common fastener used in wood is the nail. Nails are available in many styles and sizes. Common nails are large, flat-headed wire nails with a specific diameter for each length, **Figure 6.1(A)**. A finishing nail, **Figure 6.1(B)**, has a very small head so that it can be driven below the surface of the wood; it is used where a good finish is desired.

The term *penny*, which originated in England, is used to size nails. Ten-penny nails, for example, cost 10 pence (an English coin) for 100 nails; four-penny nails cost four pence per 100 nails. "Penny" is represented by the letter "d," which is the symbol for English pence. For instance, 8d describes the shape and size of the common nail. These nails can be purchased plain or coated, usually with zinc or resin. The coating protects against corrosion and helps to prevent the nail from working its way out of the wood.

A roofing nail is used to fasten shingles and other roofing materials to the roof of a building. It has a large head to keep the shingles from tearing and pulling off. A roofing nail can sometimes be used on metal strapping material to hang ductwork or tubing, **Figure 6.2(A)**. Masonry nails are made of hardened steel and can be driven into masonry, **Figure 6.2(B)**.

Figure 6.1 (A) Common nails. (B) A finishing nail.

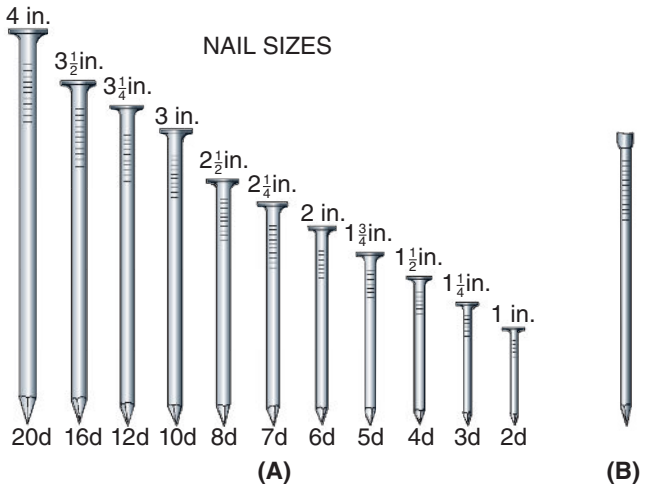

Figure 6.2 (A) A roofing nail. (B) A masonry nail.

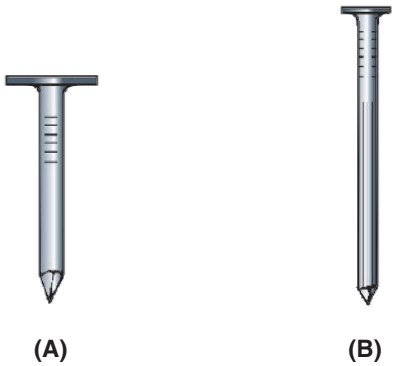

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

6.2 STAPLES AND RIVETS

STAPLES

A staple, **Figure 6.3**, is a fastener made somewhat like a nail but shaped like a U with a point on each end. Staples are available in different sizes for different uses, one of which is to fasten wire in place. The staples are simply hammered in over the wire. **SAFETY PRECAUTION:** *Never hammer staples too tightly because they can damage the wire.* Other types of staples may be fastened in place with a stapling tacker, **Figure 6.4**. By depressing the handle of a tacker, a staple can be driven through paper, fabric, or insulation into the wood. **Outward clinch tackers** will anchor staples inside soft materials. The staple legs spread outward to form a strong, tight clinch, **Figure 6.5**. They can be used to fasten insulation around heating or cooling pipes and ducts and to install ductboard. Other models or tackers are used to staple low-voltage wiring to wood.

Figure 6.3 Staples used to fasten wire to wood.

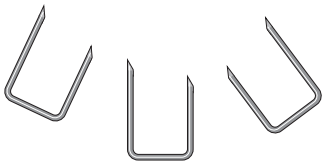

Figure 6.4 A stapling tacker.

Photo by Bill Johnson

Figure 6.5 A staple that is clinched outward is often used to fasten soft materials together.

RIVETS

Pin rivets or blind rivets are used to join two pieces of sheet metal. They are actually hollow rivets assembled on a pin, often called a **mandrel**. **Figure 6.6** illustrates a **pin rivet assembly**, how it is used to join sheet metal, and a riveting tool or gun. The rivets are inserted and set from only one side of the metal. Thus, they are particularly useful when there is no access to the back side of the metal being fastened.

To use a pin rivet, you first drill a hole in the metal the size of the rivet and insert the pin rivet in the hole with the pointed end facing out. Then you place the nozzle of the riveting tool over the pin and squeeze the handles. Jaws grab the pin and pull the head of the pin into the rivet, expanding it and forming a head on the other side. Continue squeezing the handles until the head on the reverse side forms a tight joint. When this happens, the pin breaks off and is ejected from the riveting tool. **Figure 6.7** shows what a finished rivet looks like. The rivet can only be removed by drilling it out with a drill bit that is the same size as the rivet. When the rivet is drilled out, the back side of the rivet will fall on the inside

Figure 6.6 (A) A pin rivet assembly. (B) Using pin rivets to fasten sheet metal. (C) A riveting gun.

of the sheet metal pieces that are fastened together. **SAFETY PRECAUTION:** *If you are working on an electrical panel, be sure the power is off.* Another rivet of the same size can be used to refasten the panels.

6.3 THREADED FASTENERS

We will describe only a few of the most common threaded fasteners.

WOOD SCREWS

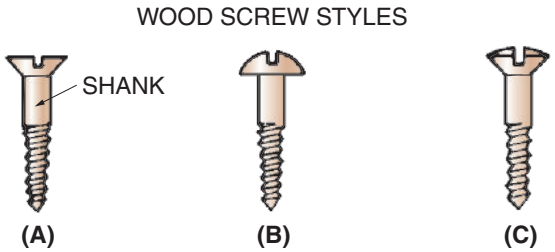
Wood screws are used to fasten many types of materials to wood. They generally have a flat, round, or oval head, **Figure 6.8**. The portion of flat- and oval-head screws beneath the head is at an angle. Holes for these screws should be countersunk so that the angular portion is recessed. Wood screws can also have a straight, slotted head or a Phillips recessed head.

Wood screw sizes are specified by length (in inches) and shank diameter (a number from 0 to 24). The larger the number, the larger the diameter or gauge of the shank. The number that represents the shank diameter can be converted to inches by using the following formula:

$$\text{Shank Diameter in Inches} = (\text{Shank Number} \times 0.013) + 0.06$$

For example, a number 8 screw has a larger shank diameter (0.1643) than a number 6 screw (0.1383). An 8-1″ wood screw and a 6-1″ wood screw are both 1 inch long, but the number 8 screw is wider. The numbering system described here is used for smaller screws up to 1/4 inch in diameter; then the system changes to fractions of an inch. Larger sizes of wood screws (screws with a tapered shaft) are called lag screws. They often come with a hexagonal or a square head and are tightened with a wrench, not a hand driver. These are typically used to fasten timber or large pieces of wood together, **Figure 6.9**.

Figure 6.8 (A) A flat-head wood screw. (B) A round-head wood screw. (C) An oval-head wood screw.



TAPPING SCREWS

Tapping or sheet metal screws are used extensively by service technicians. These screws may have a straight slot, a Phillips head, or a straight slot and hex head, **Figure 6.10**. To use a tapping screw, you drill a hole into the sheet metal the approximate size of the root diameter of the thread. Then you turn the screw into the hole with a conventional screwdriver or electric drill with a screwdriver bit.

Figure 6.11 shows a tapping screw, often called a self-drilling screw, that can be turned into sheet metal with an electric drill using a chuck similar to the one shown. This screw has a special point used to start the hole. It can be used with light to medium gauges of sheet metal. Note that self-tapping and self-drilling screws are not the same. Self-tapping screws require a hole to be drilled in the sheet metal prior to installing the screw; the self-drilling screw makes its own hole. Notice the difference in the tips of the screws in **Figure 6.10** and **Figure 6.11**.

Figure 6.9 Lag screw or bolt.

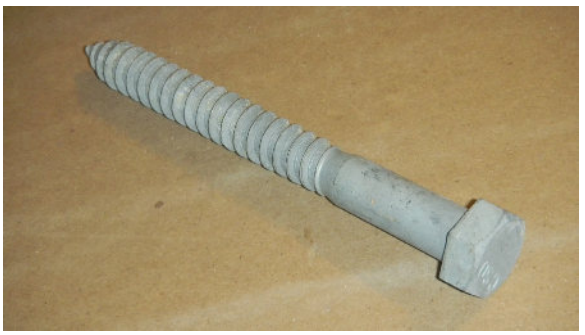


Photo by Eugene Silberstein

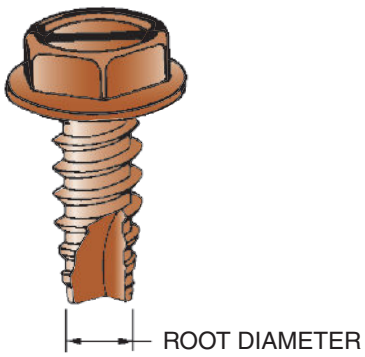
Figure 6.10 A tapping screw.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 6.11 Self-drilling screws and a drill chuck.

Photo by Eugene Silberstein

Tapping screws are identified or labeled in a specific way. The following is a typical identifying label:

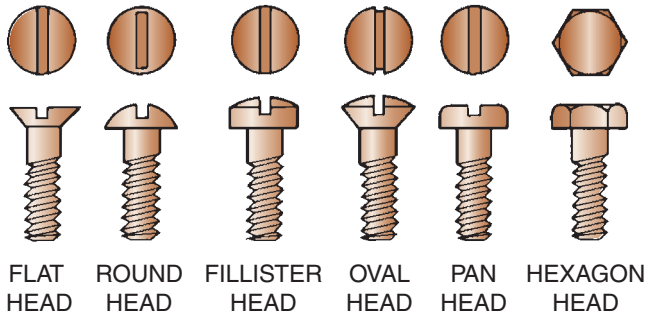
6-20 × 1/2 Type AB, Slotted hex
6 = Screw Size Number
20 = Number of threads per inch
1/2 = Length of the screw
Type AB = Type of point
Slotted hex = Type of head

MACHINE SCREWS

There are many types of machine screws. They normally are identified by their head styles. Some of these are indicated in **Figure 6.12.** A thread dimension or label indicates the following information:

5/16–18 UNC -2
5/16 = Outside thread diameter
18 = Number of threads per inch
UNC = Unified thread series (Unified National Coarse)
2 = Class of fit (the amount of play between the internal and external threads)

Figure 6.12 Machine screws.



SET SCREWS

Set screws have points, as illustrated in **Figure 6.13,** and have square heads, hex heads, or no heads. The headless type may be slotted for a screwdriver, or it may have a hexagonal or fluted socket. These screws are used to keep a pulley from turning on a shaft and for other, similar applications. The set screw that is used to hold a pulley tight on a shaft is made of hardened steel; the pulley shaft is made of soft steel. When the set screw is tightened onto the shaft, it indents the shaft with its tip.

OTHER FASTENER HEADS

Figure 6.14 is an illustration of several fastener heads and their driver tips.

Figure 6.13 Styles of set screws.

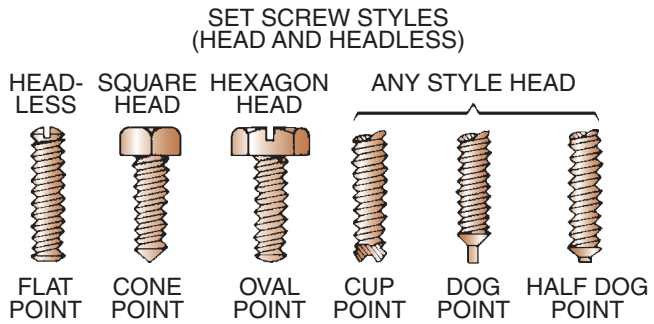


Figure 6.14 Several fastener heads and their driver tips.

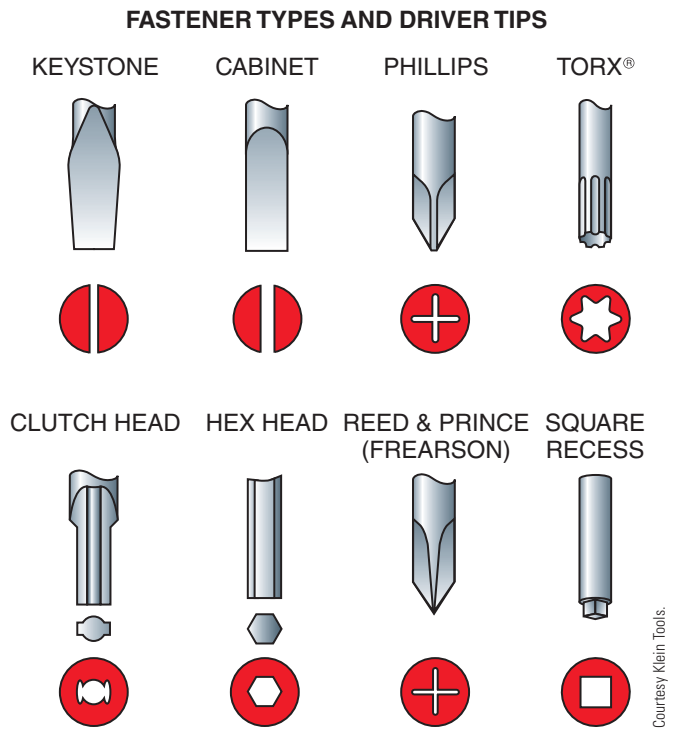

Courtesy Klein Tools.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

DRYWALL FASTENERS AND METAL HANGERS

ANCHOR SHIELDS. Anchor shields with bolts or screws are used to fasten objects to masonry or, in some instances, hollow walls. **Figure 6.15** illustrates a multipurpose steel anchor bolt used in masonry material. You drill a hole in the masonry the size of the sleeve, tap the sleeve and bolt into the hole with a hammer, and turn the bolt head. This expands the sleeve and secures the bolt in the masonry, **Figure 6.16.** A variety of head styles are available.

WALL ANCHORS. **Hollow wall anchors**, **Figure 6.17**, can be used in plaster, wallboard, gypsum board, and similar materials. Once the anchor has been set, the screw may be removed as often as necessary without affecting the anchor.

TOGGLE BOLTS. **Toggle bolts** provide secure anchoring in hollow tiles, building block, plaster over lath, and gypsum board, **Figure 6.18.** You drill a hole in the wall large enough for the toggle in its folded position to go through, making certain that the object being secured has been positioned on the bolt before screwing the toggle on the bolt, **Figure 6.19.**

Figure 6.15 An anchor shield with a screw.

Photo by Eugene Silberstein

Figure 6.20 Inserting the folded toggle into the hole in the gypsum board.

Photo by Eugene Silberstein

Push the toggle through the hole and use a screwdriver to turn the bolt head, **Figure 6.20.** You must maintain tension on the toggle or it will not tighten. **Figure 6.21** shows the completed toggle bolt installation.

PLASTIC TOGGLE DRYWALL ANCHORS. One variation on the toggle bolt is the plastic toggle, **Figure 6.22.** Once a hole of the proper size has been made in the gypsum board, the plastic toggle is folded in half and inserted into the hole, **Figure 6.23.** A special pin that comes with the anchor is

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

inserted in the anchor to ensure that it opens inside the wall, **Figure 6.24**. Once the anchor is in place, the screw is fed through the item being secured and tightened into the anchor, **Figure 6.25**. Unlike the traditional toggle bolt, constant tension on the anchor is not required for tightening.

SELF-DRILLING DRYWALL ANCHORS. Another option for drywall applications is the self-drilling drywall anchor, **Figure 6.26**. This type of anchor does not require a predrilled hole. You simply press the tip of the anchor into the

Figure 6.23 The folded plastic toggle inserted into the hole in the gypsum board.

gypsum board and turn it clockwise until it is flush with the surface, **Figure 6.27**. Once the anchor is in place, the screw is fed through the item being secured and tightened into the anchor.

THREADED ROD AND ANGLE STEEL. Threaded rod and angle steel can be used to make custom hangers for pipes or components such as an air handler, **Figure 6.28**. Threaded rod can be attached to steel I-beams with a beam clamp, **Figure 6.29**. **SAFETY PRECAUTION:** *Be sure that all materials are strong enough to adequately support the equipment.*•

THREADED ROD AND STEEL CHANNEL. Threaded rod can also be used in combination with steel channel to fabricate custom hanging arrangements, **Figure 6.30**. Common components in this type of hanger include the steel channel, threaded rod, saddle plates, square washers, round washers, and nuts, **Figure 6.31**.

Figure 6.28 Using threaded rod and angle steel to fabricate a hanger.

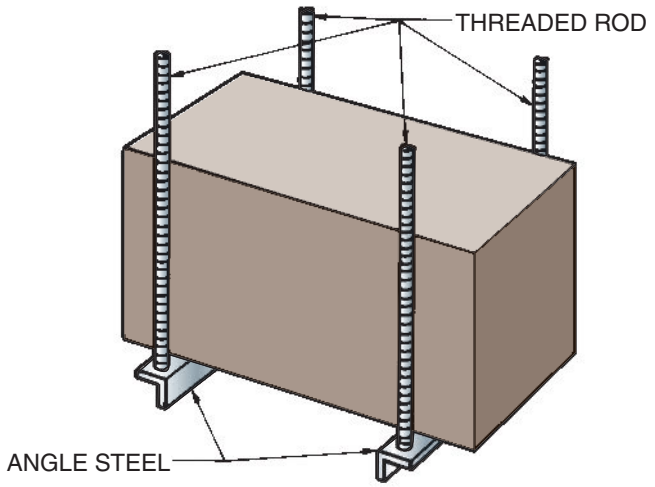

Figure 6.29 Beam clamp used to secure threaded rod.

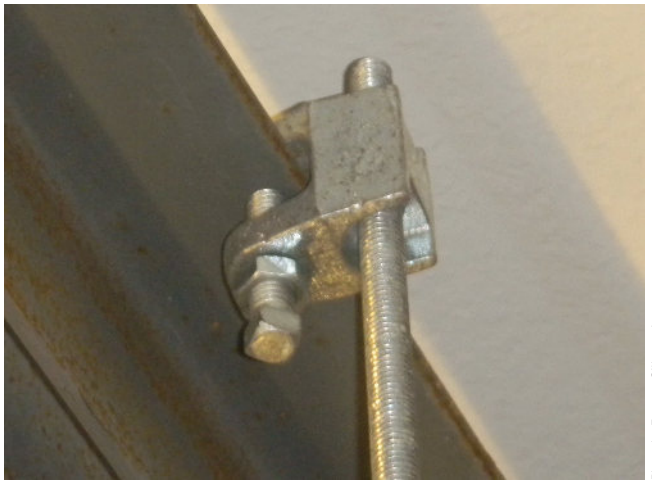

Photo by Eugene Silberstein

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

STEEL CHANNEL AND PIPE CLAMPS. Steel channel can also be used in conjunction with pipe clamps, **Figure 6.32**, on a number of different piping materials used in both refrigeration and electrical applications, **Figure 6.33**.

Figure 6.32 Steel channel and pipe clamp.

Photo by Eugene Silberstein

Figure 6.33 Steel channel and pipe clamp used to hold piping material.

Photo by Eugene Silberstein

6.4 CONCRETE FASTENERS

SCREW FASTENERS FOR CONCRETE

A concrete screw fastener may be used in poured concrete, concrete block, or brick, **Figure 6.34**. A hole must first be drilled in the base material. It is important to use the drill diameter recommended by the manufacturer for each screw size. Drill the hole slightly deeper than the length of the screw that will extend into the base material. Blow out the dust and other material from the hole to the extent possible. **SAFETY PRECAUTION:** *Wear safety goggles during this drilling and cleaning process.*• The screw may then be installed with an electric screwdriver or drill using a screwdriver bit or drill chuck, depending on the type of head on the screw.

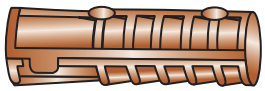
LAG SHIELD ANCHORS

A two-part shield, generally used with lag screws, has tapered internal threads for part of its length, **Figure 6.35**. To install them, drill a hole of the diameter recommended by the manufacturer for the size of shield. The hole should be drilled as deep as the length of the shield plus approximately 1/2 inch. Clean dust or loose concrete material out

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 6.34 A concrete screw fastener.

Figure 6.35 A lag shield anchor.



of the hole. **SAFETY PRECAUTION:** *Wear goggles when drilling and cleaning.* Tap the shield in with a hammer until it is flush with the surface. Position the material to be fastened with the hole over the shield and turn in the lag screw.

POWDER-ACTUATED FASTENER SYSTEMS

These systems provide another method of fastening materials to concrete, **Figure 6.36**. **SAFETY PRECAUTION:** *This type of system is very dangerous. Operators must have specific training and in many instances must be licensed. We only mention it here to make you aware that there is such a system.* A powder load, **Figure 6.37**, is used in a powder-actuated tool (PAT). When actuated, it forces a pin, threaded stud, or other fastener into the concrete. The powder loads are color-coded based on the amount of power needed for a particular job. **SAFETY PRECAUTION:** *Do not try this without the training and the license to operate this equipment.*

Many other types of fasteners are used to fasten material to concrete. Those described here are but a few examples.

Figure 6.36 A powder-actuated fastener system.

6.5 OTHER FASTENERS

COTTER PINS AND HAIRPINS

Cotter pins, **Figure 6.38**, are commonly used to secure objects on shafts. The cotter pin is inserted through the hole in the shaft and the ends of the pin are spread to keep it in place, **Figure 6.39**. Another type of clip that is similar to the cotter pin is the hairpin, **Figure 6.40**. This type of pin is also inserted through a hole in a shaft, but the configuration of the pin holds it in place, **Figure 6.41**.

PIPE HOOK

A wire pipe hook is a hardened steel wire bent into a U with a point at an angle on both ends. The pipe or tubing rests in the bottom of the U, and the pointed ends are driven into wooden joists or other wood supports, **Figure 6.42**.

PIPE STRAP

A pipe strap is used for fastening pipe and tubing to joists, ceilings, or walls, **Figure 6.43(A)**. The arc on the strap should be approximately the same as the outside diameter of the pipe or tubing. These straps are normally fastened with round-head screws. Notice that the underside of the head of a round-head screw is flat and provides good contact with the strap.

PERFORATED STRAP

A perforated strap may also be used to support pipe and tubing. Round-head stove bolts with nuts fasten the straps to themselves, and round-head wood screws fasten the straps to wood supports, **Figure 6.43(B)**.

Figure 6.42 (A) A wire pipe hook. (B) Pipe hook installation.

NYLON STRAP

To fasten round flexible duct to a sheet metal collar, apply sealer to the inner liner of the duct and clamp it with a nylon strap. A special tool is manufactured to install this strap, which applies the correct tension and cuts the strap off. The insulation and vapor barrier are positioned over the collar, which can then be secured with another nylon strap. Duct tape is applied over this strap and duct end to further seal the system. **Figure 6.44** illustrates this procedure.

RETAINING RINGS

Retaining rings, also referred to as snap-rings, are fasteners that hold a component either onto a shaft or inside some type of housing. Rings that are used to hold a wheel on a

Photo by Eugene Silberstein

shaft, for example, are referred to as external retaining rings, **Figure 6.45**, while those that are used to keep a component inside a shaft or other housing are called internal retaining rings, **Figure 6.46**. Retaining rings are intended to be positioned inside grooves in a shaft, **Figure 6.47**. When properly installed, the portion of the ring that extends past the shaft creates a shoulder that holds the wheel or component in place. Special pliers are used to remove and install retaining rings, **Figure 6.48**. The pair of pliers in **Figure 6.48** has interchangeable heads that allow the user to get into tight areas. In addition, the pliers has two sets of pins on which a head can be mounted, **Figure 6.49**. The head is mounted to the upper pins when the tool is to be used on externally mounted retaining rings. Squeezing the pliers will cause the jaws to open, allowing the tool to be used to open the ring, **Figure 6.50**. When released, the jaws close, **Figure 6.51**. The head is

mounted to the lower pins when the tool is to be used on internally mounted retaining rings. Squeezing the pliers will cause the jaws to close, allowing the tool to be used to pull the ring closed, **Figure 6.52**. When released, the jaws open, **Figure 6.53**. Another type of retaining clip is the C-clip, which is commonly used to hold a wheel on a shaft, **Figure 6.54**.

HOSE CLAMPS

Hose clamps are used to attach one end of a hose to a fitting, component, or section of pipe. Two types of hose clamps that are commonly used in the HVAC/R industry are the screw-type and the spring-type. The screw-type hose clamp, **Figure 6.55**, is a galvanized or stainless steel band into which a series of notches have been cut. One end of the

Figure 6.56 Spring-type hose clamp.

Photo by Eugene Silberstein

band has a fitting that receives the loose end of the strap. This fitting has a stationary screw connected to it. When the screw is turned, it pulls the loose end of the strap through the fitting, and tightens the clamp. For convenience, the head of the screw is often a hex-head screw, so a nut driver can be used to quickly and easily tighten or loosen the hose clamp.

The spring-type hose clamp, **Figure 6.56**, is made from a strip of spring-steel or from spring-steel wire. The clamp has two tabs on it and, when the tabs are squeezed together, the clamp opens and the diameter of the clamp is increased. At this point, the clamp is placed over the tubing to be secured. When the tabs are released, the clamp tightens and secures the tubing in place. Pliers are usually used to squeeze the tabs on the clamp together.

SOLDERLESS TERMINALS

Solderless terminals are used to fasten stranded wire to various terminals or to connect two lengths of stranded wire together. Various styles of these terminals are shown in **Figure 6.57**. **Figure 6.58** shows a typical terminal before the wire has been inserted. To connect wire to a terminal, strip a short end of the insulation. A stripping and cutting tool similar to the one in **Figure 6.59** may be used. Insert wire into the terminal as indicated in **Figure 6.60**. A crimping tool, **Figure 6.61**, is then used to crimp the solderless connector onto the wire.

Figure 6.57 Typical solderless connectors.

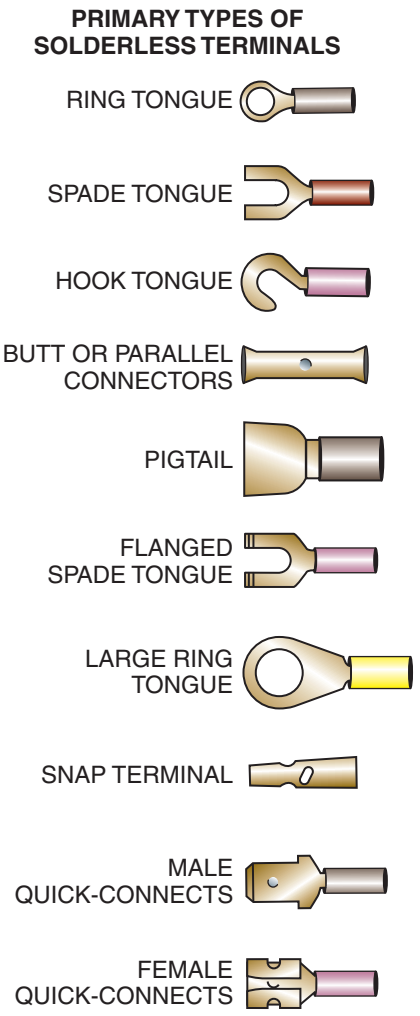

Figure 6.58 Cutaway view of a typical solderless connector.

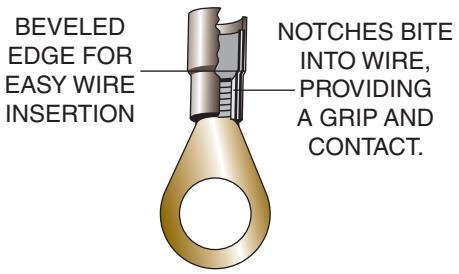

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

CONNECTING STRANDED WIRE UNDER SCREW TERMINALS. When connecting stranded wire under screw terminals it is recommended that the solderless connectors just described be used, as they provide a tight connection that will help ensure proper circuit operation. Stranded wire should not be directly connected under a screw terminal because the strands of wire can separate, resulting in a poor electrical connection, **Figure 6.62**. If stranded wire is to be connected under a screw terminal, the end of the wire should be tinned, which is the process of soldering the strands of a wire together so they will not separate, **Figure 6.63**. The tinned wire can then be secured under a screw terminal, **Figure 6.64**.

Figure 6.62 Stranded wire should not be directly connected under a screw terminal.

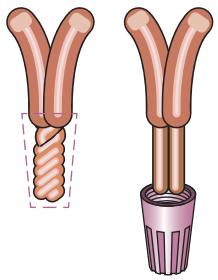
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 6.65 Screw-on wire connectors.

Photo by Eugene Silberstein

SCREW-ON WIRE CONNECTORS. Screw-on wire connectors, commonly referred to as wire nuts, are used to connect two or more wires, **Figure 6.65**. They come in various sizes for different sizes and numbers of wires. Be sure to follow the manufacturer's instructions when installing these connectors. Following is a summary of one or more manufacturers' instructions:

Figure 6.66 Installing screw-on wire connectors.



1. Strip each wire to the depth of the connector.
2. Insert the wires into the connector and twist it on, **Figure 6.66**.
3. The screw action will twist the wires together, pressing them into the threads of the connector and forming a strong bond.

SAFETY PRECAUTION: *Ensure that the connector completely covers the bare wire. Refrigeration and air-conditioning technicians normally will use these connectors on control voltage or other low-voltage circuits unless licensed for higher-voltage applications. It is important to use a connector of the proper size.*•

SUMMARY

- Technicians need to use a broad variety of fasteners.
- Some of these fasteners are nails, screws, staples, tapping screws, and set screws.
- Anchor shields, toggle bolts, and other devices are often used with screws to secure them in masonry or hollow walls.
- Typical hangers used with pipe, tubing, and ductwork are wire pipe hooks, pipe straps, perforated steel straps, and custom hangers made from threaded rod and angle steel or steel channel.
- Other specialty fasteners are available for flexible duct and fiberglass duct.
- Solderless terminals are used to fasten wires to terminals.
- Screw-on wire connectors are used to fasten two or more lengths of wire together.

REVIEW QUESTIONS

1. Three types of nails are _____, _____, and _____.
2. The term _____ is used to indicate the size of a common nail.
3. What is the abbreviation for the answer to question 2?
4. An outward clinch tacker is used to
   A. bend wire on a pipe hook.
   B. install a pin rivet.
   C. drive roofing nails.
   D. spread the ends of a staple outward.
5. Wood screws generally have
   A. a flat head.
   B. a round head.
   C. an oval head.
   D. any of the above.
6. List and describe three methods of securing an object to a wall made of gypsum board.
7. What are masonry nails made from?
8. Describe two types of staples.
9. Describe the procedure for fastening two pieces of metal together with a pin rivet.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

10. Write a typical dimension for a tapping screw. Explain each part of the dimension.
11. Sketch three types of machine screw heads.
12. Write a typical machine screw thread dimension, and explain each part of the dimension.
13. Describe the procedure for fastening two pieces of sheet metal together with a tapping screw.
14. Hollow rivets are assembled in a pin that is often called
    A. a mandrel.
    B. a nozzle.
    C. an anchor.
    D. a clinch.
15. Describe two types of tapping screws.
16. Three types of set screw points are _____, _____, and _____.
17. How are anchor shields used?
18. What is a pipe strap? What is it used for?
19. Explain the purpose of external and internal retaining clips.
20. Describe the procedure for fastening three wires together using screw-on wire connectors.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

UNIT 7

TUBING AND PIPING

OBJECTIVES

After studying this unit, you should be able to

- list the different types of tubing used in heating, air-conditioning, and refrigeration applications.
- describe two common ways of cutting copper tubing.
- list procedures used for bending tubing.
- discuss procedures used for soldering and brazing tubing.
- describe two methods for making flared joints.
- state procedures for making swaged joints.
- explain how a compression fitting is made.
- describe procedures for preparing and threading steel pipe ends.
- list four types of plastic pipe and describe uses for each.
- describe alternative, mechanical methods for joining pipe sections.

SAFETYCHECKLIST

- ☑ Use care while cutting, threading, and reaming tubing and piping; the burrs that are created can cut your skin.
- ☑ Be careful while using a hacksaw; the blade is sharp.
- ☑ Do not allow your bare skin near the flame of a torch or near material that has just been soldered, brazed, or welded; the 5000°F and higher temperatures can cause severe burns.
- ☑ Always wear eye protection while performing any task where particles may be in the air.
- ☑ Use extra caution with the oxyacetylene heat source.
- ☑ Do not allow any oil around the fittings or allow it to enter the hoses or regulators.
- ☑ Be aware of flammable materials in the area where you are soldering or brazing.
- ☑ Do not breathe excessive amounts of the adhesive used for plastic fittings.
- ☑ Only use chemicals that give off dangerous fumes in well-ventilated areas.
- ☑ Follow all manufacturers' instructions when using soldering and brazing materials.

7.1 PURPOSE OF TUBING AND PIPING

The correct size, layout, and installation of tubing, piping, and fittings helps to keep a refrigeration or air-conditioning system operating properly and efficiently and prevents refrigerant loss.

The piping system provides the path for refrigerant flow between system components. It also provides the way for oil to drain back to the compressor. Tubing, piping, and fittings are used in numerous applications, such as fuel lines for oil and gas burners and water lines for hot water heating. The tubing, piping, and fittings must be of the correct material and the proper size; the system must be laid out properly and installed correctly.

SAFETY PRECAUTION: *Careless handling of the tubing and poor soldering or brazing techniques may cause serious damage to system components. You must prevent contaminants, such as moisture and dirt, from entering air-conditioning and refrigeration systems.*

7.2 TYPES AND SIZES OF TUBING

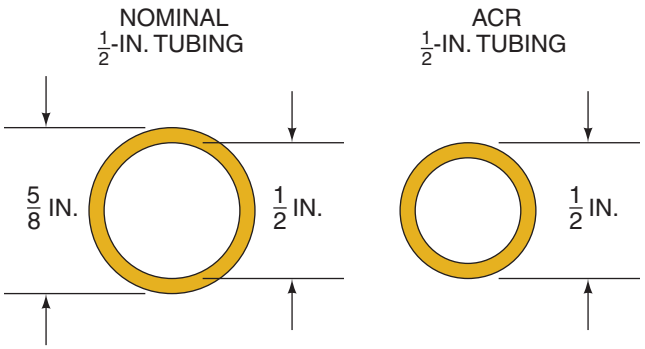
Copper tubing is generally used for plumbing, heating, and refrigerant piping. Steel and wrought iron pipe are used for gas piping and frequently for steam heating. Plastic pipe is often used for waste drains, condensate drains, water supplies, water-source heat pumps, and venting high-efficiency gas furnaces.

Copper tubing is available as soft- or hard-drawn copper. Soft copper tubing, **Figure 7.1**, may be bent or used with

Figure 7.1 Soft-drawn copper tubing typically comes in 50-ft rolls. Note that the ends of the rolls are capped to keep the interior of the tubing clean.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 7.2 Copper tubing (nominal) used for plumbing and heating is sized by its inside diameter. ACR tubing is sized by its outside diameter.



elbows, tees, and other fittings. Hard-drawn tubing is not intended to be bent and is used only with fittings to obtain the necessary configurations. This tubing is available in four standard weights: K, L, M, and DWV. K-type copper is heavy duty with a thick tubing wall. L-type copper is considered medium weight and is the type used most frequently. M is a lightweight copper and is not commonly used in the industry. DWV copper—drain, waste, and vent—is also a lightweight copper not typically used in the HVAC/R industry so far as refrigerant-carrying applications are concerned. Copper tubing used for refrigeration or air-conditioning is called ACR (air-conditioning and refrigeration) tubing and is sized by its outside diameter (OD). Therefore, if a specification calls for 1/2-in. ACR tubing, the outside diameter of the tubing would measure 1/2 in., **Figure 7.2**. Tubing used for plumbing and heating applications, called nominal-sized tubing, is sized by its inside diameter (ID). The OD for most applications in the plumbing and heating industry will be 1/8 in. larger than the size indicated. A 1/2-in. nominal-sized tubing would have an OD of 5/8 in., **Figure 7.2**. Copper tubing normally is available in diameters from 3/16 in. to greater than 6 in.

Soft copper tubing is normally available in 25-ft or 50-ft rolls and in diameters from 3/16 in. to 7/8 in. It can be special ordered in 100-ft lengths. ACR tubing is capped on each end to keep the inside clean and dry and it often has a charge of nitrogen to keep it free of contaminants. Proper practice should be used to remove tubing from the coil. Place it on a flat surface and unroll it, **Figure 7.3**. Cut only what you need and recap the ends, **Figure 7.1**. Hard-drawn copper tubing is available in lengths up to 20 ft and in larger diameters than soft copper tubing. Be as careful with hard-drawn copper as with soft copper, and recap the ends when the tubing is not in use.

Do not bend or straighten the tubing more than necessary because it will harden. This is called **work hardening**. Work-hardened tubing can be softened by heating and allowing it to cool slowly. This is called **annealing**. When annealing, do not use a high concentrated heat in one area, but use a flared flame over 1 ft at a time. Heat to a cherry red and allow to cool slowly.

Figure 7.3 A roll of soft-drawn copper tubing. Place on a flat surface and unroll.

Photo by Eugene Silberstein

7.3 TUBING INSULATION

ACR tubing is often insulated on the low-pressure side of an air-conditioning or refrigeration system between the evaporator and the compressor to keep the refrigerant from absorbing excess heat, **Figure 7.4**. Insulation also prevents condensation from forming on the lines. The closed-cell structure of this insulation eliminates the need for a vapor barrier. The insulation may be purchased separately from the tubing, or it may be factory installed. If you install the insulation, it is easier, where practical, to apply it to the tubing before assembling the line. The inside surface of the insulation is usually powdered to allow easy slippage even around most bends. You can buy adhesive to join the ends of the insulation together, **Figure 7.5**.

Figure 7.4 ACR tubing with insulation.

Photo by Eugene Silberstein

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 7.5 When joining two ends of tubing insulation, use an adhesive intended for this purpose.

Photo by Eugene Silberstein

It is not always possible or practical, however, to install the insulation on the tubing section before installing the line. When installing insulation on a section of tubing that has already been installed, you will have to slit the insulation. To help ensure a neat-looking job, here are some suggestions:

- Slit the insulation along the markings on the insulation, **Figure** 7.6.
- Slide the insulation over the tubing section, **Figure** 7.7.
- Once the insulation has been placed on the tubing, use adhesive to seal the insulation, **Figure** 7.8.
- Do not use tape, plastic wire/cable ties, or other methods to hold the insulation together.
- Rotate the insulation so that the insulation markings and the seam are not visible, **Figure** 7.9.

Do not stretch tubing insulation because that will reduce the wall thickness of the insulation, which will reduce the effectiveness of the insulation, and the adhesive may fail to hold.

Figure 7.6 Pipe insulation being slit with a sharp razor knife.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

7.4 LINE SETS

Tubing can be purchased in bundles called **line sets**, which often consist of a liquid line and an insulated suction line. One type of line set comes precharged with refrigerant and each of the lines is sealed at both ends. Precharged line sets have quick-connect fittings installed on the ends for quicker, neater, and easier installation, **Figure 7.10**. The fittings on the lines must be properly aligned with the mating fittings on the equipment before tightening to ensure that refrigerant is not released into the atmosphere. Since precharged line sets are purchased along with precharged system components, the system does not have to be evacuated prior to putting it into operation. In addition, the refrigerant charge should be perfect, since the refrigerant is added at the factory according to the particular requirements of the system. As of January 1, 2010, it became illegal to manufacture or import precharged line sets that contain R-22 or R-142b. This law covers equipment components such as line sets, condensing units, and evaporator coils. Precharged line sets, for example, can be used to service existing equipment as long as the line set was manufactured before January 1, 2010.

Another type of line set is nitrogen-charged, just like standard ACR tubing. The suction line in this line set, however, is insulated. This type of line set may be purchased with various fitting options, but if the fittings need to be changed, they can be cut off and replaced. Since these line sets are not precharged with refrigerant, the nitrogen must be released and the system must be properly evacuated prior to putting the system into operation.

(B)

7.5 CUTTING TUBING

Tubing is normally cut with a tube cutter or a hacksaw. The tube cutter is most often used with soft tubing and smaller-diameter hard-drawn tubing. A hacksaw may be used with larger-diameter hard-drawn tubing. To cut the tubing with a tube cutter, follow these steps, as shown in **Figure 7.11**.

A. Place the tubing in the cutter and align the cutting wheel with the cutting mark on the tube. Tighten the adjusting screw until a moderate pressure is applied to the tubing.
B. When properly tightened, the cutter should be held in place on the tubing and there should be no cutter wheel indentations in the copper tubing. Overtightening the cutter on the tubing will result in oblong or out-of-round edges that can cause refrigerant leaks.
C. Revolve the cutter around the tubing, keeping a moderate pressure on the tubing by gradually turning the adjusting screw, roughly 1/8 of a turn per rotation around the tubing.
D. Continue until the tubing is cut. *Do not apply excessive pressure because it may break the cutter wheel and/or constrict the opening in the tubing.*

When the cut is finished, the excess material (called a **burr**) pushed into the pipe by the cutter wheel must be removed, **Figure 7.12**. Burrs can restrict the fluid or vapor passing through the pipe. When removing burrs from the end of a cut pipe section, make every attempt to prevent the burrs from falling into the pipe. Burrs that remain in the system can restrict refrigerant flow and affect system operation and performance.

Cuts made with a hacksaw should be at a 90° angle to the tubing. After cutting, ream the tubing and file the end. Remove all chips and filings, making sure that no debris or metal particles get into the tubing. Since using a hacksaw under normal conditions produces a large amount of copper filings and burrs, this method is not preferable when using a tubing cutter is an option. Given certain conditions, however, it may be the only choice available.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 7.12 Removing burrs from inside the tubing.

7.6 BENDING TUBING

To ensure refrigerant stays in the system, the number of solder joints and mechanical fittings should be kept to a minimum. Each solder joint, fitting, and mechanical connection represents a potential leak. One way to reduce the number of solder joints in a piping system is to bend the tubing material into the desired configuration. Typically, only soft tubing should be bent. Use as large a radius bend as possible, **Figure 7.13(A)**. All areas of the tubing must remain round; *do not allow it to flatten or kink,* **Figure 7.13(B)**. Carefully bend the tubing, gradually working around the radius.

Tube bending springs may be used to help make the bend, **Figure 7.14**, and can be placed either inside or outside the tube. They are available in different sizes for different diameters of tubing, **Figure 7.15**. To remove the spring after the bend, you might have to twist it. If you use a spring on the OD, bend the tube before flaring so that the spring may be removed.

Lever-type tube benders, **Figure 7.16**, which are available in different sizes, are used to bend soft copper, aluminum, and thin-walled steel tubing. There are many different types of benders available; we describe briefly here the operation of the lever-type bender.

The lever-type bender is made up of two parts, the body and the lever, **Figure 7.17**. The body has markings that represent the amount of bend, in degrees, that will be put into a tubing section if the section is bent up to that point. The lever also has markings, which indicate the proper positions of the lever and tubing when the bend is both started and completed. The tubing position in the bender depends on whether the piping is extending from the left or the right side of the bender.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 7.16 Lever-type tube bender.

Photo by Eugene Silberstein

Figure 7.17 Markings on the lever and body of the lever-type tube bender.

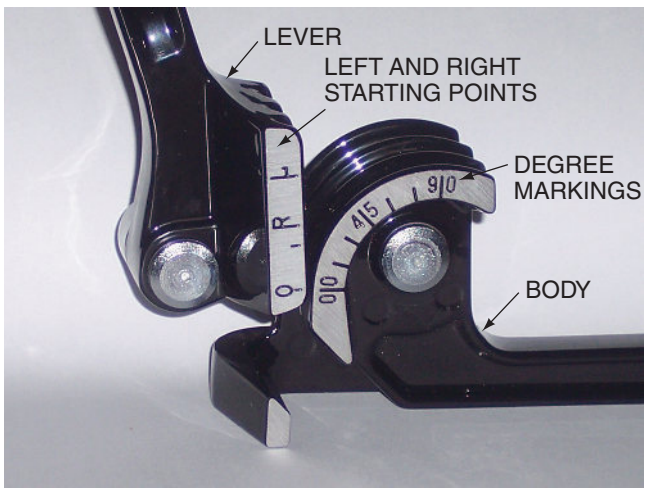

Photo by Eugene Silberstein

Let's say you wanted to put a 90-degree bend in a piece of soft-drawn copper tubing so that the length from the unbent end of the tubing to the center of the bent end is 6 inches. In this case, you would first measure and mark the tubing at the 6-inch point, **Figure 7.18**. Once marked, you insert the tubing into the bender and line up the mark with the "L," which indicates that the measured portion of tubing is extending from the left side of the bender, **Figure 7.19**. You also want to

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 7.18 Mark tubing at the desired point.

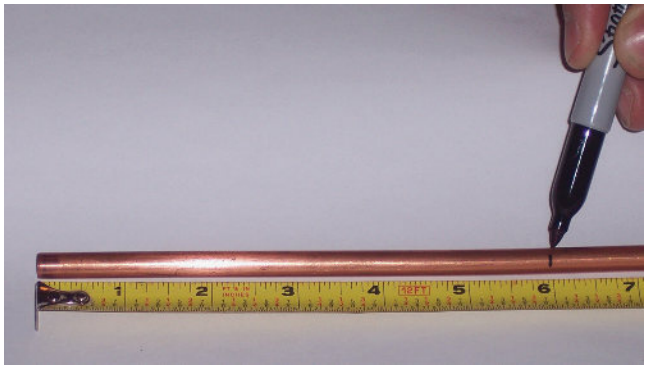

Photo by Eugene Silberstein

Figure 7.19 Proper tubing and lever positions at the beginning of the bending process.

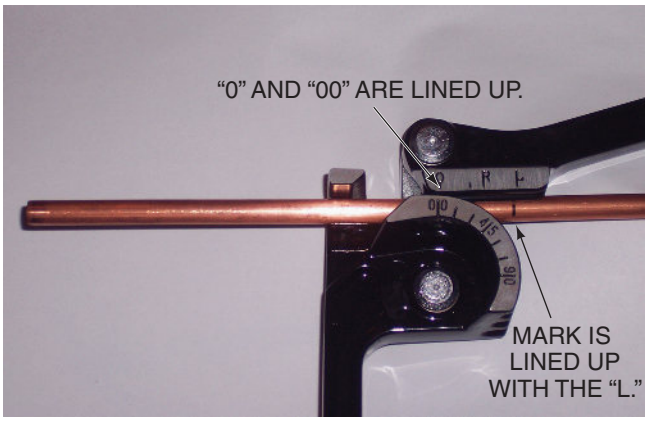

Photo by Eugene Silberstein

Figure 7.20 Completing a 90-degree bend.

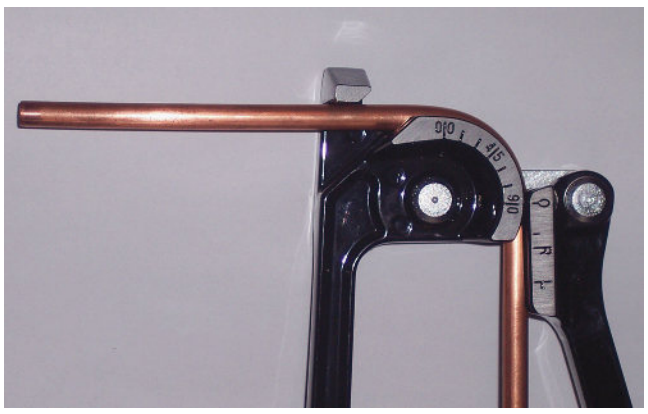

Photo by Eugene Silberstein

make certain that the "0" on the lever lines up with the "00" on the body of the bender. This ensures that the lever is in the proper position prior to bending. While holding the handle on the body of the bender, pull on the lever until the "0" on the lever is lined up with the "90" on the body. This ensures that the bend will be 90 degrees, **Figure 7.20**.

Figure 7.21 A 45-degree bend.

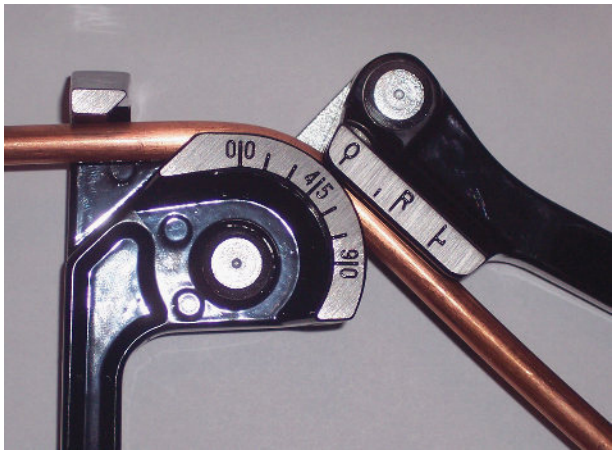

Photo by Eugene Silberstein

If, however, you wanted to make a 45-degree bend in the tubing instead of a 90-degree bend, the lever would be positioned so that the "0" on the lever is lined up with the "45" on the body, **Figure 7.21**. Be sure to practice on smaller, scrap sections of tubing to gain confidence in creating tubing bends at the desired positions. It takes a little time to get it just right, but the results will be well worth the effort.

7.7 SOLDERING AND BRAZING PROCESSES

Soldering is a process that joins piping and tubing to fittings. It is used primarily in plumbing and heating systems utilizing copper and brass piping and fittings. According to the American Welding Society, soldering, often called soft soldering, utilizes filler materials that melt at temperatures under 842°F, usually in the 361°F to 500°F range, **Figure 7.22**.

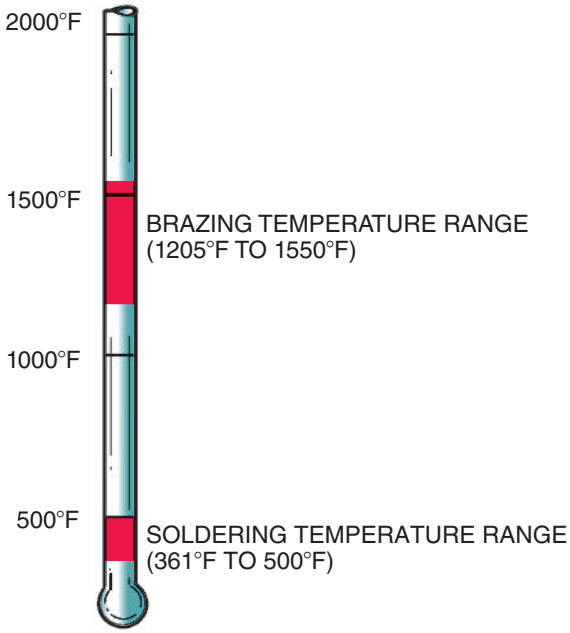
When soldering or brazing, a gap is left between the two surfaces that are to be fastened together. For example, when two lengths of copper tubing are to be fastened, a fitting or coupling may be placed between them into which each pipe slides. This requires a clearance between the tubing and the coupling or fitting. A filler metal must be used to fill this space. As it fills the gap, the filler metal actually adheres to the tubing and fitting to be joined. Only the filler metal melts.

Two common filler materials used for soldering are 50/50 and 95/5. The 50/50 tin–lead solder (50% tin–50% lead) is a suitable filler metal for moderate pressures and temperatures. A 50/50 tin–lead solder cannot be used for water-supply or potable water lines because of its lead content. For higher-pressure potable water-supply lines, or where greater joint strength is required, 95/5 tin–antimony solder (95% tin–5% antimony) can be used.

Brazing is similar to soldering but requires higher temperatures. Often called silver brazing or hard soldering, it is used to join tubing and piping in air-conditioning and

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 7.22 Temperature ranges for soldering and brazing.



refrigeration systems. Do not confuse this with welding brazing. Brazing utilizes filler materials that melt at temperatures above 842°F. The differences in temperature are necessary due to the different combinations of alloys used in the filler metals. Brazing filler metals suitable for joining copper tubing are alloys containing 15% to 60% silver (BAg) or copper alloys containing phosphorous (BCuP). Brazing filler metals are sometimes referred to as hard solders or silver solders.

In soldering and brazing, the base metal (the piping, tubing, and/or fitting) is heated to the melting point of the filler material. *The piping and tubing must not melt.* When two close-fitting, clean, smooth metals are heated to the point where the filler metal melts, the molten metal is drawn into the close-fitting space by **capillary attraction** (see **Figure 7.23** for an explanation). If the soldering is properly done, the molten solder will be absorbed into the pores of the base metal, adhere to all surfaces, and form a bond, **Figure 7.24**.

Figure 7.23 Two examples of capillary attraction. On the left are two pieces of glass spaced closely together. When the pieces of glass are inserted in water, capillary attraction draws the water into the space between them. The water molecules have a greater attraction for the glass than they do for each other. On the right is an illustration showing molten filler material being drawn into the space between the two pieces of base metal. The molecules in the filler material have a greater attraction for the base metal than they do for each other. These molecules work their way along the joint, first "wetting" the base metal and then filling the joint.

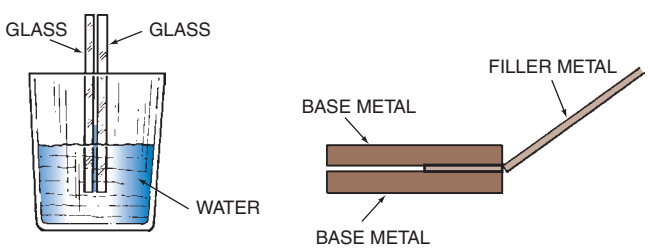


Figure 7.24 The molten solder in a soldered joint will be absorbed into the surface pores of the base metal.

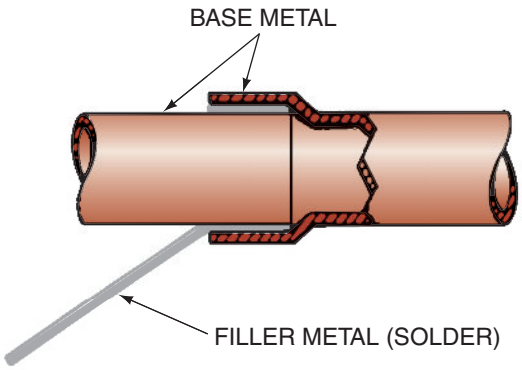

7.8 HEAT SOURCES FOR SOLDERING AND BRAZING

Propane, butane, air-acetylene, or oxyacetylene torches are the most common sources of heat for soldering or brazing. A **propane** or **butane** torch can be ignited easily and adjusted to the type and size of joint being soldered, **Figure 7.25**. An **air-acetylene** unit is often used by air-conditioning and refrigeration technicians. It usually consists of a B tank of acetylene gas, a regulator, a hose, and a torch, **Figure 7.26**. Various sizes of standard tips are available. The smaller tips are used for small-diameter tubing and for high-temperature applications. A high-velocity tip may be used to provide more concentration of heat. **Figure 7.27** illustrates a popular high-velocity tip.

Figure 7.25 A propane torch with a typical soldering tip.

(G)

C. Open the tank valve one-half turn. **SAFETY PRECAUTION:** *There is no need to open the tank valve more than one-half turn—this will give adequate flow. Leave the wrench on the tank valve stem. The valve can then be quickly closed in the event of an emergency.* Adjust the regulator valve to about midrange.

D. Spray a soap bubble solution on the hose, regulator, and torch handle.

E. Look for bubbles on the hose, regulator, and torch handle that could indicate a leak.

F. Open the needle valve on the torch slightly, and ignite the gas with the striker or spark lighter. **SAFETY PRECAUTION:** *Do not use matches or cigarette lighters.*

G. Adjust the flame using the needle valve at the handle until the flame is correct. The ideal flame on the air-acetylene torch is a carburizing flame, which has a well-defined inner cone and provides excess acetylene. The excess acetylene helps remove oxidation from the surface of the copper pipes and fittings. **SAFETY PRECAUTION:** *After each use, shut off the valve on the tank and bleed off the acetylene in the hose by opening the valve on the torch handle. Bleeding the acetylene from the hoses relieves the pressure when the hoses are not in use.*

Some technicians prefer **oxyacetylene** torches, particularly when brazing large-diameter tubing or in other applications requiring higher temperatures. The addition of pure oxygen produces a much hotter flame. **SAFETY PRECAUTION:** *This equipment can be extremely dangerous when not used properly. You must thoroughly understand what the proper procedures are for using oxyacetylene equipment before attempting to use it. When you first use the equipment, do so only under the close supervision of a qualified person.*

The following is a brief description of oxyacetylene welding and brazing equipment. As mentioned, oxyacetylene brazing and welding processes use a high-temperature flame, which is produced by mixing oxygen with acetylene gas. The equipment includes oxygen and acetylene cylinders, oxygen and acetylene pressure regulators, hoses, fittings, safety valves, torches, and tips, **Figure 7.29**.

The regulators each have two gauges, one to register tank pressure and the other to register pressure to the torch. The pressures indicated on these regulators are in pounds per square inch gauge (psig). **Figure 7.30** is a photo of an oxygen regulator and an acetylene regulator. These regulators must be used only for the gases and service for which they are intended. **SAFETY PRECAUTION:** *All connections must be free from dirt, dust, grease, and oil. Oxygen can produce an explosion when in contact with grease or oil. A reverse flow valve should be used somewhere on the hoses. These valves allow the gas to flow in one direction only and prevent the two gases from mixing in the hose, which could be very dangerous.* **Figure 7.31(A)** shows the reverse flow check valve. Follow instructions when attaching these valves because some are designed to attach to the hose connection on the torch body and some to the hose connection on the regulator.

The red hose is attached to the acetylene regulator with left-handed threads, and the green hose is attached to the oxygen regulator with right-handed threads. The torch body is then attached to the hoses and the appropriate tip to the torch, **Figure 7.31(A)**. Many tip sizes and styles are available, **Figure 7.31(B)**. Some are designed to provide heat around the

tubing and fittings, allowing the entire circumference of the tubing to be heated at one time, **Figure 7.32.** Another type of tip removes and replaces a four-way or reversing valve for a heat pump, **Figure 7.33.** All three of the copper fittings from this valve can be heated simultaneously, and the tubing can be pulled from the valve when the brazing alloys reach the proper temperature. You should learn through your specialized training how to use this equipment and which tips to use for particular applications.

The following procedure may be used to set up an oxygen acetylene torch system for use. **SAFETY PRECAUTION:** *Always turn the fuel gas (acetylene) on or off first.•* With the regulators and hoses fastened to the tank and the torch tip and the T handles on the regulators turned counterclockwise so that no pressure will go to the hoses (they may feel loose):

1. Turn the acetylene cylinder valve one-half turn so that pressure is introduced to the regulator. **SAFETY PRECAUTION:** *Always stand to the side of the regulator. If the regulator were to blow out, it would likely blow toward the T handle. The wrench should remain on the stem of the cylinder valve so the valve can be quickly turned off in case of an emergency.•* You should be able to see the pressure register on the acetylene cylinder gauge, **Figure 7.34.**

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 7.33 A tip that can be used for removing and replacing the four-way reversing valve on a heat pump system.

Courtesy Uniweld Products, Inc.

2. Slowly turn on the oxygen cylinder valve to the oxygen regulator. **SAFETY PRECAUTION:** *Again, stand to the side.* You should be able to see the pressure register on the oxygen cylinder pressure gauge, **Figure 7.35**.
3. Slightly open the valve on the torch handle that controls the acetylene (the red hose). With this valve slightly open, adjust the T handle on the acetylene regulator until the gauge on the red hose reads 5 psig, **Figure 7.36**. **SAFETY PRECAUTION:** *Now shut off the valve at the torch.* This part of the torch is ready.
4. Slightly open the valve on the torch handle that controls the oxygen (the green hose). With the valve slightly open, adjust the T handle on the oxygen regulator until the gauge reads 10 psig, **Figure 7.37**. **SAFETY PRECAUTION:** *Now shut off the valve at the torch.* This part of the torch is ready.

The following procedure may be used to light the torch. **SAFETY PRECAUTION:** *Before lighting, always point the torch tip away from you or any flammable substance. Make sure that you point the torch away from the cylinders and hoses. Failure to do so could result in tragedy.* While holding the torch handle in your left hand:

1. Slightly open the valve on the torch handle on the acetylene side and allow it to flow a moment to get any air out of the line.
2. Using only an approved lighter, light the fuel gas, acetylene. You will have a large yellow-orange flame that smokes, **Figure 7.38**.

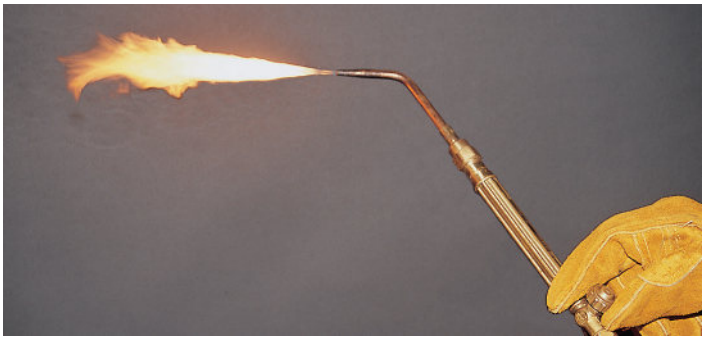
Figure 7.37 This oxygen regulator gauge indicates 10 psig.

Photo by Eugene Silberstein

Figure 7.38 An air-acetylene flame.



3. Slightly open the valve on the torch handle on the oxygen side. The flame will begin to clear up and turn blue, **Figure 7.39**. You will have to adjust the valves until you get the flame you want. The flame should be blue and be setting firmly on the torch tip, not blowing away from it.

To shut the system down, follow these procedures:

1. Shut off the fuel gas (acetylene) valve at the torch first.
2. Shut off the oxygen valve at the torch.
3. Turn off the cylinder valve on the fuel gas (acetylene).
4. Open the valve on the torch handle on the fuel gas side to relieve the pressure on the hose. Both regulators will lose their pressure to 0 psig.
5. Turn the T handle on the fuel gas regulator counterclockwise until it appears to be loose. This side of the system has now been bled of pressure. Shut off the valve on the torch handle.
6. Turn off the cylinder valve on the oxygen cylinder.
7. Open the valve on the torch handle on the oxygen side to relieve the pressure on the hose. Both regulators will lose their pressure to 0 psig. This side of the system has been bled of pressure. Turn off the torch handle valve on the torch handle.

Figure 7.39 An oxyacetylene flame.

8. Turn the T handle on the oxygen regulator counterclockwise until it feels loose.

The system is now ready for storage and/or transport.

SAFETY PRECAUTION: *If the oxygen acetylene system is to be transported, it must be moved using an approved hand cart or carrier with the tanks properly secured. If it is to be transported on the road in a truck, caps must be used on the cylinders.*•

A neutral flame should be used for most operations. See **Figure 7.40** for photos of a neutral flame, a carbonizing flame (too much acetylene), and an oxidizing flame (too much oxygen).

SAFETY PRECAUTION: *As stated previously, there are many safety precautions that should be followed when using oxyacetylene equipment. Be sure that you follow all of these precautions. You should become familiar with them during your training in how to use this equipment.*•

7.9 FLUXING

Before getting into the specific techniques for soldering and brazing, we need to discuss one important topic, namely fluxing. In terms of soldering and brazing, the main function of flux is to prevent oxidation from forming on the surfaces of the pipes being joined and in the filler materials themselves, **Figure 7.41**. Filler materials, such as solders and brazing rods, will adhere very well to the piping materials, but not the oxides that form during the soldering and brazing processes. By limiting the amount of oxides that form, and absorbing the oxides that do form when the pipes are heated, flux helps facilitate the flow of the filler material into the joint. So, to help ensure a leak-free joint, flux is used whenever needed.

SAFETY PRECAUTION: *Brazing and soldering materials, including fluxes, can produce dangerous fumes when used during soldering and brazing. Be sure to protect yourself from these fumes by wearing proper breathing masks and by working in well-ventilated areas. Always follow the manufacturers' and Material Safety Data Sheet (MSDS) instructions when soldering and brazing.*•

Figure 7.41 Flux is used to reduce the amount of oxidation on the surfaces of the pipes being soldered or brazed.

Photo by Eugene Silberstein

Although fluxing is important, too much of a good thing can have negative effects on the quality of the connection. Apply flux only to the male portion of the fitting. This will prevent excessive flux from entering the refrigerant lines, which is important because flux typically contains between 15% and 35% water and every effort should be made to limit the amount of moisture in an air-conditioning or refrigeration system. To ensure proper flux coverage, it is good field practice to rotate the male portion of the joint in the fitting, or to rotate the fitting around the pipe. Some brazing rods are coated with flux. Although this seems to be solely for convenience, there is another, more important reason why this type of product is desirable. As the rod is heated, the flux melts and flows before the filler material is introduced to the joint. This also helps avoid using too much flux.

Be sure to follow the guidelines for soldering and brazing carefully; applying too much heat to the joint can also have negative effects on the quality of the connection. If flux is used and the joint is overheated, the flux can become saturated with oxides and prevent the filler material from flowing properly. Note also that fluxes are corrosive and need to be removed after the joint has been completed.

The following sections in this unit provide detailed information about both soldering and brazing, and more

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

information regarding flux and how it affects the soldering and brazing processes.

7.10 SOLDERING TECHNIQUES

The mating diameters of tubing and fittings are designed or sized to fit together properly. For good capillary attraction, the space between the metals should be approximately 0.003 in. After the tubing has been cut to size and deburred, you must do the following for good joint soldering:

1. Clean mating parts of the joint.
2. Apply a flux to the male connection.
3. Assemble the tubing and fitting.
4. Heat the joint and apply the solder.
5. Wipe the joint clean.

CLEANING

The end of the copper tubing and the inside of the fitting must be absolutely clean. Even though the surfaces may look clean, they may contain fingerprints, dust, or oxidation. A fine sand cloth, a cleaning pad, or a special wire brush may be used for cleaning. When the piping system is to be used for a hermetic compressor, the sand cloth should be an approved nonconducting type, **Figure 7.42**.

FLUXING

Apply flux soon after the surfaces are cleaned. For soft soldering, flux may be a paste, jelly, or liquid. Apply the flux with a *clean* brush or applicator. Do *not* use a brush that has been used for any other purpose. Apply the flux only to the area to be joined and avoid getting it into the piping system. Too much flux will make it easier for the molten filler material to flow into the pipe itself, possibly restricting flow through the pipe. Be sure to apply flux sparingly and only to the male end of the joint. This will help ensure that the filler material remains in the space between the mating surfaces.

ASSEMBLY

Soon after the flux is applied, assemble and support the joint so that it is straight and will not move while being soldered.

HEATING AND APPLYING SOLDER

When soldering, heat the tubing near the fitting first for a short time. Then move the torch from the tubing to the fitting. Keep moving the torch from the tubing to the fitting. Heat the entire joint, not just one side. Keep moving the torch to spread the heat evenly and do not overheat any area. Do not point the flame into the fitting socket. Hold the torch so

that the inner cone of the flame just touches the metal. After briefly heating the joint, touch the solder to the joint. If it does not readily melt, remove it and continue heating the joint. Continue to test the heat of the metal with the solder. Do *not* melt the solder with the flame; use the heat in the metal.

When the solder flows freely from the heat of the metal, feed enough solder in to fill the joint. Watching the appearance of the flux will help determine when to apply the filler material to the joint. When the flux "melts" and starts to take on the appearance of water, it is time for the filler material to be applied. Do not use excessive solder. Using more than the recommended amount of filler material will not make the joint stronger. The excess material can accumulate inside the tubing and create flow restrictions.

Different-size pipes will require different amounts of filler material. A connection that is joining two sections of 2-in. pipe will require more filler material than a joint that is made up of two 1-in. pipes. For smaller joints, the estimated amount of filler material is about twice the diameter of the joint. For example, if a soldered joint is being made to join two sections of ½-in. pipe, about 1 in., or twice the diameter of the pipe, of filler material will be used. In the 3-in. to 6-in. range, however, the amount of filler material will be about four times the diameter of the pipe. So, a 4-in. solder joint will require about 16 in. of filler material. **Figure 7.43** shows a step-by-step procedure for heating the joint and applying the solder.

For horizontal joints, apply the filler metal first to the bottom, then to the sides, and finally on the top, making sure the operations overlap, **Figure 7.44**. On vertical joints, it does not matter where the filler is first applied.

WIPING

While the joint is still hot, you may wipe it with a rag to remove excess solder. This is not necessary for producing a good bond, but it improves the appearance of the joint. Be careful not to break the joint when wiping. In addition, it is important to remember that fluxes are corrosive and need to be removed once the joint has been completed.

Figure 7.43 The proper procedures for heating a joint and applying solder. (A) Start by heating the tubing. (B) Keep the flame moving. Do not point the flame into the end of the fitting. (C) Touch the solder to the joint to check for proper heat. Do not melt the solder with the flame. (D) When the joint is hot enough, solder will flow.

7.11 BRAZING TECHNIQUES

CLEANING

The cleaning procedures for brazing are similar to those for soldering. The brazing flux is applied with a brush to the cleaned area of the tube end. Avoid getting flux inside the piping system. Some brands of silver or copper-phosphorous alloys do not require extensive cleaning or flux when brazing copper to copper. This is because, at the higher temperatures required for brazing, the mating surfaces are cleaned by the torch flame. In addition, these filler materials are typically comprised of phosphorous and copper and are self-fluxing, so no additional flux is needed. Always follow the instructions from the filler-material manufacturer.

APPLYING HEAT FOR BRAZING

Before you heat the joint, it is good practice to introduce nitrogen into the system to purge the air (containing oxygen) and reduce the possibility of oxidation to a minimum. A pressure of 1 to 2 psig is enough to sufficiently purge the piping. Because 1 or 2 psig of pressure is very difficult read on the gauge manifold, a nitrogen flow indicator, **Figure 7.45**, can be used. This device allows the technician to maintain the desired nitrogen flow rate and also, at a quick glance, ensure that nitrogen is indeed flowing. Since more and more systems are operating with R-410A, the number of air-conditioning systems that operate with ester-based lubricants is increasing. Ester-based lubricants are more likely to separate oxidation from the inside surfaces of the piping materials than are mineral or alkylbenzene lubricants, which

Figure 7.45 A nitrogen flow indicator. The floating ball indicates flow.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

increases the potential for clogging metering devices, filter driers, and other refrigerant flow controls. By allowing a small amount of nitrogen to flow through the piping circuit while the brazing process is being performed, the amount of oxidation will be greatly reduced.

Apply heat to the parts to be joined with an air-acetylene or oxyacetylene torch. Heat the tube first, beginning about 1 in. from the edge of the fitting, sweeping the flame around the tube. It is very important to keep the flame in motion and not overheat any one area. Then switch the flame to the fitting at the base of the cup. Heat uniformly, sweeping the flame from the fitting to the tube. Apply the filler rod or wire at a point where the tube enters the socket. When the proper temperature is reached, the filler metal will flow readily by capillary attraction into the space between the tube and the fitting. As in soldering, do not heat the rod or wire itself. The temperature of the metal at the joint should be hot enough to melt the filler metal. When the joint is at the correct temperature, it will be cherry red in color. The procedures are the same as those used for soldering except for the materials used and the higher heat applied. The flux used in the brazing process will cause oxidation.

7.12 PRACTICAL SOLDERING AND BRAZING TIPS

LOW TEMPERATURE (SOLDERING)

When soldering, the surfaces between the male and female parts being joined must be clean. Clean surfaces are necessary to ensure leak-free connections. It takes much longer to prepare surfaces for soldering than it does to actually make the soldered joint. If a connection to be soldered is cleaned in advance, it may need a touch-up cleaning when it is actually soldered. Copper oxidizes and iron or steel begins to rust immediately. Some fluxes may be applied after cleaning to prevent oxidation and rust until the tubing and fittings are ready for soldering.

Only the best solders should be used for low-temperature solder connections for refrigeration and air-conditioning. Systems were soldered successfully for many years with 95/5 solder. If the soldered connection is completed in the correct manner, 95/5 can still be used, but it should never be used on the high-pressure side of the system close to the compressor. The high temperature of the discharge line and the vibration will very likely cause it to leak. A better choice than 95/5 for low-temperature solder would be a solder with a high strength and low temperature. Low-temperature solders with a silver content offer greater strength with low melting temperatures.

One of the problems with most low-temperature solders is that the melting and flow points are too close together. This is evident when you are trying to use the solder; it flows too fast, and you have a hard time keeping it in the clearance in the joint. Some of the silver-type, low-temperature solders have a wider melt and flow point and are easier to use. They also have the advantage of being more elastic during the soldering procedure. This allows gaps between fittings to be filled more easily.

HIGH-TEMPERATURE (BRAZING)

Several choices of high-temperature brazing materials are available. Some have a high silver content (45% silver) and must always be used with a flux, and some do not have high silver content (15% silver). These may not require flux when making copper-to-copper connections; however, flux may be used. Other brazing materials have no silver content. Filler materials comprised solely of phosphorous and copper (no silver) are typically over 90% copper and are intended for connections that are not subject to movement or vibrations. So if the joint will be subjected to vibration, an alternative filler material should be selected. Your experience will soon help you choose which you prefer for a particular application. Another factor that should be considered is the expansion of the materials being joined.

When brazing copper to copper, the expansion rate of the copper is not an issue since both parts of the connection will expand at the same rate when heated. On the other hand, when brazing copper to steel, the expansion rates must be taken into account since copper will expand at a faster rate than the steel or any other ferrous material. If the joint involves a copper pipe in a steel female connection, the initial fit should be very loose, as the copper will expand more than the steel when heated and reduce the clearance. If the joint involves a steel pipe and a female copper fitting, the joint can almost be force-tight, as the copper will expand more than the steel to increase the clearance.

DIFFERENT JOINTS

The type of joint dictates which solder or brazing materials to use. All connections are not copper-to-copper. Some may be copper-to-steel, copper-to-brass, or brass-to-steel. These are called dissimilar metal connections; the following are examples.

1. **A copper suction line to a steel compressor or connection.** The logical choice is to use 45% silver content because of the strength of the connection combined with the high melting temperature. Do not use filler materials that contain phosphorous on steel joints. When used on steel pipe, phosphorous filler materials produce phosphides, which are brittle and prone to cracking. This can lead to piping system leaks.
2. **A copper suction line to a brass accessory valve.** From a strength standpoint, the best choice would be 45% silver. Another choice would be a solder with a silver content that has a high strength and a low melting temperature. The valve body will not have to be heated to the high melting temperature of the 45% silver solder.
3. **A copper liquid line to a steel filter drier.** Although 45% silver brazing material is a good choice, it requires a lot of heat. A low-temperature solder with silver content

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

may be the best choice. It also gives you the option of easily removing the drier for replacement at a later date. Once again, on steel connections avoid using filler materials that contain phosphorous.

4. **A large copper suction line connection using hard-drawn tubing.** A high-temperature brazing material with low silver content is the choice of many technicians, but you may not want to take the temper out of the hard-drawn tubing. A low-temperature solder with a silver content will give the proper strength, and the low melting temperature will not take the temper from the pipe.

Any time copper tubing is heated to a temperature that causes the tubing to become red-hot, heavy oxidation occurs on the inside and the outside of the pipe. This can be noted by the black scale that accumulates on the outside of a pipe when it is brazed. The pipe looks the same on the inside, where there is black scale. The oxygen that is in the air inside the pipe causes this black scale to form. Displacing the oxygen with dry nitrogen can prevent this. All technicians should sweep the system with dry nitrogen when making high-temperature connections. When a system is made of many connections, the scale can amount to a considerable quantity. It is trapped in either the oil, the filter driers, or the metering device—whichever it reaches first.

CHOICE OF HEAT FOR SOLDERING AND BRAZING

Air-acetylene or oxyacetylene torch kits may be used as the heat source for soldering and brazing. It is important, however, to choose the best torch for the job to be done. This decision should be made, in part, by the temperature of the flames produced as well as what is referred to as the target temperature. The flame temperature is just what it sounds like: it's the temperature of the torch flame. For an air-acetylene torch, the flame temperature is approximately 4200°F, while the temperature of an oxyacetylene torch flame is in the range of 5600°F. The target temperature is significantly lower than the flame temperature, as the target temperature refers to the temperature that can actually act on the object being heated. The target temperature for an air-acetylene torch is about 2700°F, while the target temperature for an oxyacetylene torch is about 4700°F. In any event, it is important that the user of the torch keep the flame at the proper distance from the target to avoid melting the materials (base metals) being joined. Copper, for example, melts at about 2000°F. In addition to the heat source being used, the correct torch tip must be used for the solder type and pipe size. **Figure 7.46** includes a photo and table of several tip sizes for different pipe sizes and solder combinations.

Figure 7.46 Different tip sizes may be used for different pipe sizes and solder combinations.

ACETYLENE TORCH TIPS

Another heat source is MAPP™ gas. It is a composite gas that is similar in nature to propane and may be used with air. Composite gases are made up of multiple gases. The term MAPP comes from the chemical make-up of the gas, namely methylacetylene-propadiene propane. The flame temperature of MAPP gas is 5300°F, while the temperature of a propane flame is about 4000°F. The temperature of a MAPP gas flame is higher than an air-acetylene flame, but not quite as hot as an oxyacetylene flame. MAPP gas is supplied in containers that are much easier to transport and use than oxyacetylene torch kits, **Figure 7.47**.

SOLDERING AND BRAZING TIPS

1. Clean all surfaces to be soldered or brazed.
2. Keep filings, burrs, and flux from inside the pipe.
3. When making upright soldered joints, apply heat to the top of the fitting, causing the filler to rise.
4. When soldering or brazing fittings of different weights, such as soldering a copper line to a large brass valve body, most of the heat should be applied to the large mass of metal, the valve.

Figure 7.47 A MAPP™ gas kit.

Source: Thermadyne Industries, Inc.

Figure 7.48 Make a bend in the end of the solder so you will know when to stop.

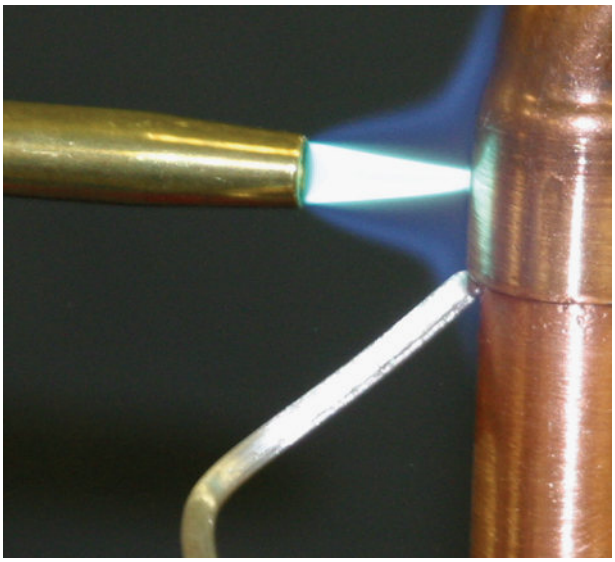

Photo by Bill Johnson

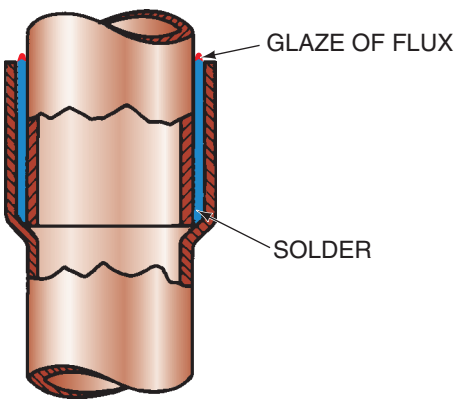
5. Do not overheat the connections. The heat may be varied by moving the torch closer to or farther from the joint. Once heat is applied to a connection, it should not be completely removed because the air moves in and oxidation occurs.
6. Do not apply excessive amounts of low-temperature solders to a connection. It is a good idea to mark the length of solder you intend to use with a bend, **Figure 7.48**. When you get to the bend, stop or you will overfill the joint, and the excess may be in the system.
7. When using flux with high-temperature brazing material, always chip the flux away when finished. **SAFETY PRECAUTION:** *Wear eye protection.* Flux is hard and appears like glass on the brazed connection, **Figure 7.49**. This hard substance may cover a leak and be blown out later.

Figure 7.49 Flux used with high-temperature brazing materials will form a glaze that looks like glass.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 7.50 Components of a flare joint.

Photo by Bill Johnson

8. When using any flux that will corrode the pipe, such as some fluxes for low-temperature solders, wash the flux off the connection or corrosion will occur. If this is not done, it will soon look like a poor job.
9. Talk to the expert at a supply house for your special solder needs.
10. When using an oxyacetylene torch for brazing, be sure to use a neutral flame, not an oxidizing flame. An oxidizing flame results when too much oxygen is supplied to the flame. This causes more oxidation to form on the surfaces of the pipes being joined.

7.13 MAKING FLARE JOINTS

Another method of joining tubes and fittings is the flare joint. A flare on the end of the tubing is made against an angle on a fitting and is secured with a flare nut behind the flare on the tubing, **Figure 7.50**. The flare on the tubing can be made with a screw-type flaring tool using the following procedure:

1. Cut the tube to the correct length.
2. Ream to remove all burrs and clean all residue from the tubing.
3. Slip the flare nut or coupling nut over the tubing with the threaded end facing the end of the tubing.
4. Clamp the tube in the flaring block, **Figure 7.51(A)**. Adjust it so that the tube is slightly above the block (about one-third of the total height of the flare).
5. Place the yoke on the block with the tapered cone over the end of the tube. Many technicians use a drop or two of refrigerant oil to lubricate the inside of the flare while it is being made, **Figure 7.51(B)**.

Figure 7.51 The proper procedure for making a flare joint using a screw-type flaring tool.

(D)

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

6. Turn the screw down firmly, **Figure 7.51**(C). Tighten and loosen the screw several times during the flaring process to prevent the work from hardening. Continue until the flare is completed.
7. Remove the tubing from the block, **Figure 7.51**(D). Inspect for defects. If you find any, cut off the flare and start over.
8. Assemble the joint.

MAKING A DOUBLE-THICKNESS FLARE

A double-thickness flare provides more strength at the flare end of the tube. This is a two-step operation. Either a punch and block or combination flaring tool is used. **Figure 7.52** illustrates the procedure for making double-thickness flares with the combination flaring tool. Many fittings are available to use with a flare joint. Each of the fittings has a 45° angle on the end that fits against the flare on the end of the tube, **Figure 7.53**.

Figure 7.52 Procedure for making a double-thickness flare. (A) Place the adapter of the combination flaring tool over the tubing in the block. Screw down to bell out the tubing. (B) Remove the adapter, place a cone over the tubing, and screw down to form the double flare.

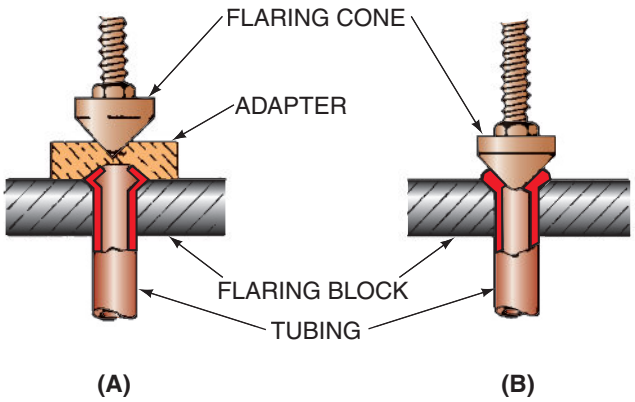

Figure 7.53 Flare fittings.

Photo by Bill Johnson

7.14 SWAGING TECHNIQUES

Swaging is not as common as flaring, but you should know how to make a swaged joint. **Swaging** is the joining of two pieces of copper tubing of the same diameter by expanding or stretching the end of one piece to fit over the other so that the joint may be soldered or brazed, **Figure 7.54**. As a general rule, the length of the joint that fits over the other is equal to the approximate OD of the tubing.

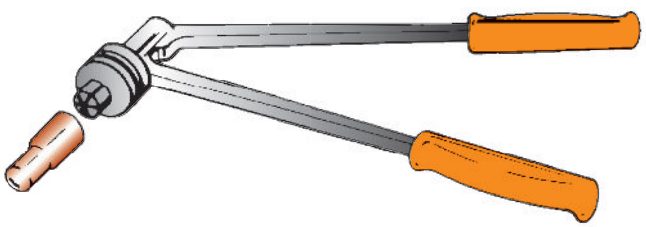
You can make a swaged joint by using a punch or a lever-type tool to expand the end of the tubing, **Figure 7.55**. Place

Figure 7.54 A swage connection.

Figure 7.55 (A) A swaging punch. (B) A lever-type swaging tool.

Photo by Bill Johnson

(A)



(B)

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

the tubing in a flare block or an anvil block that has a hole equal to the size of the OD of the tubing. The tube should extend above the block by an amount equal to the OD of the tube plus approximately 1/8 in., **Figure 7.56(A)**. Place the correct-size swaging punch in the tube and strike it with a hammer until the proper shape and length of the joint has been obtained, **Figure 7.56(B)**. Follow the same procedure with screw-type or level-type tools. A drop or two of refrigerant oil on the swaging tool will help but it must be cleaned off before soldering. Assemble the joint. The tubing should fit together easily. Always inspect the tubing after swaging to see whether there are cracks or other defects. If any are seen or suspected, cut off the swage and start over.

SAFETY PRECAUTION: *Field fabrication of tubing is not done under factory-clean conditions, so you need to be observant and careful that no foreign materials enter the tubing. When the tubing is applied to air-conditioning or refrigeration, remember that any foreign matter will cause problems. Utmost care must be taken.*•

Figure 7.56 Making a swaged joint. (A) A tube secured in a block. (B) Striking the swage punch to expand the metal.

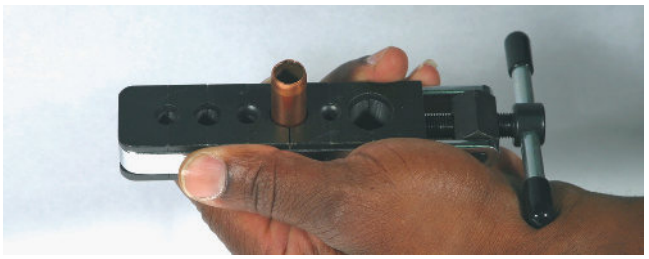


Photo by Bill Johnson

(A)

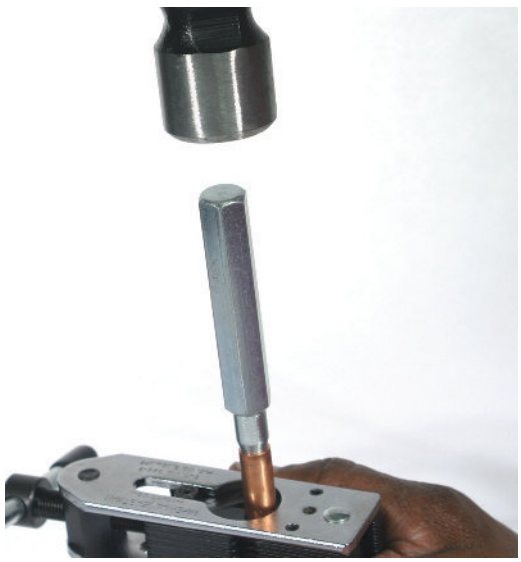

Photo by Bill Johnson

(B)

Here are some tips to help ensure that the swage is correct, neat, and straight:

- If using a swage punch, rotate the flaring block 180° every three or four strikes. This will keep the tubing on the other side of the block straight as the swage is formed.
- Do not tap the swage punch from side to side with the hammer. This will expand the swage too much and the space between the mating surfaces will be too large.
- Avoid placing the flaring block in a vise to hold the tubing while striking the swage punch.

7.15 COMPRESSION FITTINGS

Another popular method for joining sections of soft-drawn tubing materials is the compression fitting. This type of mechanical connection is primarily used on piping arrangements that carry water and are not intended for refrigerant piping circuits. The compression fitting is made up of a compression nut, a compression ring (also known as the ferrule), and the fitting itself. **Figure 7.57** shows the component parts of a compression union, which is used to join two sections of soft-drawn tubing.

To assemble a compression fitting, the compression nut is first placed over the tubing, with the female thread portion of the nut facing toward the end of the tubing section being joined, **Figure 7.58**. Then, the compression ring is placed over the tubing, **Figure 7.59**. When making the connection, it is important that the tubing be fully inserted into the fitting to ensure a proper seal. With the tubing fully inserted, the compression nut can be tightened to the fitting. When the nut is tightened, the ferrule is compressed between the nut and the fitting. This causes the ferrule to clamp onto the tubing, expand, and create a leak-free seal between the tubing, the nut, and the fitting itself. **Figure 7.60** shows the difference in appearance between a new ferrule and one that has been compressed.

Figure 7.57 Component parts of a compression fitting.

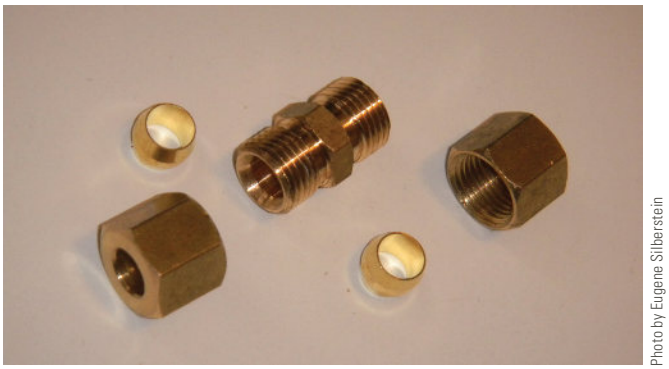

Photo by Eugene Silberstein

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 7.58 Placing the compression nut on the tubing.

Figure 7.59 Placing the ring/ferrule on the tubing.

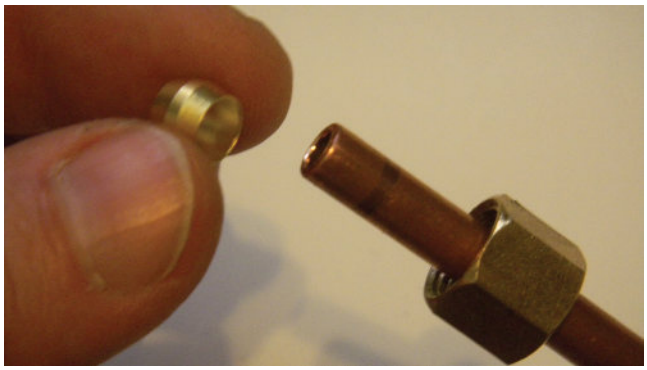

Photo by Eugene Silberstein

Figure 7.60 A compressed ring (left) and a new, uncompressed ring (right).

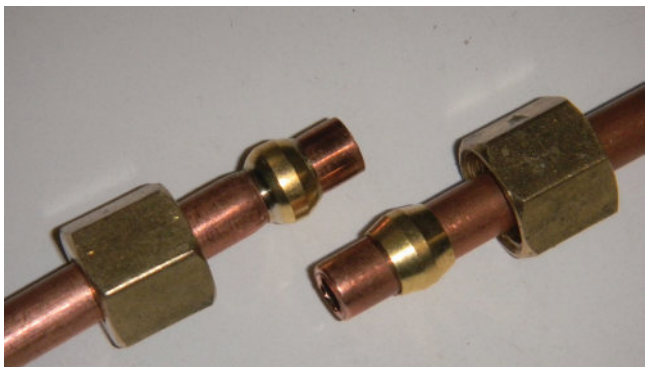

Photo by Eugene Silberstein

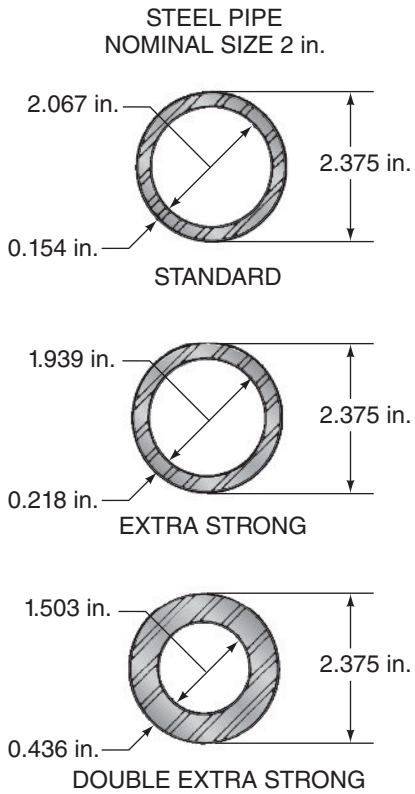
Teflon tape or other thread sealers should not be used on compression fittings because they can actually cause the joint to leak. If a compression fitting leaks, it is a good idea to replace the ferrule. Quite often, the ferrule can become damaged if the compression nut is tightened too much. This can cause the ferrule to become deformed and the connection to leak.

7.16 STEEL AND WROUGHT IRON PIPE

The terms *steel pipe*, *wrought steel*, and *wrought iron pipe* are often used interchangeably and incorrectly. When you want wrought iron pipe, specify "genuine wrought iron" to avoid confusion.

When manufactured, the steel pipe is either seam welded or produced without a seam by drawing hot steel through a forming machine. This pipe may be painted, left black, or coated with zinc (galvanized) to help resist rusting. Steel pipe is often used in plumbing, hydronic (hot water) heating, and gas heating applications. The size of the pipe is referred to as the **nominal** size. For pipe sizes 12 in. or less in diameter, the nominal size is approximately the size of the ID of the pipe. For sizes larger than 12 in. in diameter, the OD is considered the nominal size. The pipe comes in many wall thicknesses but is normally furnished in standard, extra-strong, and double-extra-strong sizes. **Figure 7.61** is a cross section showing the different wall thicknesses of a 2-in. pipe. Steel pipe is normally available in 21-ft lengths.

Figure 7.61 A cross section of standard, extra-strong, and double extra-strong steel pipe.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

JOINING STEEL PIPE

Steel pipe is joined (with fittings) either by welding or by threading the end of the pipe and using threaded fittings. The two types of American National Standard pipe threads are tapered pipe and straight pipe. In the HVAC/R industry only the tapered threads are used because they produce a tight joint and help prevent the pressurized gas or liquid in the pipe from leaking. Pipe threads have been standardized. Each thread is V-shaped with an angle of 60°. The diameter of the thread has a taper of 3/4 in./ft or 1/16 in./in. There should be approximately seven perfect threads and two or three imperfect threads for each joint, **Figure 7.62**. Perfect threads must not be nicked or broken, or leaks may occur. Thread diameters refer to the approximate ID of the steel pipe. The nominal size then will be smaller than the actual diameter of the thread. **Figure 7.63** shows the number of threads per inch for some pipe sizes. A thread dimension is written as follows: first the diameter, then the number of threads per inch, then the letters *NPT*, **Figure 7.64**. You also need to be familiar with various fittings. Some common fittings are illustrated in **Figure 7.65**.

Four tools are needed to cut and thread pipe:

- A hacksaw (one with 18 to 24 teeth per inch) or pipe cutter is generally used to cut the pipe, **Figure 7.66**. A pipe cutter is best because it makes a square cut, but there must be room to swing the cutter around the pipe.
- A **reamer** removes burrs from the inside of the pipe after it has been cut. The burrs must be removed because they restrict the flow of the fluid or gas, **Figure 7.67**.

Figure 7.62 The cross section of a pipe thread.

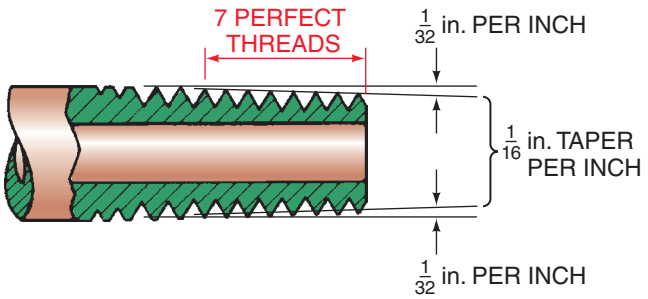


Figure 7.63 Number of threads per inch for some common pipe sizes.

PIPE SIZE (INCHES)	THREADS PER INCH
1/8	27
1/4, 3/8	18
1/2, 3/4	14
1 to 2	11 1/2
2 1/2 to 12	8

Figure 7.64 A thread specification.

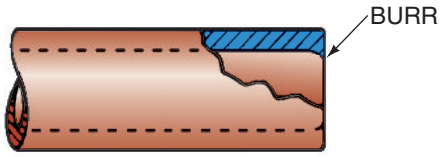
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 7.67 (A) A burr inside a pipe. (B) Using a reamer to remove a burr.



(A)

Photo by Bill Johnson

(B)

- A threader is also known as a die. The threader often has interchangeable heads to allow for the threading of different size pipes, **Figure 7.68**. The heads have sets of teeth that cut the threads in the end of the pipe, **Figure 7.69**.
- Holding tools such as the chain vise, yoke vise, and pipe wrench, **Figure 7.70**, are also needed.

When large quantities of pipe are cut and threaded regularly, special, automatic pipe-threading machines can be used.

Figure 7.68 A pipe threader with interchangeable heads.

Photo by Eugene Silberstein

Figure 7.69 Teeth inside the threader heads that create the threads on the end of the pipe.

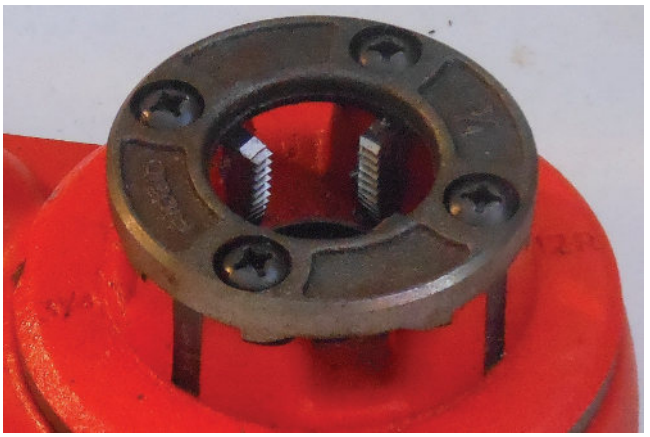


Photo by Eugene Silberstein

CUTTING

The pipe must be cut square to be threaded properly. If there is room to revolve a pipe cutter around the pipe, you can use a one-wheel cutter, **Figure 7.71**. Otherwise, use one with more than one cutting wheel. Hold the pipe in the chain vise or yoke vise if it has not yet been installed. Place the cutting wheel directly over the place where the pipe is to be cut. Adjust the cutter with the T handle until all the rollers or cutters contact the pipe. Apply moderate pressure with the T handle and rotate the cutter around the pipe. Turn the handle about one-quarter turn for each revolution around the pipe. **SAFETY PRECAUTION:** *Do not apply too much pressure because it will cause a large burr inside the pipe and excessive wear of the cutting wheel.*•

To use a hacksaw, start the cut gently, using your thumb or a holding fixture to guide the blade, **Figure 7.72**. **SAFETY PRECAUTION:** *Keep your thumb away from the teeth.*• A hacksaw will only cut on the forward stroke. Do not apply pressure on the backstroke. Do not force the hacksaw or apply excessive pressure. Let the saw do the work.

REAMING

After the pipe is cut, put the reamer in the end of the pipe. Apply pressure against the reamer and turn clockwise. Ream only until the burr is removed, **Figure 7.66(B)**.

THREADING

To thread the pipe, place the die over the end and make sure it lines up square with the pipe, **Figure 7.73**. Apply cutting oil to the pipe and turn the die once or twice. Then reverse the die approximately one-quarter turn. This is accomplished by pulling out and reversing the direction of the arrowed knob on the threader, **Figure 7.74**.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 7.70 (A) A tri-stand with a chain vise. (B) A tri-stand with a yoke vise. (C) A pipe wrench.

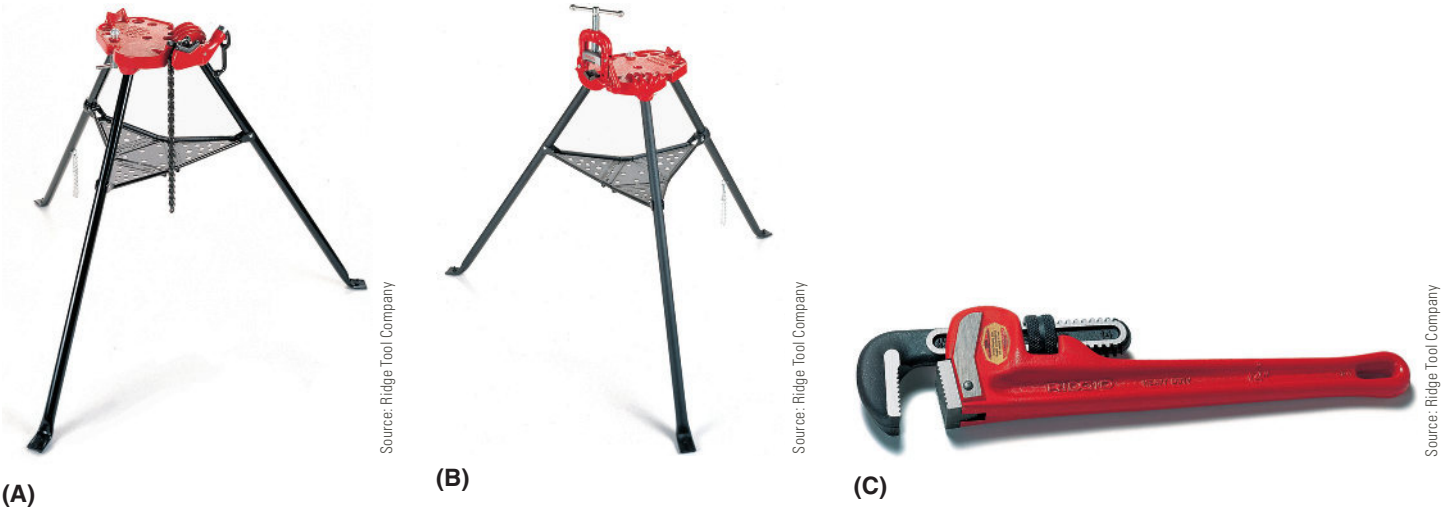

Figure 7.71 A single-wheel pipe cutter.

Figure 7.72 Cutting steel pipe with a hacksaw and a holding fixture.

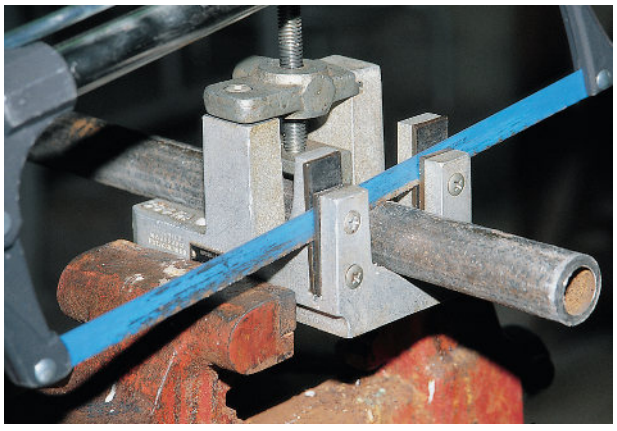

Figure 7.73 Threading pipe.

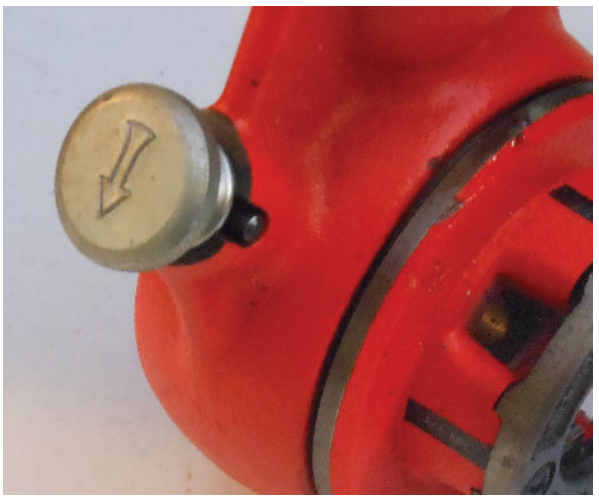
Figure 7.74 Knob used to reverse the direction of the threader.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Rotate the die one or two more turns, and reverse again. Continue this procedure and apply cutting oil liberally until the end of the pipe is flush with the far side of the die.

7.17 INSTALLING STEEL PIPE

When installing steel pipe, hold or turn the fittings and the pipe with pipe wrenches. These wrenches have teeth set at an angle so that the fitting or pipe will be held securely when pressure is applied. Position the wrenches in opposite directions on the pipe and fitting, **Figure 7.75**.

When assembling the pipe, use the *correct* pipe thread dope on the male threads. Pipe dope is a thread-sealing compound that acts to both lubricate and seal the pipe connection. Do not apply the dope closer than two threads from the end of the pipe, **Figure 7.76;** otherwise, it might get into the piping system. All state and local codes must be followed. You should continually familiarize yourself with all applicable codes. **NOTE:** *The technician should also realize the importance of installing the pipe size specified. A designer has carefully studied the entire system and has indicated the size that will deliver the correct amount of gas or fluid. Pipe sizes other than those specified should never be substituted without permission of the designer.*

Figure 7.75 Holding the pipe and turning the fitting with pipe wrenches.

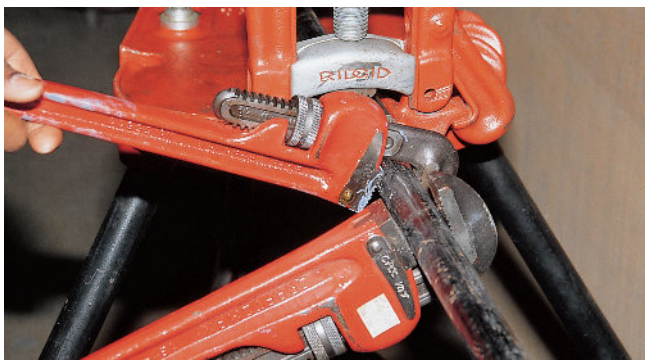


Photo by Bill Johnson

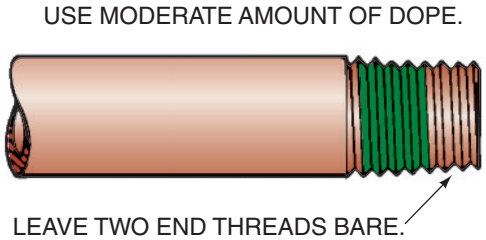
Figure 7.76 Applying pipe dope.



7.18 PLASTIC PIPE

Plastic pipe is used for many plumbing, venting, and condensate applications. You should be familiar with the following types.

ABS (ACRYLONITRILEBUTADIENE STYRENE)

ABS is used for water drains, waste, and venting. It can withstand heat to 180°F without pressure. Use a solvent cement to join ABS with ABS; use a transition fitting to join ABS to a metal pipe. ABS is rigid and has good impact strength at low temperatures.

PE (POLYETHYLENE)

PE is used for water, gas, and irrigation systems. It can be used for water-supply and sprinkler systems and water-source heat pumps. PE is not used with a hot water supply, although it can stand heat with no pressure. It is flexible and has good impact strength at low temperatures. It normally is attached to fittings with two hose clamps. Place the screws of the clamps on opposite sides of the pipe, **Figure 7.77**.

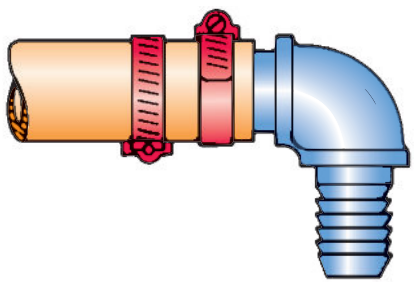
PVC (POLYVINYL CHLORIDE)

PVC can be used in high-pressure applications at low temperatures. It can be used for water, gas, sewage, certain industrial processes, and in irrigation systems. It is a rigid pipe with a high impact strength. PVC can be joined to PVC fittings with a solvent cement, or it can be threaded and used with a transition fitting for joining to metal pipe.

CPVC (CHLORINATED POLYVINYL CHLORIDE)

CPVC is similar to PVC except that it can be used with temperatures up to 180°F at 100 psig. It is used for both hot and

Figure 7.77 The position of clamps on PE pipe.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 7.78 Cutting and joining PVC or CPVC pipe (A)–(D).

(C)

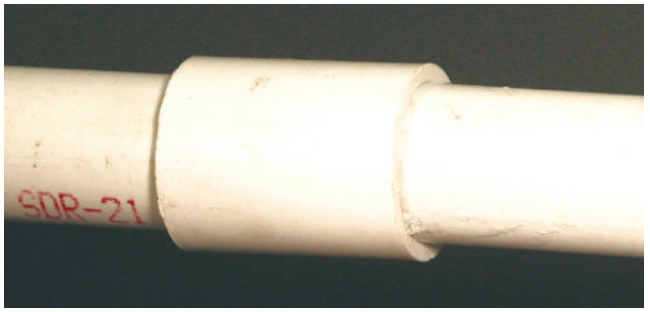

Photo by Bill Johnson

(D)

cold water supplies and is joined to fittings in the same manner as PVC. The following list and **Figure 7.78** describe how to prepare PVC or CPVC for joining.

A. Cut the end square with a plastic tubing shear, a hacksaw, or a tube cutter. The tube cutter should have a special wheel for plastic pipe.

B. Deburr the pipe inside and out with a knife or half-round file.

C. Clean the pipe end. Apply primer if required and cement to both the outside of the pipe and the inside of the fitting. (One-step primer/cement products are available for some applications. Follow instructions on primer and cement containers.) **NOTE:** *For certain PVC piping installations, typically household plumbing, some local codes require the use of purple primer,* **Figure 7.79**, *which will allow an inspector to quickly verify that the plastic pipe sections were primed before connected. Be sure to check the codes in your area to make certain you are using the correct primer.* •

D. Insert the pipe all the way into the fitting. Turn approximately one-quarter turn to spread the cement and allow it to set (dry) for about 1 min.

Schedule #80 PVC and CPVC can be threaded. A regular pipe thread die can be used. **NOTE:** *Do not use the same die for metal and plastic pipe. The die used for metal will become too dull to be used for plastic. The teeth on the plastic pipe die must be kept very sharp. Always follow the manufacturers' directions when using any plastic pipe and cement* •

Figure 7.79 A PVC connection that was primed with purple primer.

7.19 ALTERNATIVE MECHANICAL PIPING CONNECTIONS

In addition to the piping-connection methods already mentioned in this unit, a number of other alternative methods have become popular. Although each method is unique in that each is intended for specific purposes and applications, the methods are also similar in that they all require special fittings and/or equipment for making the necessary connections. Quite often, the equipment and the required fittings are far more expensive than traditional pipe fittings and connections, but the manufacturers of such product lines stress that these products result in substantial time savings that can easily translate into reliable and profitable piping systems. It is not the intention of this text to determine the reliability of these items, but to present them to the reader for the sake of comprehensiveness. Please refer to the manufacturers' literature for important information regarding applications, operating pressure ratings, and other safety-related issues.

One such mechanical piping connection is shown in **Figure 7.80**. This connector can be used with two sections of copper tubing as well as to join copper tubing to a section made of a different material, such as aluminum. There are adapters available that enable the service technician to join tubing sections of different sizes.

The mechanics of the joint involves the insertion of the ends of the tube sections to be joined into the coupling/connection device. The coupler is then pressed together to form the connection. **Figure 7.81** shows the connection before (top) and after (bottom) the fitting has been compressed. **Figure 7.82** illustrates how an installation tool is used to compress the ends of the fitting.

Two other mechanical methods are intended to eliminate the use of soldering. As with the previous method, they both use special fittings to make the connection, but neither is intended for use on refrigerant-carrying piping circuits. The fitting shown in **Figure 7.83** is intended to receive sections of pipe that are simply pushed into it. The tabs located around the interior circumference of the fitting, along with the gasket material inside the fitting, provide the seal, **Figure 7.84**.

Figure 7.80 Fitting used to mechanically join two tubing sections.

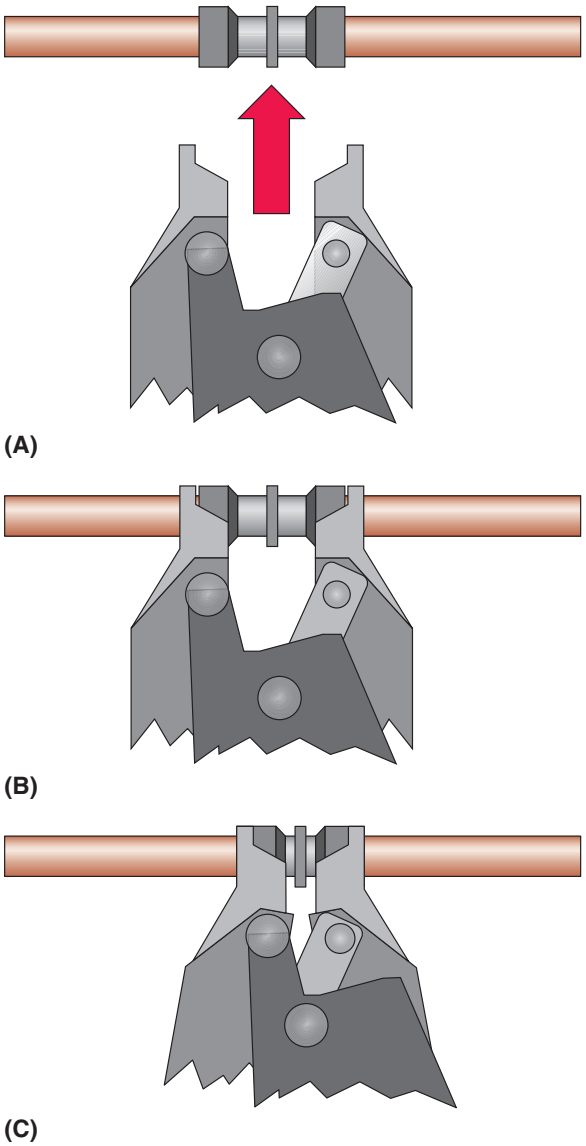
Figure 7.82 Process of compressing fitting onto two piping sections (A)–(C).



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 7.83 Push-on fitting with internal gasket and metal teeth for grabbing onto the pipe section.

Photo by Eugene Silberstein

Figure 7.84 Pipe section pushed into the fitting.

Photo by Eugene Silberstein

The connection shown in **Figure 7.85** is a press-on fitting. The fitting is placed on the pipe section and is then squeezed onto the pipe using a special tool, **Figure 7.86**. Internal gaskets in the fitting help reduce the possibility of leaks. The crimping tool used has interchangeable jaws, **Figure 7.87**, so that the same tool can be used on a number of different pipe sizes. As mentioned at the beginning of this section, please check with the individual manufacturer for information on pressure ratings and applications. Also, when installing mechanical fittings, be sure to follow the manufacturer's instructions carefully.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

SUMMARY

- Properly selecting and installing the tubing, piping, and fittings will help ensure that a refrigeration or air-conditioning system operates properly.
- Copper tubing is generally used for plumbing, heating, and refrigerant piping.
- Copper tubing is available in soft- or hard-drawn copper.
- ACR tubing can be purchased as line sets.
- Tubing may be cut with a hacksaw or tubing cutter.
- Soft tubing may be bent. Tube-bending springs or lever-type benders may be used, or the bend can be made by hand.
- Air-acetylene units are frequently used for soldering and brazing.
- Oxyacetylene equipment is also used, particularly for brazing requiring higher temperatures.
- The flare joint is a mechanical method used to join tubing and fittings.
- The swaged joint is a method used to join two pieces of same-size copper tubing together.
- The compression joint is a mechanical method of joining tubing sections that is often used on water piping arrangements.
- Steel pipe is used in plumbing, hydronic heating, and gas heating applications.
- Steel pipe is joined with threaded fittings or by welding.
- ABS, PE, PVC, and CPVC are four types of plastic pipe; each has a different use.
- Alternative mechanical piping-connection methods can be used for certain applications.

REVIEW QUESTIONS

1. The standard weight of copper tubing used most frequently in the heating and air-conditioning industry is
   A. K.
   B. L.
   C. DWV.
   D. M.
2. The size of 1/2 in. would refer to the _____ with regard to copper tubing used in plumbing and heating.
   A. ID
   B. OD
   C. length
   D. fitting length
3. The size of 1/2 in. would refer to the _____ with regard to ACR copper tubing.
   A. ID
   B. OD
   C. length
   D. fitting length
4. In what size rolls is soft copper tubing normally available?
5. Why are some ACR tubing lines insulated?
6. Describe procedures for bending soft copper tubing.
7. Describe the procedure for cutting tubing with a tube cutter.
8. What type of solder is suitable for moderate temperatures and pressures?
9. Describe the steps for making a good soldered copper tubing/fitting joint.
10. Describe the procedures for making a flare for joining copper tubing.
11. The portion of a compression fitting that actually tightens against the tubing to create the leak-free seal is the
    A. union.
    B. coupling.
    C. compression nut.
    D. ring or ferrule.
12. What is the most common cause of leaking compression fittings?
    A. Cracked compression nut
    B. Overtightening the compression nut
    C. An improperly sized ring or ferrule
    D. Both A and C are common causes of fitting leakage
13. A common filler material used for brazing is composed of
    A. 50/50 tin–lead.
    B. 95/5 tin–antimony.
    C. 15% to 60% silver.
    D. cast steel.
14. When soldering, a flux is used to
    A. minimize oxidation while the joint is being heated.
    B. allow the fitting to fit easily onto the tubing.
    C. keep the filler metal from dropping on the floor.
    D. help the tubing and fitting to heat faster.
15. List the procedures used when setting up, igniting, and using an air-acetylene unit.
16. Describe the procedure for preparing and threading the end of steel pipe.
17. Describe each part of the thread dimension 1/4–18 NPT.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

UNIT 8

LEAK DETECTION, SYSTEM EVACUATION, AND SYSTEM CLEANUP

OBJECTIVES

After studying this unit, you should be able to

- describe a standing pressure test.
- describe the six classes of leaks.
- explain the test procedures for evaporator and condenser section leaks.
- explain the test procedures for suction and liquid-line leaks.
- explain the test procedures for temperature-, pressure-, and vibration-dependent leaks.
- choose a leak detector for a particular type of leak.
- describe a deep vacuum.
- describe two different types of evacuation.
- describe a wireless, digital, micron vacuum gauge.
- describe two different types of vacuum measuring instruments.
- describe how wireless, Bluetooth technology can be used in an evacuation process.
- choose the correct high-vacuum pump.
- list some of the proper evacuation practices and techniques.
- describe a deep-vacuum single evacuation.
- describe a triple evacuation.
- explain the process involved in cleaning a system after a hermetic motor burnout.

SAFETYCHECKLIST

- ☑ Care should be used while handling any of the products from a contaminated system because acids may be encountered.
- ☑ Do not place your hand over any opening that is under high vacuum because the vacuum may cause a blood blister on the skin.
- ☑ Wear goggles and gloves while transferring refrigerant.
- ☑ Do not allow mercury from any instrument to escape. It is a hazardous material.

8.1 LEAKS

All sealed systems leak. The leak could be 1 pound per second or as low as 1 oz every 10 years. Every pressurized system leaks because "flaws" exist at every joint fitting, seam, or weld. These flaws may be too small to detect with even the best of leak detection equipment. But given time, vibration, temperature, and environmental stress, these flaws become larger, detectable leaks, **Figure 8.1**.

It is technically incorrect to state that a unit has no leaks. All equipment has leaks to some degree. A sealed system which has operated for 20 years without ever needing a charge is called a "tight system." The equipment still has leaks, but not enough leakage to read on a gauge or affect cooling performance. No pressurized machine is perfect. A leak is not some arbitrary reading on a meter. Gas escapes at different times and at different rates. In fact, some leaks cannot be detected at the time of the leak test. Leaks may plug, and then reopen under peculiar conditions. A leak is a

Figure 8.1 Electron micrograph of a "clean" silver soldered joint. Note the crack lines and other impurities of the metal. Further magnification shows actual metal separation.

physical path or hole, usually of irregular dimensions. The leak may be the tail end of a fracture, a speck of dirt on a gasket, or a microgroove between fittings.

EXPOSING THE LEAK SITE

Refrigerant vapor can flow under layers of paint, flux, rust, slag, and pipe insulation. Often, the refrigerant gas may show up quite a long distance from the leak site. This is why it is important to clean the leak site by removing loose paint, slag, flux, or rust. Pipe insulation and oil and grease must also be removed from the site because they will contaminate the delicate detection tips of electronic detectors.

TYPES OF LEAKS

1. **Standing leaks.** Standing leaks are leaks that can be detected while the unit is at rest or off, including freezer evaporator coils warmed up by the defrost cycle. Standing leaks, fortunately, are the most common of all leaks.
2. **Pressure-dependent leaks.** Pressure-dependent leaks can only be detected as the system pressure increases. Nitrogen is used to pressurize systems to around 150 psig (low side) and 450 psig (high sides). Never use air or pure oxygen. Often, a refrigerant **trace gas** is introduced into the system along with the nitrogen. The trace gas allows electronic leak detectors to detect the vicinity of the leak. Refrigerant trace gas will be covered in more detail later in the unit. Pressure-dependent leak testing should be performed if no leaks are discovered by the standing leak test. A **microfoam** solution can also be used to locate pressure-dependent leaks, **Figures 8.2(A)** and **(B)**.

NOTE: *Mixtures of nitrogen and a trace gas of refrigerant, usually of the system's refrigerant, can be used as a leak test for gases, because in these cases the trace gas is not used as a refrigerant for cooling. However, a technician cannot avoid recovering refrigerant by adding nitrogen to a charged system. Before nitrogen is added, the system must be recovered and then evacuated to appropriate levels. Otherwise, the HCFC or HFC vented along with the nitrogen will be considered a refrigerant. This will constitute a violation of the prohibition on venting. The use of a chlorofluorocarbon (CFC) as a trace gas is not permitted.* •

3. **Temperature-dependent leaks.** Temperature-dependent leaks are associated with the heat of expansion. They are usually due to high-temperature ambient air or condenser blockages or occur during a defrost period.
4. **Vibration-dependent leaks.** Vibration-dependent leaks only occur during unit operation. The mechanical strain of motion, rotation, refrigerant flow, or valve actuation are all associated with vibration-dependent leaks.
5. **Combination-dependent leaks.** Combination-dependent leaks are flaws that require two or more conditions in order to induce leakage. For example, temperature, vibration, and pressure cause the discharge manifold on a semihermetic compressor to expand and seep gas.

Source: Refrigeration Technologies, Anaheim, CA

(A)

Source: Refrigeration Technologies, Anaheim, CA

(B)

6. **Cumulative microleaks.** Cumulative microleaks are all the individual leaks that are too small to detect with standard tools. The total refrigerant loss over many years of operation slightly reduces the initial refrigerant charge. A system having many fittings, welds, seams, or gasket flanges will probably have a greater number of cumulative microleaks.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

8.2 BASIC REFRIGERANT LEAK DETECTION

SPOTTING REFRIGERANT OIL RESIDUE FROM STANDING LEAKS

Successful leak detection depends solely on the careful observation made by the testing technician. Fortunately, all refrigeration systems internally circulate compressor oil with the refrigerant. Oil will blow off with the leaking refrigerant gas and "oil mark" the general area of leakage. Oil spots appear wet and have a fine coating of dust, **Figure 8.3**. The technician must determine whether the wetness is oil and not condensate. This can be accomplished by rubbing the area with your fingers and feeling for oil slickness. Oil spotting is the technician's first quick check but is not always reliable, for the following reasons:

1. Oil is always present at Schrader valves and access ports due to the discharging of refrigerant hoses on the manifold and gauge set, **Figure 8.4**. Often, these parts are falsely identified as the main point of leakage.
2. Oil blotches can originate from motors, pumps, and other sources.
3. Oil residue may be the result of a previous leak.
4. Oil is not always present at every leak site. It may take months, even years, of unit operation to cause enough oil blow-off to accumulate on the outer side.
5. Oil may not be present with microleaks.
6. Oil may not reach certain leak positions.
7. Oil may not be present on new start-ups.

TESTING FOR EVAPORATOR SECTION LEAKS

Many leaks that go undetected are in the evaporator coil. This is because most evaporator sections are contained in cabinets, buttoned-up, or framed into areas that do not allow easy access. To avoid the time-consuming labor of stripping off covers, ducting, and blower cages or the unloading of product, there is an easy electronic screening method that can be used:

1. Turn off all system power, including evaporator fan motors.
2. Equalize high- and low-side pressures in the refrigeration or air-conditioning system and defrost any frozen evaporator coils. (If the system does not have any pressure, add a refrigerant trace gas and then add nitrogen to generate a practical test pressure.) Most system low sides have a working pressure between 150 psig and 350 psig, but always read the name plate on the evaporator section for test pressure specifications, **Figure 8.5**.
3. Calibrate an electronic leak detector to its highest sensitivity.
4. Locate the evaporator drain outlet or downstream drain trap.
5. Position the electronic leak detector probe at the drain opening, **Figure 8.6**. Be careful that the leak detector probe does not come into contact with any water.

Figure 8.5 Design test pressure specification on an evaporator nameplate of 300 psig.

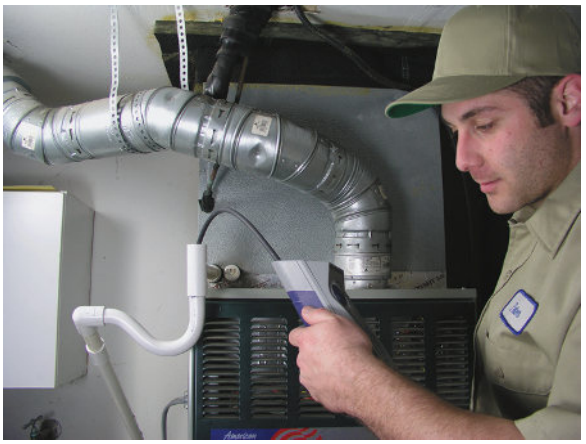
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 8.6 A service technician positioning an electronic leak detector at the drain opening of an evaporator drain.



Source: Refrigeration Technologies, Anaheim, CA

6. Sniff with an electronic leak detector for a minimum of 10 minutes or until a leak is sensed. Recalibrate the device and test again. Two consecutive "**positive**" tests confirm an evaporator leak. Two consecutive "**negative**" tests rule out an evaporator section leak.

Remember, refrigerant gas is heavier than air. Gravity will cause the gas to flow to the lowest point. If the evaporator section tests positive, the technician should expose the coil and spray coat all surfaces with a specially formulated bubble/foam promoter. Bubble/microfoam solutions are cost-effective and have been very successful in leak detection. They are superior to a soap and water solution for bubble checking because, as research has shown, a soap and water solution does not have the coagulants and wet adhesives the microfoam solutions do. In addition, household detergents often contain chlorides that will pit and corrode brass and iron. The specially formulated and patented bubble solutions form a foam "cocoon" when in contact with a leak, **Figure 8.2(B)** and **Figure 8.10**. When the solution is applied over the suspected leak area, bubbles or foam will tell the technician of the presence of a leak and its exact location. The bubbles must be allowed to stand for at least 10–15 minutes if small leaks are suspected. Even small leaks of less than a couple of ounces per year can often be found with these solutions. Bubble solutions can also be used when nitrogen or refrigerants are pressurizing the system. If the evaporator section tests negative for leaks, continue on to leak test the condensing unit.

NOTE: *Whenever applying a leak detection solution to any surface of a refrigeration or air-conditioning system, care must be taken to thoroughly wash the area with water. Simply wiping the area with a rag will not suffice. Depending on what the surface area is composed of, many leak detection solutions like some soaps and water will either oxidize, corrode, or rust the area of application. Often, brass and copper will turn green and oxidize when exposed to some soap solutions if they are not thoroughly washed with water and then dried. Also, any residue of some leak detection fluids may collect dust and appear to be a system leak.* •

TESTING FOR CONDENSING SECTION LEAKS

1. Calibrate an electronic leak detector to its highest sensitivity and place the probe at the base of the unit, usually under the compressor. The unit should be fully pressurized.
2. Cover the condensing unit with a cloth tarp or bed sheet to serve as a barrier against any outside air movement and to trap refrigerant gas, **Figure 8.7**. Do not use a plastic material because some plastics may set off some electronic leak detectors and give a false reading.
3. Monitor for leakage for 10 minutes or until a leak is sensed. Recalibrate and test again. Two consecutive positive tests confirm condensing section leakage. Two consecutive negative tests rule out a detectable leak.
4. Use the electronic leak detector to check for leaks on the bellows of the pressure controls, **Figure 8.8**. Remove the control box cover and place the probe within the

Figure 8.7 A service technician has covered the condensing unit with a sheet to serve as a barrier against any outside air movement before using an electronic leak detector. Never use a plastic cover because some plastics will set off certain electronic leak detectors and give a false reading.

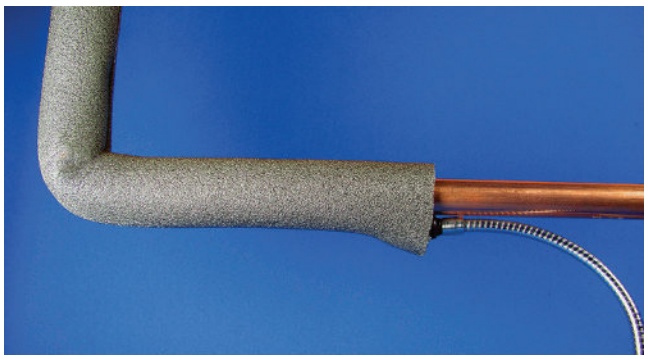
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 8.9 The probe of an electronic leak detector tucked underneath refrigerant pipe insulation sniffing for refrigerant leaks.



Source: Refrigeration Technologies, Anaheim, CA

housing. Cover the control tightly with a cloth barrier and monitor for 10 minutes, as above.

5. If the results are positive, uncover the equipment and begin spray coating with a microfoam solution, **Figure 8.2(A)**. If the results are negative, continue to the suction/liquid-line leak test described next.

TESTING FOR SUCTION- AND LIQUID-LINE LEAKS

The longer the tubing runs are between the evaporator and the condensing unit, the greater the odds of defects. Do not rule out any possibilities, whether it be a typical sight glass–drier connection leak to a poor solder joint hidden under pipe insulation.

1. The suction line can be screened by calibrating an electronic leak detector to its highest sensitivity.
2. Tuck the probe underneath the pipe insulation, **Figure 8.9**. Monitor for 10-minute intervals while the system is at rest and fully pressurized to equalization. It may be necessary to insert the probe at several downstream points.
3. If a leak is sensed, strip off the insulation and apply a bubble/foam promoter to all surfaces. If no leak is positively screened, test the liquid line.

8.3 ADVANCED LEAK DETECTION

TESTING FOR PRESSURE-DEPENDENT LEAKS

1. Pressurize the low side to 150 psig and the high side to 450 psig using dry nitrogen. The equipment rating plate usually states the maximum pressure permissible. Also, always make sure that valving and other components can take these pressures whether or not they are original equipment. If the high and low sides cannot be split by means of isolation valves, pressurize the entire system to about 350 psig if permissible.

SAFETY PRECAUTION: *Never use pure oxygen or air to raise the pressure in a refrigeration system. Pure air contains about 20% oxygen. The pure oxygen and/or the oxygen in the air can combine with refrigerant oil to form an explosive mixture. Pure oxygen and the oxygen in the air will oxidize the system's oil rapidly. In a closed system, pressure from the oxidizing oil can build up rapidly and may generate pressures to the point of exploding. Even some refrigerants can become explosive under pressure when mixed with air or oxygen. For example, HFC-134a (R-134a) is combustible at pressures as low as 5.5 psig (at 350°F) when mixed with air at concentrations of more than 60% air by volume. At lower temperatures, higher pressures are required to support combustion. Therefore, air should never be mixed with R-134a for leak detection.* •

2. Always bubble test by thoroughly saturating all surfaces with a microfoam solution. Allow up to 15 minutes' reaction time for the microfoam to expand into a visible white "cocoon" structure, **Figure 8.2(B)**. Use an inspection mirror to view any undersides and a light source for dark areas.
3. Starting at the compressor, coat all suspected surfaces. Continue to coat all suction-line connections back to the evaporator section.
4. Spray coat all fittings starting at the discharge line at the compressor to the condenser coil. Spray coat all soldered condenser coil U-joints.
5. From the condenser, continue to spray coat all liquid-line connections, including the receiver, valves, seams, pressure taps, and any mounting hardware. Continue the liquid-line search back to the evaporator section.
6. Any control line taps to the sealed system must be spray coated the entire length of their run all the way back to the bellows device.
7. Expose the evaporator section and coat all connections, valves, and U-joints.

Notice that the first sequence of searching started with the compressor and suction line due to their large surface areas. The next sequence began with the discharge line, went across the condenser to the liquid-line connection, and then to the evaporator section. The evaporator section is the last and least desirable component to pressure test in the field.

TESTING FOR TEMPERATURE-DEPENDENT LEAKS

All mechanical connections expand when heated. The connections on refrigeration and air-conditioning systems are usually made of soft metals, such as copper, brass, or aluminum. These metals actually warp when heated, then contract and seal when heat is removed.

1. Start the unit and raise the operating temperature by partially blocking the condenser's air intake. Warm water may

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

also be used to pressurize the system. For example, water chillers are usually pressurized with controlled warm water by turning off the valves for the condenser and evaporator water circuits and introducing controlled warm water to the evaporator tube bundle. This causes the rate of vaporization of the refrigerant to increase, causing higher pressures in the evaporator. One must slowly control the amount of warm water introduced to avoid temperature shock to the evaporator. The rupture disc on the evaporator may open if the pressures are raised too high. Special fittings are available from chiller manufacturers to equalize pressure inside and outside of the rupture disc to prevent rupture. Please consult with the manufacturer before attempting to service or leak check any chiller.

An electronic leak detector may be used while the system is running. However, running systems usually produce a lot of fast air currents from fans and motors that may interfere with electronic detection. It helps to cover the unit with a blanket or sheet to try to collect escaping refrigerant gases. The leaking refrigerant will be easier to pick up with an electronic detector if it can collect somewhere, instead of being dissipated by air currents.

2. Spray coat all metal connections one at a time with a microfoam solution, **Figure 8.2(A)**, and observe for leakage. Rewet any extremely hot surfaces with water to keep the fluid from evaporating too quickly.
3. When testing evaporator components, heat may be induced by placing the unit into defrost.

TESTING FOR VIBRATION-DEPENDENT LEAKS

Leaks that only occur while the unit is in operation are the rarest of all leaks. However, studies have shown that certain components and piping on refrigeration units will develop vibration leaks. They are caused by cracks that open and close from physical shaking.

An electronic leak detector or a microfoam solution can be used while the unit is running. Again, drafts have to be minimized when the unit is running. If an electronic detector is used before the microfoam, a blanket or sheet should be used to help collect escaping gases and minimize air currents. When using microfoam, start the unit and spray coat the areas in the following list with the solution. Look for foam cocoon formations or large bubbles, **Figure 8.10** and **Figure 8.11**. Large bubbles will form on larger leaks, and foam cocoons will form on small leaks.

- All compressor bolts and gasket edges
- Suction-line connection at compressor
- Suction-line connection at evaporator
- Discharge-line connection at compressor
- Discharge-line connection at condenser
- Vibration eliminators
- Any joint or fitting on unsupported pipe runs

- Sight glass

TESTING FOR COMBINATION-DEPENDENT LEAKS

Combination-dependent leak checking involves overlapping the procedures already mentioned. At least two, and usually three, procedures should be merged into one. This type of testing requires a high order of skill and observation

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

techniques. Each suspected component must be isolated and tested in the following manner:

1. Subject a valve or fitting to high pressure.
2. Spray coat the valve or fitting.
3. Tap the component repeatedly with a rubber mallet to induce vibration. If no leakage…
4. Gently add heat to the component. If no leakage, continue on to another component.

SAFETY PRECAUTION: *Do not use flames or halide torches to search for leaks. Open flames (halide flame torches or brazing torches) can release large quantities of acidic compounds in the presence of all refrigerants, and these compounds can be hazardous. Halide torches are not effective on HFC refrigerants because they are used to detect chlorine, which is not present in HFC refrigerants.*

TESTING FOR CUMULATIVE MICROLEAKS

Cumulative microleaks are detected using a helium mass spectrometer. Such superfine leak testing is beyond the normal operations of the service technician. At this time, microleaks are considered an acceptable amount of leakage in the industry.

Installation and service personnel must learn good field piping and assembly practices to ensure that systems will run efficiently as long as possible. Many field-installed systems last for 50 or more years because of good practices. It all begins with technicians knowing what they are doing when they are installing systems. After the installation or service, a proper leak test must be performed.

SAFETY PRECAUTION: *Never use handheld leak detectors to check for breathable air in enclosed working spaces. These detectors are not designed to determine if the air is safe to breathe. Use oxygen monitors to ensure that adequate oxygen is available to sustain life.*

SAFETY PRECAUTION: *If you detect a visible change in the size or color of the flame when using brazing torches to repair equipment, stop work immediately and leave the area. Ventilate the work area well and stop any refrigerant leaks before resuming work. These flame effects may be an indication of very high refrigerant concentrations, and continuing to work without adequate ventilation may result in injury or death. Overexposure to high concentrations of refrigerant vapor can cause asphyxiation and cardiac arrest. Please read all safety information before handling any refrigerant.*

8.4 STANDING PRESSURE TEST

The standing pressure test is probably the most frequently used method of leak detection. The technician can start with a standing pressure test for a newly assembled system to see if it will hold pressure. At the same time, the system can be checked with a sensitive leak detector. The technician should assemble the system first and then give it a visual test to make sure that all connections look as they should.

- The solder connections should have no gaps.
- All flanges and threaded connectors should be tight.
- All control valves must be installed in the correct direction and correctly set.
- All valve covers must be on.

There are several leak-checking procedures. The first test is to charge a trace amount of refrigerant into the system. Most technicians start at 0 psig and introduce a refrigerant trace gas into the system until the pressure reads about 10 psig. The trace gas should be the same refrigerant that is used in the system to avoid any cross-contamination of residual refrigerant once the leak-checking process is complete. Using the system's refrigerant type as a trace gas also avoids any refrigerant and oil incompatibility. The refrigerant trace gas should enter the system from the middle hose of the gauge manifold, and be evenly distributed in both the low and high sides of the system. This practice is acceptable to the Environmental Protection Agency (EPA) because there must be some refrigerant in the system to detect a leak electronically. The refrigerant trace gas is being used only to detect leaks, not as a refrigerant.

When the trace refrigerant has entered the system, dry nitrogen is then introduced to the level of a practical test pressure. The low-pressure side of most systems has a working pressure of 150 psig. Some of the new refrigerants have a higher working pressure; therefore, the system com ponents have a higher working pressure, **Figure 8.5**. The technician should check each system for the proper working pressure before pressurizing it. The components on the low-pressure side of the system are the evaporator, suction line, and compressor. The only parts of the compressor that are considered to be on the high-pressure side are the compressor head and the discharge piping, most of which is internal to the compressor. The compressor is considered a low-pressure device because the compressor shell is on the low-pressure side of the system. The high-pressure side of the system consists of the discharge line to the condenser, the condenser, and the liquid line. The test pressure for the high-pressure side for most refrigerants is at least 350 psig when the compressor shell is not pressurized. Systems using R-410A may have working pressures up to 450 psig. If the compressor has service valves, it can be isolated, **Figure 8.12**.

The pressure used to pressurize a complete system must not exceed the lowest test pressure for the system. Once pressurized, the system should be allowed to stand for about 10 minutes to allow pressures in the system to equalize. At this time, the technician should listen to each connection for an obvious leak, **Figure 8.13**. Once the pressures have equalized, the high-pressure gauge should be marked after tapping it to settle the needle down, **Figure 8.14**.

The standing pressure test should be left on the equipment for as long as practical. A 1½-ton package unit that has a small system may need to stand for 1 hour. A larger system, such as a 10-ton split system, should be allowed to stand overnight, or for 24 hours, if possible. The longer the system stands under pressure without a drop in pressure, the more confidence the technician may have that the system is leak-free. If there is a drop in pressure, a very close leak test should

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 8.12 Isolating the compressor to pressurize the condenser and evaporator.

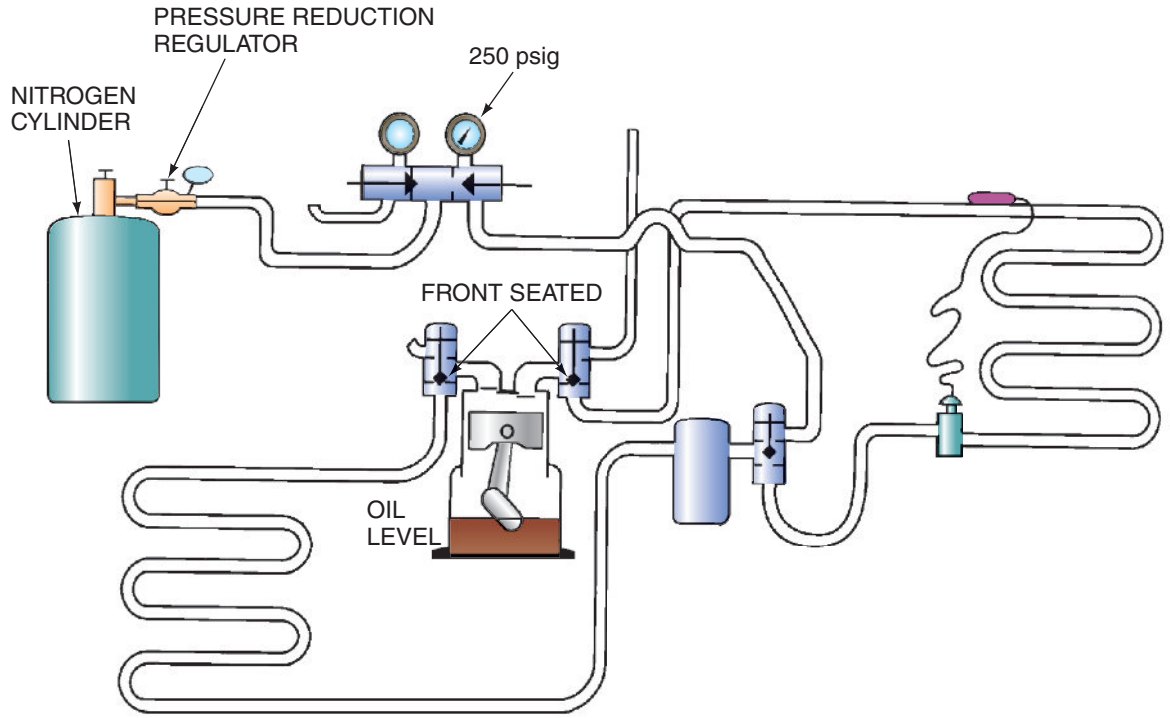

Figure 8.13 Listen for leaks.

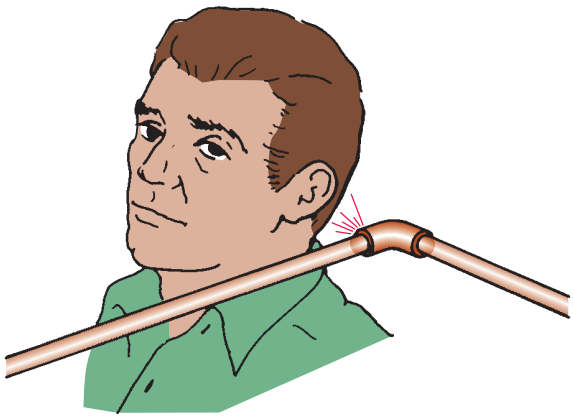

Figure 8.14 When using a pressure gauge for a standing leak test, tap it lightly to make sure the needle is free, then mark the gauge.

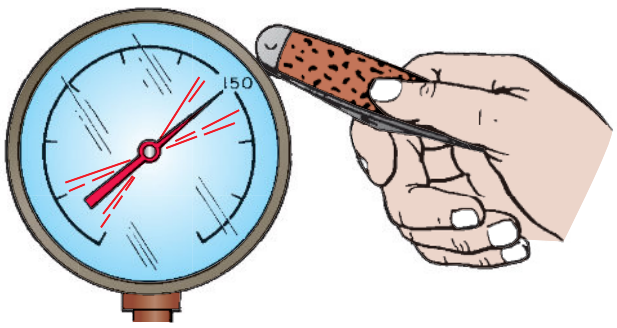

be conducted unless there is a significant drop in the ambient (surrounding) temperature. With a refrigerant trace gas in the system, an electronic leak detector can now be used to locate the vicinity of the leak. Once the vicinity of the leak is found with the electronic leak detector, a bubble/microfoam solution can pinpoint its exact location.

LEAK DETECTION METHODS

The most basic but effective method of detecting leaks is to just listen for the rush of nitrogen and refrigerant from the connections. Often, leaks can be heard but not pinpointed. When a leak is large enough to be heard, you can often find it by wetting the back of your hand and moving it around where you suspect the leak to be. The leak will spray vapor on your wet hand and evaporation will cool your hand and help locate the leak.

Halide leak detectors, like the one shown in **Figure 8.15,** are capable of detecting a leak as small as about 1 oz per year. They are powered by a propane or acetylene gas flame which creates a draft that draws a sample of whatever is in the vicinity of the sample tube. The halide detector, which has been around for a long time, is considered primitive by many people. A sample of refrigerant, for example, passes over a glowing copper element and causes the flame to change color. This change in flame color can best be viewed where there is very little light. This detector is not very effective in bright sunlight and can be used only with refrigerants that have chlorine as part of their formula, such as CFCs and HCFCs. The halide leak detector will not detect hydrofluorocarbon (HFC)-based

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 8.15 A halide torch for leak detection.

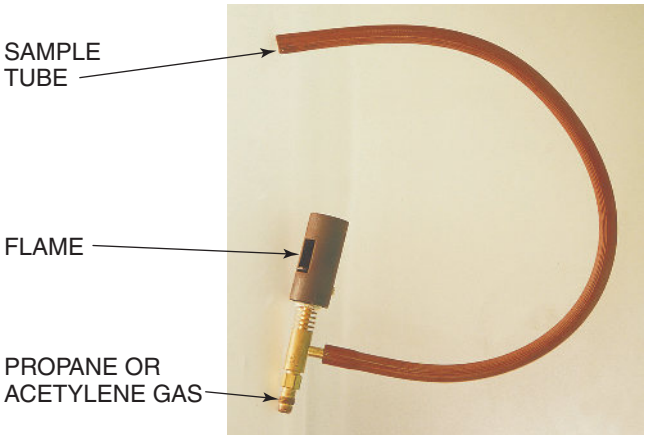

Photo by Bill Johnson

refrigerants because they do not contain chlorine. It cannot be used in an explosive atmosphere, such as around gasoline or other flammables, because of the open flame. **SAFETY PRECAUTION:** *Research has shown that some refrigerants and refrigerant blends are flammable when mixed with air. Never use a halide leak detector with these refrigerants. Never use a halide leak detector with hydrocarbon (HC) and hydrofluoro-olefin (HFO) refrigerants.*• Also, open flames can release large quantities of acidic compounds in the presence of all refrigerants, and these compounds can be hazardous. It is for these reasons that the use of the halide torch for leak checking is not strongly recommended, especially when ultrasensitive electronic leak detectors and microfoam bubble solutions are available.

Ultrasonic leak detectors have earphones, a microphone, and an amplification system to listen for the high-pitched sound of a leak. These detectors would be very good in a place where there is a lot of refrigerant in the air, **Figure 8.16**.

Ultraviolet (UV) fluorescent leak detectors work by means of a special fluorescent dye that is charged into the system. The dye mixes with the oil that circulates with the refrigerant and glows under black light when it escapes through the leak, **Figure 8.17**. Developed for the auto industry to find leaks in automatic transmissions, this technology is very effective, particularly in older systems that may be oil-soaked from prior leaks.

Dye-saturated oil is a leak detection system that causes a red dye residue to seep out wherever there is a leak and escaping oil. The dye is normally charged into the system with a special factory-charged refrigerant cylinder. Before performing this test, you should consult with the compressor manufacturer to make sure the dye is approved, particularly while the system is under warranty. If the compressor is beyond its warranty, it belongs to the customer. Most dyes are lubricant-specific, meaning a different type of dye has to be used with mineral oil, alkylbenzene, and ester-type lubricants. Notice the different oil-specific fluorescent dye tubes in the foreground of **Figure 8.17(A)**. **Figure 8.17(B)** shows a technician injecting an oil-specific fluorescent dye from a gauge line into a refrigeration system for leak detection.

Figure 8.16 An ultrasonic leak detector that listens for leaks.

Photo by Bill Johnson

Electronic leak detectors, the most accurate and probably the most often used detectors, will detect leaks as low as about 1/4 oz per year, **Figure 8.18**. They are great for certain applications. When there is a lot of refrigerant in the air, electronic detectors may have a hard time locating where to start unless they have a feature that allows them to correct for background refrigerant. The sensitivity of these instruments can be their greatest asset or their greatest liability, depending on whether the technician takes the time to understand them. Most of these detectors have very small air pumps that pull a sample of air, or air and refrigerant, over a sensor. These sensors are sensitive to moisture. They must not come in contact with water, such as in drain lines or on a wet coil.

The leak detector in **Figure 8.18(E)** features a state-of-the-art infrared sensor with a 10-year life expectancy. It also features three sensitivity levels, down to 0.1 oz/year. This leak detector has a replaceable water-blocking filter that keeps water and other contaminants out. It will not give false signals when in contact with water or oil and will detect CFC, HFC, and HCFC refrigerants along with HCFC-based refrigerant blends. The detector also features an 8-hour lithium ion battery and visual alert capabilities for noisy environments and will automatically recalibrate for working in refrigerant-contaminated areas.

8.5 LEAK DETECTION TIPS

Both a split system that is new and has not been operating and a system that has been operating can be checked for leaks. The field-installed portion of a new split system should be leak checked (as described previously) using nitrogen, a trace refrigerant, and a standing leak check.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

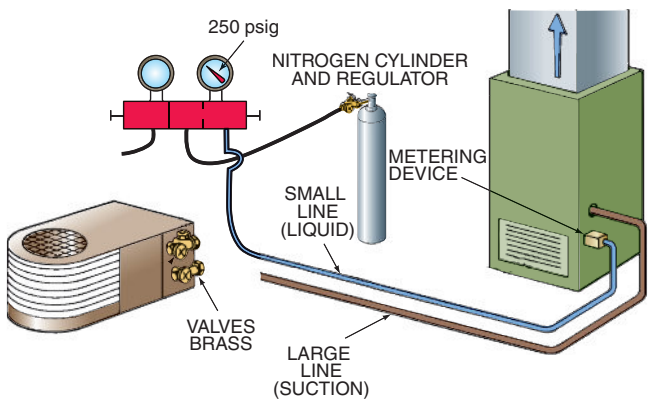
Leak checking a system that has been operating presents a different situation. This system may or may not have refrigerant in it. If it is cooling at all, at least some liquid refrigerant is in the system, and nitrogen should not be added unless the system can meet certain vacuum-level requirements established by the Environmental Protection Agency (EPA). An EPA-certified refrigerant recovery unit must be used to remove the refrigerant up to a certain level of vacuum, which depends on the size of the system, the type of refrigerant, and whether or not the recovery system was manufactured before or after November 15, 1993. Every environmentally conscious HVAC/R service technician must keep up-to-date on EPA regulations, and it is the technician's responsibility to stay informed of any changes in EPA rules. (We will cover this topic in more detail in Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting.")

To leak check a system that has refrigerant in it, the technician should shut down the compressor and let the evaporator fan run. This will boost the low-pressure side of the system up to the temperature of the air-conditioned space. Low-temperature systems may not produce pressure that is high enough for an adequate leak test, but for an air-conditioning application where the indoor pressure corresponds to the indoor temperature, the pressure may be high enough for a leak test. In either situation, the refrigerant should be properly recovered and the system pressured with a trace refrigerant and nitrogen for a high-pressure leak test. This can be very time-consuming but will produce the best results.

When investigating a persistent leak in a split system, always do a visual check to look for fresh oil or dust spots where dust collects on oil. Leaks are often caused by heat, vibration, or temperature. For example, the discharge line of the compressor is an area of high vibration and possibly great temperature changes, and the gas line on a heat pump is at high pressure and temperature in the winter and low pressure and temperature in the summer. Look at any threaded connections, such as quick-connect fittings, where expansion and contraction due to temperature difference may occur.

The system parts may be isolated by disconnecting the liquid line and the suction line at the outdoor unit and pressurizing the entire low-pressure side of the system, which would include the greater part of the field-installed system as well as the evaporator, **Figure 8.19**. This will isolate the leak to the indoor or the outdoor unit. The indoor portion

Figure 8.19 The low-pressure side of the system is isolated and pressurized.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

of the system can now be pressurized for a standing pressure and leak detection test. Never pressurize the low side of the system to a greater pressure than the low side test pressure specification. This test pressure specification is usually stamped on the evaporator section's nameplate, **Figure 8.5**. The outdoor unit may be draped with a cloth tarp or bed sheet and pressurized. The leak detector probe may be inserted under the edge of the drape after a set period of time. If a leak is detected, then the search is on for the exact location.

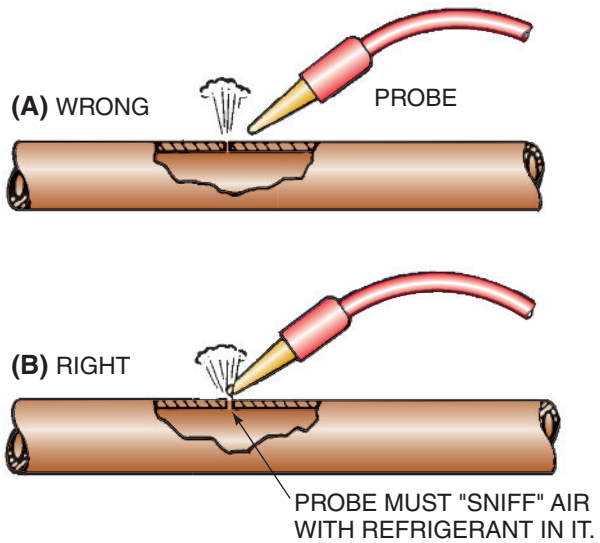
It is good practice to leak check any gauge connection ports before gauges are installed. First, if the system is cooling, there is some refrigerant in it. If the gauge ports are leaking you know where part of the refrigerant went. Many technicians will install gauges, pressurize the system, and not be able to find a leak, only to discover later that the gauge ports were the problem in the first place. **SAFETY PRECAUTION:** *When servicing Schrader valve ports, use only an approved cap, the one that came with the valve. If you screw a brass cap down too tight, you may create a real problem by crushing the delicate seat in the valve so far down that the valve core cannot ever be removed.* •

As mentioned, many technicians use a special soap or bubble solution/microfoamer to pinpoint leaks. The special additive in the soap keeps it from evaporating and makes it much more elastic so that larger bubbles develop. You have seen that some bubble solutions have a microfoam additive that forms a small cocoon of foam (resembling shaving cream) at the leak, **Figure 8.2(B)**. Remember, a very small leak of 1/2 oz a year will take time to blow a bubble. Bubbles do not work well on hot surfaces, such as the compressor discharge line. **NOTE:** *A thorough cleanup must be performed after using soap for leak detecting. The soap residue will turn the copper pipe green and it will start to corrode. Painted surfaces will start to peel if not cleaned. Carefully wiping surfaces with a wet rag or rinsing them with a hose will usually remove the residual soap.* •

Refrigerant is heavier than air and has a tendency to fall away from the leak source. It is important to start at the highest point and work downward. The technician can check an evaporator coil by stopping the evaporator fan, letting the system stand for a few minutes, and then placing the detector probe in the vicinity of the condensate drain line connection and letting it remain there for about 10 minutes (making sure the probe does not contact water in the drain line). If the probe sounds the refrigerant leak alarm, the test should be repeated. If the alarm sounds again, there is a leak in the evaporator section. Removing panels and going over the connections one at a time may find the leak.

Technicians should not rush when trying to locate a leak. Leak detection with any device is a slow process. It takes time for the instrument to respond, so the probe must be moved very slowly—about 1 in. every 2 sec is a good rate of speed. The probe tip must be directly over the leak to detect a very small leak, **Figure 8.20**. If the technician moved too fast, the probe may pass over the leak or indicate a leak that is several inches back.

Figure 8.20 (A) The electronic leak detector is not sensing the small pinhole leak because it is spraying past the detector's sensor. (B) The sensor will detect a refrigerant leak.



8.6 REPAIRING LEAKS

Repairing a very small leak in a small piece of equipment is usually not as economical as it is to add refrigerant. Therefore, the technician must know when to add refrigerant and when to repair a leak. The following EPA guidelines must be followed when making this decision:

- Systems containing less than 50 lb of refrigerant do not require repair.
- Industrial process and commercial refrigeration equipment and systems containing more than 50 lb of refrigerant require repair of substantial leaks. Substantial leaks are leaks that lose more than 35% of the refrigerant charge in a year. For example, a system with 100 lb of refrigerant may be allowed to lose 35 lb per year, and this must be documented by the owner. This is an average of 2.9 lb per month (35/12 = 2.9). When this leak rate is reached, the owner has 30 days to make a repair or to set up a retrofit or replacement program to be fulfilled within a year.
- Comfort cooling chillers and all other equipment have an allowable leak rate of 15% per year. The latest revision of the regulations states that the leak needs only to be "reduced" to a level below the required percentage.

The technician must put together a system that does not leak on initial installation. The equipment should run leak-free and correctly at least as long as the warranty period, usually the first year. If a leak develops after that, it is not covered by the warranty and is the responsibility of the owner.

Most residential systems hold less than 10 lb of refrigerant and do not require leak repair. Many homeowners think that air-conditioning equipment actually uses or consumes refrigerant because the technician just "tops off the charge" each year

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

without really looking for the leak, but this is not good practice. Often, the leak is in the Schrader valve connection, and with just a little effort it could be repaired. Environmentally conscious service technicians should should always do everything possible to prevent HVAC/R equipment from losing refrigerant. Global warming and ozone depletion are major environmental issues, and leak-free HVAC/R systems will help keep the amount of released refrigerant to a minimum.

8.7 SYSTEM EVACUATION

THE PURPOSE OF EVACUATION

Refrigeration systems are designed to operate with only refrigerant and oil circulating inside them. When systems are assembled or serviced, air enters the system. Air contains oxygen, nitrogen, and water vapor, all of which are detrimental to the system. Removing air and/or other noncondensable gases from a system with a vacuum pump is called **degassing** a system. Removing water vapor from a system is known as **dehydration.** In the HVAC/R industry, the process of removing both air and water vapor is referred to as **evacuation.**

Degassing + Dehydration = Evacuation

Gases in the air cause two problems. The nitrogen contained in air is a noncondensable gas. It will not condense in the condenser and move through like the liquid; instead, it will occupy condenser space that would normally be used for condensing refrigerants thus causing a rise in head pressure and a resulting increase in discharge temperatures and compression ratios, which produce undesirable inefficiencies. The other gases cause chemical reactions that produce acids within the system, which cause deterioration of the system's parts, electroplating of the running gear, and the breakdown of motor insulation. **Figure 8.21** is an illustration of a condenser with noncondensable vapors inside.

The acids produced by noncondensable gases can be very mild to quite strong. Electroplating that occurs in a refrigeration system, like electroplating that occurs in other systems, requires electrical current, acid, and dissimilar metals. A refrigeration system has copper, brass, cast iron, and steel, with aluminum in some systems. Electroplating in refrigeration systems seems to only plate from copper to steel—copper from the pipes and steel on the crankshaft and bearing surfaces, **Figure 8.21(B)**. The bearing surfaces have close

Figure 8.21 (A) A condenser containing noncondensable gases. (B) Copper plating of a crankshaft.

(B)

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

tolerances, so when a small amount of copper is plated onto the steel, the bearings become tight and bind. The equally serious problem of the breakdown of electric motor insulation will cause electrical short circuits and either ground or short the motor from phase to phase.

When moisture (water vapor), heat, and refrigerant are all present in a system, acids will start to form after a short period of time. Refrigerants, such as R-12, R-502, R-22, R-134a, and the newer refrigerant blends—R-404A, R-407C, R-422D, R-410A, R-507, R-422A, R-438A, to name a few—contain either chlorine or fluorine and will *hydrolyze* (a chemical reaction) with water, forming hydrochloric or hydrofluoric acids and more water. After acids form, motor windings may deteriorate, and metal corrosion and sludge can occur. Because noncondensables in a system cause system head pressures and discharge temperatures to rise, oxygen from the air in a system will react with the refrigeration oil to form organic solids. This reaction of oil and oxygen usually occurs at the discharge valve because this is the hottest place in the entire system. Sludge is a tightly bound mixture of water, acid, and oil.

Moisture + Acid + Oil = Sludge

Acids may remain in a system for years without causing obvious problems. Then, the motor may burn out or copper deposited on the crankshaft from the copper in the system will cause it to become slightly oversized and bind, scoring the rubbing surfaces and wearing them down prematurely. Sludge and corrosion cause expansion devices, filter driers, and strainers to plug and malfunction.

To avoid corrosion and sludge problems, moisture must be kept out through good service practices and effective preventive maintenance. The only sure way to rid the cooling system of moisture is through effective evacuation procedures using a high-vacuum pump. Once sludge has formed, standard cleanup procedures involving oversize driers specifically designed for sludge removal must be used. Vacuum pumps are not designed to remove solids such as sludge, and deep vacuum procedures will not take the place of liquid-line or suction-line driers for the same reason. Sludge and solids can be removed only by correct filtration.

Noncondensable gases must be removed from the system if it is to have a normal life expectancy. Many systems operate for years with small amounts of gas-produced products inside them, but they will not last or give the reliability the customer pays for. After the system is leak checked, noncondensable gases are removed by vacuum pumps. The pressure inside the system must be reduced to an almost perfect vacuum for this to be accomplished.

EVACUATION THEORY

To *pull a* ***vacuum*** means to lower the pressure in a system below the pressure of the atmosphere. The atmosphere exerts a pressure of 14.696 psia (29.92 in. Hg) at sea level. Vacuum is commonly expressed in millimeters of mercury (mm Hg); it can also be expressed in inches of mercury and microns, a unit of length. There are 25,400 microns in 1 inch. The atmosphere will support a column of mercury 760 mm (29.92 in.) high. To pull a perfect vacuum in a refrigeration system, for example, the pressure inside the system would have to be reduced to 0 psia (29.92 in. Hg vacuum). Removing all of the atmosphere, that is, pulling a perfect vacuum, has never been achieved.

A compound gauge is often used to measure vacuum level. The gauge scale starts at 0 in. Hg vacuum and reduces to 30 in. Hg vacuum. The phrase "in. Hg vacuum" applies to the compound gauge; "in. Hg" without "vacuum" applies to a manometer or barometer. Gauges used for refrigeration systems have scales graduated in in. Hg vacuum.

We can use the bell jar illustrated in **Figure 8.22** to describe a typical system evacuation. Like the bell jar, a refrigeration system contains a volume of gas. The only difference is that a refrigeration system is composed of many small chambers connected by piping. These chambers include the cylinders of the compressor, which may be partially sealed off from the system by a reed valve. Removing the atmosphere from the bell jar is often called "pulling a vacuum" or "degassing" the bell jar. Similarly, removing noncondensables from refrigeration equipment is often called degassing the system. Evacuation, as mentioned earlier, is the process of taking both noncondensables (degassing) and water vapor (dehydration) out of the HVAC/R system. As the atmosphere is pulled out of the bell jar, the barometer inside the jar changes, **Figure 8.22**. The standing column of mercury begins to drop. When the column drops down to 1 mm, only a small amount of the atmosphere is still in the jar (1/760 of the original volume).

Figure 8.22 The mercury barometer in this bell jar illustrates how the atmosphere will support a column of mercury. As the atmosphere is removed from the jar, the column of mercury will begin to fall. If all of the atmosphere could be removed, the mercury would be at the bottom of the column.

Figure 8.23 shows comparative scales for the saturation points of water. There will be more in this unit on how to use vacuum to both degas and dehydrate a system. For now, realize that the compound pressure gauge on the refrigeration manifold is only an indicator of the vacuum present. More accurate methods of measuring vacuum must be used.

When pulling a vacuum on a refrigeration system, the technician should attach the vacuum pump to the high- and the low-pressure sides of the system. This will prevent refrigerant from being trapped in one side of the system, such as when only one line is used. All large systems have gauge ports on both the high and low sides of the system.

MEASURING THE VACUUM

When the pressure in the bell jar is reduced to 1 mm Hg, the mercury column is hard to see, so another pressure measurement called the micron is used (1000 microns = 1 mm, 1 in. = 25,400 microns). Microns are measured with electronic instruments.

Accurately measuring and proving a vacuum in the low micron range can be accomplished with an electronic instrument. **Figure 8.24** shows typical electronic vacuum gauges. Several companies manufacture these gauges; a reliable supply house should be able to name the most popular. Micron gauge displays can be electronic analog, digital, or **light-emitting diode (LED)**. Today's modern solid-state technology favors either digital or LED. Some digital micron gauges today come with Bluetooth technology capabilities.

Figure 8.25 shows a digital, wireless, dual-sensor, standalone micron vacuum gauge. **Figure 8.26** shows this same gauge connected to a system using a large diameter vacuum hose for less resistance to flow, allowing deep vacuum levels to be reached faster. Only certified, large diameter, vacuum rated hoses should be connected from the HVAC/R system directly to the vacuum pump to prevent leaks and lower resistance to flow. This method avoids manifold gauge and hose attachments, which minimizes potentials for leaks. It is not necessary to have a gauge manifold and hoses involved in the evacuation process. This digital vacuum gauge can measure from

atmosphere pressure (760,000 microns) down to 1 micron with a +/−5% reading accuracy and a 1 micron resolution.

Bluetooth technology is a wireless standard that exchanges data wirelessly over short distances (100 meters) using radio wave transmissions. It is built into many products like computers, mobile phones, and medical devices. Bluetooth technology was created as an open standard to allow connectivity and collaboration between different products and industries. This technology is bringing everyday devices into the digital world, allowing them to connect to one another without wires. Today, just about all top-selling tablets, personal computers, headsets, computer mice, keyboards, and smartphones support Bluetooth technology.

The electronic vacuum gauge measures the pressure inside the system. It has a separate sensor that attaches to the system

Figure 8.26 A digital, Bluetooth capable, dual-sensor, standalone micron vacuum gauge hooked up to a HVACR system through a valve core removal tool. Large evacuation hoses are connected to both high and low sides of the HVACR system through valve core removal tools.

Courtesy Appion Inc.

and that is connected to the gauge with wires, **Figure 8.27**. Some modern, wireless, digital micron vacuum gauges have Bluetooth capabilities and need no wires, **Figure 8.25**. The sensor portion of the instrument must not be exposed to system pressure, so it is advisable to have a valve between it and the system. The sensor may also be installed using gauge lines; it is disconnected from the system before refrigerant is added, **Figure 8.28**. *The sensor should always be located in an upright position so that any oil in the system will not drain into the sensor*, **Figure 8.29**.

All micron gauges should be located on the HVAC/R system as far as possible from the vacuum pump. The Bluetooth gauge shown in **Figures 8.25** and **8.26** offers extended functionality including wireless remote vacuum measurements, a rate of change display, data-logging for trend analysis, custom alarms, and a pressure temperature library. When the vacuum gauge reaches the vacuum desired, usually about 500 to 300 microns, the vacuum pump should then be valved off and the reading marked. The instrument reading may rise for a very short time, about 1 min, then it should stabilize. When the reading stabilizes, the true system reading can be

Figure 8.29 The electronic vacuum sensor must be mounted upright to prevent oil from entering the sensor.

Courtesy Appion Inc.

recorded. If it continues to rise, either an atmospheric leak or moisture is present and is boiling to create pressure. A rising pressure could also mean refrigerant vapor is still seeping from the refrigeration system. Refrigerant could be dissolved in the compressor's crankcase oil. Often, heating the crankcase with a heat lamp or gently tapping it with a leather or rubber hammer will cause enough heat and/or vibration to release the dissolved refrigerant.

One of the advantages of the electronic vacuum gauge is its rapid response to even very small pressure rises. The smaller the system, the faster the rise. A very large system will take time to reach new pressure levels. These pressure differences may be seen instantly on the electronic instrument. *Be sure you allow for the first rise in pressure mentioned above before deciding a leak is present.* Again, it is the measurement from the meter that determines when an evacuation is complete.

The vacuum pump used to evacuate systems can often become contaminated with whatever is evacuated from a system. All contaminants seem to settle in the oil sump of the vacuum pump, which can contain acids and moisture. The oil in the vacuum pump must be changed regularly for good pump performance. The vacuum pump oil should be clean and clear; if it is cloudy, moisture is likely to be present. The pump should then be serviced by changing the oil.

NOTE: *For the best performance, only approved vacuum pump oil should be used. Any other oil will have a vapor pressure that is too high and thus prevent the achievement of deep vacuums.* • *Be sure to dispose of the old oil in the correct manner.*

With the new oil in the pump, run the pump long enough to get up to operating temperature; it will usually be too hot to touch or hold. Drain the oil again. With fresh oil in the pump, repeat the vacuum test. If it is still not satisfactory, change the oil again and observe what the oil looks like. If it is discolored, add new oil and run a new test. The pump

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

may need several changes to remove the contaminants. Fortunately, most vacuum pumps use only small quantities of oil, so there is not much expense or much oil to dispose of.

Vacuum pump oil has a very low vapor pressure and it is difficult to keep it from being contaminated while in storage. If you store your vacuum pump in the truck, it is open to the atmosphere and a certain amount of contamination will occur as moisture from the atmosphere enters the pump. In the daytime when the sun is out, the air temperature rises and the pump gets up to daytime temperatures. At night when the air cools down, the pump cools, and this moist air migrates into the pump, **Figure 8.30**. If the pump is allowed to sweat due to weather changes, even more moisture will enter the pump, **Figure 8.31**. Oil stored in a can that is not properly sealed goes through the same process. All of this means that to keep a vacuum pump in top condition for very deep vacuums, it should not be charged with fresh oil until it is time to use it. This is often not practical as you move from job to job, so frequent oil changes are required. Always cap the top of the vacuum pump oil container and vacuum pump as soon as possible to prevent atmospheric moisture from migrating to the oil.

Figure 8.30 When the vacuum pump cools down during the night, moist atmospheric air is pulled inside of the pump.

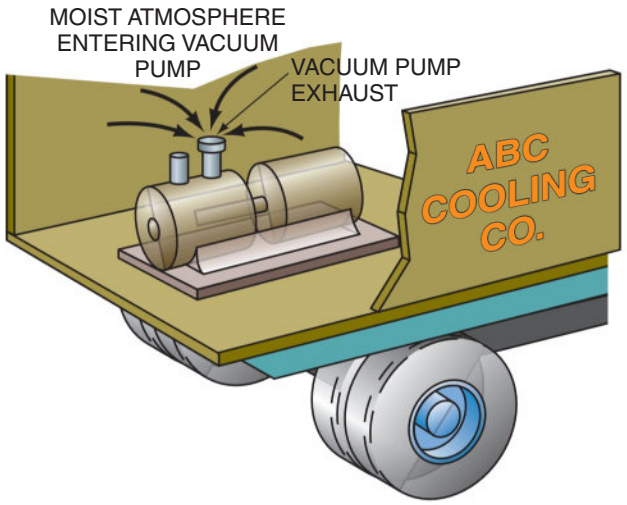

Figure 8.31 When the vacuum pump sweats on the outside, it sweats on the inside. This contaminates the oil.

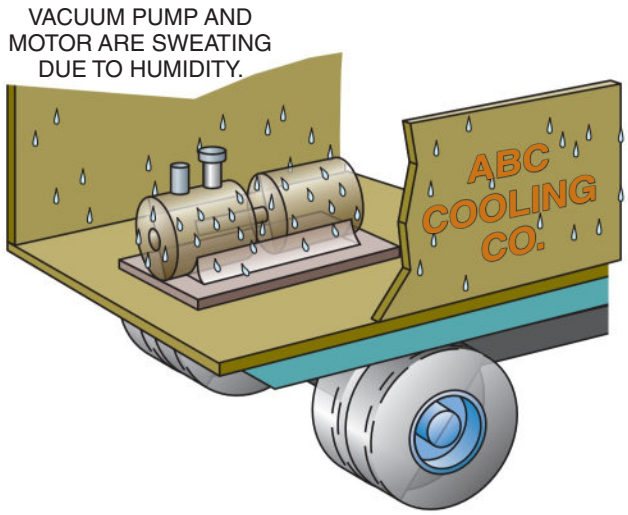

Clean oil and unrestricted flow from the HVAC/R system to the vacuum pump maximize evacuation speed. Clean and pure vacuum pump oil has a very low vapor pressure. A vacuum pump can only pull as deep as the vapor pressure of its sealing oil. The vacuum pump oil is a liquid seal between the vanes and the cylinder walls of all two-stage rotary vacuum pumps. When moisture enters the vacuum pump sealing oil, it reduces the oil's ability to maintain a low micron seal. As the oil becomes saturated with moisture, its vapor pressure rises. This in turn raises the vacuum level that can be achieved by the vacuum pump. The oil must be changed as its gets cloudy or dirty to remove the initial contamination, or the rate of evacuation will slow and a deep vacuum will never be reached. A micron gauge is the only true indicator as to when the oil needs to be changed. The vacuum pump will pull at a slower rate and the micron gauge will not reach deep vacuums with contaminated oil.

A vacuum pump needs the maximum flow to pump at its full capacity. Removing Schrader valve cores and core depressors in service hoses and using as many ½ inch or larger hoses as your system can handle will provide more evacuation channels at less resistance to flow. **Figure 8.28** shows a valve core remover tool with a digital, Bluetooth micron gauge connected. Schrader cores can cover 90% of the internal diameter of the access port. Valve core removal tools allow the service technician to remove valve cores for less resistance to flow during an evacuation process. The core can then be replaced after the evacuation is complete without disturbing the HVAC/R system.

A 1/4 inch service hose will only allow a vacuum pump to pull at 0.8 CFM, regardless of the vacuum pump's CFM rating. Never use 1/4 inch hoses for HVAC/R system evacuations. Using and 1/4 inch hoses greatly reduces the resistance to flow from the HVAC/R system through the vacuum pump. Always ensure the connecting equipment from the HVAC/R system to the vacuum pump is vacuum rated to the capability of your pump. Rotary vane vacuum pumps' capabilities are 20 to 100 microns. Avoid using manifold gauge sets for pulling vacuum because they increase the chances for leaks. Also, many manifold gauge sets and hoses offer a lot of restriction to flow from the HVAC/R system to the vacuum pump. It is not necessary to have a manifold gauge set involved in the evacuation process. **Figure 8.28** shows evacuation accesses from both the high and low side of the HVAC/R system with large diameter hoses coming from the system with a manifold gauge set. These large diameter hoses are connected to the HVAC/R system through a valve core removal tool. Both large diameter evacuation hoses are vacuum rated and connect to the vacuum pump. Also shown is a digital, wireless,

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Bluetooth micron vacuum gauge connected to the HVAC/R system, not to a gauge manifold or vacuum pump.

Some modern vacuum pumps have special features that allow a technician to monitor oil quality and to change wet or dirty oil on the fly in 5 seconds without breaking the vacuum, **Figure 8.32(D)**. A clear debris monitoring tube prevents contamination from entering and damaging the vacuum pump. The debris tube is also a positive pressure relief to eliminate accidental oil showers. The pump also has an oil "anti-suckback" feature that will not let vacuum pump oil get sucked back into the refrigeration system in case of a

power failure. Also, massive aluminum heat sinks keep the oil cool and reduce viscosity breakdown. The vacuum pump in **Figure 8.32(E)** also has a remote exhaust with a garden hose fitting, an easy-to-clean debris filter screen, and adjustable multiport hose input fittings for ¼-, ⅜-, and ½-in. hose connections for pulling single or multiple vacuums. Used in conjunction with short, large, nonrestrictive vacuum hoses and a manifold set, both industrial systems and residential systems can be evacuated in one-quarter of the time it takes with a traditional vacuum system, **Figure 8.57(C)**.

RECOVERING REFRIGERANT

4R If there is or has been refrigerant in a system, the technician must remove the refrigerant before evacuating the system to remove contaminants or noncondensable gases. This must be done with EPA-approved recovery equipment. The amount of vacuum to be achieved when removing the refrigerant depends on the size of the system, the type of refrigerant, and whether or not the recovery equipment was manufactured before or after November 15, 1993. The recovery of refrigerant is discussed in more detail in Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting." 4R

THE VACUUM PUMP

A vacuum pump capable of reducing the atmosphere in the system down to a very low vacuum is necessary. The vacuum pumps usually used in the refrigeration field are manufactured with rotary compressors, and the pumps that produce the lowest vacuums are two-stage rotary vacuum pumps, **Figure 8.32**. These pumps are capable of reducing the pressure in a leak-free vessel down to a very low micron range. It is not practical to pull a vacuum below 20 microns in a field-installed system because the refrigerant oil in the system may boil slightly and create a vapor. The usual vacuum required by manufacturers is approximately 500 microns, although some may require a vacuum as low as 250 microns.

Two-stage vacuum pumps are made up of two single-stage vacuum pumps in series. They are almost always of the rotary style because rotary vacuum pumps do not require any head clearance like piston-type pumps. This allows them to have a much higher volumetric efficiency. Two-stage vacuum pumps can pull much lower vacuums because their second stage experiences a much lower intake pressure, which is the result of the exhaust of the first-stage vacuum pump being exhausted into the intake of the second-stage vacuum pump instead of into the atmospheric pressure. This gives the first-stage pump less back pressure and, therefore, a higher efficiency. The second-stage vacuum pump begins pulling at a lower pressure, so it can pull to a lower vacuum. Two-stage vacuum pumps have the best track record because they consistently pull lower vacuums and are much more efficient when removing moisture.

When moisture is in a system, a very low vacuum will cause it to boil to a vapor. The vapor will be removed by the vacuum pump and exhausted to the atmosphere. Small amounts of moisture can be removed this way, but it is not practical to remove large amounts with a vacuum pump because boiling water produces a large amount of vapor. For example, 1 lb of water (about a pint) in a system will turn into 867 ft^3 of vapor if boiled at 70°F.

DEEP VACUUM

The **deep vacuum** method involves reducing the pressure in the system to about 250 to 500 microns. When the vacuum reaches the desired level, the vacuum pump is valved off and the system is allowed to stand for some time to see whether the pressure rises. If the pressure rises and stops at some point, a material such as water is boiling in the system. It could also mean that dissolved refrigerant is still coming out of the oil in the compressor crankcase. If this occurs, continue evacuating. If the pressure continues to rise, there is a leak and the atmosphere is seeping into the system. In this case, the system should be pressured and leak checked again.

When pressure is reduced to 250 to 500 microns and remains constant, no noncondensable gas or moisture is left in the system. Reducing the system pressure to 250 microns is a slow process, because when the vacuum pump pulls the system pressure to under about 5 mm (5000 microns), the pumping process slows down. The technician should have other work planned and let the vacuum pump run. Most technicians plan to start the vacuum pump as early as possible and finish other work while the pump does its work. Some technicians let the vacuum pump run all night because of the time involved in reaching a deep vacuum. However, if the vacuum pump's oil is saturated with moisture, even letting it run all night will not guarantee a deep vacuum.

When the vacuum pump pulls a vacuum, the system becomes a large volume of low pressure; the vacuum pump is between this volume and the atmosphere, **Figure 8.33**. If the pump shuts off during the night due to a power failure, oil may be sucked into the refrigeration system because of the strong pressure difference, **Figure 8.34**. When the power is restored and the vacuum pump starts back up, it will be without adequate lubrication and could be damaged. Having vacuum pump oil in the refrigeration or air-conditioning system can also damage the system because vacuum pump oil is designed for pumps only. Mixing vacuum pump oil with the cooling system's oil will do serious damage to the cooling system. This can be prevented by installing a large solenoid valve in the vacuum line entering the vacuum pump and wiring the solenoid valve coil in parallel with the vacuum pump motor. The solenoid valve should have a large port so that it doesn't restrict the flow, **Figure 8.35** (to be discussed in more detail later in this unit). Now, if the power fails, or if someone disconnects the vacuum pump (a good possibility at a construction

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

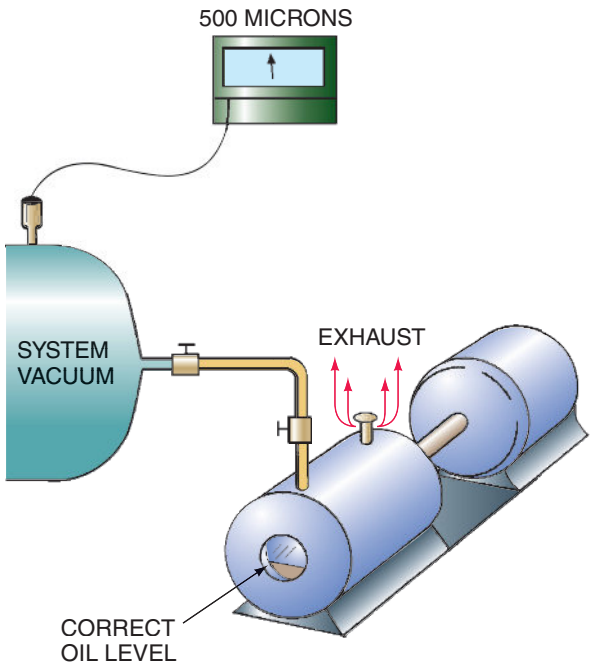

Figure 8.34 This system under vacuum has pulled the oil out of the vacuum pump.

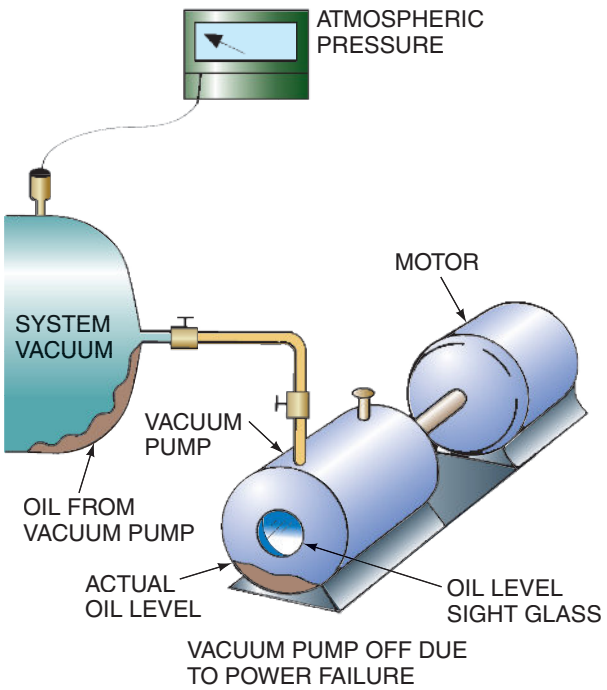
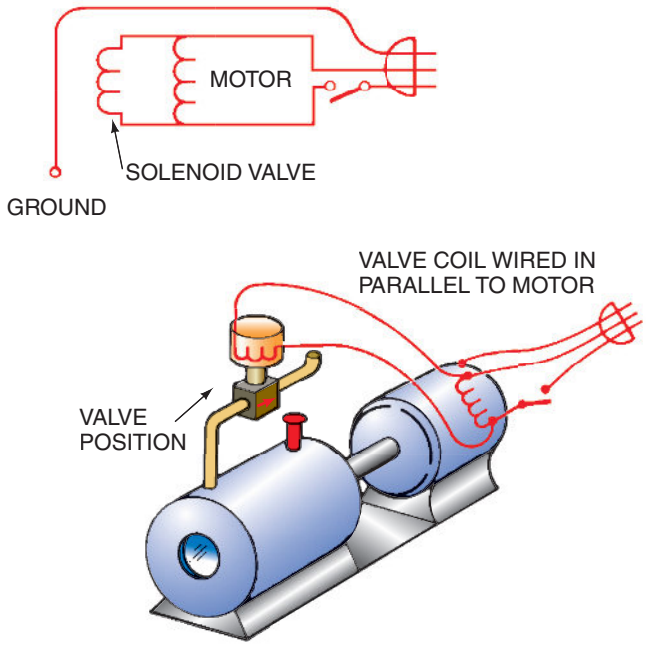


site), the vacuum will not be lost and the pump will not lose its lubrication. Most vacuum pumps manufactured today have a built-in check valve to prevent this from occurring. However, the service technician should check with the pump manufacturer to verify if the pump has a check valve.

Figure 8.35 A vacuum pump with a solenoid valve in the inlet line. Note the direction of the arrow on the solenoid valve. The valve is installed to prevent flow from the pump. It must be installed in this direction.



MULTIPLE OR TRIPLE EVACUATION

Multiple or triple evacuation is used by many technicians to evacuate a system to a deep vacuum level. It is normally accomplished by evacuating a system to a low vacuum, about 1500 microns, and then bleeding a small amount of dry nitrogen into the system. The nitrogen is then blown out to the atmosphere. The system is then evacuated until the vacuum is again reduced to 1500 microns. This procedure is repeated three times, with the last vacuum level reaching a deep vacuum of 250 to 500 microns, which is held for 10 to 15 minutes. The following is a detailed description of a multiple or triple evacuation, the latter being performed three times and called a *triple evacuation*. **Figure 8.36** is a diagram of the valve attachments.

1. Attach an electronic micron gauge to the system. The best place is as far from the vacuum port as possible. For example, on a refrigeration system, the pump may be attached to the suction and discharge service valves and the micron gauge to the liquid receiver valve port. Then start the vacuum pump.
2. Let the vacuum pump run until the micron gauge reaches 1500 microns, **Figure 8.37**.
3. Allow a small amount of dry nitrogen to enter the system until the vacuum is about 20 in. Hg. **Figure 8.38** shows the manifold gauge reading. This small amount of dry nitrogen will fill the system and absorb and mix with other vapors.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 8.38 Manifold gauge reading 20 in. Hg vacuum.

Courtesy Ferris State University. Photo by John Tomczyk

4. Open the vacuum pump valve and start the vapor moving from the system again. Let the vacuum pump run until the vacuum is again reduced to 1500 microns. Then repeat step 3.
5. When the nitrogen has been added to the system the second time, open the vacuum pump valve and again remove the vapor. Operate the vacuum pump until the vacuum on the electronic micron gauge reads from 250 to 500 microns.

Once the micron gauge reads the desired vacuum (250 to 500 microns) for 10 to 15 minutes, isolate the micron gauge and charge the system with the proper refrigerant. Adding liquid refrigerant to the high side of the system is the safest and quickest method of charging a system while under a vacuum. This will prevent any liquid from entering the low side and getting to the compressor before vaporizing. **NOTE:** *It is of utmost importance that the third vacuum pulled be a deep vacuum of 250 to 500 microns and held for 10 to 15 minutes.* •

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

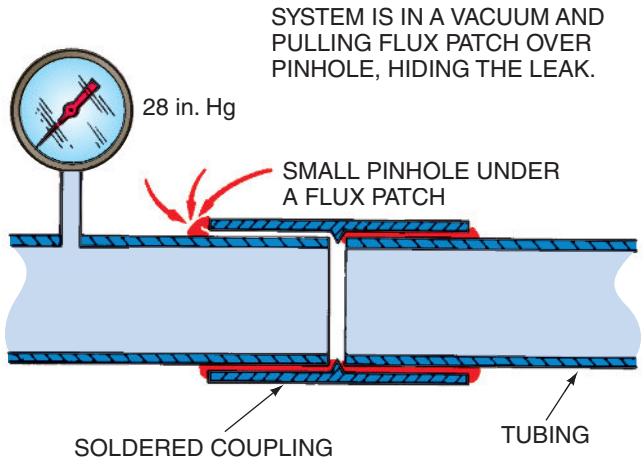
LEAK DETECTION

We mentioned that if a leak is present in a system, the vacuum gauge will start to rise if the system is still under vacuum, indicating a pressure rise. **NOTE:** *Many technicians use this as an indicator that a leak is still in the system, but this is not a recommended leak test procedure. It allows air to enter the system, and the technician cannot determine from the vacuum where the leak is. Also, when a vacuum is used for leak checking, it is only proving that the system will not leak under a pressure difference of 14.696 psi.* • If all of the atmosphere is removed from the system, only the atmosphere under atmospheric pressure is trying to get back into the system.

Checking for a leak using a vacuum is making use of a reverse pressure (the atmosphere trying to get into the system) of only 14.696 psi. The system, when fully loaded, typically has an operating pressure of 350 psig + 14.696 psi = 364.696 psia for an R-22 air-cooled condenser on a very hot day, **Figure 8.39**.

Using a vacuum for leak checking also may hide a leak. For example, the vacuum will tend to pull flux buildup into a pin-sized hole in a solder connection and may even hide it to the point where a deep vacuum can be achieved, **Figure 8.40**. Then when pressure is applied to the system, the flux will blow out of the pinhole and a leak will appear.

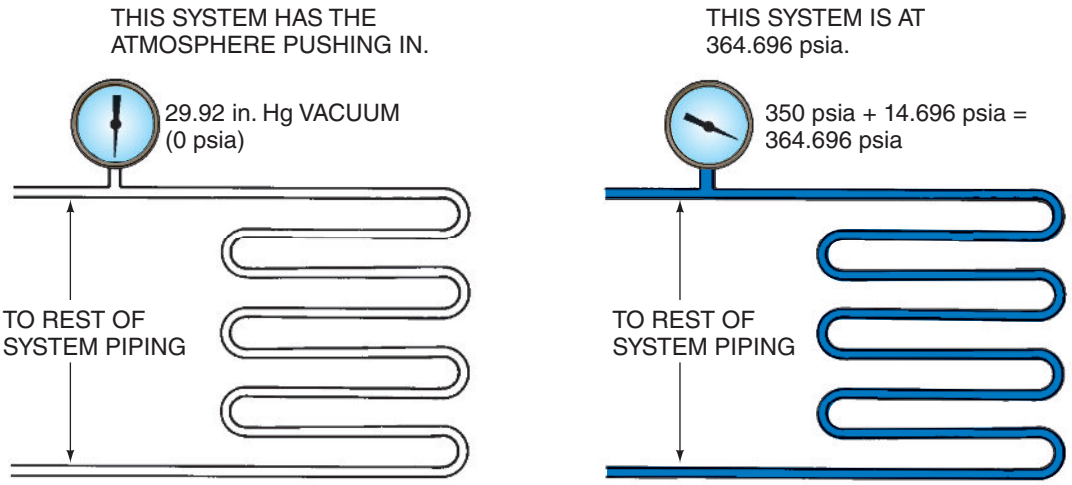
Figure 8.40 This system was leak checked under a vacuum.



REMOVING MOISTURE

A vacuum pump can be used to **remove moisture** (dehydrate) from a system. When the moisture is in the vapor state, it is easy to remove. When it is in the liquid state, removing it is much more difficult. The example given earlier in this unit showed that 867 ft^3 of vapor at 70°F must be pumped to remove 1 lb of water. This explanation is not complete, because as the vacuum pump begins to remove the moisture, the water will boil and the temperature of the trapped water will drop. For example, if the water temperature drops to 50°F, 1 lb of water will then boil to 1702 ft^3 of vapor that must be removed. This is a pressure level in the system of 0.362 in. Hg or 9.2 mm Hg (0.362 × 25.4 mm/in.). The vacuum level is just reaching the low ranges. As the vacuum pump pulls lower, the water will boil more (if the vacuum pump has the capacity to pump this much vapor), and the temperature will decrease to 36°F. The water will now create a vapor volume of 2837 ft^3. This is a vapor pressure in the system of 0.212 in. Hg, or 5.4 mm Hg (0.212 × 25.4 mm/in.). Thus, lowering the pressure level creates more vapor. It takes a large vacuum pump to pull moisture in the vapor state out of a system. (See **Figure 8.41** for the relationships between temperature, pressure, and volume.)

Figure 8.39 These two systems are being compared under different pressure situations. One is evacuated and the atmosphere, under atmospheric pressure, is trying to get into the system. The other has 350 psig + 14.696 psia. The one under the most pressure is under the most stress. Using a vacuum as a leak test is not a proper leak test of the system.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 8.41 This partial temperature/pressure relationship table for water shows the specific volume of water vapor that must be removed to remove a pound of water from a system.

If the system pressure is reduced further, the water will turn to ice and be even more difficult to remove. The ice will turn to a vapor very slowly. The process of a solid turning to vapor without passing through the liquid state is referred to as **sublimation.** If large amounts of moisture must be removed from a system with a vacuum pump, the following procedure will help:

1. Use a large vacuum pump. If the system is flooded (for example, if a water-cooled condenser pipe ruptures from freezing), a 5-cfm (cubic feet per minute) vacuum pump is recommended for systems up to 25 tons. If the system is larger, a larger pump or a second pump should be used. As a rule of thumb, the vacuum pump's cfm rating squared equals the maximum system tonnage. As an example, a 4 cfm rating is usually rated for about a 16-ton system.
2. Drain the system in as many low places as possible. Remove the compressor and pour out the water and oil from the system. **Do not add the oil back until the system is ready to be started, after evacuation. If you add it earlier, the oil may become wet and hard to evacuate.**
3. Apply as much heat as possible without damaging the system. If the system is in a heated room, the room may be heated to 90°F without fear of damaging the room and its furnishings or the system, **Figure 8.42**. The vacuum gauge should be connected at the system as far away from the vacuum pump as possible. This assures an accurate measurement of the vacuum in the system. If the vacuum gauge is connected close to the vacuum pump, it will give you the vacuum reading of the vacuum pump, not the system. If part of the system is outside, use a heat lamp, **Figure 8.43**. The entire system, including the interconnecting piping, must be heated to a warm temperature or the water will boil to a vapor where the heat is applied and condense where the system is cool. For example, if water is in the evaporator inside the structure and heat is applied to the evaporator, the water will boil to a vapor. If it is cool outside, the water vapor may condense outside in the condenser piping. The water is only being moved around.
4. Start the vacuum pump and observe its oil level. At the beginning of the evacuation, water vapor is quickly removed from the system. Because of this, if a system is heavily laden with moisture, the pump's oil can become quickly contaminated with moisture that has condensed in its crankcase. The oil then loses its lubricating and sealing qualities, and the vacuum pump will be unable to pull a deep vacuum. Some vacuum pumps have a feature called *gas ballast* that introduces some relatively dry atmospheric air between the first and second stages of the two-stage pump, **Figure 8.44**. This prevents some of the moisture from condensing in the crankcase. Regardless of the vacuum pump, watch the oil level. **NOTE:** *The water will displace the oil and push the oil out of the pump. Soon, water may be the only lubricant in the vacuum pump crankcase, and damage may occur. Pumps are very expensive and should be protected.* •

8.8 GENERAL EVACUATION PROCEDURES

Some general rules apply to deep vacuum and deep multiple evacuation procedures. If the system is large enough or if you must evacuate the moisture from several systems, you can construct a cold trap to use in the field.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 8.42 When a system has moisture in it and is being evacuated, heat may be applied to the system. This will cause the water to turn to vapor, and the vacuum pump will remove it.

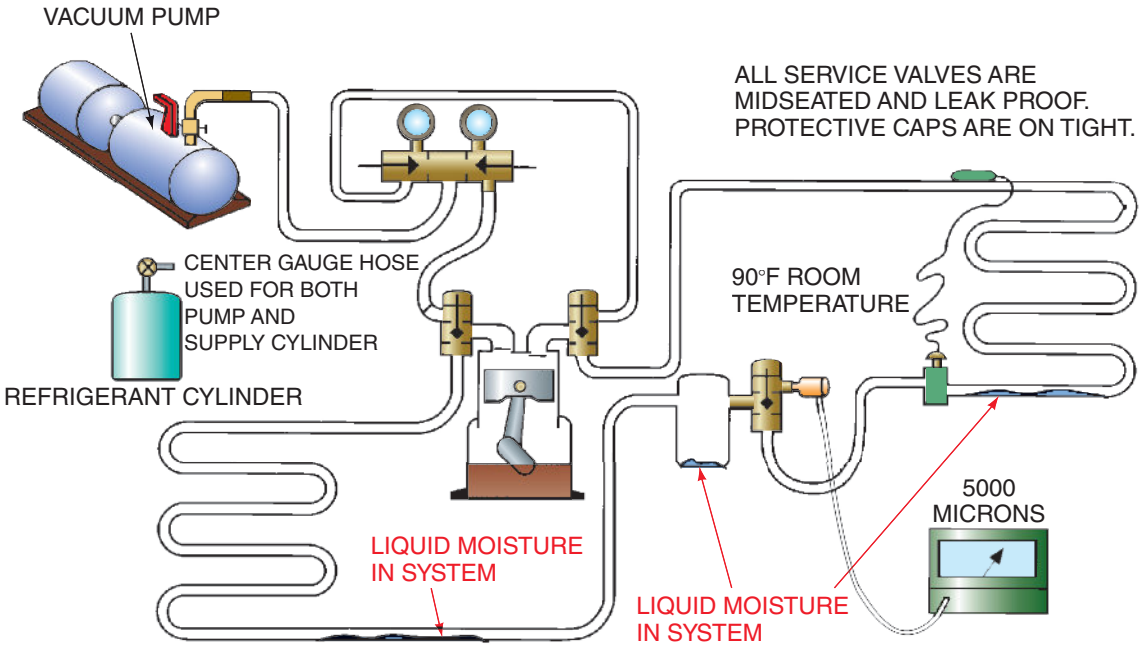

Figure 8.43 When heat is supplied to a large system with components inside and outside, the entire system must be heated. If not, the moisture will condense where the system is cool.

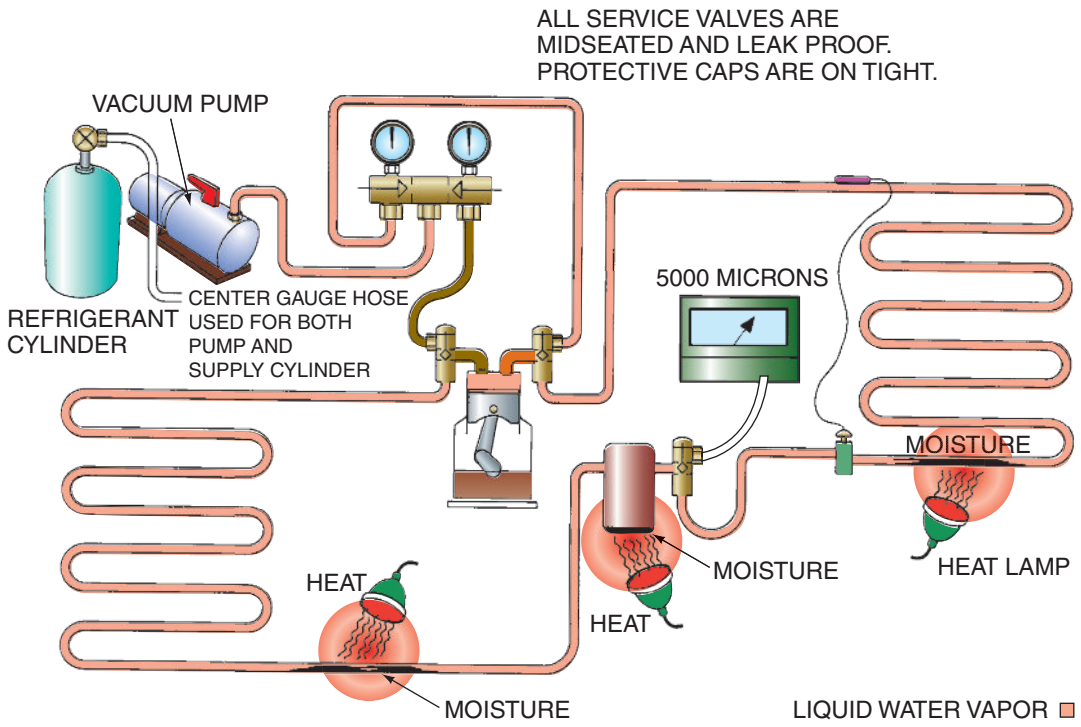
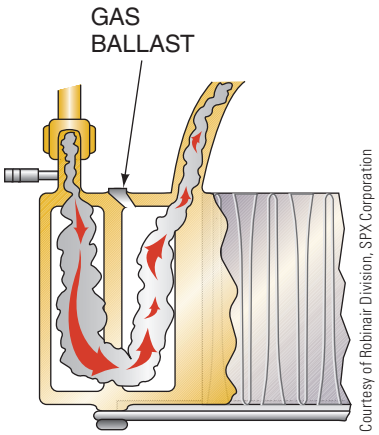


Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 8.44 This vacuum pump has a feature called gas ballast, which allows a small amount of relatively dry atmospheric air to enter between the first and second stage. This prevents some moisture from condensing in the pump and contaminating the oil.



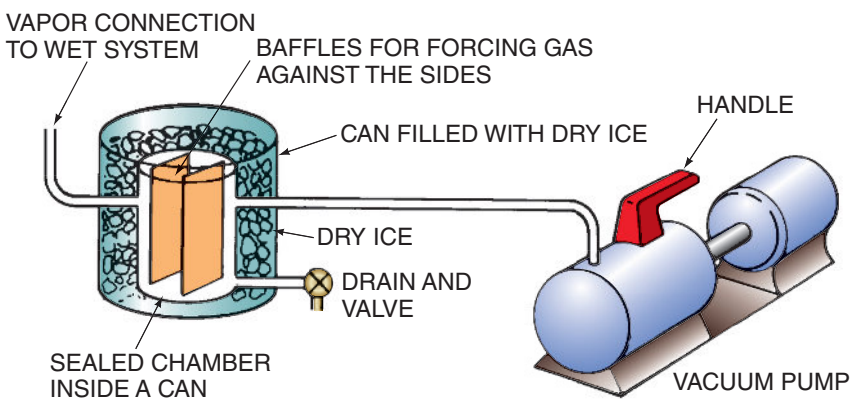
The **cold trap** is a refrigerated volume in the vacuum line between the wet system and the vacuum pump. When the water vapor passes through the cold trap, the moisture freezes to the walls of the trap, which is normally refrigerated with dry ice (CO_2), a commercially available product. The trap is heated, pressurized, and drained periodically to remove the moisture, **Figure 8.45**. **NOTE:** *The cold-trap container must be able to withstand atmospheric pressure, 14.696 psi, pushing in, when in a deep vacuum. A light-duty container can collapse.* • The cold trap can save a vacuum pump from moisture contamination.

Noncondensable gases and moisture may be trapped in a compressor and are as difficult to release as a vapor that can be pumped out of a system. A compressor has small chambers, such as cylinders, that may contain air or moisture. Only flapper valves sit on top of these chambers, but there is nothing to force the air or water to move out of the cylinder while it is under a vacuum. At times it is advisable to start up a semihermetic or open-type compressor after a vacuum has been tried, which is easy to do when using the triple evacuation method. After the first vacuum has been reached, nitrogen can be charged into the system until it reaches atmospheric pressure. The compressor can then be started for a few seconds. All chambers should be flushed at this time. **NOTE:** *Do not start a hermetic compressor while it is in a deep vacuum. Motor damage may occur.* • The fusite terminals or studs that protrude into the shell of a hermetic compressor that are connected to power must be insulated from one another with refrigerant vapor and/or oil vapor. Both refrigerant and oil are good dielectrics, meaning they are good insulators and will not conduct electricity. When a vacuum is pulled on a hermitic compressor, these dielectrics will disappear and no longer insulate the three fusite terminals inside the compressor. A short circuit will occur and damage the motor windings and fusite terminals of the compressor motor. **Figure 8.46** shows an example of vapor trapped in the cylinder of a compressor.

Water can be trapped in a compressor under the oil. Oil will float on the water because it is less dense. Because the oil has surface tension, the moisture may stay under it even under a deep vacuum. But the oil surface tension can be broken with vibration, such as the vibration that occurs when striking the compressor housing with a soft-face hammer. Any kind of movement that causes the oil's surface to shake will work, **Figure 8.47**. Applying heat to the compressor crankcase will also release the water, **Figure 8.48**.

The technician who evacuates many systems must use time-saving procedures. For example, a typical gauge manifold may not be the best choice because it has very small valve ports that slow the evacuation process, **Figure 8.49**. However, some gauge manifolds are manufactured with large valve ports and a special large hose for the vacuum pump connection, **Figure 8.50** and **Figure 8.57 (B)** and **(C)**. The gauge manifold in **Figure 8.51** has four valves and four hoses. The two extra valves are used to control the refrigerant and the vacuum pump lines. When using this manifold,

Figure 8.45 A cold trap.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 8.46 Vapor trapped in the cylinder of the compressor.

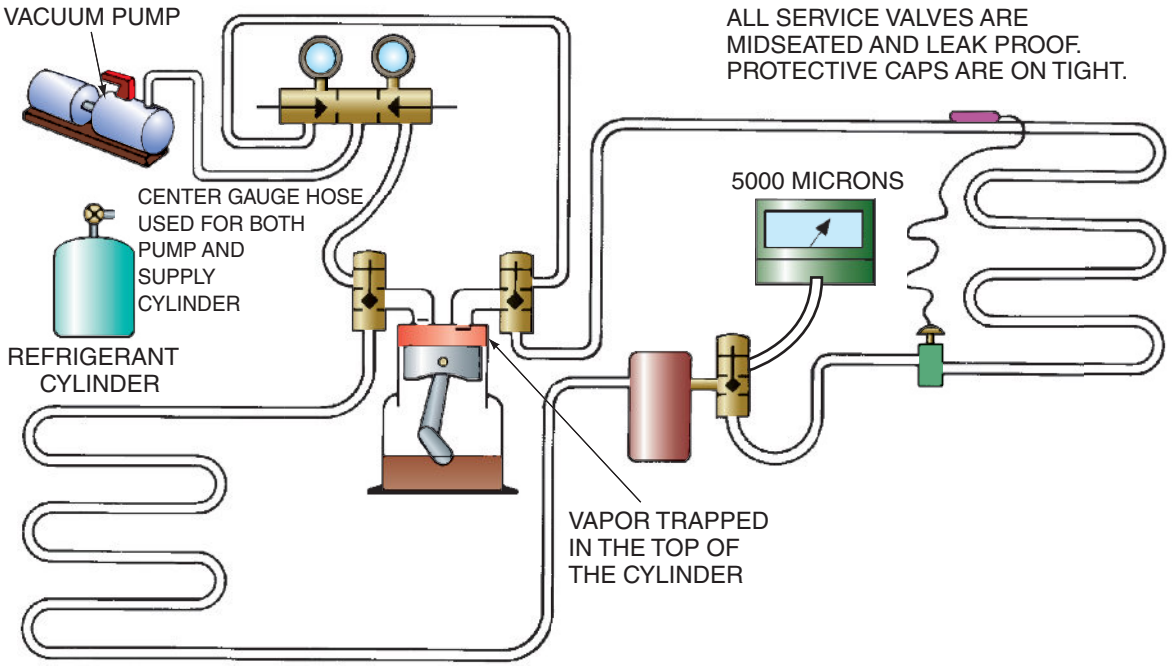


Figure 8.47 A compressor with water under the oil in the crankcase.

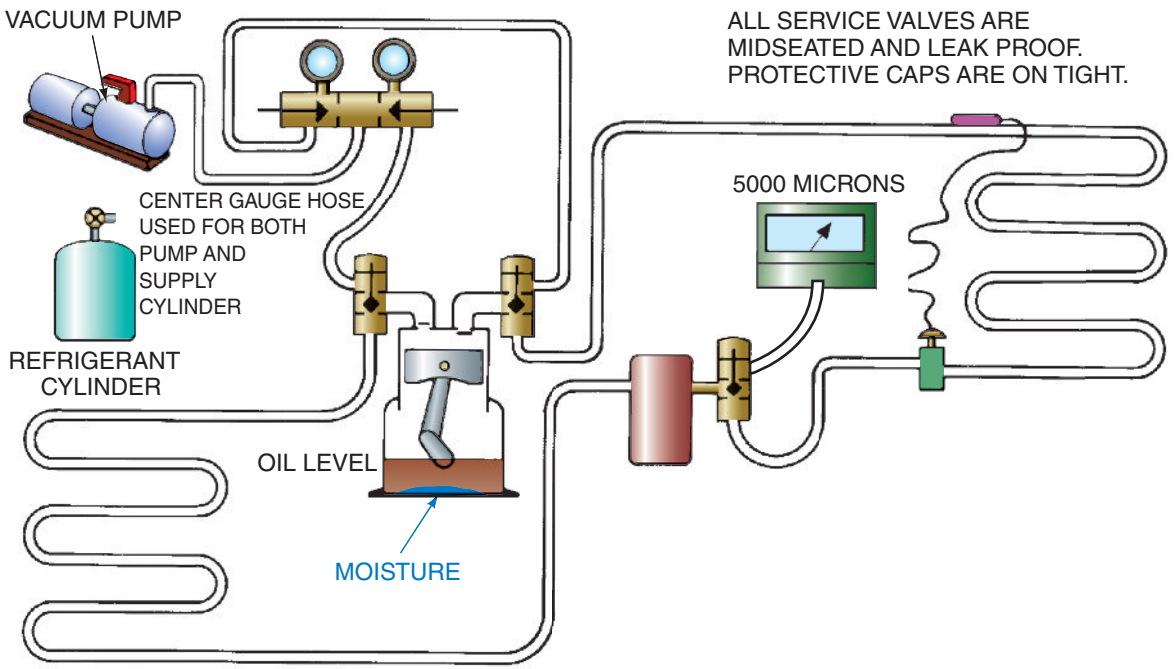

the vacuum pump need not be disconnected and the hose line switched to the refrigerant cylinder to charge refrigerant into the system. When the time comes to stop the evacuation and charge refrigerant into the system, one valve is closed and the other opened, **Figure 8.51**. This is a much easier and cleaner method of changing from the vacuum line to the refrigerant line. With a three-hose manifold, air is drawn into the hose when a gauge line is disconnected from the vacuum pump. This air must be purged from the hose at the top, near the manifold. It is impossible to get all of the air out of the manifold because some will be trapped and pushed into the system, **Figure 8.52**.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 8.48 Heat is applied to the compressor to boil water under the oil.

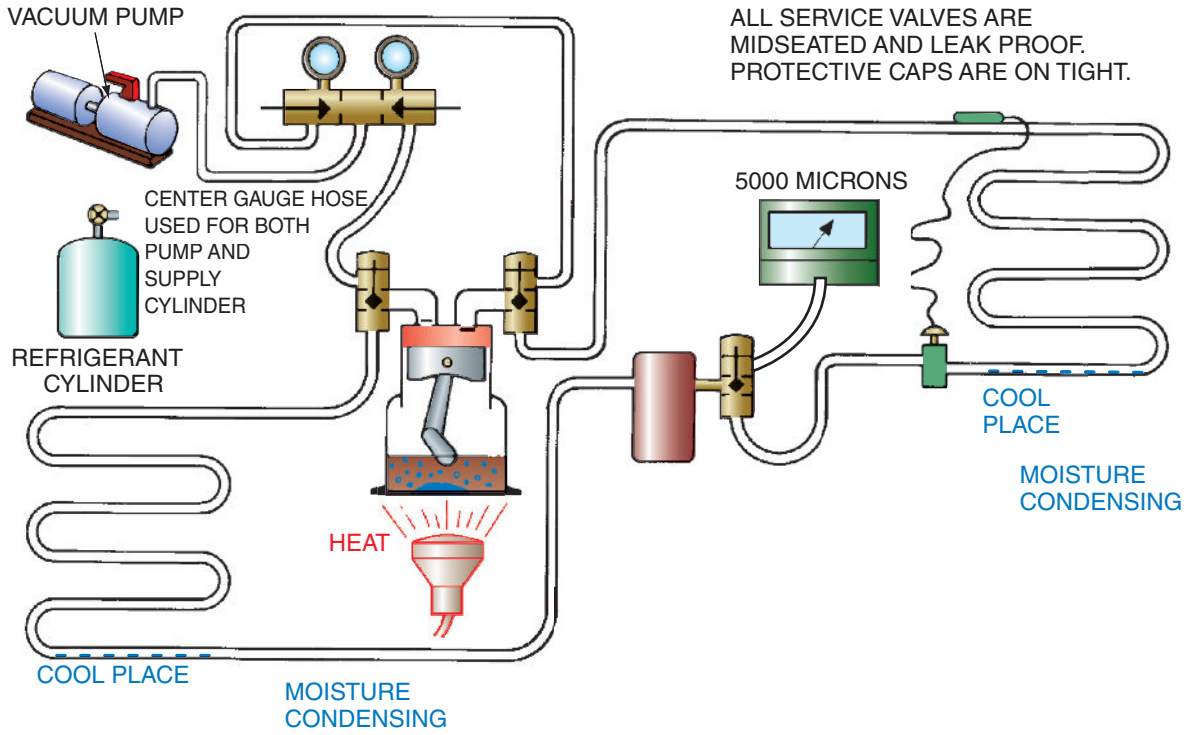

Figure 8.49 A gauge manifold with small ports.

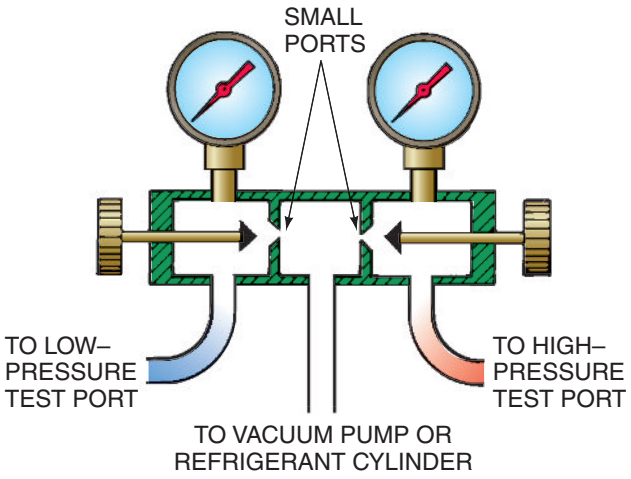

Figure 8.50 A gauge manifold with large ports.

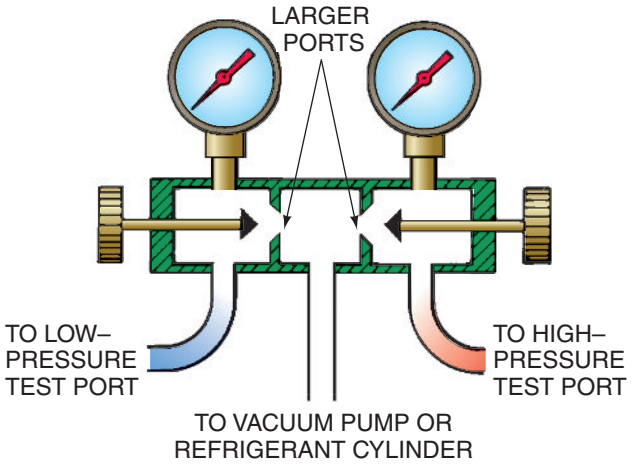

Most gauge manifolds have valve stem depressors in the ends of the gauge hoses. The depressors are used for servicing systems with Schrader access valves. These valves are much like the valve and stem on an automobile tire. The depressors restrict the evacuation process and slow down vacuum speed considerably. Many technicians erroneously use oversized vacuum pumps and undersized connectors because they do not realize that the vacuum can be pulled much faster with large connectors. The valve depressors can be removed from the ends of the gauge hoses, and adapters can be used when valve depression is needed. **Figure 8.53** shows one of these adapters. **Figure 8.54** is a small valve that can be used on the end of a gauge hose; it will even give the technician a choice as to when to depress the valve stem.

Figure 8.51 A manifold with four valves and four gauge hoses.

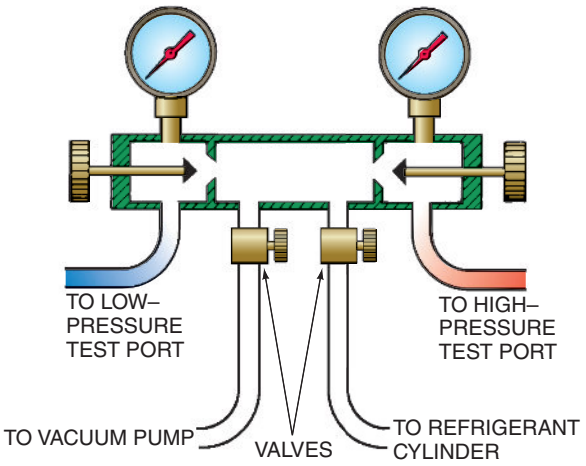

Figure 8.52 This piping diagram shows how air is trapped in the gauge manifold.

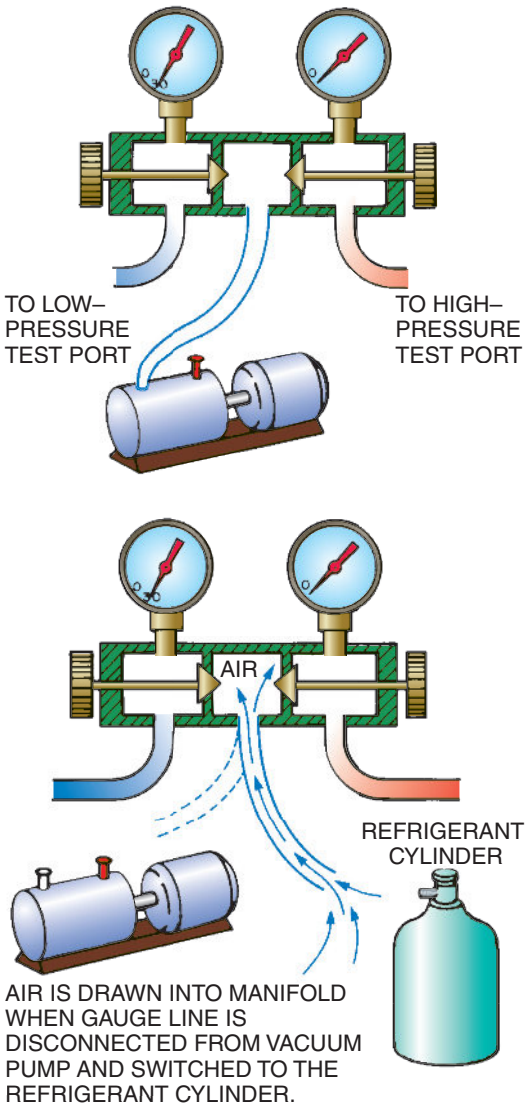

Figure 8.53 This gauge adapter can be used instead of the gauge depressors that are normally in the end of the gauge lines. The adapters may be used for gauge readings.

SYSTEMS WITH SCHRADER VALVES

A system having Schrader valves for gauge ports will take much longer to evacuate than a system with service valves. The reason is that the valve stems and the depressors act as restrictions. An alternative is to remove the valve stems during evacuation and replace them when evacuation is finished. It will take a great deal of time to evacuate water or moisture from a system if there are Schrader valve stems in the service ports. These valve stems are designed to be removed and replaced, so they can also be

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 8.55 A Schrader valve assembly.

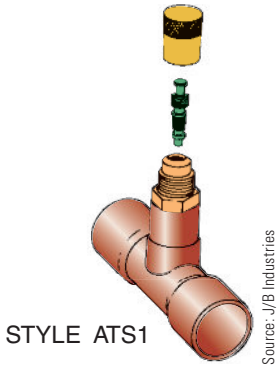

Figure 8.56 This fitting has a sensitive sealing shoulder on top. The sealing cap that comes with it has a soft neoprene gasket. If a brass flare cap is used instead and tightened down, the top of the fitting will become distorted and the valve stem cannot be removed.

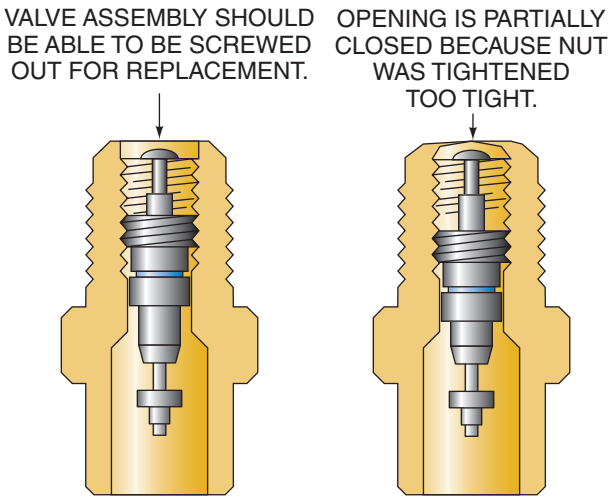

removed for evacuation, **Figure 8.55**. A special tool, called a field service valve, can be used to replace Schrader valve stems under pressure, or it can be used as a control valve during evacuation. The tool has a valve arrangement that allows evacuation of a system through it with the stem backed out of the Schrader valve, **Figure 5-61** in Unit 5, "Tools and Equipment." The stem is replaced when the evacuation is completed.

Schrader valves are shipped with a special cap, which is used to cover the valve when it is not in use. The cover has a soft gasket and should only be to cover Schrader valves. If a standard brass flare cap is used and overtightened, the Schrader valve top will be distorted and valve stem service will be difficult, if it can be done at all, **Figure 8.56.**

GAUGE MANIFOLD HOSES

The standard gauge manifold has flexible hoses with connectors on the ends. These hoses sometimes get pinhole leaks, usually around the connectors, which may leak while under a vacuum but not when the hose has pressure inside it, because the hose swells when pressurized. If there is trouble finding a leak while pulling a vacuum, substitute soft copper tubing for the gauge lines, **Figure 8.57**. Some manufacturers market gauge manifolds with large, short hoses to minimize pressure drop and to speed the evacuation process by increasing flow through the vacuum pump, **Figures 8.57(B)** and **(C)**.

SYSTEM VALVES

For a system with many valves and piping runs, perhaps even multiple evaporators, check to see whether the valves are open before evacuation. A system may have a closed solenoid valve, which may trap air in the liquid line between the expansion valve and the solenoid valve, **Figure 8.58**. This valve must be opened for complete evacuation. It may even need a temporary power supply to operate its magnetic coil. Some solenoid valves have a screw or manual-open stem on the bottom to manually jack the valve open, **Figure 8.59**.

USING DRY NITROGEN

Maintaining good work practices while assembling or installing a system can make system evacuation an easier task. *When piping is field-installed, sweeping dry nitrogen through the refrigerant lines can keep the atmosphere pushed out and clean the pipe. It is relatively inexpensive to use a dry nitrogen setup, and it saves time and money.*

Also, slowly sweeping dry nitrogen through pipes while they are being soldered or brazed will prevent oxidation on the inside and outside of the brazed joints. The 20% oxygen content of the air causes the oxidation on pipes when brazing if dry nitrogen is not used. When a system has been open to the atmosphere for some time, it needs evacuation. The task can be shortened by sweeping the system with dry nitrogen before evacuation. **Figure 8.60** shows how this is done.

8.9 CLEANING A DIRTY SYSTEM

The technician should be aware of how to use a vacuum to clean a dirty system of several types of contaminants. We have discussed water and air, but they are not the only contaminants that can form in a system. The hermetic motor inside a sealed system is the source of heat in a motor burnout. The heat can raise the refrigerant and oil to temperatures that will break them down to acids, soot (carbon), and sludge that cannot be removed with a vacuum pump. The high temperature arc of a motor burnout inside a compressor also causes a portion of the refrigerant and oil mixture to break down into carbonaceous sludge, corrosive acids, and water. These contaminants must be removed from the system, especially from the compressor crankcase.

Heat + Refrigerant + Moisture = Acids

Moisture + Acid + Oil = Sludge

System contaminants can be in the solid, liquid, or vapor state. Most contaminants will be in the compressor's oil, **Figure 8.61(B)**. It is because of these contaminants that a heavy-duty suction-line filter or filter drier is recommended for every new field installation. These filters will catch contaminants before they get to other parts of the system. A suction-line filter drier will also capture any acids generated during a compressor burnout before they cause any additional system damage. **SAFETY PRECAUTION:** *Whenever working with a burned-out system, extreme caution must be used when handling and/or operating the system. Adequate ventilation, butyle gloves,*

Figure 8.60 The technician is using dry nitrogen to sweep this system before evacuation.

(D)

and safety glasses are required for protection against acids. The oil from a burnout can cause serious skin irritation and possible burns. In some cases, the fumes are toxic. •

Let us use the example of a bad motor burnout to demonstrate how most manufacturers would expect you to clean a system. Suppose a 5-ton air-conditioning system with a fully hermetic compressor were to have a severe motor burn while running. When a motor burn occurs while the compressor is running, some of the soot, sludge, and acid from the hot oil moves into the refrigeration or air-conditioning system, **Figures 8.61 (A)** and **(B)**. The following steps should be taken to clean the system after a hermetic motor burnout:

1. Front seat (close) the inoperative compressor's service valves to isolate the compressor from the rest of the system. Recover the refrigerant from the inoperative compressor and remove it. Install the replacement compressor.
2. Take a sample of oil from the replacement compressor. Seal it in a glass bottle for comparison purposes after the cleaning procedure is complete.
3. With the compressor isolated (both service valves front seated) from the rest of the system, evacuate the compressor only. After evacuation, open the compressor service valves and close the liquid-line valve. This will minimize the amount of refrigerant handled during pump-down. Pump down the system. Some contaminants will return to the compressor during the pump-down, but the compressor will not be harmed by the short period of operation required for pump-down. The contaminants will be removed by the filter driers.
4. Inspect all system components such as expansion valves, solenoid valves, check valves, reversing valves, and contactors. Clean and replace if necessary. Remove or replace any filter driers previously installed in the system, and clean and/or replace any filters and strainers. Install a good-quality moisture indicator if the system does not have one, **Figure 8.61(D)**.

In systems without service valves, the refrigerant must be recovered. Recovery should take place through a filter drier to protect the recovery machine from acids and contamination.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The inoperative compressor should then be replaced with an operative compressor. The entire system should then be evacuated. Charge the recovered refrigerant back into the system through a filter drier. Add additional refrigerant as needed. The previous and following procedures should then be performed.

1. Install the recommended size of filter drier in the suction line. Install an oversize filter drier in the liquid line. Both liquid and suction lines will require a special temporary filter drier manufactured especially for system burnout cleaning procedures.
2. Start the compressor and run the system. As contaminants in the system are filtered out, the pressure drop across the filter driers will increase. Observe the pressure differential across the filters for a minimum of 4 hours. Use the same gauge on both sides of the drier to minimize error in gauges (driers come with pressure taps on both ends), **Figure 8.62**. For the suction line filter drier, if the pressure drop exceeds the maximum limit shown in the table in **Figure 8.63** for a temporary installation, replace the filter drier and restart the system. Note that the table in **Figure 8.63** shows the pressure drop for both permanent and temporary filter driers. During the cleanup procedure, technicians will encounter oversize filter driers.
3. Allow the system to run for 48 hours. Isolate the new compressor and take a sample of its oil. Check the odor (smell cautiously) and compare the color of the oil with the sample taken in step 2. If an acid test kit is available, test for acid content, **Figure 8.61(C)**. If the oil is discolored, acidic, has an acrid odor or if the moisture indicator indicates a high moisture content in the system, change the filter driers, **Figure 8.61(D)**. The compressor oil may also be changed if desired. Allow the system to run for another 48 hours, and recheck as before. Repeat until the oil remains clean and odor-free and the color approaches that of the original sample taken in step 2.
4. Replace the liquid line filter drier with one of normal size and for normal applications. Remove the suction-line filter drier, and replace it with a normal-size, permanent suction-line filter or filter drier.

Figure 8-62 Checking the pressure drop across a suction-line filter drier.

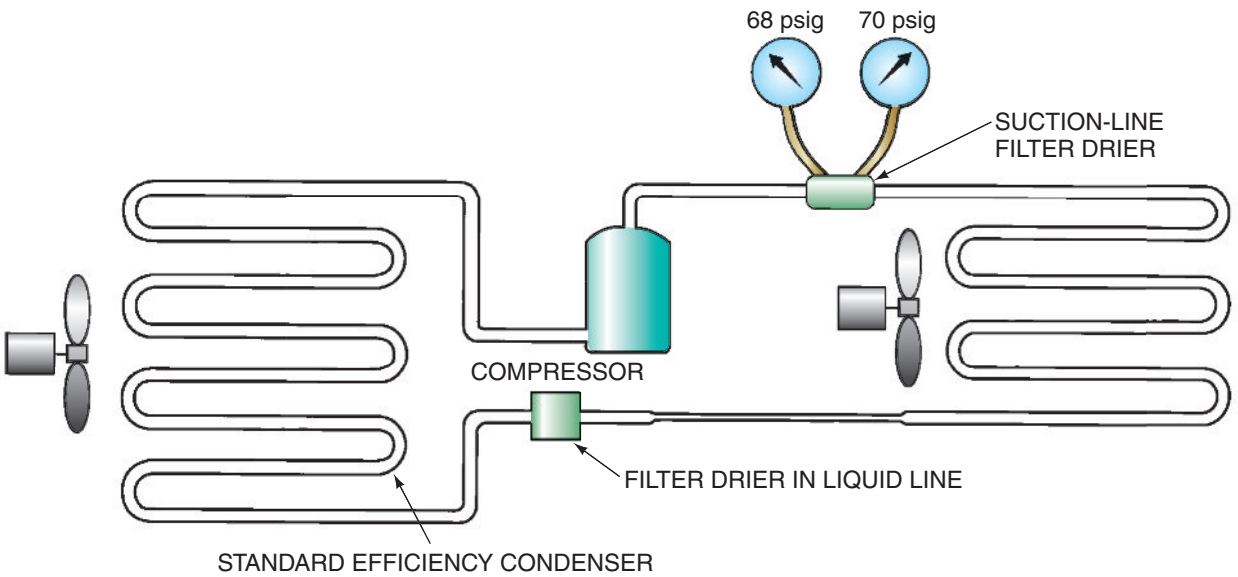

Figure 8-63 Maximum recommended pressure drop for suction-line filter driers psi (bar). Used when performing a cleanup procedure on a dirty system that usually has experienced a motor burn.

5. After the cleaning procedure is completed, recheck in approximately 2 weeks to make sure the system conditions and operation are completely satisfactory. (Note: This system cleanup procedure has been reprinted with permission from Emerson Climate Technologies.)

This system cleaning procedure has been used in countless installations over the years, and when it has been properly followed, there have been no instances of a second failure.

When recovering refrigerant from a system, certain evacuation requirements must be met. **Figure 9.23** in Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting," discusses these requirements for air-conditioning, refrigeration, and recovery/recycling equipment.

Filter-drier manufacturers have done a good job of developing filter media that will remove acid, moisture, and carbon sludge. They claim that nothing can be created inside a system by oil and refrigerant that the filter driers will not remove. It is of utmost importance that all foreign materials be removed from a system during the initial field installation. Without good suction- and liquid-line filters or filter driers, metal filings, shavings, dirt, flux, solder, metal chips, sand from sandpaper, bits of steel wool and wire from cleaning brushes could get into the compressor. Many of these contaminants are so small they will pass through a fine mesh screen like that on some compressor suction inlets. In fact, many compressors returned to the factory for replacement could have been saved if all contaminants had been removed by filter driers during the initial field installation. Returned compressors are at times reported as motor failures, but in reality the return is due to damaged bearings, valve reeds, or connecting rods caused by contaminants, which in turn caused motor damage as a secondary effect. There are many chemical flushing systems for system cleanup on the market today. However, always check to make sure they have been approved and tested by the compressor manufacturer before using.

SUMMARY

- The six classes of leaks are standing leaks, pressure-dependent leaks, temperature-dependent leaks, vibration-dependent leaks, combination-dependent leaks, and cumulative microleaks.
- Nitrogen and the system's refrigerant (used as a trace refrigerant for finding leaks) are commonly used to check a system for leaks.
- Using any refrigerant except a chlorofluorocarbon (CFC) as a trace refrigerant is acceptable because it will not be used as an operating refrigerant. The same refrigerant that is used in the cooling system is, however, the best choice for system compatibility reasons.
- The entire system must not be pressurized higher than the lowest test pressure of the system.
- It is not required by the Environmental Protection Agency to repair systems that contain less than 50 lb of refrigerant. For industrial processes equipment and commercial refrigeration equipment, systems that contain more than 50 lb of refrigerant must be repaired when the leak rate is more than 35% of their total charge in 1 year. An annual leak rate of 15% is allowed for comfort cooling chillers and all other equipment.
- Evacuation is defined as degassing and dehydrating a system.
- Evacuation using low vacuum levels removes noncondensable gases and involves pumping the system down below atmospheric pressure.
- Vapors will be pumped out by the vacuum pump. Liquids must boil to be removed with a vacuum pump.
- The most common and most accurate vacuum gauge is the digital micron gauge.
- Pumping a vacuum may be quicker by using large, unrestricted lines.
- Good workmanship and piping practice along with a dry nitrogen setup will lessen evacuation time.
- The oxygen in the air is the major problem when air is allowed to enter a system.
- Nitrogen in a system will cause excess head pressure because it takes up condensing space.
- When a vacuum pump is allowed to run unattended, the system becomes a large vacuum reservoir—and if the vacuum pump were to be shut off, the oil will be pulled into the system if the pump does not have a check valve. If this happens and the vacuum pump is then restarted, it will be operating without lubrication.
- Cleaning a system that has had a motor burn involves changing a compressor. It also involves monitoring both (temporary and permanent) suction- and liquid-line filter-drier pressure drops and checking the new compressor's oil for acid content.
- System contaminants can consist of acids, air, noncondensables, filings, shavings, dirt, solder, flux, metal chips, bits of steel wool, sand from sandpaper, and wire from cleaning brushes.
- System Schrader valve cores may be removed to shorten the time to establish a vacuum on a system; then the cores may be replaced before the system is put back into operation.
- Using dry nitrogen to sweep a contaminated system will help in evacuating a dirty system.

REVIEW QUESTIONS

1. The low-pressure side of the system must not be pressurized to more than
   A. 75 psig.
   B. 200 psig.
   C. the low-side design pressure.
   D. atmospheric pressure.
2. Name and briefly describe the six classes of leaks.
3. The _____ is both the greatest asset and the greatest liability of an electronic leak detector.
4. Why should oxygen or compressed air never be used to pressurize a system?
5. List some of the foreign matter that may enter a refrigeration system.
6. True or False: A vacuum pump can remove any type of foreign matter that enters a refrigeration system.
7. Air in a refrigeration system causes which of the following problems?
   A. Acid buildup
   B. Moisture
   C. Copper plating
   D. All of the above
8. The only two products that should be circulating in a refrigeration system are _____ and _____.
9. In order to remove moisture from a refrigeration system using a vacuum pump, it must be in a _____ state.
10. Are the best vacuum pumps one-stage or two-stage?
11. Name the two types of vacuum procedures used by technicians.
12. What can be done to get water out from under the oil level in a compressor?
13. When evacuating a refrigeration system that has solenoid valves, what special procedure must be followed?
14. What is today's most accurate type of deep vacuum gauge?
15. _____ microns are in 1 inch.
16. Briefly describe the method for cleaning up a system that has experienced a motor burn.
17. What is the advantage of using large gauge lines for evacuation?
18. Why is it important to change the oil on a vacuum pump after each evacuation?
19. Describe the meaning of a deep vacuum, and explain why it is important to reach and hold a deep vacuum when pulling a vacuum on a system.
20. List the main advantages of a microfoam leak detection solution over standard bubble solutions.
21. What could an oily dust spot on a condenser or evaporator coil indicate?
22. Why should a condenser be covered with a sheet before leak checking it with an electronic detector?
23. Leaks that occur only when the unit is in operation are called _____ dependent leaks.
24. Briefly describe a combination-dependent leak.

UNIT 9

REFRIGERANT AND OIL CHEMISTRY AND MANAGEMENT—Recovery, Recycling, Reclaiming, and Retrofitting

OBJECTIVES

After studying this unit you should be able to

- describe ozone depletion and global warming.
- discuss how CFCs deplete the earth's ozone layer.
- differentiate between CFCs, HCFCs, HFCs, HFOs, and HCs.
- discuss popular refrigerants (including R-410A) and their applications.
- discuss refrigerant blends.
- discuss temperature glide and fractionation as it applies to refrigerant blends.
- discuss refrigerant oils and their applications.
- discuss EPA regulations as they relate to refrigerants.
- define the terms *recover, recycle,* and *reclaim*.
- describe methods of recovering refrigerants, including active and passive methods.
- discuss oil-less recovery machines.
- identify a DOT-approved recovery cylinder.
- describe a quick-connect or quick-coupler as they apply to refrigerant conservation.
- discuss the general considerations in retrofitting an R-22 system.

SAFETYCHECKLIST

- ☑ Wear gloves and goggles any time you transfer refrigerant from one container to another.
- ☑ Transfer refrigerants only into DOT-approved containers.
- ☑ When retrofitting refrigerants and oils, always follow retrofit guidelines.
- ☑ Never use R-22 or any other refrigerant's service equipment on R-410A equipment. Service equipment must be rated to handle the higher operating pressures of R-410A.
- ☑ Use room sensors and alarms to detect R-123 refrigerant leaks, per ASHRAE Standard 15.
- ☑ Ensure that all refrigeration systems have some sort of pressure relief device, which should be vented to the outdoors to prevent the buildup of excessive system pressures.
- ☑ Be aware of a high-pressure reading in a recovery tank; it indicates air or other noncondensables in the tank.
- ☑ Never overheat the system's tubing while the system is pressurized. This can cause a blowout and serious injury. When certain refrigerants are exposed to high temperatures, a flame, or a glowing hot metal, they can decompose into hydrochloric and/or hydrofluoric acids and phosgene gas.
- ☑ Never energize the compressor when under a deep vacuum. This can cause a short in the motor windings at the fusite terminals or at a weak spot in the windings, which may damage the compressor.
- ☑ Always check the nameplate of the system into which dry nitrogen will enter. Never exceed the design low-side factory test pressure on the nameplate. Never pressurize a system with oxygen or compressed air because dangerous pressures can be generated from a reaction with the oil as it oxidizes.
- ☑ When using dry nitrogen, always use a pressure relief valve and pressure regulator on the nitrogen tank.

9.1 REFRIGERANTS AND THE ENVIRONMENT

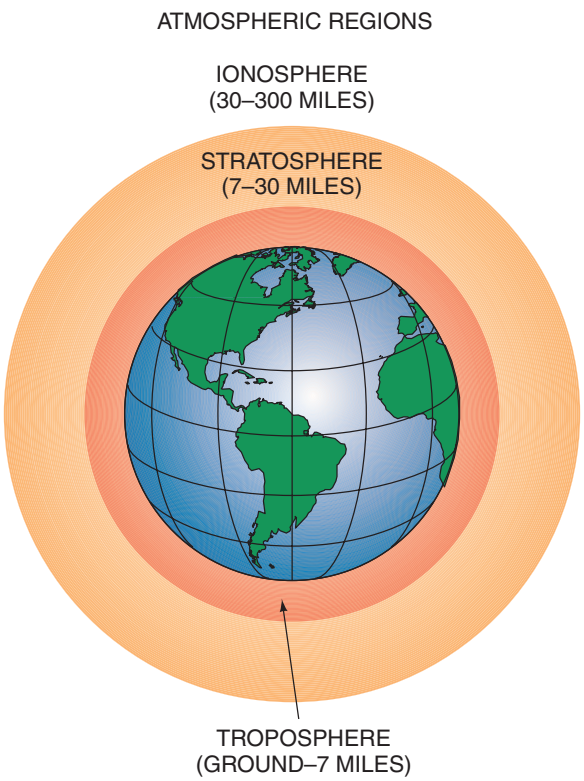
As the earth's population grows and demands increase for comfort and newer technologies, more and more chemicals are produced and used in various combinations. Many of these chemicals reach the earth's atmospheric layers and produce different types of pollution. Some of the chemicals are the refrigerants that cool or freeze our food and cool our homes, office buildings, stores, and other buildings in which we live and work. Some of these refrigerants were developed in the 1930s; many of the refrigerants manufactured a few decades ago are now banned because of their effect on the natural environment. The trend has been toward a gradual phasing out of environmentally harmful refrigerants and a search for more environmentally friendly substitutes. While contained within a system, refrigerants are stable, are not pollutants, and produce no harmful effects on the earth's atmospheric layers. Over the years, however, quantities have leaked from systems and have been allowed to escape by the willful purging or venting of systems during routine service procedures.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

9.2 OZONE DEPLETION

Ozone is a gas that is found in both the stratosphere and troposphere, **Figure 9.1**. It is a form of oxygen gas that is made up of three oxygen atoms (O_3), **Figure 9.2(A)**, instead of the two atoms in the standard oxygen molecule that we breathe (O_2), **Figure 9.2(B)**. Stratospheric ozone, which resides 7 to 30 miles above the earth, is considered good ozone because it prevents harmful ultraviolet radiation (UV-B) from reaching the earth. Tropospheric ozone, however, is undesirable ozone because it is a pollutant.

Figure 9.1 Atmospheric regions.



Stratospheric ozone is formed by the reaction that occurs when sunlight interacts with oxygen. This layer of ozone shelters the earth from UV-B radiation, a protection essential for human health. Stratospheric ozone accounts for more than 90% of the earth's total ozone and is rapidly being depleted by man-made chemicals containing chlorine, including refrigerants such as CFCs and HCFCs.

The troposphere, or lower atmosphere that extends upward from ground level up to about 7 miles, holds only about 10% of the total ozone and contains 90% of our atmosphere, which is well mixed by weather patterns. Sunlight acting on chemicals in the troposphere creates bad ozone. This ozone has a bluish color when seen from earth and may irritate mucous membranes when inhaled. A popular term for tropospheric ozone pollution is *smog*.

Once stratospheric ozone is formed, much of it is easily destroyed by the sun's ultraviolet radiation, which is very powerful and has a frequency almost as high as that of X-rays. The sun's radiation breaks down the ozone (O_3) molecule into a standard oxygen (O_2) molecule and an elemental free oxygen (O) molecule, **Figure 9.3**. At the same time, more ozone is produced through plant photosynthesis and the bonding of standard oxygen (O_2) with free oxygen (O). Thus, ozone is constantly being made and destroyed in the stratosphere, a balance that has been going on for millions of years. However, in the last several decades man-made chlorine-containing chemicals have disturbed this delicate balance.

Once in the stratosphere, ultraviolet radiation will separate a chlorine atom (Cl) from a CFC or HCFC molecule, **Figure 9.4**, which then goes on to destroy many ozone molecules. One chlorine atom (Cl) can destroy up to 100,000 ozone molecules. The depleted ozone molecules in the stratosphere let more UV-B radiation reach the earth, causing an increase in skin cancers and cataracts in humans and animals, a weakening of the human immune system, and a decrease in plant and marine life. Under the United Nations Environment Programme (UNEP) Montreal Protocol, an index called the **ozone depletion potential (ODP)** has been used for

Figure 9.2 (A) An ozone molecule (O_3) and (B) a standard oxygen molecule (O_2).

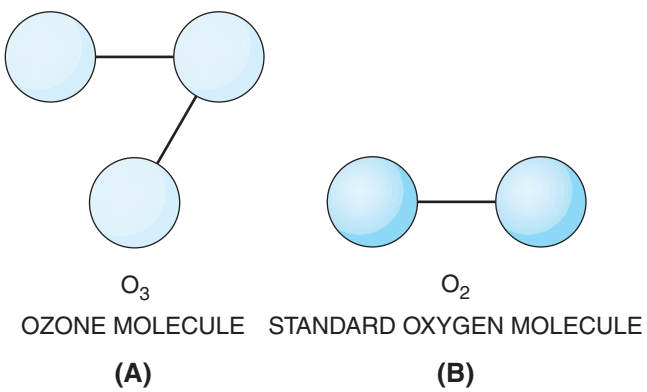


Figure 9.3 The breaking up of an ozone molecule by ultraviolet radiation.

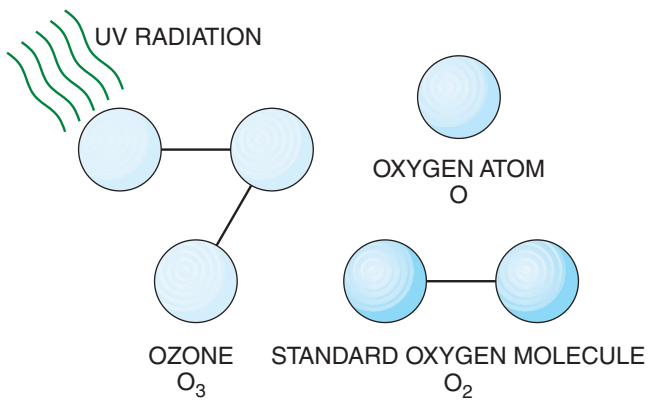

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 9.4 The ozone depletion process.

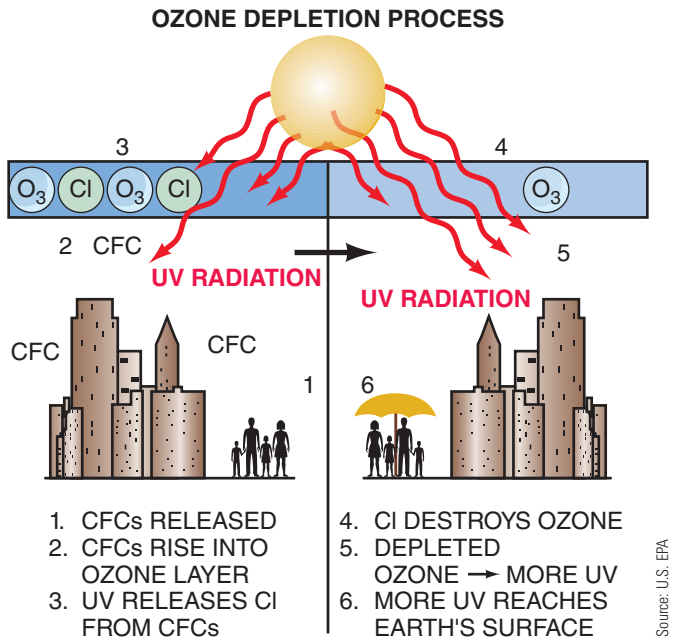

Figure 9.5 Heat generated from the breakup of an ozone molecule.

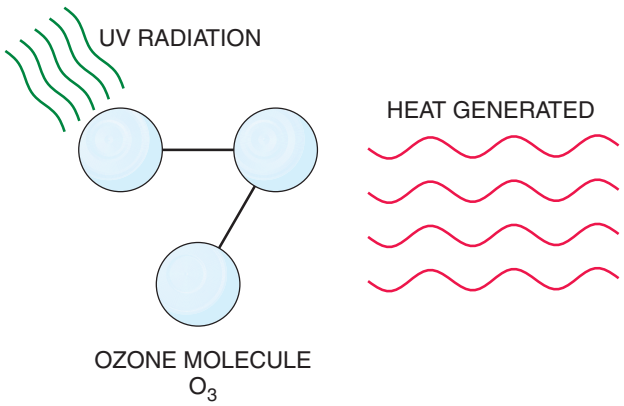


regulatory purposes. The higher the ODP, the more damaging the chemical is to the ozone layer in the stratosphere.

When stratospheric ozone intercepts ultraviolet light, heat is generated, **Figure 9.5**. This heat is the force behind stratospheric winds, which affect weather patterns on earth. By changing the amount of ozone, or even its distribution in the stratosphere, the temperature of the stratosphere can be affected. This can seriously affect weather here on earth.

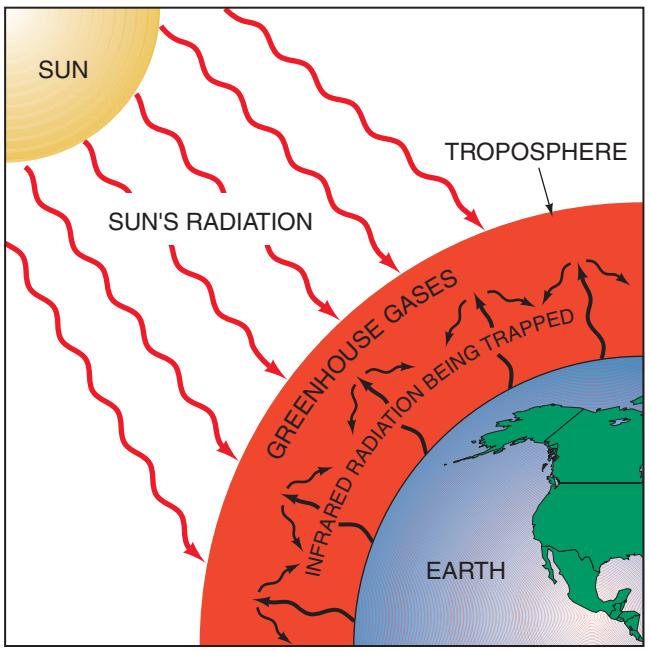
9.3 GLOBAL WARMING

Most of the sun's energy reaches the earth as visible light. After passing through the atmosphere, part of this energy is absorbed by the earth's surface and, in the process, is converted into heat energy. The earth, now warmed by the sun, radiates heat energy back into the atmosphere toward space. Naturally occurring gases and tropospheric pollutants like CFCs, HCFCs, and HFCs—as well as carbon dioxide, water vapor, and many other chemicals—absorb, reflect, and/or refract the earth's infrared radiation and prevent it from escaping the lower atmosphere, **Figure 9.6**. These gases, often referred to as *greenhouse gases*, slow the earth's heat loss, making its surface warmer than it would be if the heat energy had passed unobstructed through the atmosphere into space. The warmer earth's surface, in turn, radiates more heat until a balance is established between incoming and outgoing energy. This warming process, caused by the atmosphere's absorption of the heat energy radiated from the earth's surface, is called the *greenhouse effect*, or global warming.

The direct effects of global warming are created by chemicals that are emitted directly into the atmosphere. These direct emissions are measured by an index referred to as **global warming potential (GWP)**. Refrigerants leaking from a refrigeration or air-conditioning system contribute to global warming. Their direct effects on global warming are measured by comparing them to carbon dioxide (CO_2), which has a GWP of 1.

Carbon dioxide is the number-one contributor to global warming. Human needs have increased the amount of carbon dioxide in the atmosphere by 25% in excess of its usual amounts. Most of this increase is due to the combustion of fossil fuels, which is a by-product of the combustion of fossil fuels that is required by the modern world's need for

Figure 9.6 Greenhouse gases in the troposphere absorbing, refracting, and reflecting infrared radiation given off by the earth. This causes the greenhouse effect, or global warming.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

electricity. In fact, much of the electricity generated is used to power refrigeration and air-conditioning equipment. *The more efficient the HVAC/R equipment is, the less electrical energy needed, but even refrigeration or air-conditioning equipment with a relatively small charge of refrigerant that never leaks out may have a great impact on global warming if the equipment is undercharged or overcharged. The equipment would be very inefficient under these conditions, and the carbon dioxide generated from the longer run times created by these inefficiencies would contribute to global warming more than the leaking of refrigerant because the longer run times would require more electricity, resulting in more carbon dioxide from the combustion of more fossil fuels. In the United States, fossil-fuel combustion is used for much of the generation of electricity. This is an example of an indirect effect of global warming.*

The indirect effects of global warming are what concern scientists. Most of the newer refrigerants introduced to the HVAC/R industry are more energy-efficient than the ones they are replacing; however, some are not as efficient. Even though some of the newer refrigerants do not contribute to ozone depletion, they still can contribute to the direct and indirect effects of global warming. The newer refrigerant HFC-134a is an example. It has a 0 ozone depletion index but contributes to global warming directly via refrigerant leaks and indirectly through being used in an inefficient system with a longer run time caused by refrigerant leaks. Many other refrigeration or air-conditioning system problems may create higher amp draws, higher power usage, and/or longer run times and thus contribute to the indirect effects of global warming. Some of these system problems may include the following:

- Dirty condensers
- Dirty evaporators
- Frosted evaporator coils
- Incorrect refrigerants
- Mixture of refrigerants
- Inefficient compressors
- Wrong line size set
- Too long refrigerant lines
- Nonfunctioning condenser fans
- Nonfunctioning evaporator fans
- Undercharges
- Overcharges
- Dirty or clogged filter driers
- Wrong TXV settings for superheat
- Air in the system
- Moisture in the system
- Low oil
- Too much oil
- Partially plugged metering devices
- Inappropriate coil matching
- Improper retrofitting procedures

The **total equivalent warming impact (TEWI)** takes into consideration both the direct and indirect global warming effects of refrigerants. Refrigerants with the lowest global warming and ozone depletion potentials will have the lowest TEWI. Using HFC and HCFC refrigerants in the place of CFCs will also reduce the TEWI. All of the newer refrigerant alternatives that have been introduced have a much lower TEWI.

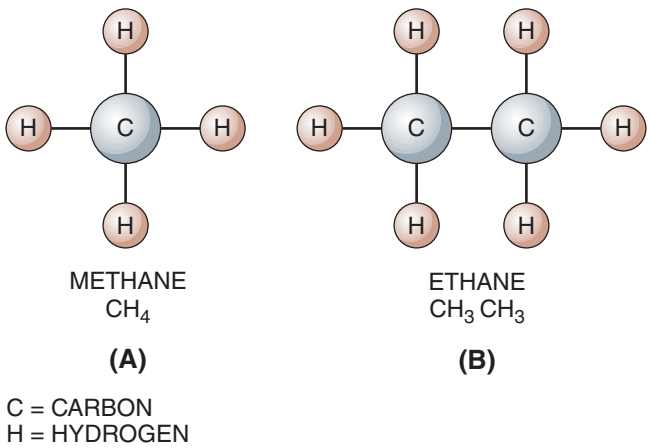
9.4 REFRIGERANTS

Most refrigerants are made from two molecules, methane and ethane, **Figure 9.7**. These two molecules contain hydrogen (H) and carbon (C) and are referred to as **pure hydrocarbons (HCs)**. Pure hydrocarbons were at one time considered good refrigerants, but because of their flammability they were not used after the 1930s to any large degree. However, hydrocarbons are making a comeback in Europe, where they are used in domestic refrigerators, and are also making a comeback in the United States as a small percentage of the mixture in refrigerant blends for nonflammable applications. An example of a refrigerant that is not methane- or ethane-based is ammonia. Ammonia contains only nitrogen and hydrogen (NH_3) and is not an ozone-depleting refrigerant.

Any time some of the hydrogen atoms are removed from either the methane or ethane molecule and replaced with either chlorine or fluorine, the new molecule is said to be either chlorinated, fluorinated, or both. Abbreviations are used to describe refrigerants chemically and to make it simpler for technicians to differentiate between them. The following are some common abbreviations:

- Chlorofluorocarbons (CFCs)
- Hydrochlorofluorocarbons (HCFCs)
- Hydrofluorocarbons (HFCs)
- Hydrocarbons (HCs)
- Hydrofluoro-olefins (HFOs)

Figure 9.7 Most refrigerants originate from (A) methane and (B) ethane molecules. Both molecules are hydrocarbons.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

SAFETY PRECAUTION: *Most refrigerants are heavier than air. Because of this, they can displace air and cause suffocation. Always vacate and ventilate the area if large refrigerant leaks occur. In fact, some sort of self-contained breathing apparatus should be worn if you have to work in the area of a large refrigerant leak. Inhalation of large amounts of refrigerant can cause cardiac arrest and eventually death.*•

9.5 CFC REFRIGERANTS

The CFCs contain chlorine, fluorine, and carbon and are considered the most damaging because their molecules are not destroyed before they reach the stratosphere. Because of their stable chemical structure CFC molecules have a very long life when exposed to the atmosphere. They can be blown up into the stratosphere by atmospheric winds, where they react with ozone molecules and cause destruction. CFCs also contribute to global warming. As of July 1, 1992, it is illegal to intentionally vent CFC refrigerants into the atmosphere. Following is a chart of CFCs showing the chemical name and formula for each.

Chlorofluorocarbons (CFCs)

Refrigerant No.	Chemical Name	Chemical Formula
R-11	Trichlorofluoromethane	CCl_3F
R-12	Dichlorodifluoromethane	CCl_2F_2
R-113	Trichlorotrifluoroethane	CCl_2FCClF_2
R-114	Dichlorotetrafluoroethane	$CClF_2CClF_2$
R-115	Chloropentafluoroethane	$CClF_2CF_3$

All of the refrigerants in the CFC group were phased out at the end of 1995. One important refrigerant is R-12, because it is commonly used for residential and light commercial refrigeration and for centrifugal chillers in some commercial buildings. The other refrigerants are used in other applications. For example, R-11 is used for many centrifugal chillers in office buildings and also as an industrial solvent to clean parts. R-113 is used in smaller commercial chillers in office buildings and also as a cleaning solvent. R-114 has been used in some household refrigerators in the past and in centrifugal chillers for marine applications. R-115 is part of the blend of refrigerants that make up R-502 used for low-temperature refrigeration systems.

9.6 HCFC REFRIGERANTS

The second group of refrigerants in common use is the HCFC group. HCFCs do have some global-warming potential, but it is much lower than most CFCs. HCFCs contain hydrogen, chlorine, fluorine, and carbon. The amount of chlorine is small, but they also have hydrogen, which makes them less stable in the atmosphere. Although these refrigerants have much less potential for ozone depletion because they tend to break down in the atmosphere, releasing the chlorine before it reaches and reacts with the ozone in the stratosphere, the HCFC group is scheduled for a total phaseout by the year 2030. As of July 1, 1992, it became illegal to intentionally vent HCFC refrigerants into the atmosphere. HCFC-22 (R-22) is an exception; it has an earlier phaseout date of 2010 for new equipment and a total production phaseout of 2020 under the **Montreal Protocol**. Total phaseout means no production and no importing of the refrigerants. At the time of this writing, all HCFCs will be totally banned by the year 2030.

Even though HCFCs have lower ODPs than chlorofluorocarbons (CFCs), it wasn't low enough for the Europeans, so the United States began to phase out HCFCs. In fact, the Montreal Protocol was modified in 2007 and the HCFC phaseout schedule was accelerated. Below is a history and timeline of the schedule:

1987	Montreal Protocol sets reduction rates for HCFCs and other ozone-depleting substances.
1992	Illegal to intentionally vent HCFCs into the atmosphere.
1994	Mandatory technician certification for servicing A/C or refrigeration equipment.
1996	Capping of HCFC levels under the Montreal Protocol goes into effect.
2004	HCFC refrigerant production reduced by 35%.
2007	Reduction of HCFC production was accelerated from 65% to 75% from the baseline production year of 1989.
2010	HCFC-22 is banned in new equipment. No production or importing of HCFC-22 and HCFC-142b, except for use in equipment manufactured before January 1, 2010.
2015	90% cap on HCFC-22 production from the baseline production year of 1989. No production or importing of any HCFC, except for use as refrigerants in equipment manufactured before January 1, 2010.
2020	Total ban on HCFC-22 production. No production and no importing of R-22 and R-142b.
2030	Total ban on all HCFC production. No production and no importing of any HCFC.

These accelerated rulings affect the developed countries, such as the United States, Canada, and countries in Europe, but the new agreement also affects developing countries, such as China, India, and Mexico, which will now phase out production of HCFCs by 2030 instead of 2040. Also, these countries will phase out the use of such refrigerants more rapidly. These new rulings mean that all new refrigeration and air-conditioning equipment produced in the United States will

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

be required to use a 0-ODP refrigerant. Among this group of refrigerants are the following:

Hydrochlorofluorocarbons (HCFCs)

Refrigerant No.	Chemical Name	Chemical Formula
R-22	Chlorodifluoromethane	$CHClF_2$
R-123	Dichlorotrifluoroethane	$CHCl_2CF_3$
R-124	Chlorotetrafluoroethane	$CHClFCF_3$
R-142b	Chlorodifluoroethane	CH_3CClF_2

9.7 HFC REFRIGERANTS

The third group of refrigerants is the HFC group, which contain hydrogen, fluorine, and carbon atoms. HFC molecules contain no chlorine atoms and will not deplete the earth's protective ozone layer, but they do have a small potential for contributing to global warming. HFCs are the long-term replacements for many CFC and HCFC refrigerants. On November 15, 1995, it became unlawful to intentionally vent HFC refrigerants into the atmosphere. The original plan was to replace R-12 with R-134a, but this plan is complicated by the fact that R-134a is not compatible with any oil left in an R-12 system. It is also not compatible with some of the materials used to construct R-12 systems. However, an R-12 system can be retrofitted to an R-134a system, a task that must be performed by an experienced technician because it requires a complete oil change. The residual oil left in the system pipes must be removed, and all system gaskets must be checked for compatibility. To be sure the compressor materials are compatible, they must be checked by contacting the manufacturer.

Following is a list of refrigerants in the HFC group:

Hydrofluorocarbons (HFCs)

Refrigerant No.	Chemical Name	Chemical Formula
R-125	Pentafluoroethane	CHF_2CF_3
R-134a	Tetrafluoroethane	CH_2FCF_3
R-23	Trifluoromethane	CHF_3
R-32	Difluoromethane	CH_2F_2
R-125	Pentafluoroethane	CHF_2CF_3
R-143a	Trifluoroethane	CH_3CF_3
R-152a	Difluoroethane	CH_3CHF_2
R-410A	Blend	CH_2F_2/CHF_2-CF_3

9.8 HYDROFLUORO-OLEFIN (HFO) REFRIGERANTS

Hydrofluoro-olefin (HFO) refrigerants are referred to as fourth generation refrigerants for the 21st century. HFO refrigerants are actually unsaturated hydrofluorocarbon (HFC) refrigerants and are widely recognized as the next generation of refrigerants because of their environmental friendliness, cost effectiveness, and great energy efficiencies. HFOs are distinguished from HFCs by being derivatives of olefins rather than alkanes (paraffins). Olefins have carbon atoms linked by a double bond where alkanes have single bonds between carbons atoms. Hydroflourocarbon (HFC) refrigerants like R-134a, R-125, R-143a, R-152a and HFC-based refrigerant blends like R-507, R-407A, R-407B, R-407C, and R-410A are all composed of hydrogen, fluorine, and carbon connected by single bonds between the atoms. Hydrofluoro-olefin (HFO) refrigerants are also composed of hydrogen, fluorine, and carbon atoms, but contain at least one double bond between the carbon atoms.

Two popular HFO refrigerants are HFO-1234-yf and HFO-1234ze. Both HFO-1234yf and HFO-1234ze have a zero Ozone Depletion Potential (ODP) with extremely low Global Warming Potentials (GWP). Refer to the following chart for ODP and GWP values. Because of their lower GWP values, these refrigerants have a much shorter lifecycle in the atmosphere. These two HFO refrigerants have an A2L safety classification, meaning they have low toxicity but are slightly flammable, **Figure 9.13**. HFOs do exist that have A1 (non-flammable) safety ratings, however, further research and testing needs to be done with these refrigerants.

HFO-1234yf is a low GWP replacement for R-134a intended for use in mobile air conditioning (MAC) systems in the automotive industry. HFO-1234ze is intended to replace R-410A in residential and light commercial air conditioning and heat pump applications while offering a 75% reduction in GWP. It can be used in both air cooled and water cooled chillers in supermarkets and commercial buildings. Other applications include vending machines, fridges, beverage dispensers, air dryers, and carbon dioxide cascade systems in commercial refrigeration. HFO-1234ze also offers excellent energy efficiency, is cost effective, and can be used in existing equipment design with minimal changes. HFO-1234ze also has significant advantages over R-32 which has medium GWPs, an A2 refrigerant safety rating, and high discharge temperatures. High discharge temperatures can affect system performance and durability in hot climates. Also, oil changes may be needed with R-32.

HFOs are miscible in Polyolester (POE) type lubricating oils. The miscibility of HFOs with POE lubricants is comparable to that of R-134a. HFOs are not soluble in mineral oil or alkylbenzene lubricants.

Because of HFOs' slight flammability, extensive studies have been conducted for its safety in automobiles, centrifugal chillers, and other stationary applications. A key consideration for widespread acceptance of HFO refrigerants is the development of standards and codes for safe use of these mildly flammable A2L refrigerants.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

9.9 HYDROCARBON (HC) REFRIGERANTS

The fourth group of refrigerants is the hydrocarbon (HC) group. HC refrigerants are classified by ASHRAE in the A3 safety group. Refrigerants in the A3 safety group are highly flammable. Refer to **Figure 9.13** for safety classification of refrigerants. Pure HC refrigerants have no chlorine or fluorine in their molecules; they contain nothing but hydrogen and carbon, thus they have a zero ozone depletion potential (ODP). As an example, two hydrocarbon molecules, methane and ethane are illustrated in **Figure 9.7**. Many CFC, HCFC, and HFC refrigerants originate from these two base molecules of ethane and methane. HC refrigerants do contribute to global warming, but their global warming potential (GWP) is very low when compared to CFC, HCFC, and HFC refrigerants. Listed below are some GWP values for comparison purposes.

Refrigerant	Type	ODP	GWP	Level
R-32	HFC	zero	675	Medium
R-134a	HFC	zero	1430	Medium
R-404A	HFC	zero	3922	High
R-410A	HFC	zero	2088	Medium
R-290	HC	zero	3.0	Low
R-600a	HC	zero	3.0	Low
R-1234yf	HFO	zero	4.0	Low
R-1234ze	HFO	zero	6.0	Low

Note: GWP values are from the IPCC 4th Assessment Report, 2007, (100 year) carbon dioxide=1

HC refrigerants have better energy efficiencies and reduced energy usage when compared to currently used HFC refrigerants. Hydrocarbon refrigerants are created by nature, not a chemical company, and are often referred to as **natural refrigerants**. The most efficient and environmentally safe refrigerants that exist in the world today are all natural refrigerants. These refrigerants include hydrocarbons, ammonia, air, water, and carbon dioxide. Hydrocarbon refrigerants are used as stand-alone refrigerants in Europe for many applications. Listed below are some of these applications:

- Commercial refrigerators and bottle coolers
- Split air conditioning units
- Domestic refrigerators and freezers

In the USA, only some HC refrigerants have been approved by the EPA under its Significant New Alternative Policy (SNAP). SNAP has approved HC refrigerant use in the USA only in new equipment, in limited conditions, and with limited refrigerant charge amounts because of their high flammability. For many years, small percentages of HC refrigerants have been used in many HCFC- and HFC-based refrigerant blends in the United States to assist in oil return to the compressor. However, these refrigerant blends containing a small amount of HC refrigerants are not flammable. This is because the HC refrigerant constitutes only a small percentage (less than 3%) of the total refrigerant blend. Some hydrocarbon (HC) refrigerants are:

- Propane
- Butane
- Isobutane
- Isopentane
- Methane
- Ethane
- R-441A (HC blend of ether, propane, isobutene, and n-butane)

SAFETY PRECAUTION: *Many of these chemicals may be used for multiple purposes. However, when used as a refrigerant, a refrigerant-grade purity level is required. Never use anything but refrigerant-grade HCs when using them as a refrigerant in a system. For example, propane is used both as a fuel and as a refrigerant. However, different purity levels are required for each application. Never use fuel-grade (LPG) propane in a refrigerant system. The quality of fuel grade propane's composition varies substantially and can have high levels of moisture and unsaturated hydrocarbons. Also, fuel-grade propane contains a stenching agent, methyl mercaptan, which smells like rotten eggs and is easily detected by humans. Methyl mercaptan will cause unwanted by-products and corrosion in an HC refrigeration system, leading to system failure.*•

Some refrigerant blends that incorporate HC refrigerants in small percentages for oil return purposes include:

- R-402A
- R-402B
- R-403A
- R-406A
- R-438A

FLAMMABLE REFRIGERANT APPLICATIONS ALLOWED AND CHARGE AMOUNTS

At time of this writing, only R-600a (isobutane), R-290 (propane), R-170 (Ethane), HFC-32 (Difluoromethane) and R-441A (HC blend) have been approved by the EPA's SNAP program for use in the USA. HFC-32 is a flammable refrigerant but is not a HC refrigerant. The EPA also exempted all of the substances listed below, except HFC-32 from the clean Air Act venting prohibition. Uses for these flammable refrigerants include:

- R-290 (Propane) can be used in household refrigerators, freezers, combination refrigerators and freezers, vending machines and room air conditioning units as long as the refrigerant charge does not exceed 5.3 ounces (150 grams).
- R-600a (Isobutane) can be used in retail food refrigeration (stand-alone commercial refrigerators and freezers) and vending machines as long as the refrigerant charge size does not exceed 2.0 ounces (57 grams).

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Ethane (HC-170) can be used in very low-temperature refrigeration and non-mechanical heat transfer.
- R-441A can be used in retail food refrigeration (stand-alone commercial refrigerators and freezers), vending machines, and room air-conditioning units as long as the refrigerant charge size does not exceed 2.0 ounces (57 grams).
- HFC-32 (difluoromethane) in room air conditioning units.

Notice that the EPA's SNAP program only allows some HC's and flammable refrigerants use in the USA in limited applications and for new equipment only. Retrofitting equipment containing HC refrigerants and other flammable refrigerants is not allowed in the USA. Only use authorized refrigerants listed on the compressor and system's nameplate in each specific piece of equipment. Even replacement parts for equipment containing a flammable refrigerant must be compatible for that specific refrigerant. Local regulations governing flammable refrigerant usage as a refrigerant may also apply in certain municipalities. It is the responsibility of the servicing technician to stay abreast of local, national, and global regulations that govern flammable refrigerants. It is recommended that service technicians working on flammable refrigerants receive some sort of training and/or certification on safety and handling of these refrigerants. Education is the answer to working smartly and safely when working around or with these flammable refrigerants. Contact a local trade organization for information on safety and certification when working a flammable refrigerant.

NAMEPLATES AND LABELS

One of the first steps in working safely with flammable HC refrigerants is to identify the refrigerant being used in the piece of equipment that is being serviced. As mentioned, use only the HC refrigerant on the system and/or compressor's nameplate or serial label. The serial label or nameplate on the compressor will indicate what HC refrigerant can be used in that system and compressor. Often, both warning labels and flammable refrigerant labels will be displayed on the compressor. Specific labeling that identifies the refrigerant used is a requirement for equipment incorporating a flammable refrigerant, **Figure 9.8**.

Other sections to be labeled warning the service technician or equipment operator include:

- Evaporator sections
- The compressor or condensing unit compartment
- The exterior of the refrigerator
- Exposed refrigerant tubing

The labeling is required in order to be SNAP approved. Below are examples of such labeling:

DANGER—Risk of fire or explosion. Flammable refrigerant used. Do not use mechanical devices to defrost evaporator. Do not puncture refrigerant tubing.

DANGER—Risk of fire or explosion. Flammable refrigerant used. To be repaired only by trained service personnel. Do not puncture refrigerant tubing.

CAUTION—Risk of fire or explosion. Flammable refrigerant used. Consult the repair manual or owner's guide before attempting to service this product. All safety precautions must be followed.

CAUTION—Risk of fire or explosion. Flammable refrigerant used. Dispose of properly in accordance with federal or local regulations.

CAUTION—Flammable refrigerant used. Risk of fire or explosion due to puncture of refrigerant tubing. Follow handling instructions carefully.

CAUTION—Sudden release of refrigerant in the proper concentration with air can cause flash fire, explosion, or a sustained fire.

SERVICE ACCESS AND TUBE PAINTING

All refrigerant piping through which the refrigerator or freezer is serviced must be colored red. This red must be Pantone Matching System (PMS) #185. The red color must be present on the refrigerant process tubing and service ports or wherever a service technician may puncture the tubing for service purposes. This red piping must extend at least 1 inch or 2.54 centimeters from the compressor. If the color has been worn or has been removed, it must be repainted on by the service technician.

SAFETY PRECAUTION: *Data from both the cabinet and compressor or condensing unit should match when identifying the type of refrigerant. If it doesn't, an unauthorized retrofit may have been done. Remember, retrofitting a system with an HC or other flammable refrigerant is not allowed in the United States. An immediate stoppage of work should follow if an HC or other flammable refrigerant system is suspected to be retrofitted and appropriate authorities should be notified.*•

COMPRESSOR TERMINAL VENTING

Figure 17.35 in Unit 17, "Types of Electric Motors" illustrates a hermetic compressor motor's terminal pins extending from the shell of the compressor. These pins often represent run, start, and common in single-phase compressors and Line 1, Line 2, and Line 3 in three-phase compressors. These terminal pins are connected to the compressor motor's electrical windings. The windings are in an environment of refrigerant and oil under pressure within the shell of the compressor. Often, an electrical short can occur from the motor windings to ground or from one electrical line to another causing **terminal venting**. Terminal venting is when one or more terminal pins blows out of its ceramic fusite terminal, allowing a pressurized refrigerant and oil spray to escape into the atmosphere. This refrigerant and oil spray can become ignited by the electrical sparking from electrical shorts or from other ignition sources nearby causing flash fires, severe injury, and even death. These terminal pins can also become damaged from misuse or from a physical jolt.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 9.8 Specific labeling which identifies a refrigerant used is a requirement for HVACR equipment incorporating a flammable refrigerant.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Following the safety precautions below can help prevent terminal venting:

- Make sure all power supplies are disconnected before removing the compressor's protective cover.
- Make sure all power legs are open.
- If you hear any electrical type noises coming from the compressor, disconnect power and leave the area immediately.
- Make sure the compressor's terminal covers are in place before energizing the compressor.
- Make sure the compressor and entire chassis system are properly grounded.
- Always check for a ground fault interrupt.
- Always check for blown fuses or tripped circuit breakers, which may indicate improper grounding.

BOILING POINTS AND SAFETY CLASSIFICATIONS

Hydrocarbon refrigerants, like HCFC and HFC refrigerants, have boiling points that are desirable for refrigeration and/or air conditioning applications. However, because of these refrigerants' low boiling points, safety precautions must be taken. **SAFETY PRECAUTION:** *Exposure to the skin can cause severe frostbite. Exposure to the eyes can cause blindness.* **Figure 9.9** *lists some known CFC, HCFC, HFC, HFO, HC, and natural refrigerants with their safety classifications and boiling points at atmospheric pressure for comparison purposes.*

Figure 9.9 A list of some known CFC, HCFC, HFC, HC, HFO and natural refrigerants with their safety classifications and boiling points at atmospheric pressure for comparison purposes.

REFRIGERANT	BOILING POINT AT ATMOSPHERIC PRESSURE	ASHRAE 34 SAFETY CLASSIFICATION
R-11	74.7°F (23.7°C)	A1
R-12	−21.6°F (−29.8°C)	A1
R-22	−41.5°F (−40.8°C)	A1
R-123	82.1°F (27.8°C)	B1
R-1234yf	−21.2°F (−29.6°C)	A2L
R-1234ze	−2.1°F (−18.9°C)	A2L
R-134a	−14.9°F (−26.1°C)	A1
R-290 (propane)	−43.8°F (−42.1°C)	A3
R-401A	−16.9°F (−27.2°C)	A1
R-404A	−49.8°F (−45.4°C)	A1
R-407C	−33.9°F (−36.6°C)	A1
R-410A	−60.5°F (−51.4°C)	A1
R-422D	−37.0°F (−38.3°C)	A1
R-441A	−4.6°F (−20.3°C)	A3
R-507A	−52.1°F (−46.7°C)	A1
R-600a (isobutane)	10.9°F (−11.7°C)	A3
R-717 (ammonia)	−28.0°F (−33.3°C)	B2L
R-718 (water)	212°F (100°C)	A1
R-744 (carbon dioxide)	N/A	A1
R-1150	−155°F (−104°C)	A3

HC REFRIGERANT HANDLING AND WORK SAFETY. Because HC refrigerants are flammable, certain safety precautions must be followed. All service technicians should be familiar with the safety precautions for flammable refrigerants. Material Safety Data Sheets (MSDS) are required to be available to all employees where HC and other flammable refrigerants are being used. MSDS are also required to be available to local fire departments.

The **lower exposure limit (LEL)** of a gas is the lowest concentration of the gas in air capable of producing a flash or fire in the presence of an ignition source. Propane (R-290) has an LEL of 2.1% concentration in air. Isobutane (R-600a) has an LEL 1.8% concentration in air. Concentrations below the LEL are too "lean" to burn. The **upper exposure limit (UEL)** of a gas is the highest concentration of a gas in air capable of producing a flash or fire in the presence of an ignition source. Propane has a UEL of 9.5% concentration in air. Isobutane has a UEL of 8.5% concentration in air. Concentrations above the UEL are too "rich" to burn.

Flame or sparks from any HVAC/R equipment or tools could cause a fire or explosion when using HC refrigerants. Always check with the local authorities having jurisdiction for other safety precautions. Listed below are some important handling and safety practices for HC refrigerants and related accessories:

- Sparks from a vacuum pump switch, pressure switch, contactors, electronic leak detector, halide torch, light switch, defrost timers, or thermostats can cause explosions when exposed to the proper concentrations of HC gas and air.
- Never disconnect power or unplug anything or begin a service procedure before checking for flammable refrigerants in the area with a combustible gas leak detector or monitor, **Figure 5.55**.
- Service technicians must: ***Monitor – Ventilate – Eliminate***. Monitor the area for combustible gasses. Ventilate the area to get rid of any combustible gasses. Eliminate any sources of ignition.
- Always use non-ignitable type leak detectors for HC gases such as ultrasonic detectors, liquid solutions, or ultraviolet additives.
- Electronic leak detectors for flammable gases are manufactured which are non-ignitable.
- Make sure all relays and overloads are sealed. **Figure 9.10** illustrates an enclosed relay and overload. Many manufacturers are using positive temperature coefficient resistors (PTCR) because they are spark free, **Figure 17.41**.
- If a component has to be replaced, it is best to replace the part with an original equipment manufacturer (OEM) part.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 9.10 An enclosed relay and overload.

Photo Courtesy of Tecumseh Products Company.

- Service technicians should use spark-proof tools. Many brass tools are spark-proof.
- Flammable gas leak detectors and/or exposure limit monitors should be used before entering a confined space where HC refrigerants are used. Try to eliminate all ignition sources and ventilate the area. Do not turn the monitor off until you leave the service area.
- Never use a torch to remove refrigerant components. Always use tubing cutters.
- Always use approved components when replacing parts.
- Never smoke at or near the confined space where HC refrigerants exist.
- Recovery equipment must be rated for HC refrigerants and only equipment designed for flammable refrigerants should be used.
- All original and replacement parts must be listed by the manufacturer and must be spark free when in use.

TRANSPORTATION OF HC REFRIGERANT CYLINDERS

- The vehicle must be labeled to let the general public know it is carrying a flammable gas.
- The contents of the vehicle must be inventoried.
- HC cylinders must be transported in the upright position.
- Some municipalities and/or states require venting space to the exterior and that cylinders be stored in explosion-proof cabinets.
- All required signage and placarding must be used.
- HC and other flammable refrigerants must be transported in approved containers.
- Always check with the local department of transportation for more detailed requirements.

HYDROCARBON CYLINDER STORAGE

- Store cylinders away from any ignition source.
- A combustion gas monitor must be installed.
- Access must be limited to authorized personnel.
- HC cylinders must be stored away from all air intakes.
- Cylinders must be stored at ground level.
- Cylinders must be stored in a secured and locked cage.

9.10 NAMING REFRIGERANTS

An easier way to refer to refrigerants is by number instead of by their complex chemical names. The DuPont Company has created an easy system for naming refrigerants, depending upon their chemical composition.

1. The first digit from the right is the number of fluorine atoms.
2. The second digit from the right is the number of hydrogen atoms plus 1.
3. The third digit from the right is the number of carbon atoms minus 1. If this number is zero, omit it.

Example 1

HCFC-123 $CHCl_2CF_3$ Dichlorotrifluoroethane

Number of fluorine atoms	= 3
Number of hydrogen atoms +1	= 2
Number of carbon atoms −1	= 1
Thus, HCFC-123	

The number of chlorine atoms is found by subtracting the sum of fluorine, bromine, and hydrogen atoms from the total number of atoms that can be connected to the carbon atom(s).

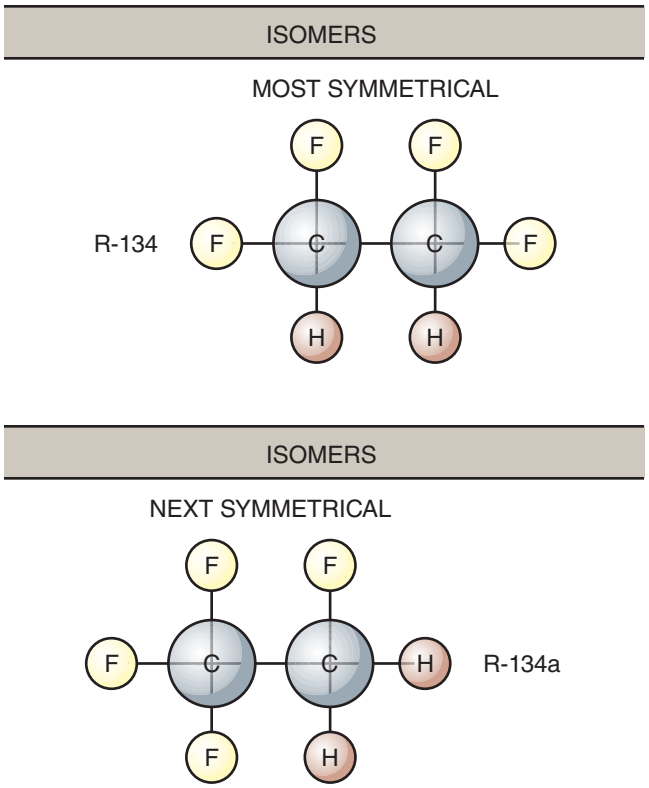
Example 2

CFC-12 CCl_2F_2 Dichlorodifluoromethane

Number of fluorine atoms	= 2
Number of hydrogen atoms +1	= 1
Number of carbon atoms −1	= 0 (omit)
Thus, CFC-12	

The small letters "a, b, c, d, . . ." at the end of the numbering system represent how symmetrical the molecular arrangement is. An example is R-134a and R-134. These are completely different refrigerants with completely different properties. Both have the same number of atoms of the same elements but differ in how they are arranged. These molecules are said to be isomers of one another. In the following diagram, notice that the R-134 molecule has perfect symmetry. As isomers of this molecule start to get less and less symmetrical, the small letters a, b, c, d, . . . are assigned to their ends.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

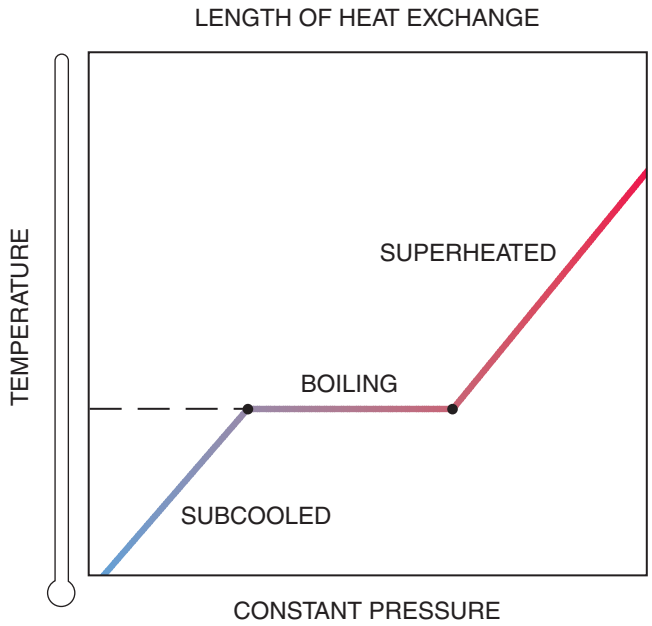


9.11 REFRIGERANT BLENDS

Ozone depletion and global-warming issues have stimulated much research on **refrigerant blends**. Refrigerant blends have been used successfully in both comfort cooling and refrigeration. Blends can have as many as five refrigerants mixed together to provide properties and efficiencies similar to the refrigerants they will replace. HCFC-based blends are short-term replacements for many CFC and HCFC refrigerants, whereas HFC-based blends are long-term replacements.

Azeotropes or azeotropic mixtures are blended refrigerants made up of two or more liquids. When mixed together, they behave like R-12 and R-22 when phase changing from liquid to vapor. There is only one boiling point and/or one condensing point for each given system pressure. **Figure 9.11** illustrates a temperature/pressure graph of an azeotropic refrigerant blend showing the refrigerants boiling at one temperature at a given pressure through the length of the heat exchanger (evaporator). Pure compounds or single-component refrigerants like R-12 and R-22 also exhibit this behavior as they evaporate and condense. Azeotropic blends are not new to the HVAC/R industry; both R-500 and R-502 are azeotropic blends that have been used in the industry for years. R-500 is made up of 73.8% R-12 and 26.2% R-152a (by weight). R-500 is used in some cooling systems. R-502 is made up of 48.8% R-22 and 51.2% R-115 and has been an excellent low-temperature refrigerant since the 1960s.

Figure 9.11 An azeotropic refrigerant blend showing only one temperature for a given pressure as it boils.



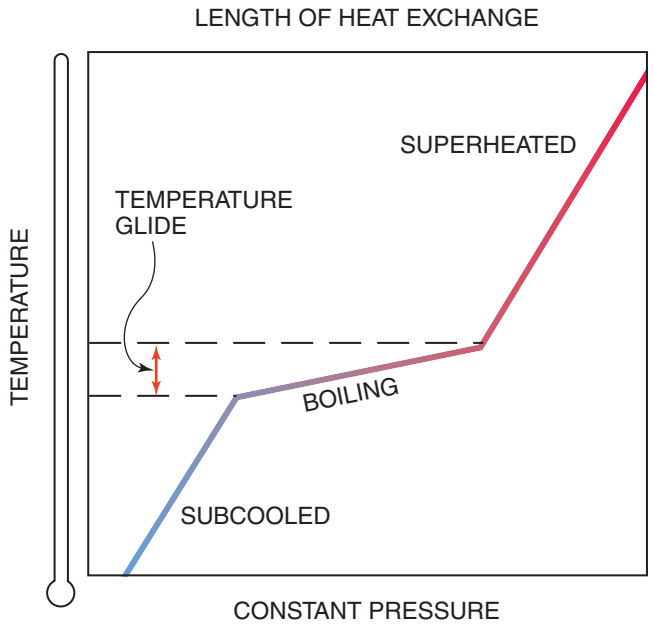
However, many refrigerant blends are not azeotropic but are near-azeotropic mixtures. Such blends can still separate into individual refrigerants. These blends act differently because more than one molecule is present in any one sample of liquid or vapor (for example, sugar water and saltwater). This is why there is a difference between the temperature/pressure relationships of the near-azeotropic blends versus refrigerants like CFC-12, HCFC-22, HFC-134a, and azeotropic blends.

Near-azeotropic blends experience a temperature glide. Temperature glide occurs when the blend has many temperatures as it evaporates and condenses at a given pressure. **Figure 9.12** illustrates a temperature/pressure graph of a near-azeotropic refrigerant blend showing the refrigerants boiling at many temperatures (temperature glide) for a given pressure through the length of the heat exchanger. In fact, as the near-azeotropic refrigerant blend changes phase from liquid to vapor and back, more of one component in the blend will transfer to the other phase faster than the rest. Zeotropic refrigerant blends also exhibit these properties, but to a greater extent. This is different from refrigerants like R-12, R-134a, and R-22, which, as shown in previous units, evaporate and condense at one temperature for a given pressure.

Near-azeotropic refrigerant blends may also experience **fractionation**. Fractionation occurs when one or more of the refrigerants in the blend condense or evaporate at different rates than the other refrigerants. This different rate is caused by the slightly varied vapor pressures of each refrigerant in the blend. Fractionation will be discussed in detail

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 9.12 A near-azeotropic refrigerant blend showing temperature glide as it boils at a constant pressure.



in Unit 10, "System Charging." Zeotropes, or zeotropic blends, also have temperature glide and fractionation but to a larger extent than near-azeotropic blends. The terms *zeotropic blends* and *near-azeotropic blends* are used in the industry because they both undergo temperature glide and fractionation. Charging methods for refrigerant blends will be covered in Unit 10, "System Charging."

"R" NUMBERS FOR THE BLENDS

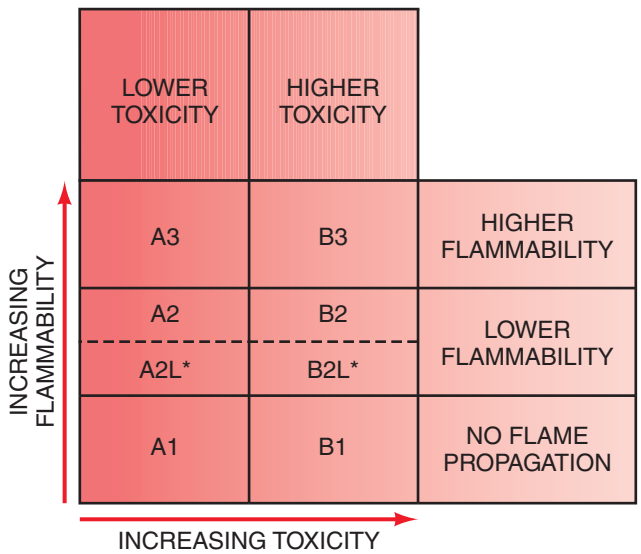
- The 400-series blends are the near-azeotropic (zeotropic) blends. If a blend has an R-410 designation, it is a near-azeotropic blend. The 10 indicates that it is the tenth blend to be commercially produced. All 400-series blends have temperature glide and can fractionate.
- The 500-series blends represent the azeotropic blends, for example, R-502. The 2 means that it is the second one produced on the market.
- Blends can also be named by the percentage of each refrigerant that makes up the blend. The refrigerant with the lowest boiling point at atmospheric pressure will be listed first. For example, a blend of 20% (R-12) and 80% (R-22) would be represented as R-22/12 (80/20). Because R-22 has the lowest boiling point, it is listed first.
- Blend names can also have capital letters at the end. The capital letters at the end of R-401A, R-401B, and R-401C mean that the same three refrigerants make up these near-azeotropic blends, but their individual percentages differ.

9.12 POPULAR REFRIGERANTS AND THEIR COMPATIBLE OILS

The following are some of the more popular refrigerants and refrigerant blends used in the HVACR industry. **NOTE:** *At the time of this writing, the Environmental Protection Agency (EPA) has proposed rules for refrigerant substitutes. The rules involve a change in the listing status for certain refrigerant substitutes under the Significant New Alternatives Policy Program (SNAP). Some of the refrigerants and refrigerant blends listed as follows may be affected when this proposed rule becomes mandatory. Many refrigerants and refrigerant blends that have high global warming potentials (GWPs) will no longer be allowed even as retrofit refrigerants. These refrigerants and blends will still be listed because they exist in HVAC/R equipment from past installations and retrofits. It is important that service technicians understand what these refrigerants and blends consist of for service purposes. It is the service technician's responsibility to keep abreast of the most recent laws and rules concerning refrigerant use and service.*

HFC-134a (R-134a), with temperature/pressure and capacity relationships similar to those of R12, **Figure 9.14,** has been the alternative refrigerant of choice to replace **CFC-12** in many medium- and high-temperature stationary refrigeration and air-conditioning applications and automotive air-conditioning applications. However, other refrigerants like hydrofluoro-olefins (HFOs) may soon replace R-134a because of their lower GWP. Its safety classification is A1, **Figure 9.13**. R-134a is a pure compound, not a refrigerant

Figure 9.13 ANSI/ASHRAE Standard 34-2013 Designation and Safety Classification of Refrigerants.



* A2L and B2L are lower flammability refrigerants with a maximum burning velocity of < 10 cm/s (3.9 in/s).

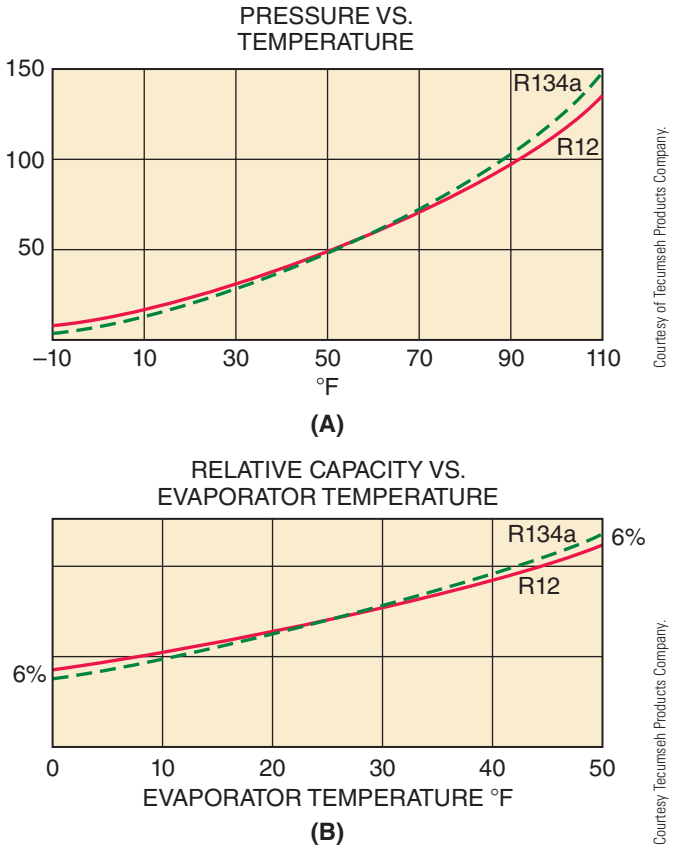
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 9.14 (A) Pressure/temperature and (B) capacity curves for R-134a.



blend. Because of the smaller size of the R-134a molecule, it will tend to leak more readily than R-12. Consequently, it is important that proper leak detection techniques be employed. R-134a also suffers small capacity losses when used as a low-temperature refrigerant. R-134a contains no chlorine in its molecule and thus has a 0 ODP; its GWP is 1430. Polarity differences between commonly used organic mineral oils and HFC refrigerants make R-134a insoluble and thus incompatible with mineral oils used in many refrigeration and air-conditioning applications today. R-134a systems must employ synthetic **polyol ester (POE)** or **polyalkylene glycol (PAG)** lubricants. R-134a has also replaced R-12 and R-500 in many centrifugal chiller applications. Ester-based lubricants are also required in these applications because of R-134a's incompatibility with organic mineral oils. In many centrifugal chiller applications, efficiencies have improved but not without some reductions in capacity. **SAFETY PRECAUTION:** *R-134a is not a direct drop-in replacement for R-12. Retrofit guidelines must be followed carefully when converting a system from R-12 to R-134a.* An example of a retrofit guideline from a major manufacturer is included toward the end of this unit.

HCFC-22 (R-22) is a pure compound containing only one molecule, and therefore not a refrigerant blend. Its safety classification is A1, meaning it has very low toxicity and no flame propagation properties. The molecule contains hydrogen, carbon, chlorine, and fluorine. Its chemical name is chlorodifluoromethane, meaning its molecule has one chlorine atom, two fluorine atoms, and its base molecule is methane. HCFC-22 is classified as a hydrochlorofluorocarbon (HCFC). 2010 was the phaseout date for new equipment, with a total production phaseout of 2020. For many years, it has been the primary refrigerant used in commercial and residential air-conditioning systems. It has also been used in large, industrial, centrifugal-chiller air-conditioning applications. Industrial cooling equipment also uses R-22. Before its phase-out for new equipment in 2010, R-22 was replacing R-502 in low-temperature commercial supermarket refrigeration. However, because of its high discharge temperatures in low-temperature commercial refrigeration applications, these systems required compound compression systems with interstage cooling or liquid injection for compressor heat protection.

HFC-407A (R-407A) is a near-azeotropic refrigerant blend of R-32, R-125, and R-134a. It is an R-22 retrofit refrigerant blend for medium- and low-temperature commercial refrigeration systems. It is not recommended for air conditioning applications. HFC-407A has capacities similar to those of R-22. The blend has an evaporator temperature glide of 9–10°F, which gives it fractional potential. Its safety classification is A1. R-407A has a bit higher head pressure than R-22 but has lower superheated compressor discharge temperatures. These lower discharge temperatures reduce the need for compressor heat protection, such as liquid injection. This blend also works well with heat reclaim systems. R-407A works with existing capillary tubes or TXVs; however, TXV adjustments may be necessary. POE lubricant must be used with R-407A, but it will operate with partial POE lubricant when retrofitting.

HFC-407C (R-407C) is a near-azeotropic refrigerant blend of R-32, R-125, and R-134a. R-407C is a long-term replacement refrigerant for R-22 in residential and commercial air-conditioning and medium- and high-temperature commercial refrigeration applications. Its safety classification is A1. It is being used by manufacturers in new equipment and can also be used as a retrofit refrigerant blend replacing R-22. R-407C works well with R-22 expansion devices, which include TXV, capillary tube, and orifice tube. Some TXV adjustments may be necessary. Always follow retrofit guidelines when retrofitting from R-22 to R-407C. POE lubricant must be used with R-407C. However, when retrofitting an air-conditioning system containing R-22 to R-407C, research has shown that only one oil change is necessary. After a single oil change, the remaining system's mineral oil mixed well with the added POE lubricant, and the combination circulated well with HFC refrigerants. This simplifies the retrofit process for HFC refrigerants. Critical elastomeric seals must be changed for this retrofit.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

HFC-410A (R-410A) is a near-azeotropic refrigerant blend of R-32 and R-125. R-410A is a higher-efficiency, long-term replacement refrigerant for R-22 in new residential and light commercial air-conditioning applications. Its safety classification is A1. Retrofitting an R-22 system to an R-410A system is not recommended because R-410A systems operate at much higher pressures (60% higher) in air-conditioning applications than a conventional R-22 system. If an air-conditioning system is operating at a 45°F evaporating temperature and a 110°F condensing temperature, the corresponding pressures would be as follows:

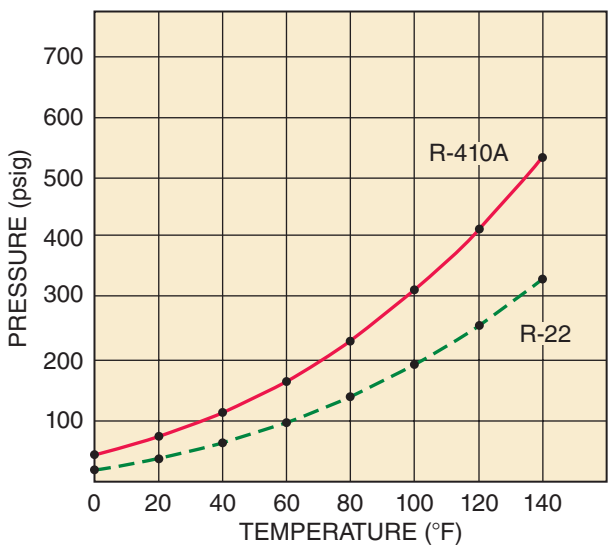
R-410A .....130 psig evaporating pressure
365 psig condensing pressure
R-22.....76 psig evaporating pressure
226 psig condensing pressure

Figure 9.15 illustrates pressure/temperature comparisons of R-410A with R-22 in tabular and graphical format. Gauge manifold sets, hoses, recovery equipment, and recovery storage cylinders all have to be designed to handle the higher pressures of R-410A. Different gauge line connections are used for the two refrigerants, preventing the technician from making a mistake. In fact, the gauge and manifold set for R-410A is required to range up to 800 psig on the high side and 250 psig on the low side with a 550-psig low-side retard. All R-410A hoses must have a service rating of 800 psig. Even filter driers for R-410A must be rated for and compatible to the higher pressures. **SAFETY PRECAUTION:** *Never use any other refrigerant service equipment on R-410A equipment. Service equipment must be rated to handle the higher operating pressures of R-410A. Air-conditioning equipment has been redesigned and safer service tools have been introduced to handle the higher pressures of R-410A. As with all refrigerants, safety glasses and gloves must always be worn when handling R-410A.* Because R-410A is a near-azeotropic refrigerant blend, it has a very small evaporator temperature glide (0.2°F) and has negligible fractionation potential. R-410A systems use POE lubricant in their crankcases.

Figure 9.15 Pressure/temperature comparison of R-410A with R-22 in (A) tabular and (B) graphical format.

TEMP.	PRESSURE (psig)	
°F	R-410A	R-22
0	48.3	24.0
20	78.4	43.0
40	118.2	68.5
60	169.9	101.6
80	235.4	143.6
100	317.1	195.9
120	417.4	259.9
140	539.1	337.2

(A)



(B)

HFC-437A (R-437A) is a near-azeotropic retrofit refrigerant blend for CFC-12 and CFC-12 service blends, like R-401A and R-409A, in domestic and commercial refrigeration applications.

HFC-438A (R-438A) is an R-22 retrofit refrigerant blend for direct-expansion residential and commercial air-conditioning and medium- and low-temperature commercial refrigeration systems. It consists of R-32/R-125/R-134a/R-600/R-601a. R-600 is the hydrocarbon (HC) butane and R-601a is the hydrocarbon isopentane. These two hydrocarbons constitute a very small percentage of the total blend (1.7% and 0.6%, respectively), but they help thin the mineral oil so that it has a lower viscosity, enhancing oil return to the compressor crankcase. This characteristic was intentionally designed into the blend to achieve mineral oil compatibility. Because of the small percentages of these two hydrocarbons, R-438A is not flammable. Its ASHRAE safety group classification is A1. R-438A is versatile and can be used for retrofitting R-22 direct-expansion (DX) systems in air-conditioning applications (high temperature) and medium- and low-temperature commercial refrigeration applications.

The evaporator and condenser temperature glide of R-438a is typically in the range of 6° to 7°F. Like most refrigerant blends, R-438A is not recommended for use in systems with a flooded evaporator or a centrifugal compressor, as the vapor/liquid composition difference associated with the temperature glide may inversely impact performance. R-438A has pressure and enthalpy characteristics similar to those of R-22 in low- and medium-temperature commercial refrigeration systems and air-conditioning applications. It is compatible with mineral oil, alkylbenzene, and polyol ester lubricants through all of the temperature ranges mentioned above, and oil changes may not be necessary when retrofitting.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Oil changes are system-dependent. If the system has a complicated piping arrangement, a liquid receiver, or a suction accumulator acting as a low-pressure receiver and oil-return problems are a concern, replacement of all, or part (10%–25%) of the compressor's oil charge with POE lubricant is recommended. For most systems, R-438A may have 5% to 10% lower capacities with a similar Energy Efficiency Ratio (EER) when compared to R-22. Because most R-22 systems in service today have excess compressor capacity, this small percentage in capacity loss will not be significant. The compressor simply runs a bit longer each cycle. Existing TXVs can be used with minimal adjustment to the superheat setting. R-438A can be used as a retrofit refrigerant blend in air-conditioning and refrigeration applications with minimal system changes. When retrofitting R-22 systems to R-438A, or any HFC refrigerant, it is recommended that critical elastomeric seals, such as Schrader valve core seals, liquid-level receiver gaskets, solenoid valves, ball valves, and flange seals be changed. **Critical seals** are defined as those components that are difficult to isolate and/or service while operating or that require removal of the entire refrigerant charge. Always consult with the compressor manufacturer or follow its specific retrofit guidelines and procedures before performing a retrofit on any R-22 system or any other refrigeration system.

HFC-417A (**R-417A**) is a near-azeotropic refrigerant blend of R-134a, R-125, and R-600. R-600 is the hydrocarbon butane. It is an efficient and cost effective, non-ozone depleting HFC-based refrigerant blend. Its safety classification is A1. R-417A has been used primarily in new and existing R-22 systems utilizing direct-expansion metering devices. R-417A has also been used as an R-22 direct drop-in replacement refrigerant. Its applications range from large-tonnage industrial refrigeration to commercial packaged air-conditioning units. It has been best suited to replace R-22 in smaller split air conditioning systems. It is a non-ozone-depleting, HFC-based refrigerant blend with a low global-warming impact. It has a moderate temperature glide. R-417A is compatible with all standard refrigeration oils which include mineral oil, alkylbenzene, and polyol ester lubricants. R-417A operating pressures are slightly lower than R-22 operating pressures. It also has lower discharge temperatures than R-22.

HFC-417C (**R-417C**) is a near-azeotropic retrofit refrigerant blends for CFC-12 and CFC-12 service blends, like R-401A and R-409A, in domestic and commercial refrigeration applications.

HFC-404A (**R-404A**) is a near-azeotropic refrigerant blend of R-125, R-143a, and R-134a. Its safety classification is A1. R-404A had been used primarily in the medium- and low-temperature commercial refrigeration markets. R-404A used to be the long-term substitute refrigerant for R-502, but it is not a direct drop-in replacement for R-502. It was possible to retrofit an R-502 system to an R-404A system, but retrofit guidelines had to be followed carefully. R-404A has slightly higher working pressures than R-502. R-404A, as with most HFC-based refrigerants, uses POE lubricants in the crankcase. R-404A has a small evaporator temperature glide (1.5°F) over its refrigeration operating range and has a small fractionation potential over these same temperature ranges.

HFC-422A (R-422A) is a near-azeotropic refrigerant blend consisting of HFC-125, HFC-134a, and R-600a. It has been replacing R-502 and R-502 service refrigerant blends like R-402A and R-408A in commercial refrigerant applications, and R-22 in certain low-temperature applications. It has similar performance to R-404A. It is compatible with traditional lubricants. However, because of its high GWP, it may soon be an unacceptable refrigerant and be replaced with lower GWP refrigerants.

HFC-407F (**R-407F**) is a near-azeotropic refrigerant blend of R-32, R-125, and R-134a. Its safety classification is A1. It is an alternative to R-22 and R-404A in low- and medium-temperature commercial refrigeration applications. There is a slight decrease in capacity and efficiency compared to R-22, however, R-407F can can be used in essentially the same equipment to perform the same job. New systems built with R-407F must have POE lubricants. Retrofitted R-22 systems would need their residual oil flushed with POE lubricant.

HFC-422B (**R-422B**) is a near-azeotropic refrigerant blend of R-125, R-134a, and HC-600a. Its safety classification is A1. R-600a is the hydrocarbon isobutane used for oil-return purposes. R-422B has been an R-22 retrofit blend for air-conditioning. Its retrofit guidelines will call for possible POE lubricant additions or replacement of mineral oil and possible component changes.

HFC-422C (**R-422C**) is a near-azeotropic refrigerant blend of R-124, R-134a, and HC-600a with different percentages than R-422A and R-422B. Its safety classification is A1. R-422C has been a retrofit refrigerant blend for R-22, R-502, R-402A, R-402B, R-408A, R-404A and R-507. It has very similar properties to R-404A in commercial refrigeration applications. Its retrofit guidelines will call for possible POE lubricant addition or replacement of mineral oil. Also, certain component changes will be necessary. The hydrocarbon component (HC-600a) in the blend will help promote oil return in systems containing mineral oil or alkylbenzene lubricant.

HFC-422D (**R-422D**) is a near-azeotropic refrigerant blend of R-125, R-134a, and R-600a with different percentages than both R-422B and R-422C. Its safety classification is A1. It has been a R-22 retrofit blend for both air-conditioning and commercial refrigeration. It has a moderate temperature glide and its typical lubricant is POE and mineral oil. Its retrofit from R-22 will call for possible POE lubricant additions or replacement of mineral oil and possible component changes.

HFC-427A (**R-427A**) is a near-azeotropic refrigerant blend of R-32, R-125, R-143a, and R-134a. Its safety

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

classification is A1. It has been a retrofit refrigerant blend for R-22 in both air-conditioning and commercial refrigeration applications, but has been preferred for commercial refrigeration applications. Its retrofit guidelines will call for partial POE replacement of mineral oil. No component changes will be necessary.

HFC-507 (R-507) is an azeotropic refrigerant blend of R-125 and R-143a. R-507 has been used primarily in medium- and low-temperature commercial refrigeration applications. Its safety classification is A1. R-507 has been a replacement refrigerant for R-502, but it is not a direct drop-in replacement. R-507 has slightly higher pressures than both R-502 and R-404A and has slightly higher capacities compared to R-404A. Because R-507 is an azeotropic blend of refrigerants, it has negligible temperature glide and fractionation potential. R-507 requires POE lubricant in the compressor crankcase.

HFC-507A (R-507A) is an azeotropic mixture of R-125 and R-143a. It has a higher efficiency than R-404A and also a higher efficiency than low-temperature R-22. Polyol ester lubricant must be used with R-507A. It is a very close match to R-502.

The following are some of the refrigerants still in use in today's refrigeration and air-conditioning systems. However, because of current or near-future bans, these refrigerants are, or soon will be, no longer manufactured. Even though it is unlawful to produce these refrigerants, they can still be used when recovered or reclaimed from an existing system, as long as certain Environmental Protection Agency (EPA) guidelines are followed. More detailed information on recovering and reclaiming refrigerants is provided later in this unit.

CFC-11 (R-11) is a low-pressure refrigerant used in centrifugal chillers. Its safety classification is A1. R-11 has been in the HVAC/R industry since 1932. Centrifugal chillers employing R-11 as the refrigerant have low operating costs and are one of the most inexpensive ways to supply large amounts of chilled water to large commercial and industrial buildings for air-conditioning purposes. In 1996, environmental concerns about ozone depletion and global warming forced the production of R-11 to be banned. R-11 centrifugal chiller systems operate in a vacuum on their low sides. Because of this, any leaks will introduce air into the system. Efficient purge systems have been designed to rid these systems of unwanted air. The interim replacement refrigerant for R-11 is R-123. However, a retrofit procedure is required when retrofitting an R-11 system to an R-123 system. **SAFETY PRECAUTION:** *Always consult with the original equipment manufacturer for retrofit guidelines when retrofitting any system.* Newer chiller systems may come with R-123, R-134a, or ammonia. Lithium bromide and water absorption systems may also be used in newer chiller applications.

CFC-12 (R-12) has been widely used in the HVAC/R industry since it was invented in 1931. Its safety classification is A1. R-12 has been used extensively in small- and large-scale refrigeration and air-conditioning system applications. Systems ranging in size from small hermetic systems to large centrifugal positive-pressure chiller applications have incorporated R-12. Its main applications have been automotive air-conditioning; high-, medium-, and low-temperature refrigeration; and other commercial and industrial refrigeration and air-conditioning applications. In 1996, environmental concerns about ozone depletion and global warming forced the production of R-12 to be banned. R-134a has been the most popular refrigerant to replace R-12 in medium- and high-temperature stationary refrigeration and air-conditioning systems. R-134a has been the refrigerant replacing R-12 in automotive air-conditioning systems. However, hydrofluoro-olefin (HFO) refrigerants may be the future for automotive air conditioning because of their low GWP. R-134a is not a direct drop-in replacement for R-12 in any application. Many interim refrigerant blends that are listed here have also entered the market to replace R-12, with minimal retrofit. Always refer to the manufacturer's retrofit guidelines and procedures when retrofitting any system.

CFC-502 (R-502) is an azeotropic refrigerant blend of R-22 and R-115. Its safety classification is A1. R-502 was first manufactured in 1961. In 1996, environmental concerns about ozone depletion and global warming forced a production ban on R-502 also. R-22 has been used as an interim replacement for R-502, but it usually requires a compound compression system with intercoolers for low-temperature refrigeration applications. As mentioned earlier, R-22 is considered an interim replacement refrigerant because it has a current phaseout date for new equipment of 2010 and a total production phaseout of 2020. R-502 has been a popular low-temperature refrigerant for low-temperature refrigeration applications. One of the main advantages of R-502 over R-22 in low-temperature refrigeration is its ability to operate in positive pressure even with a −40°F evaporating temperature. Also, because of its relatively higher pressures, R-502 operates with lower compression ratios than R-12 in low-temperature refrigeration applications. Lower compression ratios lead to improved capacity as compared with R-12 and R-22 systems. R-502 also has much lower discharge temperatures as compared to R-22. Because of these advantages, R-502 can perform low-temperature refrigeration with single-stage compression and relatively inexpensive compressors.

HCFC-123 (R-123) is an interim replacement refrigerant for R-11 in low-pressure centrifugal chiller applications. The American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE) has given R-123 a safety classification rating of B1, meaning there is evidence of toxicity at concentrations below 400 ppm, **Figure 9.13**. This means levels of exposure are reduced for persons exposed to R-123 in the course of normal daily operations in machine rooms and

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

service conditions. Special precautions for R-123 and machine room requirements are covered in ASHRAE Standard 15, "Safety Code for Mechanical Refrigeration." **SAFETY PRECAUTION:** *ASHRAE Standard 15 requires the use of room sensors and alarms to detect R-123 refrigerant leaks. The machine room shall activate an alarm and mechanical ventilation equipment before the concentration of R-123 exceeds certain limits.* • When retrofitting an R-11 system to an R-123 system, retrofit guidelines must be followed. R-123 systems may require new seals, gaskets, and other system components to prevent leaks and get maximum performance and capacity.

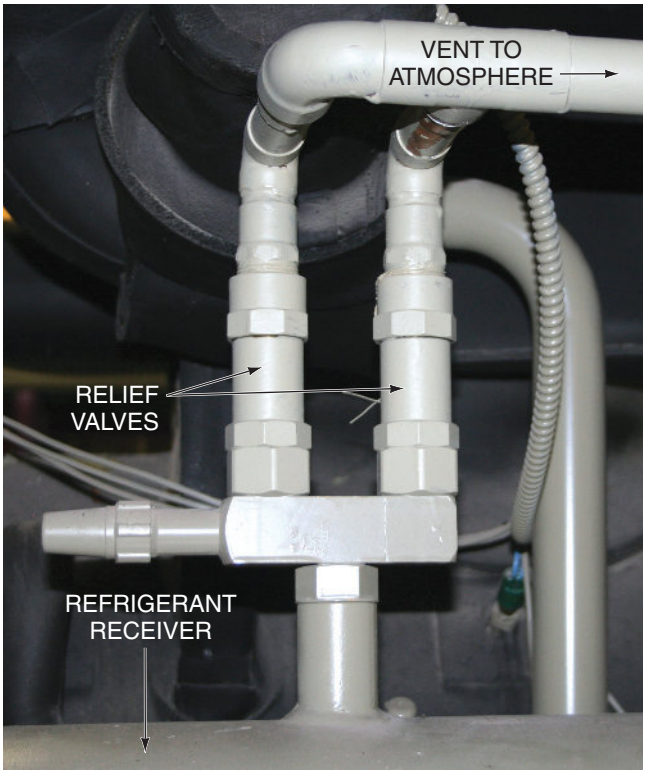
HCFC-401A (R-401A) is a near-azeotropic refrigerant blend of R-22, R-152a, and R-124. Its safety classification is A1. R-401A has been intended for use as a retrofit refrigerant for R-12 or R-500 systems with only minor modifications. It is especially designed for systems with evaporator temperatures ranging from 10°F to 20°F, because the pressure/ temperature curve closely matches that of R-12 in these ranges. There is a drop in capacity at lower temperatures as compared with R-12 systems. An 8°F temperature glide in the evaporator is typical when R-401A is being used. There is an increase in discharge pressure and a slight increase in discharge temperature as compared with R-12. An oil retrofit to an **alkylbenzene** lubricant is recommended when retrofitting from R-12 to R-401A.

HCFC-402A (R-402A) is a near-azeotropic refrigerant blend of R-22, R-125, and R-290 (propane). The hydrocarbon propane is added to enhance oil solubility and circulation with the refrigerant for oil-return purposes. Its safety classification is A1. R-402A has been intended for use as an R-502 retrofit refrigerant with minimal retrofitting. R-402A will have 25- to 40-psi increases in discharge pressure over R-502 but will not significantly increase the discharge temperature. An oil retrofit to an alkylbenzene lubricant is recommended when retrofitting from R-502 to R-402A.

HCFC-402B (R-402B) is a refrigerant blend of R-22, R-125, and R-290 that contains more R-22 and less R-125 than R-402A does. Its safety classification is A1.R-402B has been intended for use as an R-502 ice-machine retrofit refrigerant because of its lower discharge pressures and higher discharge temperatures as compared with R-502. The higher discharge temperatures make for quicker and more efficient hot-gas defrosts in ice-machine applications. An oil retrofit to an alkylbenzene lubricant is recommended when retrofitting from R-502 to R-402B.

HCFC-409A (R-409A) is a refrigerant blend of R-22, R-142b, and R-124. Its safety classification is A1. R-409A was designed for retrofitting R-12 systems having an evaporator temperature between 10°F and 20°F. R-409A systems usually experience a 13°F temperature glide in the evaporator. R-409A has been used in retrofitting R-12 and R-500 direct-expansion refrigeration and air-conditioning systems. R-409A operates with higher discharge pressures and temperatures than R-12 and has a capacity similar to that of R-12 down to −30°F evaporator temperatures. R-409A mixes well with mineral oil lubricants down to 0°F, so oil retrofitting may not be necessary above this temperature. However, an alkylbenzene lubricant should be used in place of the mineral oil lubricant in evaporator temperatures below 0°F.

Figure 9.16 Dual pressure relief valves installed in parallel.



Courtesy: Ferris State University. Photo by John Tomczyk

SAFETY PRECAUTION: *Always consult with the original equipment manufacturer for retrofit guidelines when retrofitting any system.* •

SAFETY PRECAUTION: *All refrigeration systems are required to have some sort of pressure relief device, usually a pressure relief valve, which should be vented to the outdoors to prevent the buildup of excessive system pressures. Pressure relief valves should always be installed in parallel with one another, never in series,* **Figure 9.16**. •

SAFETY PRECAUTION: *Any refrigerant can be hazardous if used improperly. Hazards include liquid or vapor under pressure and frostbite from the escaping liquid.* •

9.13 REFRIGERANT OILS AND THEIR APPLICATIONS

Today, almost as many new oils are on the market as there are refrigerants. The compressor manufacturers specify what oil to use in any application. If you are unsure please call the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

manufacturer or use its specification data and performance curve literature.

9.14 OIL GROUPS

Oils fall into three basic groups:

- Animal
- Vegetable
- Mineral

Neither animal nor vegetable oils are good refrigeration or air-conditioning lubricants. However, mineral oils are proven lubricants for these applications. The three groups of mineral oils are:

- Paraffinic
- Naphthenic
- Aromatic

Of the three mineral oil groupings, naphthenic oils are used most often with refrigeration and air-conditioning applications. *Synthetic oils* for refrigeration applications have been used successfully for many years. Three popular synthetic oils are:

- Alkylbenzenes
- Glycols
- Esters

HCFC-based blends work best with alkylbenzene lubricants. Today, alkylbenzenes are used quite often in refrigeration applications. The HFC-based blends perform best with an ester lubricant, and manufacturers are using a synthetic ester-based lubricant for many HFC-based refrigerant blends. Extensive oil flushing is required when retrofitting a CFC/mineral oil system to an HFC/ester oil system. Mineral oils do not mix completely with the HCFC-based refrigerant blends, which are soluble with mineral oil up to a 20% concentration. Mineral oil systems retrofitted with HCFC-based refrigerant blends will not require a lot of oil flushing. However, some HFC-based refrigerant blends may only require one oil change from mineral oil to a POE lubricant when retrofitting from an HCFC refrigerant to a HFC-based blend. This is often referred to as a partial-POE oil retrofit, because there is still some residual mineral oil left in the system when the POE lubricant is added. For example, when retrofitting from an HCFC-22 mineral oil system to an HFC-based blend like HFC-407A or HFC-407C, research has shown that after a single oil change, the remaining mineral oil mixed well with the added POE lubricant and the combination circulated well with the HFC-based refrigerant blend. Always follow manufacturer's guidelines when performing any retrofit procedure.

SAFETY PRECAUTION: *Always follow the refrigerant manufacturer's retrofit guidelines when performing any refrigerant/oil retrofit procedure. Retrofit guidelines vary from refrigerant to refrigerant and from manufacturer to manufacturer.*•

Figure 9.17 A refractometer used in the field for checking the percentage of residual oil left in the system.

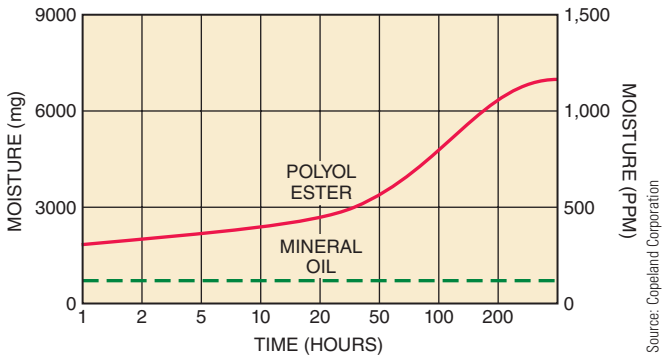
Source: Nu-Calgon Wholesaler, Inc.

As mentioned earlier, a popular glycol-based lubricant is polyalkylene glycol (PAG). PAGs are used in automotive applications. PAG lubricants attract and hold moisture readily and will not tolerate chlorine. When retrofitting a mineral oil system to a PAG system, a labor-intensive retrofit is involved.

Ester-based oils are also synthetic oils. They are wax-free oils and are used with HFC refrigerants like R-134a and HFC-based refrigerant blends. R-134a is a non-ozone-depleting refrigerant with properties very similar to R-12 at medium- and high-temperature applications, **Figure 9.14**. Notice the increase in capacity at the higher-temperature applications and the decrease in capacity at lower temperatures. R-134a is not compatible with current refrigerant mineral oils. Systems will have to come from the factory as virgin systems with ester oil, or the technician will have to go through a step-by-step flushing process in an effort to eliminate the residual mineral oil. The system cannot contain more than 1% to 5% mineral oil after retrofitting. **Figure 9.17** shows a refractometer that a technician can use in the field to make sure the system has no more than 1% to 5% residual mineral oil left in it. **SAFETY PRECAUTION:** *Even though the EPA has ruled that refrigeration oils are not hazardous waste unless they are contaminated, disposing of used oil in a careless manner is against the law. Check with your local waste-disposal codes when disposing of refrigeration oil.*•

Polyol esters, ester-based lubricants, have become very popular recently. POEs do, however, absorb atmospheric moisture more rapidly than mineral oils, **Figure 9.18**. POEs

Figure 9.18 The moisture-absorbing capability of mineral oil versus polyol ester lubricant.



Source: Copeland Corporation

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

not only absorb moisture more readily but also hold it more tightly. Refrigeration-system evacuation procedures may require longer times because of this. Containers of POE oil, therefore, should not be exposed to the atmosphere any longer than possible to avoid moisture contamination. Many manufacturers are using metal oil containers for POE oils instead of plastic ones to prevent moisture penetration through the walls of the oil container. **Figure 9.19** lists the appropriate oils for many popular refrigerants. However, always consult with the compressor or condensing unit manufacturer when unsure of what oil to use.

Polyvinylether (PVE) is a non-POE synthetic lubricant for HFC commercial HVAC/R equipment. PVE is a polymer-based lubricant consisting of chains of monomers. This lubricant first started to be used by original equipment manufacturers (OEMS) in the USA in 2010. Since then, more and more manufacturers are using PVE lubricant extensively in the USA. Many Chinese, Japanese, and Korean air conditioning manufacturers are using PVE lubricant in their compressors. PVE is very popular in Asia for carbon dioxide refrigeration systems and R-410A air conditioning applications. Because of its increased usage, the commercial availability of PVE lubricant is expanding. Some main advantages of using PVE in an HVAC/R system are:

- No hydrolysis (reaction with water)
- Compatible with all HFC refrigerants
- Resists capillary tube blockages due to no hydrolysis
- Excellent anti-wear properties
- Excellent lubrication properties
- Excellent electrical resistivity
- Excellent chemical stability
- Excellent miscibility with HCF refrigerants
- Adaptive to many HVAC/R applications

Some of the larger compressor and chemical manufacturers have written retrofit guidelines for changing a system over to a newer, alternative refrigerant and its appropriate oil. Always consult with the compressor manufacturer before retrofitting any system. Later in this unit a section named "Refrigerant Retrofitting" will cover retrofit guidelines for retrofitting an existing R-22 system to an R-407C system.

9.15 REGULATIONS

The United States, Canada, and more than 30 other countries met in Montreal, Canada, in September 1987 to try to solve the problems caused by released refrigerants. This conference, known as the Montreal Protocol, agreed to reduce by 1999 the production of refrigerants believed to be harmful ozone-destroying chemicals by 50%. The agreement would take effect when ratified by at least 11 countries representing 60% of the global production of these chemicals. Additional meetings have been held since 1987 and further reduction of these refrigerants has been agreed on. The use of refrigerants

as we have known them has changed to some extent and will change dramatically in the near future.

The United States Clean Air Act Amendments of 1990 regulate the use and disposal of CFCs and HCFCs. The Environmental Protection Agency (EPA) is charged with implementing the provisions of this legislation. The act affects the technician servicing refrigeration and cooling equipment, and according to the act, technicians may not "knowingly vent or otherwise release or dispose of any substance used as a refrigerant in such an appliance in a manner which permits such substance to enter the environment." This prohibition became effective July 1, 1992. Severe fines and penalties can be imposed, including prison terms. For the first offense, the act empowers the EPA to obtain an injunction against the offending party that prohibits the discharge of refrigerant to the atmosphere. The second level is a $27,500 fine per day and a prison term not exceeding 5 years. Also, rewards of up to $10,000 are offered to persons furnishing information that leads to the conviction of a person in violation. New legislation made it illegal to manufacture CFC refrigerants after January 1, 1996.

9.16 RECOVER, RECYCLE, OR RECLAIM

You should become familiar with these three terms: *recover*, *recycle*, and *reclaim*—terms the industry and its technicians must understand. *Technicians must contain all refrigerants except those used to purge lines and tools of the trade, such as the gauge manifold or any device used to capture and save the refrigerant. The Clean Air Act Amendments of 1990 charged the EPA with issuing regulations to reduce the use and emissions of refrigerants to the lowest achievable level. The law states that the technician shall not "knowingly vent or otherwise release or dispose of any substance used as a refrigerant in such an appliance in a manner which permits such substance to enter the environment."* De minimus releases associated with good-faith attempts to recapture and recycle or safely dispose of any such substance shall not be subject to prohibition set forth in the preceding sentence." This prohibition became effective July 1, 1992. *De minimus* releases means the minimum amount possible under the circumstances.

Some situations requiring the removal of refrigerant from a component or system are the following:

1. A compressor motor is burned.
2. A system is being removed to be replaced. It cannot be disposed of at a salvage yard with refrigerant in the system.
3. A repair must be made to a system, and the refrigerant cannot be pumped using the system compressor and captured in the condenser or receiver.

When refrigerant must be removed, the technician must study the system and determine the best procedure for removal. For example, the system may have several different valve configurations, the compressor may or may not be operable, or sometimes the system compressor may be used to assist in refrigerant recovery. We will consider only the refrigerants and systems covered in this text. The following situations where refrigerant must be removed from a system may be encountered by the technician in the field:

1. The compressor will run and the system has no service valves or access ports, for example, a unit like a domestic refrigerator, freezer, or window unit being discarded.
2. The compressor will *not* run and the system has no access ports, for example, a burnout on a domestic refrigerator, freezer, or window unit.
3. The compressor will run and the unit has service ports (Schrader ports) only, as in a central air conditioner.
4. The compressor will *not* run and the unit has service ports (Schrader ports) only, as in a central air conditioner.
5. The compressor will run and the system has some service valves, for example, a residential air-conditioning system with liquid- and suction-line isolation valves in the line set.
6. The compressor will *not* run and the system has some service valves, for example, a residential air-conditioning system with liquid- and suction-line isolation valves in the line set.
7. The compressor will run and the system has a complete set of service valves, for example, a refrigeration system.
8. The compressor will not run and the system has a complete set of service valves, for example, a refrigeration system.
9. A heat pump with any combination of service valves.

The technician trying to recover the refrigerant in these cases requires a certain amount of knowledge and experience. The condition of the refrigerant in the system must also be considered. It may be contaminated with air, another refrigerant, nitrogen, acid, water, or motor burn particulates. Cross-contamination to other systems must never be allowed because it can damage the system into which the contaminated refrigerant is transferred. This damage may occur slowly and may not be known for long periods of time. Warranties of compressors and systems may be voided if contamination can be proven. Food loss from inoperative refrigeration systems and money loss in places of business when the air-conditioning system is off can be a result.

The words *recover, recycle,* and *reclaim* may be used to mean the same thing by many technicians, but they refer to three entirely different procedures.

RECOVER REFRIGERANT

"**To remove refrigerant in any condition from a system and store it in an external container without necessarily testing or processing it in any way**" is the EPA's definition of recovering refrigerant. The refrigerant may be contaminated with air, another refrigerant, nitrogen, acid, water, or

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 9.20 Maximum contaminant levels of recycled refrigerant in the same owner's equipment.

CONTAMINANTS	LOW-PRESSURE SYSTEMS	R-12 SYSTEMS	ALL OTHER SYSTEMS
Acid content (by wt.)	1.0 ppm	1.0 ppm	1.0 ppm
Moisture (by wt.)	20 ppm	10 ppm	20 ppm
Noncondensable gas (by vol.)	N/A	2.0%	2.0%
High-boiling residues oil (by vol.)	1.0%	0.02%	0.02%
Chlorides by silver nitrate test	no turbidity	no turbidity	no turbidity
Particulates	visually clean	visually clean	visually clean
Other refrigerants	2.0%	2.0%	2.0%

motor-burn particulates. *In fact, an Industry Recycling Guideline (IRG-2) states that the only way recovered refrigerant can change hands from one owner to another is when it is brought up (cleaned or known to be cleaned) to the Air Conditioning, Heating and Refrigeration Institute (AHRI) Standard 700 purity levels by an independent EPA-certified testing agency. It must also remain in the contractor's custody and control. If the refrigerant is to be put back into the "same owner's" equipment, the recycled refrigerant must not exceed the maximum contaminant levels listed in* **Figure 9.20**. The purity levels in **Figure 9.20** can be reached by field recycling and testing, followed by documentation. Another option is to send the refrigerant to a certified refrigerant reclaimer. The following are four options for handling recovered refrigerant:

- Charge the recovered refrigerant back into the same owner's equipment without recycling it.
- Recycle the recovered refrigerant and charge it back into the same system or back into another system owned by the same person or company.
- Recycle the refrigerant to ARI 700 standards before reusing it in another owner's equipment. The refrigerant must remain in the original contractor's custody and control at all times from recovery through recycling and reuse.
- Send the recovered refrigerant to a certified reclaimer.

If the technician is removing the refrigerant from an operable system, it may be charged back into the system. For example, assume a system has no service valves and a leak occurs. The remaining refrigerant may be recovered and reused in this system only. It may not be sold to another customer without meeting the ARI 700 specification standard. Analysis of the refrigerant to the ARI 700 standard may be performed only by a qualified chemical laboratory. This test is expensive and is usually performed only on larger volumes of refrigerant. Some owners of multiple equipment may reuse refrigerant in another unit they own if they are willing to take the chance with their own equipment. It is up to the technician to use an approved, clean, refrigerant cylinder for recovery to avoid cross-contamination.

RECYCLE REFRIGERANT

"To clean the refrigerant by oil separation and single or multiple passes through devices, such as replaceable core filter driers, which reduce moisture, acidity and particulate matter" is the EPA's definition of recycling refrigerant. This term usually applies to procedures implemented at the job site or at a local service shop." If the refrigerant is suspected to be dirty with certain contaminants, it may be recycled, which means to filter and clean. Filter driers may be used only to remove acid, particles, and moisture from a refrigerant. In some cases, the refrigerant will need to pass through the driers several times before complete cleanup is accomplished. Purging air from the system may be done only when the refrigerant is contained in a separate container or a recycling unit. **Figure 9.21** and **Figure 9.22** both illustrate modern refrigerant recycling machines.

A recycling unit removes the refrigerant from the system, cleans it, and returns it to the system. Some units have an air purge that allows any air introduced into the system to be purged before transferring the refrigerant back into the system.

RECLAIM REFRIGERANT

"To process refrigerant to new product specifications by means which may include distillation" is the EPA's definition of reclaiming refrigerant. "It will require chemical analysis of the refrigerant to determine that appropriate product specifications are met. This term usually implies the use of processes or procedures available only at a reprocessing or manufacturing facility." The refrigerant is recovered at the job site, stored in approved cylinders, and shipped to the reprocessing site, where it is chemically analyzed and declared able to be reprocessed (reclaimed). It is then reprocessed and shipped as reclaimed refrigerant because it meets the AHRI 700 standard. At this time, there is no way of testing to the AHRI 700 standard in the field. When reclaimed refrigerant is sold, it is not subject to an excise tax because the tax applies only to newly manufactured refrigerant. This tax saving is an incentive to save and reclaim old refrigerant.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

9.17 METHODS OF RECOVERY

Several methods of refrigerant recovery are used in the systems mentioned in this text. All of these refrigerants are regarded as high-pressure refrigerants; they are also called low-boiling-point refrigerants. Some of the CFC refrigerants, such as R-11, are low-pressure refrigerants that have a high boiling point. R-11 boils at 74.9°F at atmospheric pressure. It is very hard to remove from a system because of its high boiling point, and a very low vacuum must be pulled to boil it all from the system. Refrigerant 134a has a boiling point of −15.7°F; this makes it much easier to remove from a system. The boiling points of some refrigerants at atmospheric pressure are as follows:

Refrigerant	Boiling Point (°F)
R-11	+74.9
R-12	−21.62
R-22	−41.36
R-123	+82.2
R-125	−55.3
R-134a	−15.7
R-500	−28.3
R-502	−49.8
R-410A	−61
R-404A	−51
R-402A	−54
R-402B	−51
R-407A	−49.9
R-407C	−43.6
R-417A	−43.2
R-422B	−40.5
R-422C	−50.7
R-422D	−45.8
R-427A	−44.8
R-438A	−44.2

The following chart shows that most of the common refrigerants discussed in this text have high vapor pressures and will be relatively easy to remove from systems. The vapor pressures at a room temperature of 70°F would be as follows:

Refrigerant	Vapor Pressure at 70°F
R-12	70 psig
R-22	121 psig
R-125	158 psig
R-134a	71 psig
R-500	85 psig
R-502	137 psig
R-410A	201 psig
R-404A	148 psig
R-402A	158 psig
R-402B	147 psig

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The boiling point is important because the EPA has established rules on how low the pressure in a system must be reduced to meet the recovery guideline.

PASSIVE RECOVERY

The service technician's use of the internal pressure of the system or the system's compressor to aid in the refrigerant recovery process is called **passive recovery** or system-dependent recovery. If the compressor is inoperative and passive recovery is to be performed, the refrigerant must be recovered from both the low and the high side of the system to meet the recovery efficiency requirements. A seasoned service technician will gently tap the side of the compressor's shell with a soft wood, rubber, or leather mallet. This action will agitate the crankcase oil and cause any refrigerant dissolved in it to vaporize and be recovered more easily. Because the compressor is not working, the service technician can also use a vacuum pump as long as it does not discharge into a pressurized container but only into the atmosphere. If the compressor is working, the technician can recover refrigerant only from the high side of the system. All manufacturers of appliances containing Class I (CFC) or Class II (HCFC) refrigerants must include a service aperture or process stub on the system, and nonpressurized containers must be used to capture the refrigerant, **Figure 9.38**. Passive recovery is used often on small appliances that contain 5 lb or less of refrigerant in their systems. The recovery techniques for small appliances are covered in this unit under the subsection "Recovering Refrigerant from Small Appliances."

ACTIVE RECOVERY

Active recovery with a certified, self-contained refrigerant recovery machine is the method most often used by technicians. The compressor of the refrigeration or air-conditioning system is not used in active recovery. The recovery machines are usually capable of both the recovery and recycling of refrigerant. To speed the process, always recover at the highest possible ambient temperature to induce a higher pressure in the system being recovered. **SAFETY PRECAUTION:** *A high-pressure reading in a recovery tank is an indication of air or other noncondensables in the tank, which could result in dangerous pressures. After the tank has cooled to the ambient temperature, determining the temperature/pressure relationship to the ambient temperature will indicate what the recovery tank pressure should be. Before starting a recovery, it is always important to know what type of refrigerant is in the system.* Unintentional mixing of refrigerants can also cause high pressures in a recovery tank, so always make sure that this does not occur. The following are some suggestions for how to avoid mixing refrigerants in a recovery tank:

- Use pressure/temperature charts for refrigerant in the recovery cylinder.
- Make sure the recovery machine has a self-clearing feature.
- Dedicate a lubricant-specific recovery unit to specific refrigerants.
- Dedicate refrigerant cylinders to a specific refrigerant and mark the cylinder appropriately.
- Use commercially available refrigerant identifiers and air-detection devices on the recovery tank.
- Keep appropriate records of refrigerant in inventory.

Effective August 12, 1993, all companies have had to certify to the EPA that they have the recovery equipment capable of performing adequate recovery of the refrigerants for the systems they service. Equipment manufactured before November 15, 1993 must meet the regulations set for that time period, Figure 9.20. Equipment manufactured after November 15, 1993 must be approved by an AHRI-approved, third-party laboratory to meet AHRI Standard 740. As of November 15, 1993, the following is the EPA guide for evacuation of all equipment except small appliances and motor vehicle air-conditioning:

1. HCFC-22 appliance, or isolated component of such appliance, normally containing less than 200 lb of refrigerant, 0 psig.
2. HCFC-22 appliance, or isolated component of such appliance, normally containing more than 200 lb of refrigerant, 10 in. Hg vacuum.
3. Other high-pressure appliance, or isolated component for such appliance, normally containing less than 200 lb of refrigerant (R-12, R-500, R-502, R-114), 10 in. Hg vacuum.
4. Other high-pressure appliance, or isolated component of such appliance, normally containing 200 lb or more of refrigerant (R-12, R-500, R-502, R-114), 15 in. Hg vacuum.
5. Very high pressure appliance (R-13, R-503), 0 psig.
6. Low-pressure appliance (R-11, R-113, R-123), 25 mm Hg absolute, which is 29 in. Hg vacuum, **Figure 9.23**.

The exception to these requirements would be a system that could not be reduced to these pressure levels; for example, when the system has a large leak, there is no need to pull the system full of air.

Since November 14, 1994, technicians have required certification to purchase refrigerant. The EPA defines a **technician** as: "Any person who performs maintenance, service, or repair that could reasonably be expected to release Class I (CFC) or Class II (HCFC) substances into the atmosphere, including but not limited to installers, contractor employees, in-house service personnel, and, in some cases, owners." There are four different certifications for the different types of service work. A person must take an EPA-approved proctored test and pass both the core section and either the Type I, Type II, or Type III certification sections to become certified. Certification types are discussed in the following paragraphs. A person who passes the core and certification Types I, II, and III is automatically Universally Certified. A company's training official, industry chapters, or local wholesale supply houses can supply training information, testing dates, and test sites.

Once a technician is certified, it is the certified technician's responsibility to comply with any changes in the law.

TYPE I CERTIFICATION. Small Appliance—Manufactured, *charged and hermetically sealed with 5 lb or less of refrigerant.* Includes refrigerators, freezers, room air conditioners, *package terminal heat pumps,* dehumidifiers, under-the-counter ice makers, vending machines, and drinking-water coolers.

TYPE II CERTIFICATION. High-Pressure Appliance—Uses refrigerant with a boiling point between −50°C (−58°F) and 10°C (50°F) at atmospheric pressure. Includes 12, 22, 114, 500, and 502 refrigerant, and the replacement refrigerants for these.

TYPE III CERTIFICATION. Low-Pressure Appliance—Uses refrigerant with a boiling point above 10°C (50°F) at atmospheric pressure. Includes 11, 113, 123, and their replacement refrigerants.

UNIVERSAL CERTIFICATION. Certified in Types I, II, and III. The assumption is that certification should ensure that the technician knows how to handle the refrigerant in a safe manner without exhausting it into the atmosphere.

Refrigerant may be removed from the system as either a vapor or a liquid or in a partial liquid and vapor state. It must be remembered that lubricating oil is also circulating in the system with the refrigerant. If the refrigerant is removed in the vapor state, the oil is more likely to stay in the system. This is desirable from two standpoints:

1. If the oil is contaminated, it may have to be handled as a hazardous waste. Much more consideration is necessary, and a certified hazardous-waste technician must be available.
2. If the oil remains in the system, it will not have to be measured and then replaced in the system. Time may be saved in either case, and time is money. The technician should pay close attention to the management of the oil from any system.

The cylinder must be clean and in a deep vacuum before the active recovery or recycle process is begun. One suggestion is that the cylinder be evacuated to 1000 microns (1 mm Hg) before recovery is started. With this level of vacuum, refrigerant from a previous job will be removed. All lines to the cylinder must be purged of air before connections are made.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 9.24 Approved Department of Transportation (DOT) cylinders.

Source: National Refrigerants, Inc.

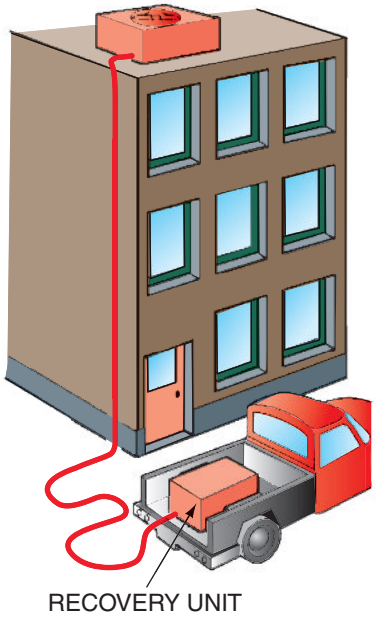
SAFETY PRECAUTION: *Refrigerant must be transferred only to Department of Transportation (DOT)–approved refrigerant cylinders. Never use the DOT 39 disposable cylinders. The approved cylinders are recognizable by their color and valve arrangement: They are yellow on top with gray bodies and have a special valve that allows liquid or vapor to be added to or removed from the cylinder,* **Figure 9.24.**•

9.18 MECHANICAL RECOVERY SYSTEMS

Among the many mechanical recovery systems available, some recover refrigerant only, some are designed to recover and recycle, and a few sophisticated systems are said to have reclaim capabilities. AHRI certifies the equipment specifications, and the machines are expected to meet AHRI 740 specifications. Some of the equipment is designed to be used in the shop where refrigerant is brought in for recycling. For recovery and recycle equipment to be useful in the field, however, it must be portable, able to both recover and recycle, and capable of being easily moved to rooftops, where many systems are located. This presents a design challenge. Equipment must be small enough to be hauled in the technician's truck, and units for use on rooftops should not weigh more than approximately 50 lb, because anything heavier may require two technicians, rather than one, to haul it up a ladder.

Some technicians may overcome the weight problem by using long hoses to reach from the rooftop to the recovery unit, which may be left on the truck or on the top floor of a building, **Figure 9.25**, but this is not often done because the refrigerant must also be recovered from the long hose, which slows the recovery process. Many units have wheels so they may be rolled to the top floor, **Figure 9.26(A)**, while some recovery units can be easily carried by the technician. **Figures 9.26(B)** and **(C)** show two more portable recovery units. Manufacturers are meeting this portability challenge in several ways. Some have developed modular units that may be carried to the rooftops or remote jobs as separate components, **Figure 9.27**. Some are reducing the size of the units by limiting the internal components to recovery only. In this case, the refrigerant may be recovered to a cylinder, taken to the shop for recycling, and then returned to the job. However, every time the refrigerant is transferred from one container to another, some will be lost.

Figure 9.25 The refrigerant is recovered from this unit through a long hose to the unit on the truck. This is a slower process.



Manufacturers are continuing their attempts to provide a unit that is small as well as practical, yet will still perform the task of removing the refrigerant from the system properly. The units must remove vapor, liquid, and vapor/liquid mixtures and deal with oil that may be suspended in the liquid refrigerant. Many manufacturers have added a small hermetic compressor to the unit to pump out the refrigerant vapor. As the compressors become larger, however, they become heavier and also require larger condensers, which adds to the weight. Deeper vacuums may be required in the future for removing more of the system refrigerant. Rotary compressors may pull a deeper vacuum on a system with less effort than a reciprocating compressor. All of these compressors in recovery units also pump oil, so some method of oil

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

return is needed to return the oil to the recovery unit compressor crankcase.

The *fastest* method of removing refrigerant from a system is to take it out in the liquid state, when it occupies a smaller volume per pound of refrigerant. If the system is large enough, it may have a liquid receiver where most of the charge is collected. Many systems, however, are small, and if the compressor is not operable it cannot pump the refrigerant. The *slowest* method of removing refrigerant is to remove it in the vapor state. A recovery/recycle unit will remove the vapor faster if the hoses and valve ports are not restricted and if a greater pressure difference can be created. The warmer the system is, the warmer and denser the vapor is, and the compressor in the recovery/recycle unit will be able to pump more pounds in a minute. As the vapor pressure in the system is reduced, the vapor becomes less dense, and the recovery unit capacity is reduced. More time will be required as the system pressure drops. For example, when removing R-134a from a system, if saturated vapor is removed at 70 psig, only 0.566 ft^3 of refrigerant vapor must be removed to remove 1 lb of refrigerant. When the pressure in the system is reduced to 20 psig, 1.353 ft^3 of vapor must be removed to remove 1 lb of refrigerant. When the pressure is reduced to 0 psig, there is still refrigerant in the system, but 3.052 ft^3 of refrigerant vapor must be removed to remove 1 lb of refrigerant, **Figure 9.28**. The unit recovery rate will slow down as the refrigerant pressure drops because the compressor pumping rate is a constant.

Equipment must operate under the conditions for which it will be needed. It may be 100°F on a rooftop, and so the unit will be functioning under some extremely hot conditions. Due to the ambient temperature, the system pressure may be very high, which may tend to overload the unit compressor. A crankcase pressure regulator is sometimes used in recovery/recycle units to prevent overloading the compressor with high suction pressure. The recovery unit may also have to condense the refrigerant using the 100°F air across the condenser, **Figure 9.29**, so the condenser on the unit must have enough capacity to condense this refrigerant without overloading the compressor.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 9.28 Refrigerant vapor has less weight per cubic foot as the pressure is reduced.

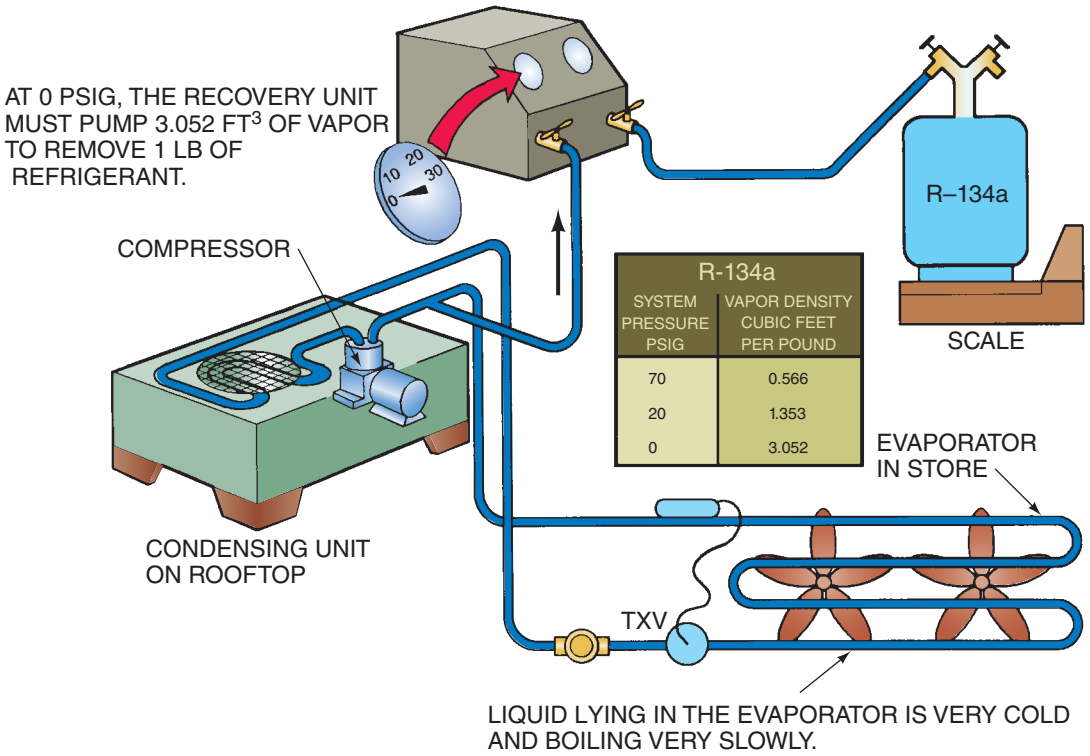

Figure 9.29 The unit will have to condense the refrigerant using 100°F air on the rooftop. The condenser must be large enough to keep the pressure low enough so that the compressor is not overloaded.

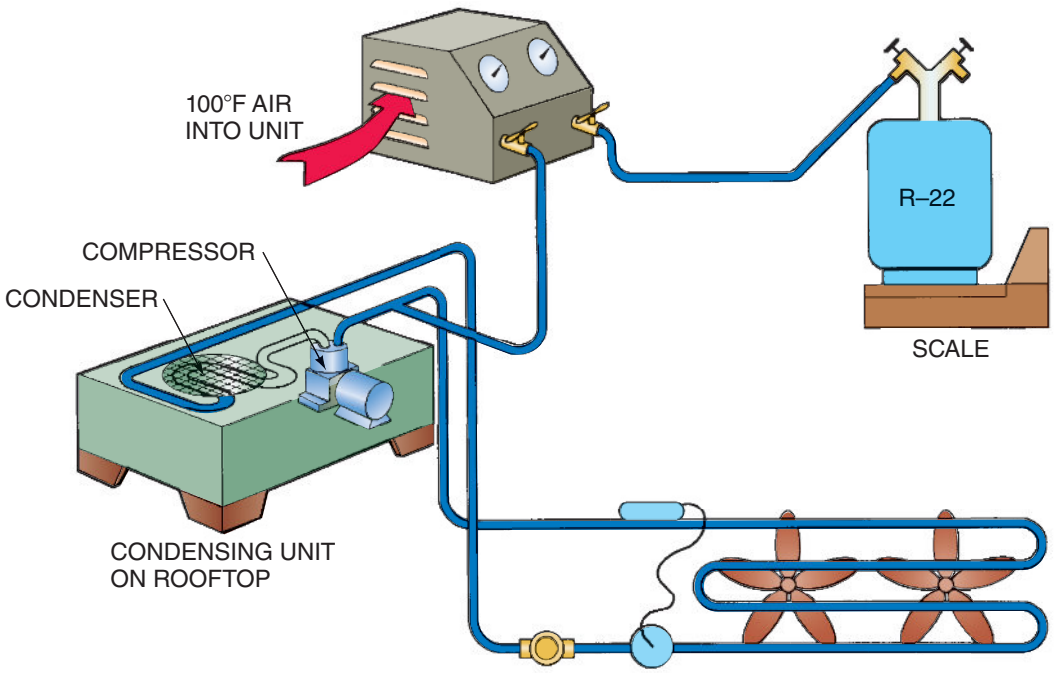

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Recovery/recycling unit manufacturers provide the typical pumping rate for their equipment in the specifications. The rate at which the equipment is capable of removing refrigerant is generally 2 to 6 lb/min, which will be more constant and faster while refrigerant is being removed in the liquid state. More factors must be considered when removing vapor. When the system pressure is high, the unit will be able to remove vapor relatively fast. When the system pressure is lowered, the rate of vapor removal will slow down. With a small compressor, the rate of removal will become very slow when the system vapor pressure reaches about 20 psig.

The compressor in the recovery/recycle unit is a vapor pump. Liquid refrigerant cannot be allowed to enter the compressor because it will cause damage. Different methods may be used to prevent this from occurring. Some manufacturers use a push-pull method of removing refrigerant by connecting the liquid-line fitting on the unit to the liquid-line fitting on the cylinder. A connection is then made from the unit discharge back to the system. When the unit is started, vapor is pulled out of the recovery cylinder from the vapor port and condensed by the recovery unit. A very small amount of liquid is pushed into the system, where it flashes to a vapor to build pressure and push liquid into the receiving cylinder, **Figure 9.30**. A sight glass is used to monitor the liquid, and the recovery cylinder is weighed to prevent overfilling. When it is determined that no more liquid may be removed, the suction line from the recovery unit is reconnected to the vapor portion of the system, and the unit discharge is fastened to the refrigerant cylinder, **Figure 9.31**. The unit is started, and the remaining vapor is removed from the system and condensed in the cylinder.

Figure 9.31 The hoses are reconnected to remove the system's vapor.

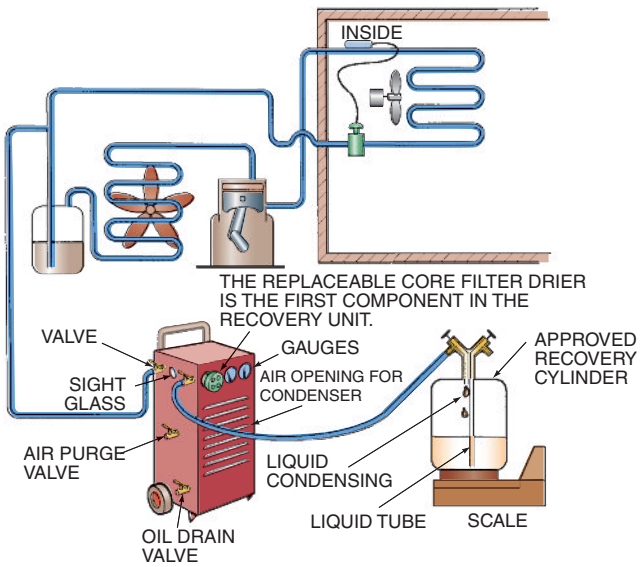

Figure 9.30 This unit uses a push-pull method of removing liquid refrigerant from a system. Vapor is pulled out of the recovery cylinder, creating a low pressure in the cylinder. A small amount of condensed liquid is allowed back into the system to build pressure and push liquid into the cylinder.

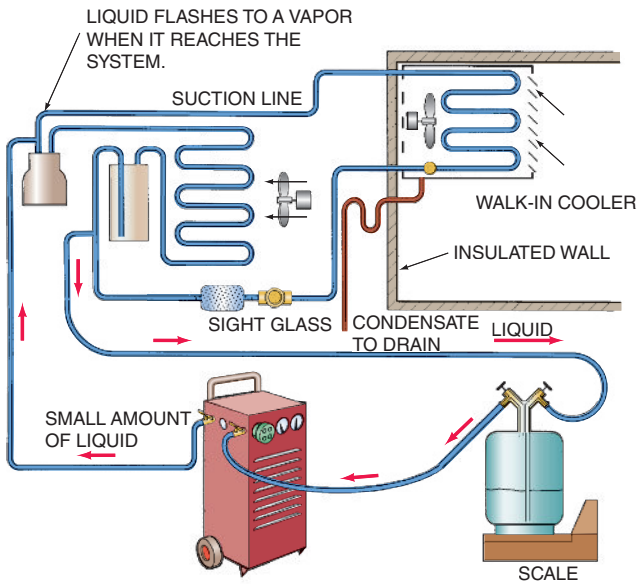

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

A crankcase pressure-regulating valve is often installed in the suction line to the compressor in the recovery/recycle unit to protect it from overloading and offer some protection from liquid refrigerant, **Figure 9.32**. The liquid removed contains oil, and the oil will be in the refrigerant in the cylinder. When the liquid refrigerant is charged back into the system, the oil would go with it if not stopped by the oil separator. Any oil removed must be accounted for and added back to the system, **Figure 9.33**. An acid check of the system's oil should be performed if there is any question as to its quality, such as after a motor burn, **Figure 9.34**.

Figure 9.32 A system with some of the possible features incorporated, including a crankcase pressure-regulating valve for protecting the compressor.

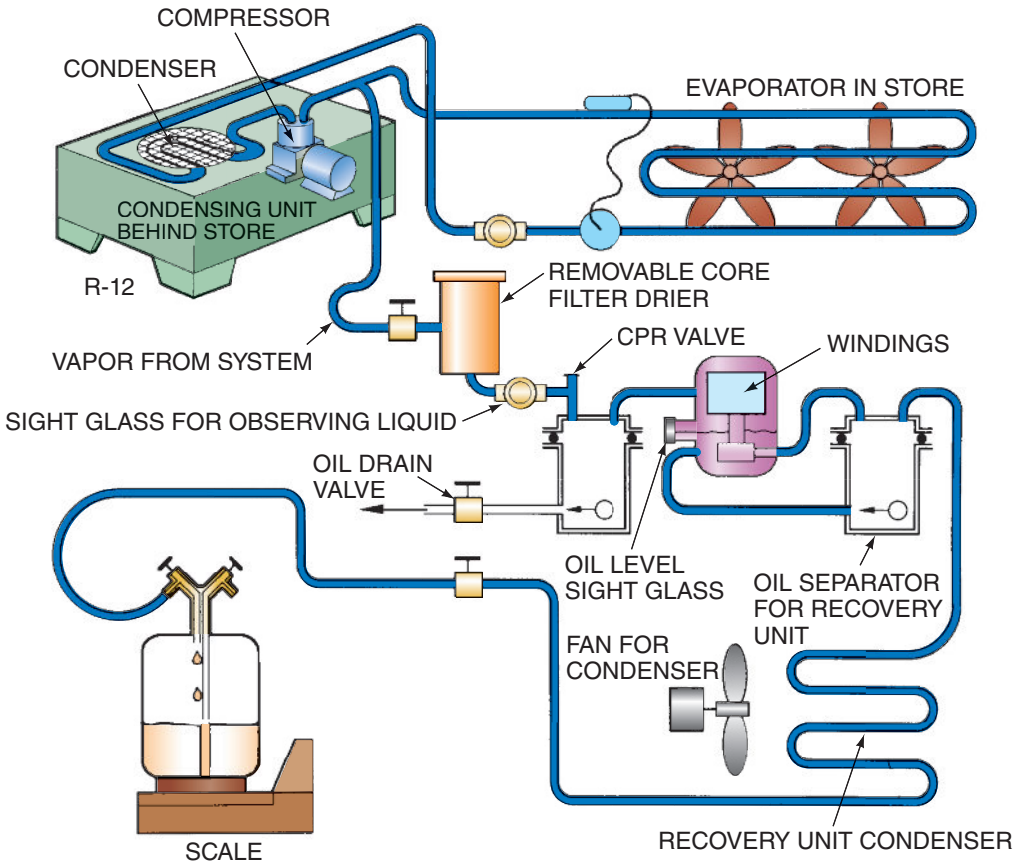

Figure 9.33 All oil removed from a system must be accounted for.

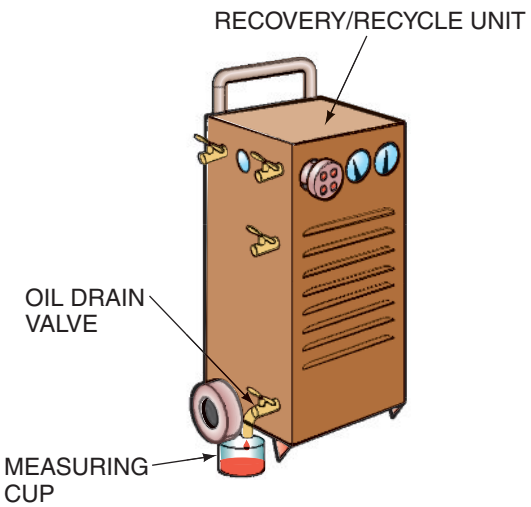

Figure 9.34 An acid test may be performed on the refrigerant oil in the field.

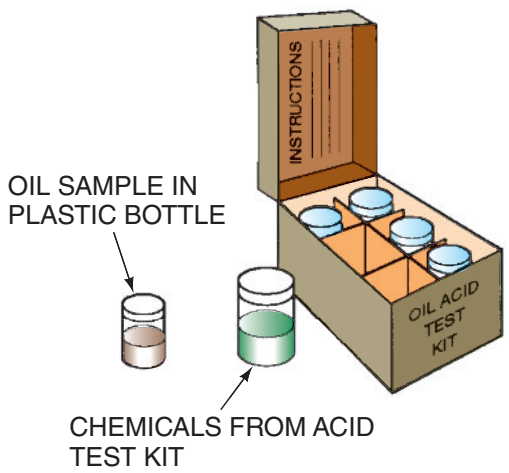


Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The DOT-approved cylinder used for some of the recovery/recycle systems has a float and switch that will shut the unit off when the liquid in the cylinder reaches a certain level. At this point, the cylinder is 80% full. This switch helps prevent overfilling the cylinder with refrigerant. It also helps compensate for oil that may be in the refrigerant. When oil and refrigerant are added to a cylinder, the amount of weight that the cylinder can hold changes because oil is much lighter than refrigerant. If a cylinder contains several pounds of oil due to poor practices, it can easily be overfilled with refrigerant if the cylinder is filled only by weight. The float switch prevents this from happening, **Figure 9.35**. **NOTE:** *The recovery cylinder must be clean, empty, and in a vacuum of about 1000 microns before recovery is started.* • Other methods besides a float device are being used to make sure recovery cylinders are not overfilled. These include electronic thermistors built into the recovery cylinder's wall and simply weighing the recovery cylinder before and after the refrigerant recovery process. Always make sure the recovery tank is free of oil when using the weighing method.

As mentioned earlier, overfilling a recovery cylinder with liquid can create a dangerous situation. **Hydrostatic pressures** can quickly build inside the tank when the temperature rises if the tank is overfilled with liquid. The recovery cylinder must have at least a 20% vapor head, which acts as a cushion for expansion when the tank's temperature changes. If there is no vapor head inside the recovery tank and the tank is full of liquid from overfilling, any slight rise in the temperature of the tank will cause an extremely large pressure increase inside. Because of this, a service technician must know and understand the calculations involved in filling a recovery cylinder to no more than 80% of its internal volume.

As mentioned earlier, weighing the cylinder before and after the recovery process is a proven way to safely fill a recovery cylinder. This can be accomplished by placing the recovery cylinder on an electronic scale and monitoring the weight of the cylinder during the recovery process. When the cylinder reaches a weight equal to 80% of its total capacity, the recovery process must be stopped. However, the service technician must know what 80% of the cylinder's weight carrying capacity (maximum cylinder weight) is. To find out:

1. Calculate the internal volume of the recovery cylinder being used.
2. Determine the liquid density of the refrigerant being used.
3. Determine the **tare weight** of the recovery cylinder.
4. Maximum Cylinder Weight = (Cylinder Volume × Liquid Refrigerant Density @ 130°F × 0.80) + (Cylinder Tare Weight).

To calculate the internal volume of the recovery cylinder, divide the **water capacity** of the recovery cylinder by the density of water, which is 62.5 lb/ft³. The water capacity of the recovery cylinder is the weight of the recovery cylinder if it were full of water. The water capacity (W.C.) of the cylinder is stamped on the outside of the cylinder and its units are in pounds. **Figure 9.36** shows a recovery cylinder with a W.C. of 47.6 lb. So the internal volume of the recovery cylinder is:

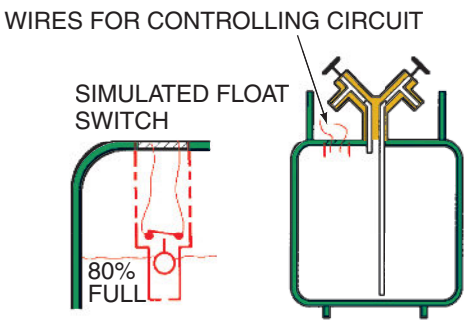
$$\text{Internal Cylinder Volume} = (47.6\ \text{lb}) \div (62.4\ \text{lb/ft}^3) = 0.76\ \text{ft}^3$$

Determine the liquid density of the refrigerant to be recovered at a saturation temperature of 130°F. This data is published by refrigerant manufacturers, usually in the form of tables. Most of the time, the saturated liquid density of a refrigerant can be extracted from a thermodynamic table. If the refrigerant is R-404A, from a thermodynamic table of R-404A, the saturated liquid density at 130°F is 53.18 lb/ft³.

Temperature (°F)	Saturated Liquid Density (lb/ft³)
129	53.50
130	**53.18**
131	52.84

The tare weight of the recovery cylinder is the weight of the empty recovery cylinder. The tare weight of a recovery cylinder, stamped on the outside of the recovery cylinder, is rated in pounds. **Figure 9.34** shows a recovery cylinder with a tare weight (T.W.) of 28 lb. The maximum cylinder weight can now be calculated.

Figure 9.35 (A) This DOT-approved cylinder has an 80% float switch to prevent overfilling. (B) An 80% full switch for a recovery tank.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 9.36 Refrigerant recovery tank specifications stamped on the protective head of the tank, showing tare weight and water capacity.

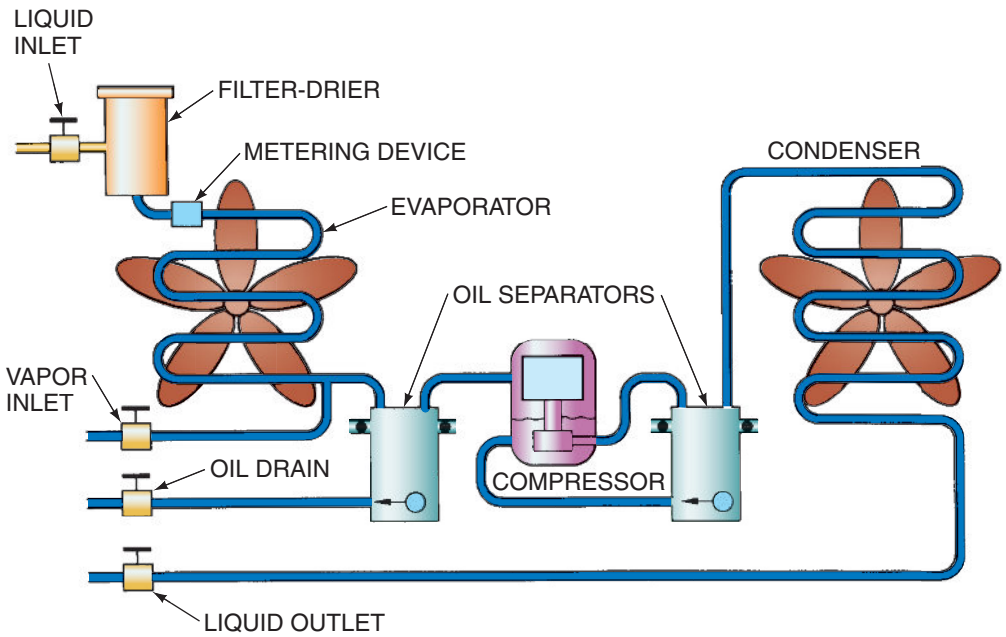
Courtesy Ferris State University. Photo by John Tomczyk

Maximum Cylinder Weight = (Cylinder Volume × Liquid Refrigerant Density @ 130°F × 0.80) + (Cylinder Tare Weight)

Maximum Cylinder Weight = (0.76 ft^3 × 53.18 lb/ft^3 × 0.8) + (28 lb) = 60.33 lb

SAFETY PRECAUTION: *The service technician should stop the refrigerant recovery process once the recovery cylinder weight has exceeded 60.33 lb. Otherwise, hydrostatic pressures will build rapidly and cause a very dangerous situation. Moreover, some of the system's oil will also be removed by the recovery machine and will enter the recovery cylinder. Before using the calculation above, always make sure the recovery cylinder is free of oil.*

Figure 9.37 This system removes either liquid or vapor.



Some recovery units pass liquid from the system through a metering device and an evaporator that is used to boil the liquid to a vapor. The compressor in the recovery/recycle unit evaporates the refrigerant from any oil that has also been removed, **Figure 9.37**. The oil must then be separated out, usually by an oil separator, or it will collect in the unit compressor. The oil from the separator must be drained periodically and measured to determine how much oil to add back to a system that is to be put back in service. At this time oil may be checked for acid content using an acid test kit. All recovery/recycle unit compressors will pump oil out of the discharge line and should have an oil separator to direct the oil back to the unit compressor crankcase.

Manufacturers may use other devices to accomplish many of these same tasks. Keep in mind that manufacturers try to incorporate features in their equipment that make it lightweight, dependable, and efficient. Always follow the manufacturers' instructions; they know the capabilities of their equipment. Technicians should ask certain questions and choose carefully when purchasing a recovery unit:

Recovery Units

1. Will the unit run under the conditions faced in the majority of the jobs to be done? For example, will it operate properly on the rooftop in hot or cold weather?
2. Will it recover both liquid and vapor if necessary?
3. What is the pumping rate in the liquid and vapor state for the refrigerants to be recovered?
4. Are the drier cores standard, and can they be purchased locally?

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

5. Is the unit portable enough to conveniently perform service jobs?
6. Is the recovery unit oil-less? If oil-less, it can be used on systems with different lubricants such as mineral oils, alkylbenzenes, esters, and glycols. Oil changes and oil contamination are no longer a problem with an oil-less recovery unit.

Oil-less recovery units operate on the principle that there is enough residual oil vapor coming back to the recovery unit's compressor from the system under recovery to provide proper lubrication of the recovery compressor's moving parts. The recovery unit's compressor crankcase carries no reservoir of oil and is referred to as "oil-less." This makes the recovery system more versatile and prevents cross-contamination of oil within the refrigeration systems on which it is used. These units can be used on most types of refrigerant and oil systems, and they have very few moving parts. **Figures 9.38(A)** and **(B)** show four oil-less recovery units used in the HVAC/R industry today. **Figure 9.38(C)** shows the internal structure of an oil-less recovery unit's compressor and related parts. Most modern refrigerant recovery units manufactured today are oil-less.

Recovery/Recycle Units

1. Will the unit run under the conditions faced in the majority of the jobs to be done?
2. Will it recycle enough refrigerant for the types of jobs encountered?
3. What is the recycle rate, and does it correspond with the rate needed for the size of the systems to be serviced?
4. Are the drier cores standard, and can they be purchased locally?
5. Is the unit portable enough for the jobs and transportation available?

9.19 RECOVERING REFRIGERANT FROM SMALL APPLIANCES

A small appliance is defined as a system that is manufactured, charged, and hermetically sealed with 5 lb or less of refrigerant. This includes refrigerators, freezers, room air conditioners, packaged terminal heat pumps, dehumidifiers, under-the-counter ice makers, vending machines, and drinking-water coolers. Recovering refrigerant from small appliances may be easier than from larger systems because not as much refrigerant is involved. Recovery in small appliances can be either active or passive. As mentioned earlier, active recovery makes use of a recovery machine that has its own built-in compressor. Passive recovery uses the refrigeration system's compressor or internal vapor pressure for the recovery process. However, in passive recovery, the refrigerant must be recovered in a nonpressurized

Figure 9.38 (A) An oil-less recovery unit. (B) Three modern, portable, oil-less refrigerant recovery units. (C) An oil-less refrigerant recovery unit showing motor, crankcase, piston, cylinder, and cylinder head.

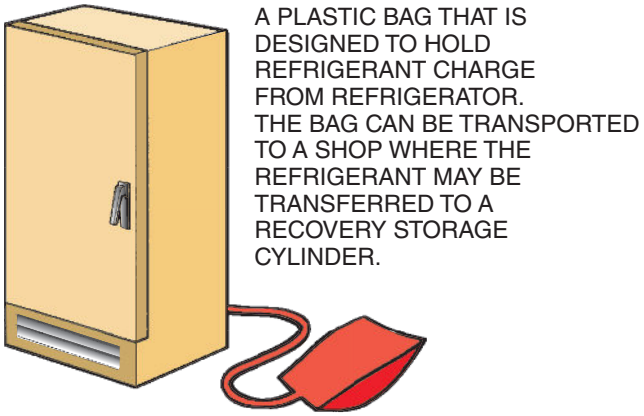
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 9.39 Removing refrigerant to a special plastic bag.



container, **Figure 9.39**. *No matter what kind of recovery device is used, an environmentally conscious service technician should do a daily leak check with a refrigerant leak detector on the recovery device.* To speed up the recovery process, a technician can:

- Put the recovery cylinder in cold water to lower its vapor pressure.
- Heat the refrigeration system to cause the vapor pressure inside the system to increase. Heating the compressor's crankcase will surely release a lot of refrigerant dissolved in the oil. Heat lamps, electric blankets, and heat guns work best. Use of the system's defrost heater will also suffice. Never use an open flame to heat the system.
- Make sure the ambient temperature around the system being recovered is as high as possible. This will ensure high vapor pressures inside the system.
- Softly tap the compressor's crankcase with a soft wood, rubber, or leather mallet to agitate the crankcase oil and release refrigerant.

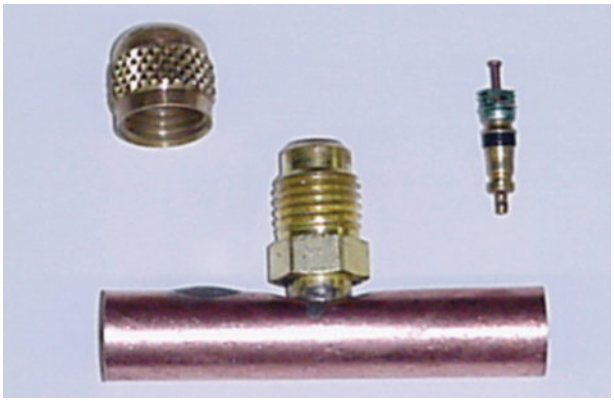
LOW-LOSS FITTINGS

Any recovery equipment manufactured after November 15, 1993, must have low-loss fittings. **Figure 9.45** shows an example; there are many different types of **low-loss fittings** on the market today. The fittings can be either closed off manually or automatically when a service technician takes them off a pressurized refrigeration system or recovery device.

SCHRADER VALVES

A lot of small appliances have **Schrader valves**, **Figure 9.40**. *To prevent refrigerant leaks, Schrader valves must be periodically examined for defects like bends, cracks, or loose cores and caps.* If leaks do occur in the Schrader valve, replace the valve core and make sure the cap is on finger tight. Schrader valve caps help prevent leaks and also help prevent the valve core from accumulating dirt and dust. Accidental depression of the valve core can also be prevented by placing a cap on the valve.

Figure 9.40 A Schrader valve with core and cap.



Courtesy Ferris State University. Photo by John Tomczyk

PIERCING VALVES

Many service technicians access small appliances by using a **piercing valve**, **Figure 9.41**. The sharp pin of the piercing valve is driven through the system's tubing, and when the needle is retracted, access is gained to the system. Piercing valves come as both clamp-on types and solder-on types. The clamp-on piercing valves are used where temporary system access is needed, such as a recovery and charging process. All clamp-on valves should be removed when service is finished because their soft rubber gaskets can rot over time and cause leaks. It is a good idea to leak check these valves before the system's tubing is pierced. Piercing valves are not recommended for use on steel tubing.

Solder-on piercing valves are used for permanent access to a system. Once the valve is soldered onto the system's

Figure 9.41 (A) A gasket-type piercing valve. (B) A solder-on piercing valve.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

tubing, leak check the assembly before piercing the tubing. This can be done by pressurizing the assembly. **SAFETY PRECAUTION:** *Never heat the system's tubing to a cherry red color. This can cause a blowout and serious injury. When certain refrigerants are exposed to high temperatures, a flame, or a glowing-hot metal, they can decompose into hydrochloric and/or hydrofluoric acids and phosgene gas.* The recovery process on a system with 0 psig pressure should not be continued. A pressure reading of 0 psig could mean that there is a leak in the system or that the line has not been successfully pierced. If the system has leaked and is not actually at 0 psig, noncondensables like air with water vapor are in the system and the recovery device will only take in these contaminants.

If the compressor of a small appliance is inoperative, both high- and low-side access is recommended to speed up the recovery process and to make sure the required vacuum levels are reached. **Figure 9.42** lists recovery requirements for small appliances. A vacuum pump can assist in a passive recovery with an inoperative compressor, but the refrigerant must be recovered in a nonpressurized container, as in **Figure 9.39**. This is because vacuum pumps cannot handle pumping against anything but atmospheric pressure. Too large a vacuum pump will freeze any moisture in the system due to a speedy drop in system pressure. The technician should then introduce dry nitrogen to increase pressure and avoid moisture freezing.

SAFETY PRECAUTION: *Never energize the compressor when under a deep vacuum. This can result in a short in the motor windings at the fusite terminals or at a weak spot in the windings and cause compressor damage.* Compressor damage can happen because under a vacuum there is no oil vapor or refrigerant vapor in the compressor's crankcase to insulate the fusite terminals from one another. Both oil and refrigerant are excellent dielectrics, meaning they are good electrical insulators. For accuracy in pulling a vacuum with a vacuum pump, the system's vacuum gauge should be located as close to the system tubing and as far away from the vacuum pump as possible. To determine how long it will take to pull a deep vacuum (500 microns), the vacuum pump's capacity and the diameter of the service hose coming from the vacuum pump are two important factors. Make sure the vacuum pump is turned off or valved off when checking the final vacuum.

Never recover from a small appliance in the following situations:

- Systems having sulfur dioxide, methyl chloride, or methyl formate
- 0 psig pressure in the system to be recovered
- Refrigerants like water, hydrogen, or ammonia, which are found in recreational vehicles and absorption systems
- A strong odor of acid, as in a compressor burnout
- Nitrogen mixed with R-22 as a trace gas for electronic leak detection, or nitrogen used as a holding charge

Even though it is not necessary to repair a leak on a small appliance, every service technician should find and repair leaks because of environmental concerns, which include ozone depletion and global warming. Also, a service technician cannot avoid recovering refrigerant by adding nitrogen to a system that already has a refrigerant charge in it. The system must first be evacuated to the levels in **Figure 9.42** *before nitrogen can be added.*

SAFETY PRECAUTION: *Always check the nameplate of the system that dry nitrogen will enter. Never exceed the design low-side factory test pressure on the nameplate,* **Figure 9.43**. *When using dry nitrogen, always use a pressure relief valve and pressure regulator on the nitrogen tank because of its high pressures (over 2000 psi). Pressure relief valves must never be installed in series. Never pressurize a system with oxygen or compressed air because dangerous pressures can be generated from a reaction with the oil as it oxidizes.*

Figure 9.42 Small-appliance recovery requirements.

RECOVERY EFFICIENCY REQUIREMENTS FOR SMALL APPLIANCES*		
Recovery Efficiencies Required	Recovered Percentages	Inches of Mercury Vacuum
For active and passive equipment manufactured after November 15, 1993, for service or disposal of small appliances with an operative compressor on the small appliance.	90%	4*
For active and passive equipment manufactured after November 15, 1993, for service or disposal with an inoperative compressor on the small appliance.	80%	4*
For grandfathered active and passive equipment manufactured before November 15, 1993, for service or disposal with or without an operating compressor on the small appliance.	80%	4*

*AHRI 740 Standards

RECOVERY RULES AND REGULATIONS

Effective August 12, 1993, contractors must certify to the EPA that the equipment they are using is capable of meeting

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 9.43 A condensing unit nameplate showing factory test.

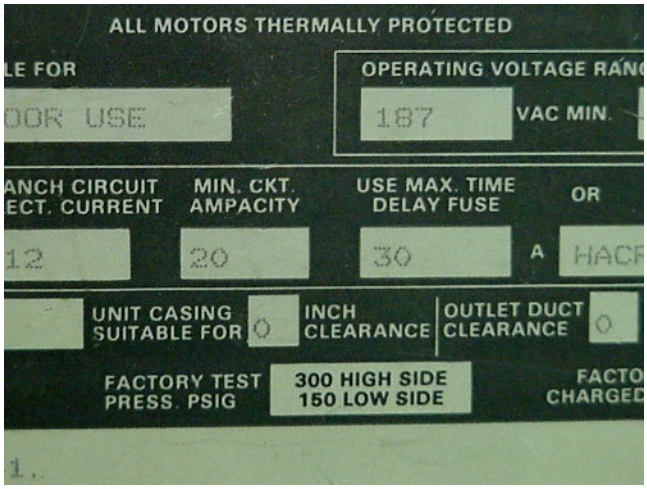

Photo by John Tomczyk

the recovery requirements of AHRI Standard 740, listed in **Figure 9.42.** Also, any recovery equipment manufactured after November 15, 1993 and used on small appliances must be certified by an EPA-approved lab. Within 20 days of opening a new business, a technician must register or certify to the EPA that the recovery equipment is able to recover at least 80% of the refrigerant charge or able to pull a 4-in. Hg vacuum.

DISPOSAL OF SMALL APPLIANCES

The following must be done before disposing of a small appliance:

- Recover the refrigerant from the appliance.
- Secure a signed statement that the refrigerant has been recovered, with the date of recovery.

Refrigerant bags are available for recovery of refrigerant from small appliances. These plastic bags will hold the charge of several refrigerators, **Figure 9.39**. The technician must have enough room in the service truck to haul the bag. When it is full, it may be taken to the shop and the refrigerant transferred into the reclaim cylinder for later pickup by or shipment to the reclaim company.

9.20 RECLAIMING REFRIGERANT

Because refrigerant must meet the AHRI 700 standard before it is resold or reused in another customer's equipment, all reclaimed refrigerant must be sent to a reclaim company to be checked and stored (provided it is in good enough condition to be used). Many service companies will not recycle refrigerant in the field because of the complications and the possibility of cross-contamination of products. Since the refrigerant cannot be vented, reclaiming it is another option. Refrigerant that meets the AHRI 700 specification can be purchased from reclaim companies, without the added tax. The reclaim companies will accept only large quantities of refrigerant (cylinders of 100 lb and larger), so the service shop will need a cylinder of the correct size for each of the refrigerants that will be shipped. Only DOT-approved cylinders with the proper labels can be used, **Figure 9.44**. Some companies buy recovered refrigerant and accumulate it for reclaiming.

The refrigerant in the reclaim cylinders must be of one type. The refrigerants cannot be mixed, or the reclaim company cannot reclaim it. As mentioned, mixed refrigerants cannot be separated. When the reclaim company receives refrigerant that cannot be reclaimed, it must be destroyed by incinerating it in such a manner that the fluorine in the refrigerant is captured. This is an expensive process, so technicians must be careful not to mix the refrigerants.

9.21 REFRIGERANT RETROFITTING

Most new air-conditioning systems today will be manufactured with R-410A refrigerant, and many air-conditioning systems will be retrofitted with a refrigerant blend. However, there is no one refrigerant blend that is a "perfect" drop-in replacement for retrofitting R-22 systems. Each blend has advantages and disadvantages, which have to be balanced against each other to choose the best overall blend for the specific application. There are many retrofit guidelines and procedures for a variety of refrigerants and lubricants. It would be impossible to cover them all in detail here. Major chemical companies and compressor manufacturers can provide these guidelines, and they can also be accessed on the Internet. The service technician can print them out to develop a retrofit library.

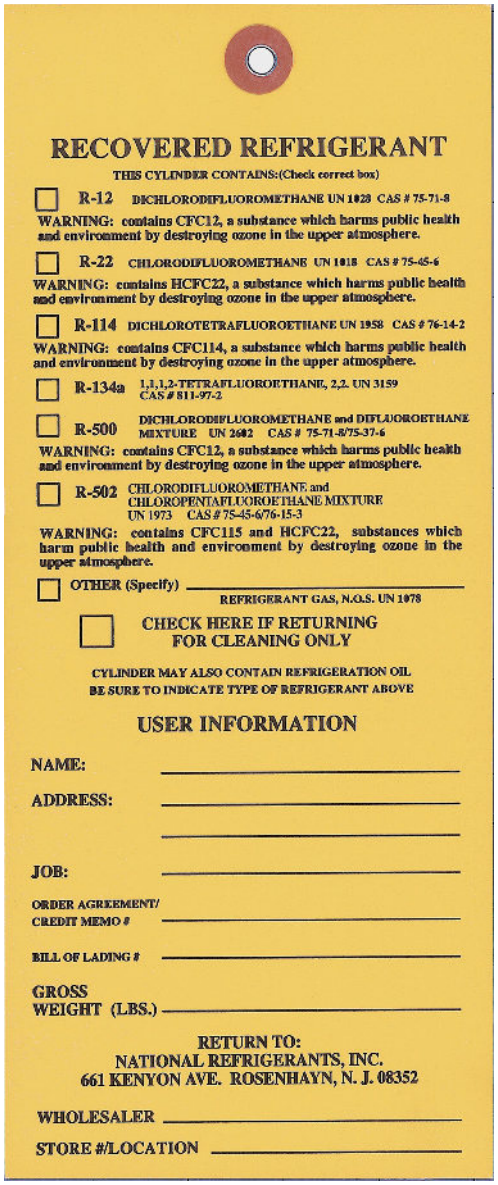
At the time of this writing, U.S. regulations under the Montreal Protocol are that there can be no production and no importing of HCFC-22 (R-22), except for use in equipment manufactured before January 1, 2010, and no production or importing of "new" equipment that uses R-22. Because of these rulings, many existing R-22 refrigeration and air-conditioning systems will be retrofitted because the price of R-22 will steadily increase due to dwindling supply and availability. What follows are some general considerations for retrofitting an HCFC-22 system with an HFC-based refrigerant. We will use R-22 in this example because of the recent regulations and its gradual decline in use and production.

HCFC-22 (R-22) RETROFITTING

As mentioned, most new air-conditioning systems will be manufactured with HFC-410A (R-410A). However, technicians and equipment owners often ask what the best retrofit refrigerant blend for existing R-22 systems is. There is no one

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 9.44 Returnable refrigerant cylinder labels for recovered refrigerant.



quick-fix solution or answer to this question; the answer depends on several key factors:

- Evaporator temperatures (air-conditioning vs. refrigeration)
- Application of the equipment
- Size of the equipment

AIR-CONDITIONING VS. REFRIGERATION EVAPORATOR TEMPERATURES. Refrigerant retrofit blends will behave differently when exposed to different evaporator temperatures. Some refrigerant blends will closely match R-22 properties for air-conditioning evaporating temperatures (35° to 5°F), while others will be better suited for the lower evaporating temperatures of medium- and low-temperature refrigeration applications (20° to −20°F).

EQUIPMENT CAPACITY. Equipment capacity and run time also influences what refrigerant blend to incorporate in a system. One blend may have a lower capacity than another. Often, air-conditioning systems have an "off" cycle. The systems are designed for the hottest days of the year, but on milder days the system will cycle off. By having longer run or "on" times, these systems can tolerate a lower-capacity blend. This also holds true for refrigeration storage facilities.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

However, refrigerants in systems that run all of the time are sized to load match, or exactly match, the capacity of the load. The solution here is to use a refrigerant blend with a higher capacity so the system can run at peak performance.

EQUIPMENT SIZE. How easy a system is to retrofit is a major factor in selecting a refrigerant retrofit blend. Retrofitting larger refrigeration or air-conditioning systems may require lubricant changes, component replacement, adjustment of controls, and maybe even seal and gasket changes. This often requires planned shut-downs and will generally be time-consuming and expensive. Choosing a retrofit blend based on performance and property matches that minimize component changes will be more important than "ease of retrofit" issues such as changing oil. On the other hand, smaller equipment may not provide direct access to the oil and may not have parts that can be individually changed. In this case, retrofit blends that minimize the work to be done during retrofits may be desirable even though performance may suffer. Often, depending on the equipment's age and condition, simply replacing the entire unit may be the more economical solution with smaller equipment.

ADDITION OF POLYOL ESTER (POE) LUBRICANT OR PARTIAL POE LUBRICANT REPLACEMENT. The retrofit refrigerant blends just listed are all HFC-based blends. Some contain hydrocarbons (HC) like R-600 (butane) and R-600a (isobutane). The small percentages of hydrocarbons help with oil return to the compressor. The hydrocarbons will soak into the mineral oil and thin it so it can be more easily returned to the compressor's crankcase on the low side of the system. However, for larger refrigeration and air-conditioning systems with receivers, oil that escapes the compressor will eventually form a layer on top of the liquid refrigerant in the receiver. These hydrocarbons will not mix with the liquid oil layer in the receiver on the high side. The solution is the addition of some POE lubricant or partial POE replacement of the mineral oil to help dissolve the oil back into the liquid refrigerant in the receiver and keep it in circulation through the refrigeration or air-conditioning system. Eventually, this lubricant will make it back to the compressor's crankcase.

In conclusion, no refrigerant blend will be a perfect drop-in replacement for retrofitting R-22 systems. Each refrigerant blend has advantages and disadvantages. These advantages and disadvantages have to be balanced to choose the best overall choice for your specific application.

NOTE: *Always consult with the refrigerant manufacturer or the compressor manufacturer and follow their specific retrofit guidelines before performing a retrofit on any R-22 system or any other refrigeration and/or air-conditioning system.* •

What follows are excerpts from DuPont Fluorochemical's "Refrigerant Changeover Guidelines" for replacing HCFC-22 with HFC-407C. These guidelines are used with permission from DuPont Fluorochemicals, Wilmington, DE. All retrofit refrigerants for R-22 have retrofit guidelines, and R-407C was arbitrarily chosen as an example for the reader.

DuPont™ Suva®

Refrigerants

RETROFIT GUIDELINES FOR DUPONT™ SUVA® 407C

Introduction

Over the past five decades, HCFC-22 (R-22) has been used as a refrigerant in various refrigeration, industrial cooling, air conditioning, and heating applications. The low ozone depleting potential of R-22 compared to CFC-11 and CFC-12, along with its excellent refrigerant properties have helped facilitate the transition from CFCs. However, HCFCs, including R-22, are scheduled for eventual phaseout under the Montreal Protocol. DuPont supports the current Montreal Protocol phaseout schedule for HCFCs and is committed to helping the industry prepare for the eventual phaseout of R-22. DuPont has developed DuPont™ Suva® 407C as the similar pressure replacement for R-22 in positive displacement, direct expansion air conditioners and heat pumps. This refrigerant is also suitable for use in many medium temperature refrigeration systems that formerly used R-22. Suva® 407C is the registered trademark for a blend of HFC-32/HFC-125/HFC-134a with a corresponding composition of 23/25/52 wt.%. Suva® 407C is commercially available for retrofit of existing equipment and as a long-term replacement option for R-22 in new equipment. Using these retrofit guidelines, many R-22 systems can be retrofitted for use with Suva® 407C in air conditioning, heat pump applications and refrigeration applications, to allow existing equipment to continue to operate safely and efficiently, even after R-22 is no longer available.

Environmental Properties and Safety

Suva® 407C offers improved environmental properties versus R-22, with an equivalent Global Warming Potential (GWP) and zero Ozone Depletion Potential (ODP). Refer to DuPont Technical Bulletin P-407C/410A for more detailed information on properties and performance characteristics for Suva® 407C. Refer to the Material Safety Data Sheet (MSDS) for safety information on the use of this product.

Materials Compatibility

The compatibility of plastics and elastomers should be considered before retrofitting to Suva® 407C/polyol ester oil. Testing shows that there will be no one family of elastomers or plastics that will work with all the alternative refrigerants. It is recommended that gaskets, shaft seals, and O-rings be reviewed with the equipment manufacturer before retrofit. Field experience has shown that

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

some systems retrofitted directly from CFC or HCFC to HFC refrigerants can have increased leakage of elastomers (o-rings, gaskets) following removal of the CFC or HCFC refrigerant even if the existing elastomer is compatible with the HFC refrigerant. This is because the old elastomers will have swelled a certain amount due to exposure to the CFC or HCFC refrigerant and will swell a different amount when exposed to the HFC. The difference in swelling may cause a poor seal. If this problem is encountered, replace the used-rings with new ones of the same material. They will then swell due to exposure only to the new refrigerant and will seal as required. Materials compatibility information is available through the DuPont Suva Answer Line, 1-800-235-7882 or at the DuPont Suva® website, www.suva.dupont.com under hypertext link "Tech Info." On the website, general property and material compatibility information for Suva® 407C is contained in the Properties, Uses, Storage and Handling (PUSH) section. Thermodynamic property information is available in the "Tech Info" area of the website, in the Thermodynamic Properties section.

Lubricants

Lubricant selection is based on several factors, which can include lubricant return to the compressor, lubricity, and materials compatibility. Polyol ester lubricants are recommended for use in most HFC systems. There are many polyol ester lubricant manufacturers; to determine which lubricant is recommended for the refrigeration system, contact the compressor manufacturer, equipment manufacturer, or a DuPont distributor. Special care should be taken when handling polyol ester lubricants due to their tendency to absorb water. Contact with air should be minimized, and the lubricant should be stored in a sealed metal container. When retrofitting R-22/mineral oil systems to Suva® 407C/polyol ester lubricant, to achieve equivalent miscibility the residual mineral oil should be around 5 wt.% or less of the total lubricant used in the system. Allowable residual mineral oil is highly dependent on system configuration and operating conditions. If the system shows signs of poor heat transfer in the evaporator or poor oil return to the compressor, it may be necessary to further reduce the residual mineral oil. A series of successive lubricant changes using polyol esters can normally reduce the mineral oil concentration to low levels. Lubricant manufacturers have developed field test methods for determining the weight percent of mineral oil in polyol ester lubricant. Contact the lubricant manufacturer for the recommended test method.

Performance Characteristics in Existing R-22 Designs

Suva® 407C provides similar energy efficiency and capacity to R-22 with a lower discharge temperature and slightly higher discharge pressure. As a result, minimal system modifications are anticipated when retrofitting R-22 systems to Suva® 407C. Original equipment manufacturers should be contacted to determine if discharge pressure controls will need to be adjusted to compensate for the higher discharge pressure.

Charging a Unit with Suva® 407C

As with any other refrigerant blend, when charging equipment with Suva® 407C, remove liquid refrigerant from the cylinder to charge the unit. Returnable cylinders containing Suva® 407C are equipped with liquid and vapor valves. The liquid valve is attached to a dip-tube that extends to the bottom of the cylinder so that liquid can be removed from the cylinder as it is standing upright. Disposable containers (DACs) have instructions and arrows printed on the container which show how to orient the container to remove liquid or vapor. Note that Suva® 407C is not designed for use in conjunction with other refrigerants. Adding Suva® 407C to any other refrigerant can form mixtures that could cause system performance problems.

Overview of Retrofit Process

Retrofit of an existing R-22 system with Suva® 407C can be accomplished using service practices and equipment commonly used by trained mechanics or service contractors in the field.

The key steps involved in the retrofit are:

- Begin with baseline data for R-22.
- Remove mineral oil or alkylbenzene oil from compressor, and replace with a recommended polyol ester (POE) lubricant. Run system for at least 8 hours or more if system has complex tubing circuits, and determine residual oil content. Perform additional lubricant changes if necessary. Three or four lubricant changes are usually sufficient to get the residual oil content in the POE down to 5% or less.
- Recover R-22 charge from the system.
- Replace filter/drier with new drier compatible with the retrofit refrigerant and POE lubricant.
- Charge system with the retrofit refrigerant.
- Start system, and adjust charge and/or controls to achieve desired operation.

For the majority of systems, the compressor lubricant charge, a filter/drier change, and a possible adjustment to the superheat setting (in systems with expansion valves) will be the only system modifications required in a retrofit to Suva® 407C. For systems that are still under warranty, we recommend contacting the equipment or compressor manufacturers prior to performing the retrofit. Some equipment or compressor warranties may be impacted by a change from the refrigerant or lubricant originally

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

specified for the system or compressor. Most compressor manufacturers are familiar with Suva® 407C and can give an indication of how the compressor will operate with the retrofit refrigerant.

Equipment and Supplies Needed for Retrofit

- Safety equipment (gloves, glasses)
- Manifold gauges
- Thermocouples to read line temperatures
- Vacuum pump
- Leak detection equipment
- Scale
- Recovery unit
- Recovery cylinder
- Container for recovered lubricant
- Replacement lubricant
- Replacement refrigerant
- Replacement filter/drier
- Labels indicating the refrigerant and lubricant charged into the system

Retrofit Procedure

Summarized as follows is a more detailed discussion of the recommended procedure for retrofitting an R-22 system to Suva® 407C.

1. **Begin with Baseline Data for R-22.** For service contractors performing their initial retrofits with Suva® 407C, it is recommended that system performance data be collected while R-22 remains in the systems. Check for correct refrigerant charge and operating conditions. The baseline of temperatures and pressures with the correct charge of R-22 at various points in the system (evaporator, condenser, compressor suction and discharge, expansion device, etc.) will be useful when optimizing operation of the system with Suva® 407C. A System Data Sheet is attached for recording this baseline data.
2. **Drain/Charge System Lubricant.** Where mineral oil or alkylbenzene oil is the existing lubricant in the system, it will have to be drained. This may require removing the compressor from the system, particularly with small hermetic compressors that have no oil drain. In this case, the lubricant can be drained from the suction line of the compressor. In most small systems, 90 to 95% of the lubricant can be removed from the compressor in this manner. Larger systems may require drainage from additional points in the system, particularly low spots around the evaporator, to remove the majority of the lubricant. In systems with an oil separator, any lubricant present in the separator should also be drained.

   In all cases, *measure* the volume of lubricant removed from the system. Compare to the compressor/system specifications to ensure that the majority of lubricant has been removed. Polyol ester lubricant is recommended for use with Suva® 407C. In order to achieve equivalent miscibility to R-22/oil, the residual oil should be about 5 wt.% or less of the total lubricant used in the system. In larger systems, this amount of residual mineral oil can be achieved by using a flushing technique. Three or more lubricant flushes may be required. Lubricant flushes involve:

   - Draining existing lubricant from the system, as described.
   - Selecting a polyol ester lubricant with similar viscosity to the existing lubricant.
   - Charging an amount of polyol ester equal to the amount of lubricant removed.
   - Running the system with R-22 for thorough mixing of polyol ester/existing lubricant (48 to 72 hours of operation may be required).

   Repeat these steps two more times. On the last flush, R-22 will be replaced with the retrofit refrigerant.
3. **Remove R-22 Charge.** R-22 should be removed from the system and collected in a recovery cylinder using a recovery device capable of pulling 10 to 20 in. Hg vacuum (34 to 67 kPa, 0.34 to 0.67 bar). If the correct R-22 charge size for the system is not known, weigh the amount of refrigerant removed, as the initial quantity of the retrofit refrigerant charged in the system will be determined from this figure.
4. **Reinstall Compressor** (if removed from system in Step 2). Use normal service practice.
5. **Replace Filter/Drier.** It is routine practice to replace the filter/drier following system maintenance. There are two types of filter/driers commonly used in R-22 equipment:

   a. Loose fill driers, which contain only the molecular sieve desiccant.

   b. Solid core driers, in which the molecular sieve desiccant is dispersed within a solid core binder. XH-11 desiccant from UOP is compatible with Suva® 407C, making it a suitable replacement for use in loose fill driers with these refrigerants. For solid core driers, consult the drier manufacturer for their recommended drier for use with Suva® 407C. In the United States, Sporlan and Alco have solid core driers, which show acceptable compatibility with this new refrigerant.

6. **Reconnect System and Evacuate.** Use normal service practices. To remove air or other noncondensables in the system, evacuate the system to near full vacuum (29.9 in, 500 microns, 0.14 kPa, 0.0014 bar).
7. **Leak Check System.** Use normal service practices. If a leak detector is used, consult the leak detector

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

manufacturer for the unit's sensitivity to Suva® 407C. Re-evacuate the system following leak check if necessary.

8. **Charge System with Suva® 407C.** This refrigerant should be removed from the cylinder as a liquid. *The proper cylinder position for liquid removal is indicated by arrows on the cylinder and cylinder box*. Once liquid is removed from the cylinder, the refrigerant can be charged to the system as liquid or vapor as required. Use the manifold gauge set or a throttling valve to flash the liquid to vapor if needed. The refrigerant system will typically require less weight of Suva® 407C than R-22. The optimum charge will vary depending on the operating conditions, size of the evaporator and condenser, size of the receiver (if present), and the length of pipe or tubing runs in the system. For most systems, the optimum retrofit refrigerant charge will be between 90 and 95% by weight of the original equipment manufacturer's R-22 charge. It is recommended that the system be initially charged with the retrofit refrigerant to about 80% by weight of the correct R-22 charge. Add as much as possible of the initial charge to the high pressure side of the system (compressor not running). When the system and cylinder pressures equilibrate, load the remainder of the refrigerant into the suction side of the system (compressor running). Liquid refrigerant should never be allowed to enter the suction side of the compressor.
9. **Start Up System and Adjust Charge.** Start up the system and let conditions stabilize. If the system is undercharged, add more of the retrofit refrigerant in small amounts until the system conditions reach the desired levels. Refer to this refrigerant Pressure-Temperature chart to compare system operating

pressures and temperatures with those of R-22. Suva® 407C will have higher discharge pressures and lower discharge temperatures when compared to R-22 operation.

10. **Note: Label Components and System.** After retrofitting the system with Suva® 407C, label the system components to identify the refrigerant and lubricant in the system, so that the proper refrigerant and lubricant will be used to service the equipment in the future. Suva® refrigerant identification labels are available from DuPont.

Summary

With the phaseout of CFCs and HCFCs, existing refrigeration equipment will need to be replaced with new equipment or retrofitted with alternative refrigerants. Using the procedures described, existing refrigerant R-22 systems can be retrofitted for use with Suva® 407C, allowing them to continue in service for the remainder of their useful life.

9.22 REFRIGERANTS AND TOOLS IN THE FUTURE

All refrigerants in the future will have to be environmentally friendly. Soon, all refrigerants will have 0 ODPs and very low GWPs. It will pay the technician of the future to stay up-to-date on all developments as they occur, for example, by joining local trade organizations that watch

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

industry trends. Each technician should make an effort to know what the latest information and technology is and practice the best techniques available. The tools used to handle refrigerant will also change in the future. One improvement needed is gauge lines that will not leak refrigerant. Many older gauge lines seep refrigerant while connected. Gauge lines are required to have valves to reduce the amount of refrigerant lost when they are disconnected from Schrader connections. These valves are located at the end of the hoses to hold the refrigerant in the hose when disconnected, **Figure 9.45**.

Figure 9.45 Quick-couples or quick-connects to help reduce refrigerant loss.

SUMMARY

- Refrigerants must not be vented into the atmosphere.
- Ozone is a form of oxygen, with each molecule consisting of three atoms of oxygen (O_3). The oxygen we breathe contains two atoms of oxygen (O_2).
- The ozone layer, located in the stratosphere 7 to 30 miles above the earth's surface, protects the earth from harmful ultraviolet rays from the sun, which can cause damage to human beings, animals, and plants.
- Ozone depletion potentials (ODPs) have been established by the Montreal Protocol.
- Global warming is a process that takes place in the lower atmosphere, or troposphere.
- Global warming has both direct and indirect effects.
- Global warming potentials (GWPs) are assigned to refrigerants.
- Chlorofluorocarbons (CFCs) contain chlorine, fluorine, and carbon atoms.
- Hydrochlorofluorocarbons (HCFCs) contain hydrogen, chlorine, fluorine, and carbon atoms.
- Hydrofluorocarbons (HFCs) contain hydrogen, fluorine, and carbon atoms.
- Some hydrocarbons (HCs) are entering the market as a component of refrigerant blends to assist with oil return to the compressor.
- Both zeotropic and azeotropic refrigerant blends have become very popular as replacements for both CFC and HCFC refrigerants.
- Both near-azeotropic and zeotropic blends exhibit temperature glide and fractionation when they evaporate and condense.
- Synthetic oils have gained popularity and are being used with a lot of the newer refrigerants.
- Refrigerant and oil retrofitting guidelines have been established for service purposes because of the transition to newer refrigerants and oils.
- To recover refrigerant is "to remove refrigerant in any condition from a system and store it in an external container without necessarily testing or processing it in any way."
- To recycle refrigerant is "to clean the refrigerant by oil separation and single or multiple passes through devices, such as replaceable core filter-driers, which reduce moisture, acidity, and particulate matter. This term usually applies to procedures implemented at the job site or at a local service shop."
- To reclaim refrigerant is "to process refrigerant to new product specifications by means which may include distillation. It will require chemical analysis of the refrigerant to determine that appropriate product specifications are met. This term usually implies the use of processes or procedures available only at a reprocessing or manufacturing facility."
- Active recovery involves recovering refrigerant through the use of a certified self-contained recovery machine.
- Passive recovery or system-dependent recovery is the use of the internal pressure of the system and/or the system's compressor to aid in the refrigerant recovery process.
- Recovery from small appliances involves the use of different methods and different evacuation levels.
- Refrigerant can be transferred only into Department of Transportation (DOT)–approved cylinders and tanks.
- Manufacturers have developed many types of equipment to recover and recycle refrigerant.
- Most modern refrigerant recovery units being manufactured today are oil-less to avoid cross-contamination of oil in refrigeration systems and allow them to handle multiple refrigerants.

REVIEW QUESTIONS

1. What is the difference between the oxygen we breathe and the ozone located in the earth's stratosphere?
2. Describe the difference between good and bad ozone.
3. Explain the process of ozone depletion resulting from the breaking up of a CFC molecule in the stratosphere.
4. Which refrigerants have a 0 ODP?
   A. HFCs
   B. HCFCs
   C. CFCs
   D. Both A and B
5. An increase in the natural greenhouse effect that leads to heating of the earth is called _____.
6. True or False: Only CFCs and HCFCs contribute to global warming.
7. Explain what a global warming potential (GWP) is.
8. Describe the differences between global warming and ozone depletion.
9. Describe the difference between a direct and an indirect global warming potential.
10. What measurement or index takes into consideration both the indirect and direct global warming effects of refrigerants?
    A. Total equivalent warming impact (TEWI)
    B. Greenhouse effect number
    C. Global warming number
    D. Greenhouse effect index
11. Describe the differences between CFCs, HCFCs, HFCs, and HCs.
12. CFCs are more harmful to the stratospheric ozone layer than HCFCs because they contain _____.
13. True or False: HFCs do not damage the ozone layer but still contribute to global warming.
14. Describe the difference between an azeotropic refrigerant blend and a near-azeotropic or zeotropic refrigerant blend.
15. Why are there more safety precautions for R-410A than with other popular refrigerants like R-22 and R-404A?
16. The three most popular synthetic oils in the refrigeration and air-conditioning industry are _____, _____, and _____.
17. What is the name of the conference that was held in Canada in 1987 to attempt to solve the problem of refrigerants released into the atmosphere?
18. What agency of the federal government is charged with implementing the United States Clean Air Act Amendments of 1990?
19. Explain the differences between active and passive recovery methods.
20. Are federal excise taxes on reclaimed refrigerants the same as those for new refrigerants?
21. To recover refrigerant means to _____.
22. To recycle refrigerant means to _____.
23. To reclaim refrigerant means to _____.
24. Explain what is meant by a nonpressurized recovery container, and briefly explain which applications it is used for.
25. What is the name of the federal agency that must approve containers into which refrigerant may be transferred?
26. What is a quick-couple or quick-connect and where are they used?
27. The standard that a refrigerant must meet after it has been reclaimed and before it can be sold to another owner is
    A. ANSI 7000.
    B. ANSI 700.
    C. EPA 7000.
    D. AHRI 700.
28. Briefly describe the two types of piercing valves used in the industry, and list some advantages and disadvantages of both.
29. Briefly describe an oil-less refrigerant recovery unit.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

UNIT 10

SYSTEM CHARGING

OBJECTIVES

After studying this unit, you should be able to

- describe how refrigerant is charged into systems in the vapor and liquid states.
- state the advantage of using electronic scales for weighing refrigerant into a system.
- describe the terms "temperature glide" and "fractionation" as they apply to blended refrigerants.
- charge air-conditioning systems with fixed orifice, capillary tube, or piston-type metering devices using charging charts and curves.
- use the subcooling method of charging to charge air-conditioning and heat pump systems that incorporate a thermostatic expansion valve (TXV) as the metering device.
- use temperature/pressure charts to help properly charge air-conditioning and refrigeration systems.
- differentiate between "bubble point" and "dew point" values on a temperature/pressure chart and properly use these values to calculate superheat and subcooling values on systems that operate with blended refrigerants.

SAFETYCHECKLIST

- ☑ Never use a torch to apply heat to a refrigerant cylinder. If needed, place the refrigerant tank in a tub of warm water no hotter than 90°F.
- ☑ Do not charge liquid refrigerant into the suction line of a system unless it is vaporized before it reaches the compressor. Liquid refrigerant must not enter the compressor.
- ☑ Use a charging device that allows liquid refrigerant to flash into a vapor before entering the compressor. Liquid refrigerant can cause severe damage to the compressor.
- ☑ When charging blended refrigerants into a system, the refrigerant must leave the tank as a liquid to avoid fractionation.
- ☑ Wear safety glasses and gloves when working with refrigerant. Refrigerant can be extremely cold and can cause frostbite.

10.1 CHARGING A REFRIGERATION SYSTEM

System charging refers to the adding of refrigerant to a refrigeration system. *The correct charge must be added so that a refrigeration system can operate as effectively and efficiently as it was designed to. This is not always an easy task to accomplish.* Some refrigerants, namely single-compound refrigerants, may be added to the system in either the vapor or liquid states, while blended refrigerants must be charged in the liquid state. A scale should be used to determine the amount of refrigerant that is added to a system. The system's charge is evaluated by using superheat and subcooling calculations or manufacturer-supplied charging tables and charts. When using system charging charts and tables to evaluate the system charge, a number of factors should be taken into account. These factors include, but are not limited to, high- and low-side saturation pressures and temperatures, ambient temperatures, evaporator superheat, condenser subcooling, compressor amperage draw, and temperature differentials across heat exchange surfaces.

This unit describes how to add the refrigerant correctly and safely in the vapor and the liquid state. The correct charge for a particular system will be discussed in the unit where that system is covered. Heat pump charging, for example, is covered in Unit 43, "Air Source Heat Pumps."

10.2 VAPOR REFRIGERANT CHARGING

The **vapor refrigerant charging** of a system is accomplished by allowing vapor to flow out of the refrigerant cylinder and into the refrigeration system. When the pressure in the system is lower than the pressure in the refrigerant tank—for example, when the system has just been evacuated—refrigerant can be added to both the high- and low-pressure sides of the system. This is because the pressure on both sides of the system is lower than the pressure in the refrigerant tank. Remember that high pressure flows to low pressure.

When the system is operating, however, refrigerant must be added to the low-pressure side of the system. This is because the compressor raises the pressure of the refrigerant on the high side of the system and lowers the pressure on the low side. The high-side pressure of an operating refrigeration system is typically higher than the pressure of the refrigerant in the tank. For example, an R-134a system may have a head pressure of 185 psig on a 95°F day (this is determined by taking the outside temperature of 95°F and adding 30°F, which gives a condensing temperature of 125°F, which corresponds to a pressure of 185 psig for R-134a). The cylinder is exposed to the same ambient temperature of 95°F but the refrigerant, assuming that it is saturated, is at a pressure of only 114 psig (from the temperature/pressure chart), **Figure 10.1**. It should be noted that, if valve B in **Figure 10.1** is opened, refrigerant will flow toward the refrigerant tank. If the tank is a "one-trip" tank that is used only for new, "virgin" refrigerant, the

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 10.1 This refrigerant cylinder has a pressure of 114 psig. The high side of the system has a pressure of 185 psig. Pressure in the system will prevent the refrigerant in the cylinder from flowing into the system.

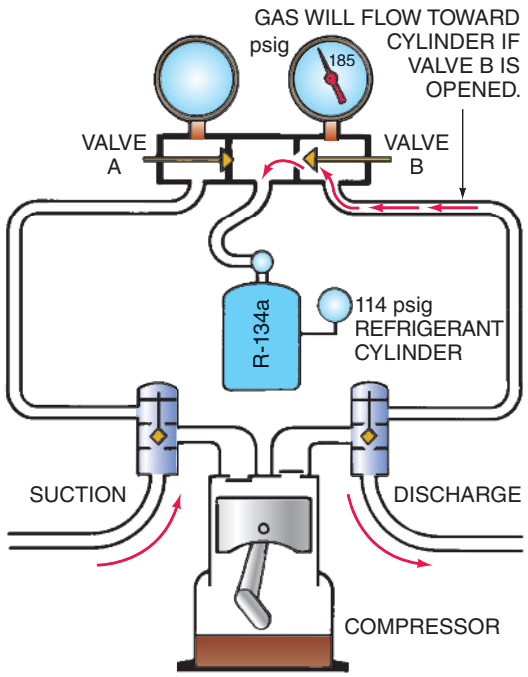

Figure 10.2 The temperature of the cylinder is 95°F. The pressure inside the cylinder is 114 psig. The low-side pressure is 20 psig.

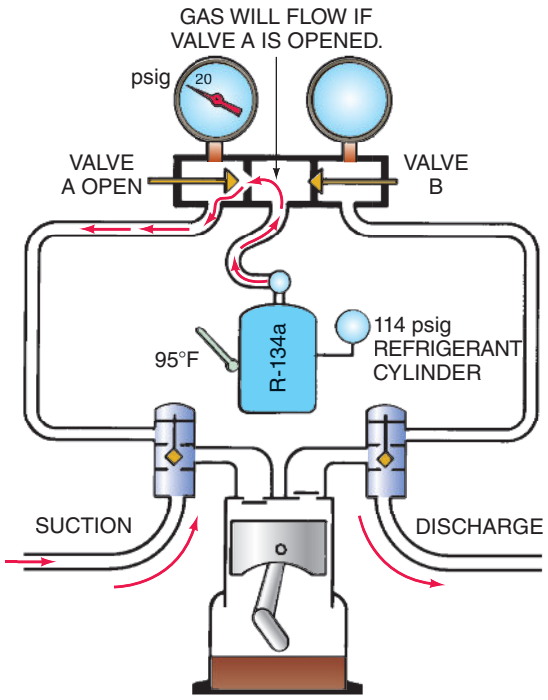
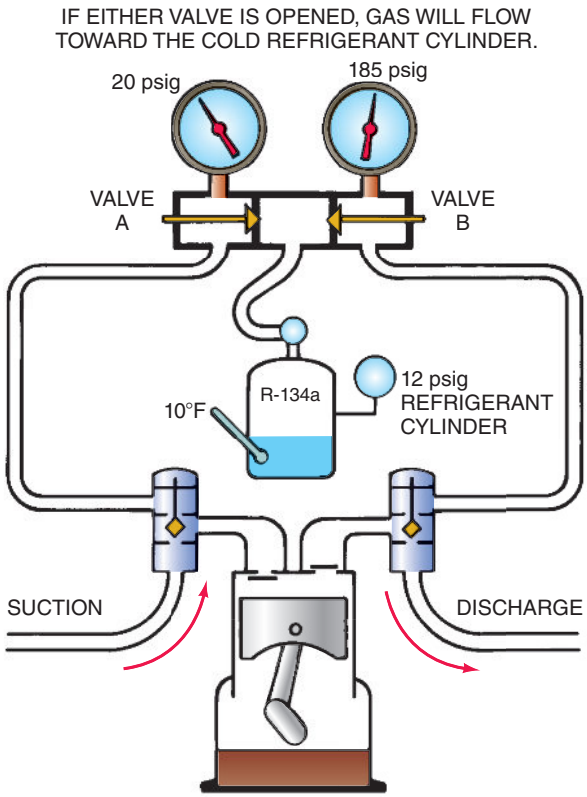


refrigerant will not enter the tank. This is because one-trip tanks are manufactured with check valves that only allow refrigerant to leave the tank, not enter it. If the tank is a reusable, recovery-type, tank, there are no check valves and system refrigerant can enter the tank as long as the system pressure is higher than the pressure in the tank.

The low-side pressure in an operating system is much lower than the cylinder pressure if the cylinder is warm. For example, on a 95°F day, the cylinder of saturated R-134a will have a pressure of 114 psig, but the evaporator pressure may be only 20 psig. Refrigerant will easily move into the system from the cylinder, **Figure 10.2**. In the winter, however, the cylinder may have been in the back of a truck all night, and its pressure may be lower than the low side of the system, **Figure 10.3**. In this case, the cylinder will have to be warmed to get refrigerant to move from the cylinder to the system. It is a good idea to have a cylinder of refrigerant stored in the equipment room of large installations. It will always be there in case you have no refrigerant in the truck, and the cylinder will be at room temperature even in cold weather.

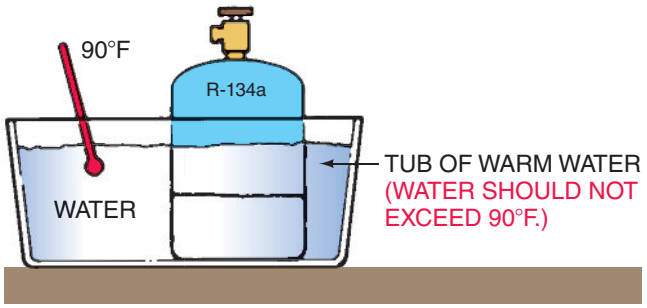
When vapor refrigerant is pulled out of a refrigerant cylinder, the vapor pressure is reduced and the liquid boils to replace the vapor that is leaving. This reduction in vapor pressure causes a lower saturation temperature for both the liquid and the vapor in the cylinder because of the associated temperature/pressure relationship. As more and more vapor is released from the cylinder, the liquid in the bottom of the cylinder continues to boil and its temperature decreases. If enough refrigerant is released, the cylinder pressure will decrease to the

Figure 10.3 The refrigerant in this cylinder is at a low temperature and pressure because it has been in the back of a service truck all night in cold weather. The cylinder pressure is 12 psig, which corresponds to 10°F. The pressure in the system is 20 psig.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 10.4 This refrigerant cylinder is in warm water to keep the pressure up.



low-side pressure of the system. Heat will have to be added to the liquid refrigerant to keep the pressure up. **SAFETY PRECAUTION:** *Never use concentrated heat from a torch. Gentle heat, such as the heat from a tub of warm water, is safer. The water temperature should not exceed 90°F. Electric heating blankets manufactured for this purpose are also safe to use.* This will maintain a cylinder pressure of 105 psig for R-134a if the refrigerant temperature is the same as the temperature of the water in the tub, **Figure 10.4**. A water temperature of 90°F is desired because it is the approximate temperature of the human hand. If the water begins to feel warm, it is getting too hot.

The larger the volume of the liquid refrigerant in the bottom of the cylinder, the longer the cylinder will maintain the pressure. When large amounts of refrigerant must be charged into a system, use the largest cylinder available. For example, do not use a 30-lb cylinder to charge 25 lb of refrigerant into a system if a 125-lb cylinder is available.

If you are planning on charging vapor into a system that is operating with a blended refrigerant, care must be taken to ensure that the blend does not fractionate, or separate into its component parts. Refer to Section 10.8 in this unit as well as Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting," for important information regarding blended refrigerants and the charging procedures that must be used when working with them.

10.3 LIQUID REFRIGERANT CHARGING

Liquid refrigerant charging of a system is normally accomplished in the liquid line. For example, when a system is out of refrigerant, liquid refrigerant can be charged into the **king valve** on the liquid line or receiver, **Figure 10.5**. If the system is in a vacuum or has been evacuated, you can allow liquid refrigerant to enter the system until flow has nearly stopped. Upon entering the system, the liquid refrigerant will move toward the evaporator and condenser coils. When the system is started, the refrigerant will be about equally divided between them, and there is no danger of liquid flooding back to the compressor, **Figure 10.6**. When large amounts of refrigerant are needed, adding the liquid through the king valve is preferable to other methods because it saves time.

The king valve is used to help perform a number of system service tasks that include taking pressure readings on the high side of the system and trapping all of the system refrigerant in the receiver. In the past, king valves were used primarily as safety valves on ammonia and sulfur dioxide systems. They were located outside the mechanical equipment rooms. By positioning the stem on the king valve so that the liquid line was sealed off, refrigerant could not leave the receiver, causing the remaining system refrigerant to become stored in the receiver. This process is referred to as "pumping down" and, in the case of sulfur dioxide systems, could be done from outside the equipment room so that the technician would not have to enter a toxic environment in the event of a refrigerant leak. Service valves that have their stems turned all the way clockwise into the valve to seal off the liquid line are referred to as *front seated*. The king valve has four positions: back seated, cracked-off-the-back-seat, midseated, and front seated, **Figure 10.7**.

Figure 10.5 Liquid-line service valve located on the refrigerant receiver.

Photo by Eugene Silberstein

The back-seated position, **Figure 10.7(A)**, is the normal operating position of the valve. Refrigerant flows freely from the receiver to the liquid line, while the service port is closed off. This is the port where the high-side gauge hose is connected. When the valve is cracked-off-the-back-seat, the service port is open to the system and the technician can take operating pressure readings from the high side of the system, **Figure 10.7(B)**. While in the cracked-off-the-back-seat position, refrigerant still flows freely from the receiver to the liquid line. The midseated position, **Figure 10.7(C)**, is used for performing standing pressure tests and for system evacuation. The front-seated position, **Figure 10.7(D)**, is used for system pumpdown. In this position, the refrigerant flows to the receiver but cannot leave it. This traps all of the system refrigerant in the receiver, enabling the technician to service the low-pressure side of the system.

When a system has a king valve, it may be front seated while the system is operating and the low-side pressure of the system will drop. This happens because the rest of the liquid line, expansion valve, evaporator, suction line, and compressor are now being starved of refrigerant. Liquid from the cylinder may be charged into the system at this time through an

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 10.6 This system is being charged while it has no refrigerant in it. The liquid refrigerant moves toward the evaporator and the condenser. No liquid refrigerant will enter the compressor.

extra charging port. The liquid from the cylinder is actually feeding the expansion device. *Be careful not to overcharge the system*, **Figure 10.8.** The low-pressure control may have to be bypassed during charging to keep it from shutting the system off. Be sure to remove the electrical bypass when charging is completed, **Figure 10.9.** **NOTE:** *Every manufacturer cautions against charging liquid refrigerant into the suction line of a compressor. Precautions must be taken when charging liquid into the suction line of a system. Liquid must be vaporized once it leaves the charging cylinder to prevent any liquid from entering the compressor, as damage can result if the compressor attempts to compress liquids, which are not compressible. When working with blended refrigerants, note that the refrigerant must leave the cylinder as a liquid in order to prevent fractionation.*

On split-type air-conditioning systems, there are service valves located in the liquid and suction lines at the points where these lines are connected to the condensing unit. These valves are configured so that when the valves are front-seated (the position they are in when the condensing unit is shipped) the service port is open to the line port. This allows the technician to pressurize the field-installed refrigerant lines for leak-testing purposes and evacuate the system without disturbing the unit's factory charge of refrigerant that is contained in the condensing unit.

Some commercially available charging devices allow the refrigerant cylinder to be attached to the suction line to charge an operating system with liquid refrigerant. These orifice-metering devices, **Figure 10.10**, act as restrictions between the gauge manifold and the system's suction line. These devices meter liquid refrigerant into the suction line, where it flashes into a vapor. The same thing may be accomplished using the gauge manifold valve, **Figure 10.11**. The pressure in the low-pressure hose on the gauge manifold is maintained at not more than 10 psig higher than the system suction pressure. This will meter the liquid refrigerant into the suction line, where it will vaporize before reaching the compressor. During the process of throttling the liquid refrigerant through the

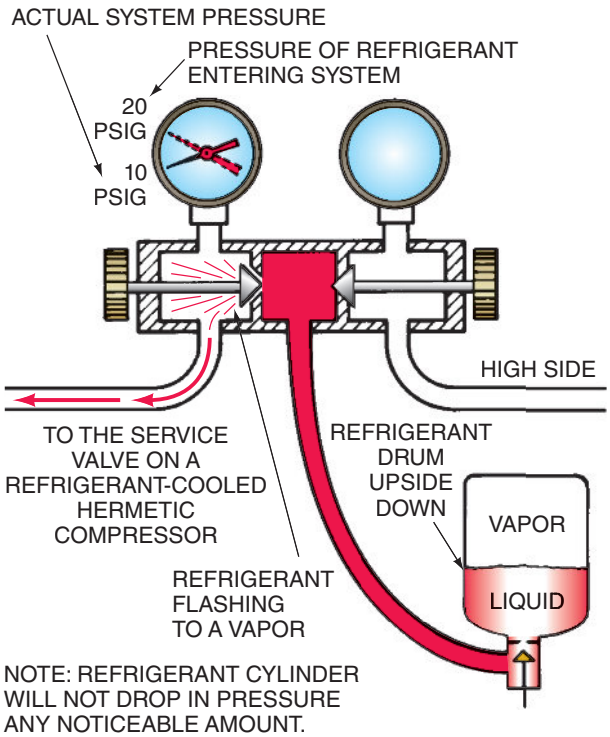
Figure 10.11 A manifold gauge set used to accomplish the same purpose as that in Figure 10.10.



gauge manifold, the portion of the gauge manifold where the center hose is connected should be warm, while the portion of the manifold where the low-side hose is connected should be cold. The temperature difference that exists between the center and low-side connections on the gauge manifold is due to the fact that the vaporizing liquid will absorb heat from the manifold. **NOTE:** *The gauge manifold valve should be used only on compressors where the suction gas passes over the motor windings. This will boil any small amounts of liquid refrigerant that may reach the compressor. If the lower portion of the compressor casing becomes cold, stop adding liquid. This process should be performed only under the supervision of an experienced person. Throttling liquid refrigerant from a charging cylinder, however, must be done when charging certain refrigerant blends to avoid fractionation, regardless of whether the compressor is refrigerant cooled or air cooled.*•

When a known amount of refrigerant must be charged into a system, it should be weighed into the system or measured in by using a graduated charging cylinder. The recommended charge for package systems such as air conditioners and refrigerated cases will be printed on the nameplate. Attempting to weigh refrigerant into the system when it contains a partial charge will lead to inaccurate charging and improper system operation. The remaining charge must first be recovered and then the system must be properly evacuated before the nameplate charge can be added to the system.

10.4 WEIGHING REFRIGERANT

Weighing refrigerant may be accomplished using various scales. Bathroom and other inaccurate scales should *not* be used. The most popular type of scale used today is the electronic scale, **Figure 10.12(A)**. These scales can be adjusted to zero with a full cylinder, **Figure 10.12(B)**, so as refrigerant

Figure 10.12 (A) Digital scale used to measure the amount of refrigerant added to or removed from the system. (B) The scale's display can be zeroed out to reduce the number of manual calculations.

is added to the system the scales read a positive value. For example, if 28 oz of refrigerant is needed in a system, put the refrigerant cylinder on the scale and set the scale at 0. As the refrigerant leaves the cylinder, the scale counts upward. When 28 oz is reached, the refrigerant flow can be stopped. Electronic scales are available with different features; some have automatic charging capability, **Figure 10.13**, which enables the technician to program the amount of refrigerant to be charged into the system. A solid-state microprocessor automatically stops the charging process once the desired amount of refrigerant has been introduced. Other electronic scales, such as the one shown in **Figure 10.14**, have unique features that include control by wireless remote.

Figure 10.14 A refrigerant charging scale that is controlled by a wireless remote.

10.5 USING CHARGING DEVICES

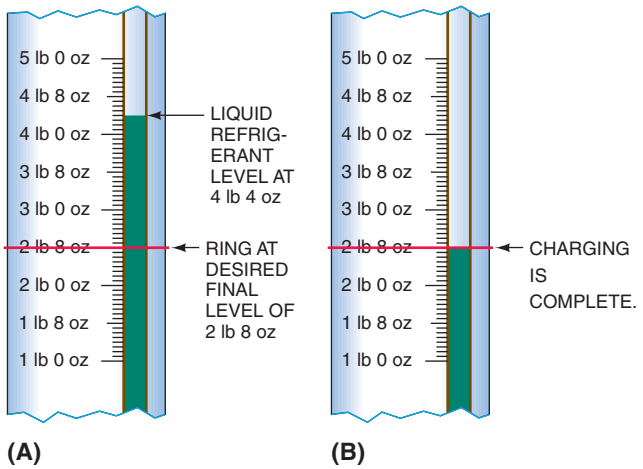
Graduated cylinders, Figure 10.15, are often used to add refrigerant to smaller air-conditioning and refrigeration systems, such as domestic refrigerators and window or through-the-wall air conditioners. These appliances have relatively small refrigerant charges ranging from a few ounces to about 2 pounds, and the actual refrigerant charge is provided on the appliance's nameplate. Charging cylinders are clear so that you can observe the liquid level inside the cylinder and have a pressure gauge located at the top from which the saturation pressure and temperature of the refrigerant is read. The saturation temperature gives the temperature of the surrounding ambient air, which is needed to properly prepare the cylinder for use. The volume of liquid refrigerant in the cylinder changes as the surrounding air temperature changes, so the cylinder must be calibrated before each use. The outer casing, or shroud, on the charging cylinder provides the calibration scales. This casing is rotated until the pressure indicated on the shroud corresponds to the pressure of the refrigerant in the charging cylinder. This calibration compensates for any changes in refrigerant volume due to temperature changes. The amount of liquid refrigerant in the cylinder, in pounds and ounces, can then be read from the graduated scale on the sides of the cylinder.

Figure 10.15 A graduated charging cylinder.

Photo by Bill Johnson

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 10.16 (A) The ring is set to the refrigerant level desired once the charging process has been completed. (B) When the refrigerant level is even with the position of the ring, the system has been charged.



Once calibrated, the amount of liquid refrigerant in the cylinder is recorded. The amount of refrigerant that must be added to the system is then subtracted from the amount in the cylinder. The result is the amount of refrigerant that must remain in the cylinder after the charging process has been completed. This level is marked with a sliding ring, **Figure 10.16(A)**. The final liquid level inside the cylinder must then be calculated.

Suppose a properly calibrated graduated cylinder contains 4 lb 4 oz of R-134a and is to be used to charge 28 oz of refrigerant into a unit. The system charge of 28 oz is subtracted from the 4 lb 4 oz as follows:

$$\text{Cylinder contains 4 lb 4 oz} = 68 \text{ oz}$$

Then

$$68 \text{ oz} - 28 \text{ oz} = 40 \text{ oz}$$

is the final cylinder level:

$$40 \text{ oz} \div 16 \text{ oz/lb} = 2.5 \text{ lb} = 2 \text{ lb } 8 \text{ oz}$$

The sliding ring is then positioned at the 2 lb 8 oz mark on the cylinder. When the charging process is completed, the level of the liquid refrigerant in the graduated charging cylinder will be level with the sliding ring, **Figure 10.16(B)**. Some graduated cylinders have heaters in the bottom to keep the refrigerant temperature from dropping when vapor is pulled from the cylinder or when it is being used in a cold surrounding temperature.

When selecting a graduated cylinder for charging purposes, be sure to select one that is large enough for the systems with which you will be working. It is difficult to use a cylinder twice for one accurate charge. When charging systems with more than one type of refrigerant, you need a charging cylinder for each type.

Other available refrigerant charging devices may be more convenient to use when charging refrigerant into a system. **Figure 10.17** is an example of one of these. This device can be set to charge a system using pressure or weight. A predetermined amount of refrigerant can be charged in 1-oz increments. This type of device also has many other features, so be sure to follow the manufacturer's instructions carefully.

10.6 USING CHARGING CHARTS

Some manufacturers supply charts or curves, called *charging charts* or **charging curves, Figure 10.18**, to assist the service technician in correctly charging air-conditioning and heat pump units. The style and type of superheat charging chart or curve may vary with the manufacturer. Often, the type of charging chart supplied depends on what type of metering device the equipment incorporates. In the HVAC/R industry, charging charts or curves that utilize superheat measurements, such as the one shown in **Figure 10.18**, are typically used in conjunction with fixed-bore metering devices—capillary tubes, fixed orifices, and pistons (short-tube devices). Charging curves that rely on subcooling measurements are typically used on systems that are equipped with thermostatic expansion valves. The same basic underlying principles hold for just about all charging curves or charts. However, the safest and most accurate way to charge any unit is to follow the manufacturer's charging instructions on the unit or in a manual supplied with the unit.

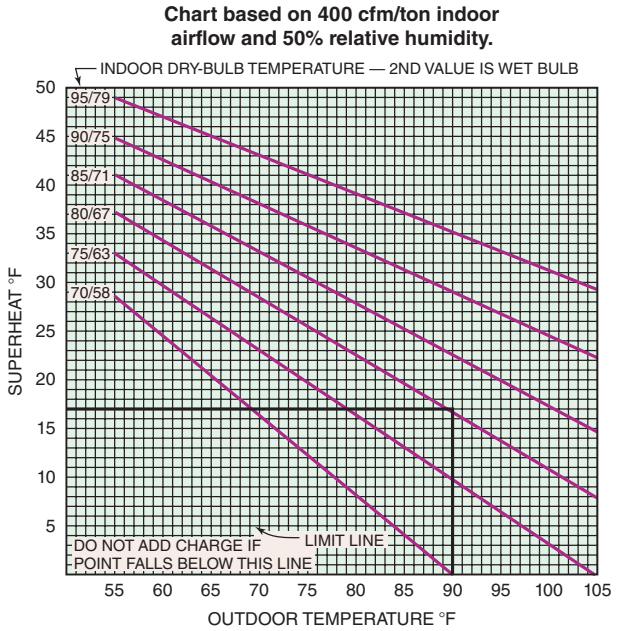
The charging curve in **Figure 10.18** is based on 400 cfm/ton of airflow at 50% relative humidity across the evaporator coil. To use a charging curve to charge a split air-conditioning system that incorporates a capillary tube for a metering device, follow these steps:

Step 1 Measure the indoor dry-bulb temperature (DBT). This is the return air at the air handler. **NOTE:** *Use wet-bulb temperature (WBT) if the percentage of relative humidity is above 70% or below 20%.* •

Step 2 Measure the outdoor DBT at the outdoor unit. This is the temperature of the air coming into the condenser.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 10.18 A charging curve used for charging a split-type air-conditioning system that incorporates a capillary tube metering device.



Step 3 Measure the suction pressure at the service valve on the outdoor condensing unit and convert to a temperature using a temperature/pressure chart.

Step 4 Measure the suction-line inlet temperature on the suction line near the service valve on the outdoor condensing unit.

Step 5 Calculate the amount of superheat by subtracting the temperature obtained in step 3 from the temperature obtained in step 4.

Step 6 Find the intersection where the outdoor temperature and the indoor temperature meet and read the degrees of superheat.

The superheat that is being calculated here is *not* the evaporator superheat. Since the suction-line temperature reading is being taken from a point near the compressor, the sensible heat being picked up in the suction line is included in the calculation. This superheat calculation is often referred to as the **system superheat**. If the superheat of the system is more than 5°F above what the charging chart reads, add refrigerant into the low side of the operating system until the superheat is within 5°F of the chart. If the superheat of the system is more than 5°F below what the chart reads, recover some refrigerant from the system until the superheat is within 5°F of the chart.

NOTE: *Always let the system run for at least 15 min after adding refrigerant or recovering refrigerant before recalculating system superheat. To avoid fractionation in the charging cylinder when using a refrigerant blend that has a temperature glide and fractionation potential, liquid refrigerant has to be taken from the charging cylinder and then throttled into the low side of the system as a vapor while the system is running. For a review of refrigerant blends with temperature glide and fractionation potential, refer to Unit 9, "Refrigeration and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting."* •

Example

R-22 capillary tube or fixed orifice system
Indoor DBT = 80°F
Outdoor DBT = 90°F
Suction pressure at service valve of condensing unit = 60 psig or 34°F using a P/T chart
Suction-line temperature at service valve = 54°F
System superheat is (54°F – 34°F) = 20°F

The intersection of the 90°F outdoor temperature with the 80°F indoor temperature indicates that there should be about 17°F of superheat. The system has 20°F of superheat, which is within 5°F of the superheat chart, so the system is fully charged. The technician would not have to add any refrigerant to the system.

The theory behind these charging curves is simple. Let us take the charging curve in **Figure 10.18** as an example. As you move to the right on the bottom axis, the outdoor temperature rises. Notice that for a constant indoor DBT or WBT (lines that slant downward from left to right), the operating compressor superheat decreases as the outdoor ambient temperature increases. The reason for this is that there is now more head pressure on the high side of the system pushing the subcooled liquid out of the condenser's bottom through the liquid line and the capillary tube metering device. This will force more refrigerant into the evaporator and give less superheat. This explains why some air-conditioning systems incorporating capillary tubes or fixed orifice metering devices will flood or slug liquid at the compressor on a day with hot outdoor ambient temperatures when the devices are overcharged. The superheat curve will prevent this from occurring if it is followed properly.

Referring to **Figure 10.18**, if we assume a constant indoor DBT of 75°F across the evaporator coil and increase the outdoor DBT from 70°F to 105°F, we can see that the operating compressor superheat will fall from 23°F to 0°F. The hotter outdoor ambient temperature results in higher head pressures, pushing more liquid through the capillary tube and into the evaporator. So it is normal for the system to run with 23°F of compressor superheat when the outdoor ambient temperature is 70°F. Do not add any refrigerant to this system, because if the outdoor ambient temperature climbed to 95°F later in the day, the system's compressor would slug liquid or flood.

NOTE: *In terms of the manufacturer's charging curve in **Figure 10.18**, if the relative humidity is above 70% or below 20%, use WBTs instead of DBTs across the evaporator coil to compensate for the varying latent (moisture) loads.* •

If the outdoor temperature stays constant and the indoor DBT or indoor WBT increases, the operating superheat will increase. This loading of the indoor coil with either sensible or latent heat or both will cause a more rapid vaporization of refrigerant in the evaporator. This will cause high compressor superheat, a normal occurrence. Many technicians will add refrigerant in this case and overcharge the system. It is completely normal for a capillary or fixed orifice metering device system to run with high superheat at high evaporator loadings.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Again referring to **Figure 10.18**, as the outdoor ambient temperature stays constant at 95°F, and the indoor DBT across the evaporator coil rises from 75°F to 95°F, the operating superheat will rise from 6°F to 33°F. At a 95°F indoor air DBT and a 95°F outdoor air DBT, the superheat should normally be 33°F, according to the chart. These conditions make for an inefficient system and an inactive evaporator, which is the greatest disadvantage of a fixed orifice metering device. However, this is the only way to prevent slugging and flooding of refrigerant with the varying indoor and outdoor loads that air-conditioning systems often experience.

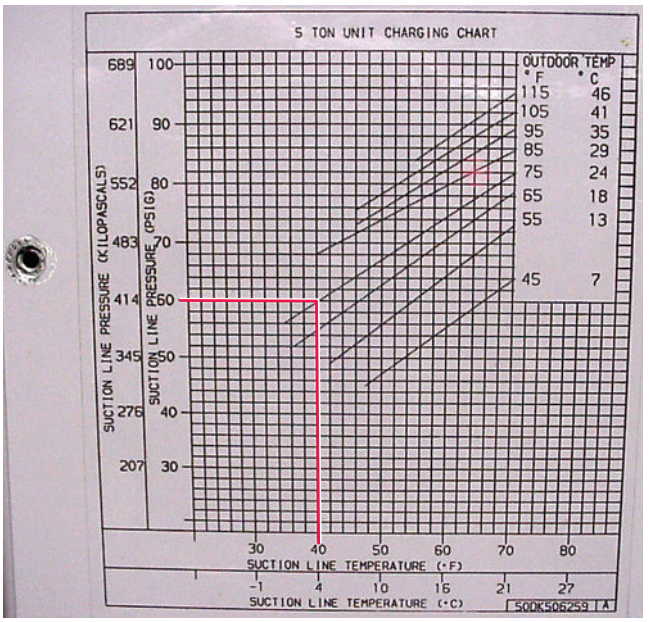
Although charging capillary tube, fixed orifice, and piston (short-tube) systems in air-conditioning applications follow much the same underlying idea, we strongly recommend that the technician consult with the equipment manufacturers to determine the exact methods for charging, following their charging curves and tables. Some manufacturers use different curves and tables for different models of their equipment. Some manufacturers have eliminated the need for a WBT because of custom-made charging curves that represent their laboratory tests on the equipment.

Figure 10.19 is a charging chart for a 5-ton, unitary air-conditioning system using a capillary tube as a metering device. This charging chart was affixed to the side of the unit by the manufacturer to help the service technician in servicing and charging the unit. There are only three variables on the chart: the outdoor temperature, suction-line temperature, and suction pressure. The service technician must first establish what the outdoor ambient temperature is and then read the suction-pressure gauge at the condensing unit's service valve. With these two conditions known and the charging chart handy, the technician can determine what the appropriate suction-line temperature entering the condensing unit at the service valve should be. If the suction-line temperature is high, add some refrigerant; if the suction-line temperature is low, recover some refrigerant.

Example: R-22 system

Outdoor temperature = 75°F
Suction pressure = 60 psig
Suction-line temperature at the condensing unit's service valve should be 40°F (see **Figure 10.19**).

Figure 10.19 A charging chart from the side of a 5-ton, unitary air-conditioning system.



Courtesy Ferris State University, Photo by John Tomczyk

If the suction-line temperature measured at the service valve is 60°F, the service technician would have to add refrigerant. If the temperature measured is 32°F, the service technician would have to recover some refrigerant from the unit. Always give the unit an ample amount of time (15 to 20 min) to reach equilibrium when adding or removing refrigerant and before using the charging chart again. It is much easier to add refrigerant to reach the correct charge than to remove refrigerant to reach the correct charge level.

Although the goal of charging charts, curves, and tables is the same, their appearance may differ. Some manufacturers provide two charts that, when used together, allow the technician to properly charge the system. The charts in **Figure 10.20** and **Figure 10.21** are for an R-410A system. What follows is a set of sample guidelines only; be sure to check with the manufacturer of the equipment for specific

Figure 10.20 This table provides superheat information based on outdoor air temperature and the wet-bulb temperature of the air entering the evaporator.

charging procedures to make certain you get it right the first time!

1. Start up the system and allow it to operate for at least 10 min.
2. Obtain the suction pressure at the inlet of the condensing unit.
3. Obtain the suction-line temperature at the condensing unit using a high-quality thermistor-type thermometer.
4. Measure the outside air temperature using a high-quality thermometer.
5. Measure the wet-bulb temperature of the air entering the evaporator coil with a sling psychrometer or similar instrument.
6. Using the table in **Figure 10.20**, find the intersection point between the outdoor air temperature and the wet-bulb temperature of the air entering the evaporator coil.
7. Record the superheat value from the chart at the intersection point.
8. Using the table in **Figure 10.21**, locate the superheat value recorded in step 7 in the left-hand column of the table.
9. Locate the column that corresponds to the system's suction pressure found in step 2.
10. Identify the required suction-line temperature by identifying the intersection point of the row and column located in steps 8 and 9.
11. Compare this value to the suction-line temperature obtained in step 3.
12. If the actual suction-line temperature is higher than the suction-line temperature in the chart, add refrigerant to the system until the charted temperature is reached.
13. If the actual suction-line temperature is lower than the suction-line temperature in the chart, recover refrigerant from the system until the charted temperature is reached.

Example: R-410A system

Outdoor air temperature: 90°F
Evaporator entering air: 70°FWB
Suction pressure at suction service port: 126 psig
Suction-line temperature at suction service port: 75°F

Using the table in **Figure 10.20**, locate the superheat value in the body of the table by using the 90°F outside temperature line and the 70°FWB column. The obtained value is 20°F. Using the table in **Figure 10.21**, locate the required suction-line temperature by using the 20°F superheat row and the 126 psig column. The required suction-line temperature is 63°F. Because the actual temperature reading is 75°F, refrigerant must be added to the system.

10.7 SUBCOOLING CHARGING METHOD FOR TXV SYSTEMS

The previous charging examples were for fixed restrictor-type metering devices such as capillary tubes, fixed orifices, or piston (short-tube) devices. The main advantage of fixed orifice metering devices is their inexpensive cost and simplicity. However, some air-conditioning units, especially high-efficiency units, come with thermostatic expansion valves (TXVs) as their metering devices. When systems have a TXV, the device will maintain a constant amount of evaporator superheat and keep the evaporator active under both high- and low-heat loadings. TXV systems also maintain a constant superheat in the evaporator under changing outdoor ambient temperatures. For a review of TXVs, refer to Unit 24, "Expansion Devices."

The use of TXVs as metering devices in air-conditioning applications requires a refrigerant charging method known as the "subcooling method." This method involves measuring

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

the amount of subcooling exiting the outdoor condensing unit, which will include condenser subcooling and a small part of the liquid line that the outdoor condensing unit employs. The subcooling method for charging a cooling system that employs a TXV follows these steps:

Step 1 Operate the system for at least 15 min before taking any pressure or temperature measurements. If the outdoor temperature is below 65°F, make sure the condensing temperature is at least 105°F. This would be a minimum pressure of 340 psig for R-410A and 210 psig for R-22. This can be done by covering up part of the outdoor condenser's coil and restricting some of its airflow.

Step 2 Measure the high-side (condensing) pressure at the outdoor condensing unit's service valve using a pressure gauge. Convert the high-side pressure to a saturation temperature using a temperature/pressure chart.

Step 3 Measure the liquid-line temperature at the outdoor condensing unit's service valve where the high-side pressure reading was taken.

Step 4 Refer to the unit's data plate or technical manual to find the required subcooling value for the unit. In the absence of any data plate or manual, use a subcooling value of approximately 15°F.

Step 5 Subtract the subcooling value (read from the data plate or technical manual) from the saturation temperature (corresponding to the high-side pressure in step 2) to determine the desired liquid-line temperature at the outdoor condensing unit.

Step 6 If the measured liquid-line temperature is higher than the value in step 5, add refrigerant to the unit. If the liquid-line temperature is lower than the value in step 5, recover refrigerant from the unit. (Only a 3°F to 4°F variance from the temperature desired is necessary when using this method.) Adding or removing refrigerant from the unit should be done in small increments, allowing at least 15 min before the next reading of pressures and temperatures. This allows the system to reach a new equilibrium.

Refer to **Figure 10.22**, which shows a high-efficiency, split air-conditioning system incorporating R-410A as the

Figure 10.22 The subcooling charging method for a high-efficiency, split R-410A air-conditioning system with a TXV metering device.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

refrigerant. This system has a TXV as the metering device. The technician lets the air-conditioning system run for 15 min and takes a pressure reading (390 psig) at the liquid service valve on the outdoor condensing unit. By using a temperature/pressure chart for R-410A, the service technician converts this pressure to a saturation temperature (115°F) and then measures the liquid-line temperature (110°F) at the same place the pressure reading was taken at the service valve of the outdoor condensing unit. Referring to the data plate specifications on the unit, the technician finds out that this unit should have 15°F of subcooling when charged properly. The technician then subtracts this 15°F value from the saturation temperature of 115°F to get the desired liquid-line temperature (100°F) at the outdoor condensing unit. See the following equation:

Saturation Temperature	–	Data Plate Subcooling Value	=	Desired Liquid-Line Temperature
115°F	–	15°F	=	100°F

The technician then compares the measured liquid-line temperature of 110°F with the desired liquid-line temperature of 100°F. Since the measured temperature is higher than the desired temperature, the technician adds refrigerant to the unit while it is running. Because R-410A is a near-azeotropic refrigerant blend, refrigerant must leave the charging cylinder as a liquid to prevent fractionation. It must then be throttled (vaporized) before it reaches the compressor. The technician must wait at least 15 min for this added refrigerant charge to stabilize in the system. The pressure- and temperature-measuring process must then be repeated until the measured temperature and desired temperature at the liquid line of the outdoor condensing unit are within 3°F to 4°F of one another.

10.8 CHARGING NEAR-AZEOTROPIC (ZEOTROPIC) REFRIGERANT BLENDS

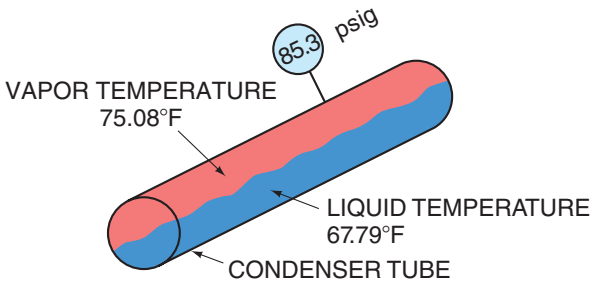
Refrigerant blends and their characteristics were covered in Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting." A more in-depth look at refrigerant blends and their characteristics is needed when charging them into a refrigeration or air-conditioning system.

As mentioned in Unit 9, refrigerant blends are nothing more than two or more refrigerants blended to create another refrigerant. This new refrigerant will have properties completely different from those of the original refrigerants. Two azeotropic blends that were used for many years in the HVAC/R industry are CFC-502 and CFC-500, which consist of azeotropic mixtures of HCFC-22/CFC-115 and CFC-12/HFC-152a, respectively. However, environmental concerns such as ozone depletion and global warming caused both of these blends to be phased out in 1996.

Azeotropic blends are mixtures of two or more liquids that when mixed together behave like the commonly known refrigerants R-12, R-22, and R-134a. Each system pressure will have only one boiling point and/or one condensing point. For a given evaporator or condensing saturation pressure, there is only one corresponding temperature. However, many refrigerant blends in use today, called *near-azeotropic* blends or *zeotropes*, act very differently when they evaporate and/or condense. Each sample of liquid combines two or three molecules instead of one. The temperature/pressure relationships of these blends are not at all like those of azeotropic blends and other refrigerants, such as CFC-12, HCFC-22, or HFC-134a.

Zeotropic blends have a temperature glide when they boil and condense. Temperature glide occurs when the refrigerants that make up a blend evaporate and condense at different temperatures at a given pressure—actually, the liquid and vapor temperatures for each refrigerant will be different for one given pressure. **Figure 10.23(A)** shows a zeotropic blend (R-401A) as it is phase changing in a condenser tube. Notice that for a given pressure of 85.3 psig, the liquid and vapor temperatures are different. An examination of **Figure 10.23(B)** clearly shows that the liquid phase and vapor phase of this blend have two distinct temperatures for one given pressure. In fact, at a condensing pressure of 85.3 psig, the liquid temperature (L) is 67.79°F and the vapor temperature (V) is 75.08°F. Its condensing temperature glide range is then from

Figure 10.23 (A) and (B) The temperature/pressure relationship for R-401A, a near-azeotropic refrigerant blend. R-401A is made up of R-22, R-152a, and R-124 at percentages of 53%, 13%, and 34%, respectively.



(A)

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

75.08°F to 67.79°F. Its condensing temperature glide would be 7.29°F (75.08°F − 67.79°F). This means that the condensing process in the condenser is taking place through a range of temperatures. The condensing temperature is an average of the condensing temperature glide range, or (75.08°F + 67.79°F) ÷ 2 = 71.43°F. Temperature glide happens only when near-azeotropic (zeotropic) blends change phase.

One temperature no longer corresponds to one pressure as with refrigerants such as R-12, R-22, or R-134a. Temperature glides may range from 0.2°F to 14°F in refrigeration and air-conditioning applications, depending on the specific blend. Usually, the higher-temperature applications like air-conditioning will have a greater temperature glide. Most blends have low temperature glides with little effect on the refrigeration system. However, because of temperature glide, calculating superheat and subcooling is done differently. (These methods will be covered in later units.)

Examples of some near-azeotropic (zeotropic) refrigerant blends are R-401A, R-401B, R-402A, R-402B, R-404A, R-407C, and R-410A. Even though R-410A is listed as a near-azeotropic refrigerant blend, it has a very low temperature glide of 0.3°F, which can be ignored in air-conditioning applications. Refrigerants like R-12, R-22, R-134a, or azeotropic refrigerant blends like R-500 and R-502, however, boil and condense at a constant temperature for each pressure. Notice in **Figure 10.24**, R-134a has both a liquid and vapor temperature of 79.0°F at 85.3 psig as it changes phase in the condenser tube. This is because R-134a has no temperature glide.

Figure 10.24 (A) and (B) The temperature/pressure relationship of R-134a.

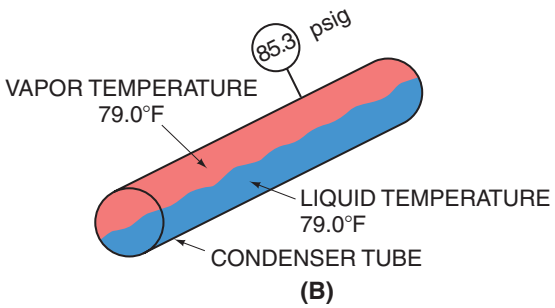
(A)



(B)

New temperature/pressure charts make it easier for the service technician to check a system for the right amount of refrigerant charge when dealing with near-azeotropic refrigerant blends that have a temperature glide. For example, the pressure/temperature chart in **Figure 10.25** instructs the service technician who is checking for a superheat value on the system to use **dew point** values. Dew point is the temperature at which saturated vapor first starts to condense. For a subcooling value, the chart instructs the technician to use the **bubble point** values only. Bubble point is the temperature at which the saturated liquid starts to boil off its first bubble of vapor.

Example

A service technician takes the following reading on a low-temperature refrigeration system incorporating R-404A as the refrigerant.

Head pressure = 250 psig
Suction pressure = 33 psig
Condenser outlet temperature = 90°F
Evaporator outlet temperature = 10°F

The technician wants to determine the condenser subcooling and the evaporator superheat. According to the pressure/temperature chart in **Figure 10.25**, the corresponding condensing temperature for a 250-psig head pressure is 104°F. Notice that the chart will let the technician use only the bubble point temperature for the pressure/temperature relationship. This way there is no confusing a liquid or vapor temperature from the chart when subcooling or superheat readings are taken. The condenser subcooling amount would then be:

Condensing Temperature	−	Condenser Outlet Temperature	=	Condenser Subcooling
104°F	−	90°F	=	14°F

To find the evaporator superheat, the technician would again refer to the chart in **Figure 10.25** and find that the corresponding evaporating temperature for a 33-psig suction pressure is 0°F. Notice again that the chart will let the technician use only the dew point temperature for the pressure/temperature relationship. Again, this ensures that there is no way of confusing a liquid with a vapor temperature from the chart when subcooling or superheat readings are taken. The evaporator superheat amount would then be:

Evaporator Outlet Temperature	−	Evaporating Temperature	=	Evaporator Superheat
10°F	−	0°F	=	10°F

The pressure/temperature chart in **Figure 10.25** is less confusing than the chart in **Figure 10.23(B)**, which lists both a liquid temperature and a vapor temperature for the same pressure.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Another property of zeotropic refrigerant blends is fractionation. As mentioned, because zeotropic blends are made up of different refrigerants and mix together as several molecules, they act differently from refrigerants like R-12, R-22, R-134a, and azeotropic blends when changing phase in the evaporator and condenser. Fractionation occurs when some of the blend condenses or evaporates before the rest of the blend does. Phase changes actually will happen at different rates within the same blend. The many different refrigerants in the blend all have vapor pressures that are slightly different, which causes them to condense and evaporate at different rates.

If a zeotropic blend leaks (vaporizes), the refrigerant in the blend with the lowest boiling point (highest vapor pressure) will leak faster than the other refrigerants in the blend. The refrigerant in the blend with the next lowest boiling point (next higher vapor pressure) will also leak out, but at a slower rate than the refrigerant with the lowest boiling point. Many blends are made up of three refrigerants (ternary blends), resulting in three different leakage rates all at once. This is a problem because once the leak is found and repaired, the refrigerant blend that is left in the system after the leak will not have the same percentages of refrigerants that it had when initially charged. Fractionation happens only when the leak occurs as a vapor leak; it will not occur when the system is leaking pure liquid. This is because vapor pressures are involved, and liquid and vapor need to coexist for fractionation to occur.

Fractionation also happens when refrigerant vapor is taken out of a charging cylinder when the technician is charging with a zeotropic blend. The charging or recharging of a refrigeration system using a near-azeotropic or zeotropic blend should be done with liquid refrigerant. As long as virgin liquid refrigerant is used in recharging a system that has leaked, capacity losses from leak fractionation will be small and harmless. Remove liquid only from the charging cylinder to ensure that the proper blend of percentages or composition enters the refrigeration system. If vapor is removed from the charging cylinder, fractionation will occur. However, once the right amount of liquid is removed from the charging cylinder to another holding cylinder, the refrigerant can be charged as vapor as long as all of the refrigerant vapor is put in the system. This will ensure that the proper percentages of the blend enter the system.

Refrigerant cylinders containing zeotropic refrigerant blends often, but not always, have dip tubes that run to the bottom of the cylinder to allow liquid to be removed from the cylinder when upright, **Figure 10.26**. This should ensure that liquid will always be removed from the cylinder when a system is charged. The cylinder has to be tipped upside down to remove vapor. Of course, the technician cannot look inside the refrigerant tank to determine whether or not there is a dip tube in the cylinder. Refer to the side of the refrigerant tank for information regarding the correct positions of the tank for liquid or vapor removal. Arrows on the tank will provided this information.

When adding liquid refrigerant to the suction line of a system that is running, the liquid, once out of the charging cylinder,

has to be restricted and vaporized into the system to avoid any damage to the compressor. Some sort of a restricting valve must be used to make sure that the liquid refrigerant is vaporized

Figure 10.27 Taking a current reading at the compressor.

Photo by Eugene Silberstein

before it enters the compressor. **Figure 10.10** and **Figure 10.11** show examples. Keep an ammeter on the compressor's power lead and monitor the running current of the compressor when charging this way, **Figure 10.27**. These precautions avoid overloading the compressor and creating nuisance overload trips caused from refrigerant vapors that are too dense when they enter the compressor. If the current increases too much over the nameplate rating current, discontinue charging until the current stabilizes at a lower reading. The gauge manifold could also be used to restrict the liquid further, which would introduce the refrigerant into the system more slowly. This would result in less-dense vapors entering the compressor, which would create a lower current draw. The compressor's three-way suction service valve can also be cracked just off its back seat, which will create a throttling effect and help vaporize any liquid refrigerant trying to enter the compressor.

SUMMARY

- Refrigerant may be added to the refrigeration system in the vapor state or the liquid state under proper conditions.
- When refrigerant is added in the vapor state, the refrigerant cylinder will lose pressure as the vapor is pushed out of the cylinder.
- Liquid refrigerant is normally added in the liquid line and only under the proper conditions.
- With certain refrigerant blends, refrigerant must leave the tank as a liquid. This will prevent fractionation. Once out of the charging cylinder, the liquid must be restricted and vaporized to prevent liquid refrigerant from entering the compressor.
- Liquid refrigerant must never be allowed to enter the compressor.
- Refrigerant is measured into systems using weight and volume.
- It can be difficult to add refrigerant with dial scales because the final cylinder weight must be calculated. The scales are graduated in pounds and ounces.
- Electronic scales may have a cylinder-emptying feature that allows the scales to be adjusted to zero with a full cylinder of refrigerant on the platform.
- Graduated cylinders rely on the volume of the liquid refrigerant. This volume varies at different temperatures, so these charging cylinders must be calibrated before each use.
- Near-azeotropic or zeotropic blends have come into use in the refrigeration and air-conditioning industry with increased environmental concerns regarding ozone depletion and global warming.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Zeotropic blends can exhibit temperature glide (when changing phase) and fractionation (when leaking vapor or charging as a vapor).
- All zeotropic blends must come out of the charging cylinder as a liquid to avoid fractionation.
- Some sort of restricting device must be used with zeotropic blends when charging to vaporize the liquid refrigerant before it enters the compressor.
- Manufacturer charging charts and curves can assist the service technician in correctly charging an accurate amount of refrigerant into an air-conditioning or heat pump system.
- The subcooling method of refrigerant charging is used on air-conditioning and heat pump systems incorporating a thermostatic expansion valve as a metering device.
- Manufacturers have designed new pressure/temperature charts that make it easier for service technicians to check a system for the right amount of refrigerant charge when dealing with near-azeotropic refrigerant blends that have a temperature glide.

REVIEW QUESTIONS

1. How can liquid refrigerant be added to the refrigeration system when the system is out of refrigerant?
2. How is the refrigerant cylinder pressure kept above the system pressure when a system is being charged with vapor from a cylinder?
3. Why does the refrigerant pressure decrease in a refrigerant cylinder while charging with vapor?
4. What type of equipment normally has the refrigerant charge printed on the nameplate?
5. Why are digital scales preferred over other types for charging refrigeration and air-conditioning systems?
6. How does a graduated cylinder account for the volume change due to temperature changes?
7. What methods besides weighing and measuring are used for charging systems?
8. Two or more refrigerants combined together to create another refrigerant is referred to as a(n) _____.
9. Define temperature glide, and give examples of where it occurs in a refrigeration system.
10. A portion of a refrigerant blend that is evaporating or condensing before the rest of the same blend is called_____.
11. What is the main difference between a zeotropic and an azeotropic refrigerant blend?
12. What is meant by "restricting" liquid refrigerant into a refrigeration system when charging?
13. What causes fractionation in certain refrigerant blends?
14. When should a service technician use the subcooling method of charging air-conditioning and heat pump systems?
15. A service technician is charging an air-conditioning system that has a TXV as the metering device using the subcooling method of charging. The high-side saturation temperature is 110°F and the unit's technical manual specifies 10°F of liquid subcooling. What would the desired liquid-line temperature be at the condensing unit?
16. A technician takes the following readings on an R-404A refrigeration system:
    Head pressure = 205 psig
    Suction pressure = 30 psig
    Condenser outlet temperature = 80°F
    Evaporator outlet temperature = 10°F
    Using the pressure/temperature chart in **Figure 10.25**, find the condenser subcooling and evaporator superheat amounts.

CALIBRATING INSTRUMENTS

OBJECTIVES

After studying this unit, you should be able to

- describe various test instruments used by technicians in the heating, air-conditioning, and refrigeration industry.
- test and calibrate a basic thermometer at the low- and high-temperature ranges.
- check an ohmmeter for accuracy.
- describe the comparison test for an ammeter and a voltmeter.
- describe procedures for checking pressure instruments above and below atmospheric pressure.
- check flue-gas analysis instruments.

11.1 CALIBRATION

The service technician cannot always see or hear what is occurring within a machine or piece of equipment. Instruments such as multimeters, pressure gauges, and thermometers help the technician discover what the internal conditions are. Therefore, these instruments must be reliable. Although they should be calibrated by the manufacturer, the instruments do not always remain in calibration. They may need to be checked before use and on a periodic basis. Even if they are perfectly calibrated at one time, they may not stay in calibration due to use and being exposed to moisture and vibration. For example, instruments may be transported in a truck over rough roads to the job site and stay in the truck through extremes of hot and cold weather; the instrument compartment may sweat (due to condensation of humidity from the air). All of these things cause stress to the instruments. Technicians are very dependent on tools and equipment and should always take proper care of them. There is no substitute for good common sense, careful use, and proper storage of tools and equipment.

SAFETY PRECAUTION: *Some instruments are used to check for voltage to protect from electrical shock. They must function correctly for safety's sake.*•

Some instruments can be readily calibrated; some must be returned to the manufacturer for calibration; and some cannot be calibrated at all. **Calibration** means changing the instrument's output or reading to correspond to a standard or correct reading. For example, if a speedometer shows 55 mph for an automobile actually traveling at 60 mph, the speedometer is out of calibration. If the speedometer's settings, circuitry, or sensors can be adjusted so that it records the correct speed, it can be calibrated. Some instruments designed for field use will stay calibrated longer than others. Typically, electronic instruments with digital readout features stay in calibration longer than analog (needle) types and are more appropriate for field use.

This unit describes the instruments most commonly used for HVAC/R system troubleshooting. These instruments measure temperature, pressure, voltage, amperage, and resistance; check for refrigerant leaks; and make flue-gas analyses. To check and calibrate instruments, you must have reference points to which the instrument's readings are compared. We recommend whenever buying an instrument that you check some readings against known values. If the instrument is not within the manufacturer's standards, it should be returned to the supplier or manufacturer. (Save the box the instrument came in as well as the directions and warranty to save time and energy.)

11.2 TEMPERATURE-MEASURING INSTRUMENTS

Temperature-measuring instruments measure the temperature of vapors, liquids, and solids. Commonly, the temperature of air, water, flue gases, and refrigerant in copper lines are measured. Regardless of the medium to be measured, the methods for checking instrument accuracy are similar.

Refrigeration technicians should have thermometers that are accurate over a wide range to measure the temperature of refrigerant lines as well as the temperatures being maintained inside the coolers. Higher temperatures are encountered when measuring ambient temperatures as well as refrigerant line temperatures on the high-pressure side of the system. Heating and air-conditioning technicians must measure air temperatures from 40°F to 150°F and liquid temperatures as high as 220°F for normal service, which can require a wide range of instruments. For temperatures above 250°F—for example, flue-gas analysis in gas- and oil-burning equipment—special thermometers are used. The stack thermometer, **Figure 11.1**, for example, is included as part of a flue-gas analysis kit.

In the past, most technicians relied on glass-stem mercury or alcohol thermometers. These are easy to use for measuring fluid temperature when the thermometer can be inserted into

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 11.1 The thermometer is included in the flue-gas analysis kit. Note the high temperature range of the thermometer.

Photo by Eugene Silberstein

the fluid, but they are difficult to use when measuring the temperature of solids. The electronic thermocouple thermometer, which is very popular, has, for the most part, replaced the glass-stem thermometer. Electronic thermocouple thermometers are easy to use, economical, and extremely accurate, **Figure 11.2.** Digital, pocket thermometers, **Figure 11.3**, are very convenient to carry with you and can be used effectively for taking quick field readings.

Figure 11.2 A digital-type electronic thermocouple thermometer.

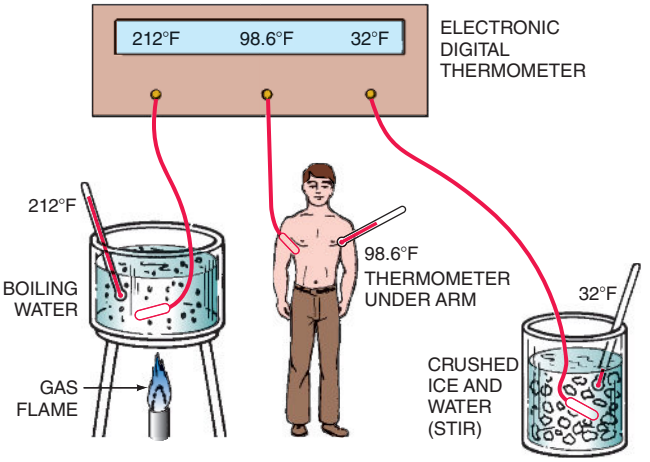
Figure 11.4 Three reference points that a service technician may use.



Three easily accessible reference points for checking temperature-measuring instruments are 32°F (ice and water), 98.6°F (body temperature), and 212°F (boiling point of water at standard atmospheric conditions), **Figure 11.4**. The reference points used should be close to the temperature range in which the technician is working. When using any of these as a reference for checking the accuracy of a temperature-measuring device, remember that a thermometer indicates the temperature of the sensing element. Many technicians make the mistake of thinking that the sensing element indicates the temperature of the medium being checked. This is not necessarily the case. Many inexperienced technicians merely set a thermometer lead on a copper line and read the temperature, but the thermometer's temperature-sensing element has more contact with the surrounding air than with the copper line, **Figure 11.5**. For an accurate reading, the thermometer must be in contact with the medium being measured long enough for the sensor to become the same temperature as the medium. When reading the temperature of a refrigerant line, it is also beneficial to wrap the sensor and the line with foam insulation tape. This will help ensure that the probe is

Figure 11.5 Simply holding the temperature-sensing element to a pipe will not yield accurate temperature measurements.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 11.6 Wrapping the temperature-sensing element will insulate it from the surrounding air, giving a more accurate temperature reading.

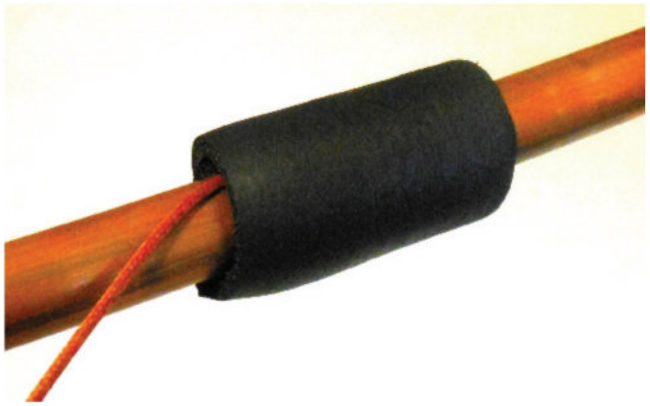

Photo by Eugene Silberstein

sensing the temperature of the line and not the surrounding air, **Figure 11.6.** When measuring the temperature of a liquid, it is desirable to completely submerge the probe in the liquid.

One method of checking temperature instruments is to submerge the sensing element into a known temperature condition (such as ice and water while the change of state is occurring) and allow the sensing element to reach the known temperature. The following is a method for checking an electronic thermometer with four plug-in leads that can be moved from socket to socket.

1. Fasten the four leads together as shown in **Figures 11.7** and **11.8**. Something solid can be attached to them so that they can be stirred in ice and water.
2. For a low-temperature check, crush about a quart of ice, preferably made from pure water. If pure water is not available, make sure the water has no salt or sugar because either one changes the freezing point. The ice must be crushed very fine (wrap it in a towel and pound it with a hammer), or there may be warm spots in the mixture.
3. Pour enough water, pure if possible, over the ice to almost cover it. **Do not cover the ice completely with water** or it will float and may be warmer on the bottom of the mixture. The ice must reach the bottom of the vessel.
4. Stir the temperature leads in the mixture of ice and water, where the change of state is taking place, for at least 5 min. The leads must have enough time to reach the temperature of the mixture.

Figure 11.7 The four leads to the temperature tester are fastened at the ends so they can all be submerged in water at the same time.

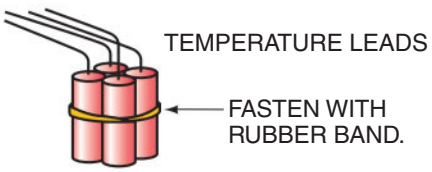

Figure 11.8 A pencil is attached to the group to give the leads some rigidity so that they can be stirred in the ice and water. Note that the ice must reach the bottom of the container.

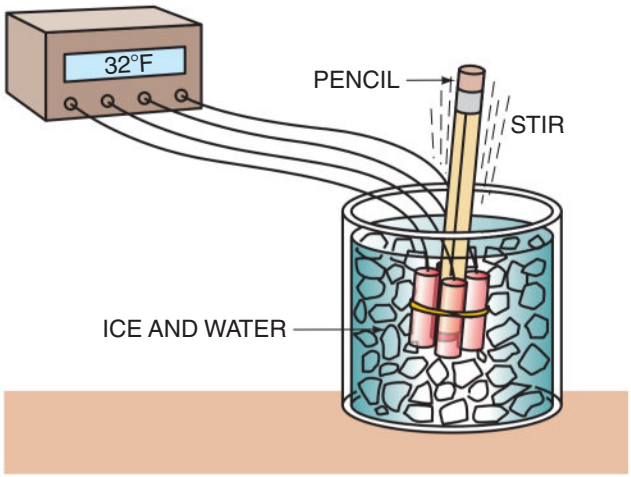
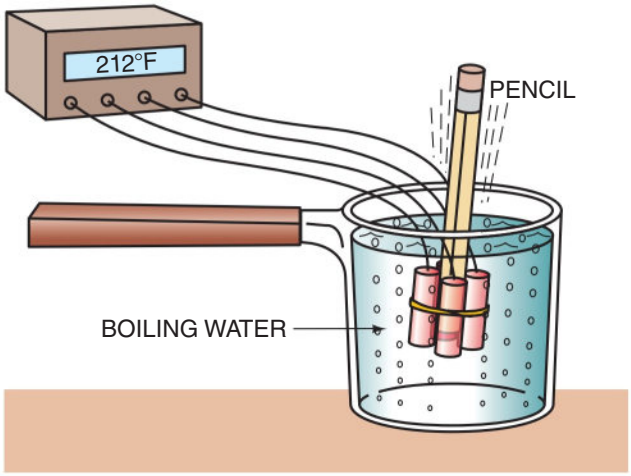


5. If the temperature readings of each lead vary, note which leads are in error and by how much. The leads should be numbered and the temperature differences marked on the instrument case or the leads themselves.
6. For a high-temperature check, put a pan of water on a stove-top heating unit and bring the water to a boil. Make sure the thermometers you are checking are capable of registering the temperature of boiling water. If they are, immerse the sensors in the boiling water. **NOTE:** *Do not let them touch the bottom of the pan or they may conduct heat directly from the pan bottom to the lead,* **Figure 11.9.** Stir the thermometers for at least 5 min and check the readings. It is not critical that the thermometers be accurate to a perfect 212°F because at these temperature levels, a

Figure 11.9 A high-temperature test for the accuracy of four temperature leads.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

degree or two one way or the other does not make a big difference. If any lead reads more than 4°F from 212°F, it is defective. Remember that water boils at 212°F at sea level under standard conditions. Any altitude above sea level will make a slight difference. If the instrument is to be used more than 1000 ft above sea level, we highly recommend a laboratory glass thermometer as a standard instead of the boiling water temperature.

Accuracy is more important in the lower temperature ranges where small temperature differences can translate into larger percentage errors. A 1°F error does not sound like much until one lead is off +1°F and another is off −1°F and you try to measure accurately a temperature drop across a water heat exchanger that operates with a 10°F difference across it.

Consider the situation where a thermometer has two probes, A and B. Probe A is always off by −1°F and probe B is always off by +1°F. The thermometer is being used to measure the temperature difference across a heat exchanger and the actual temperatures of the lines are 45°F and 55°F, **Figure 11.10.** If probe A is attached to the 45°F line and probe B is attached to the 55°F line, the calculated temperature difference across the heat exchanger will be 12°F, **Figure 11.11.** However, if probe A is attached to the 55°F line and probe B is attached to the 45°F line, the calculated temperature difference across the heat exchanger will be 8°F, **Figure 11.12.**

Glass thermometers often cannot be calibrated because the graduations are etched on the stem. However, graduations printed on the back of the instrument may be adjustable. A laboratory-grade glass thermometer is certified as to its accuracy and may be used as a standard for calibrating field instruments. It is a good investment for use in calibrating electronic thermometers, **Figure 11.13.** Many dial-type thermometers can be easily adjusted. These instruments may be tested for accuracy and calibrated, if possible, as we have described.

Figure 11.10 Two ends of a heat exchanger. One end is at a temperature of 45°F and the other end is at a temperature of 55°F. The temperature difference across the heat exchanger is 10°F.

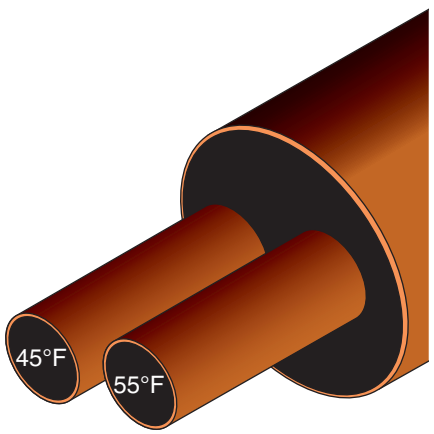


Figure 11.11 Although the actual temperature difference across the heat exchanger is 10°F, these readings indicate a temperature difference of 12°F.

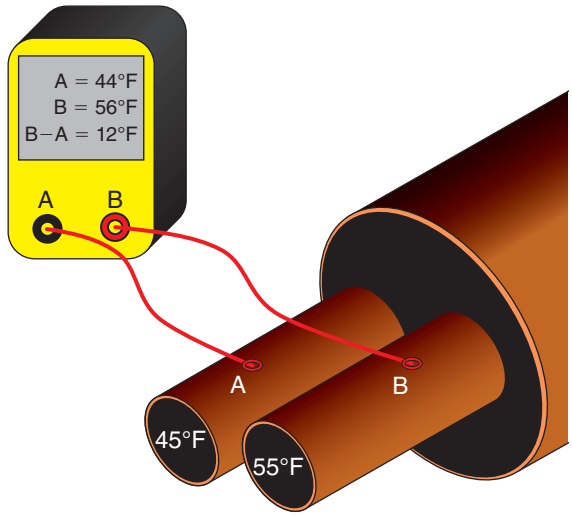

Figure 11.12 Although the actual temperature difference across the heat exchanger is 10°F, these readings indicate a temperature difference of 8°F.

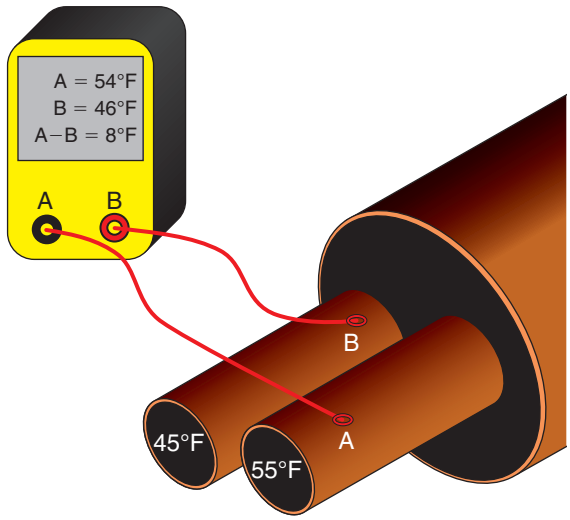

Figure 11.13 A laboratory-grade glass thermometer.

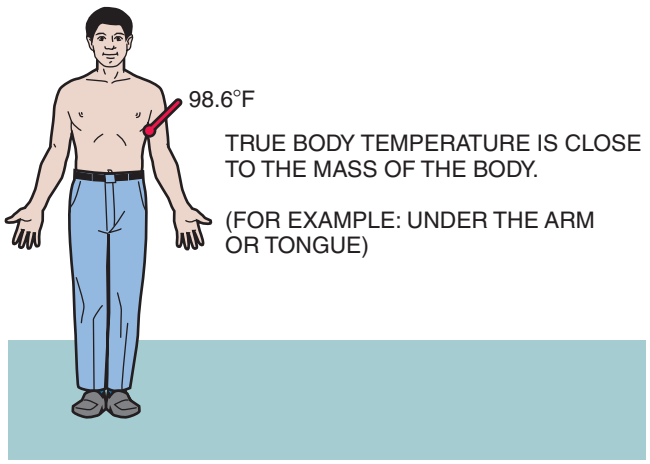
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 11.14 Using the human body as a standard.



Body temperature may also be used as a standard when applicable. Remember that the outer extremities, such as the hands, are not at body temperature. The body is, on average, 98.6°F in the main blood flow, next to the trunk of the body, **Figure 11.14**.

11.3 PRESSURE TEST INSTRUMENTS

Pressure test instruments register pressures above and below atmospheric pressure. The gauge manifold and its construction were discussed in Unit 1, "Heat, Temperature, and Pressure." The technician must be able to rely on these gauges and have some reference points with which to check them periodically. This is particularly important when there is reason to doubt gauge accuracy. The gauge manifold is used frequently and is subject to considerable abuse, **Figure 11.15**.

The pressure/temperature relationship of gauge readings taken from a cylinder of refrigerant can be compared in the following manner. Open the gauge manifold to the atmosphere, and check both gauges to see that they read 0 psig. *It is impossible to determine a correct gauge reading if the gauge is not set at 0 at the start of the test.* Connect the gauge manifold to a cylinder of fresh new refrigerant that has been in a room at a fixed temperature for a long time. Purge the gauge manifold of air. Note that using an old refrigerant cylinder or a recovery tank may lead to errors due to cylinder pollution by air or another refrigerant. If the cylinder pressure is not correct due to refrigerant contaminants, it *cannot* be used to check the gauges. The cylinder pressure is the standard and must be reliable. New virgin/disposable refrigerant cylinders have check valves that allow the refrigerant to leave the cylinder—but nothing to enter it. It is not likely that one of these cylinders will contain any contaminants.

Figure 11.15 Refrigeration gauge manifold.

Photo by Eugene Silberstein

If the cylinder temperature is known, the refrigerant should have a certain pressure. If the refrigerant is R-134a and the room is 75°F, the cylinder and refrigerant should be at 75°F if they have been left in the room for a long enough time. When the gauges are connected to the cylinder and purged of any air, the gauge reading should compare to 75°F and read 78.7 psig. (Refer to **Figure 3.15**, which shows the temperature/pressure chart for R-134a.) The cylinder can be connected to the center hose of the gauge manifold so that both gauges (the low and high sides) may be checked at the same time. The same test can be performed with R-22; the reading will be higher: at 75°F it should be 132 psig. Performing the test with both refrigerants checks the gauges at two different pressures.

Checking the low-side gauge in a vacuum is not as easy as checking the gauges above atmosphere because there is no readily available known vacuum. One method is to open the gauge to atmosphere and make sure that it reads 0 psig. Then connect the gauge to a two-stage vacuum pump and start the pump. When the pump has reached its lowest vacuum, the gauge should read close to 30 in. Hg (29.92 in. Hg vacuum), **Figure 11.16**. If the gauge is correct at atmospheric pressure and at the bottom end of the scale, you can assume that it is correct in the middle of the scale. If more accurate vacuum readings are needed for monitoring a system that runs in a vacuum, you should buy a larger, more accurate vacuum gauge, **Figure 11.17**.

A digital manometer and an electronic micron gauge may be checked together in the following manner. This field test is not 100% accurate, but it is sufficient to tell the technician whether the instruments are within a working tolerance or not.

1. Prepare a two-stage vacuum pump for the lowest vacuum that it will pull. Change the oil to improve the pumping capacity. Connect a gauge manifold to the vacuum pump with the digital manometer and the micron gauge as shown in **Figure 11.18**. The low-pressure gauge, the micron gauge, and the digital manometer may be compared at the same time. As the vacuum pump starts to operate, the readings on the micron gauge and the digital

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 11.16 When evacuated, the gauge should read 30 in. Hg vacuum. If this is the case, all points between 0 psig and 30 in. Hg should be correct.

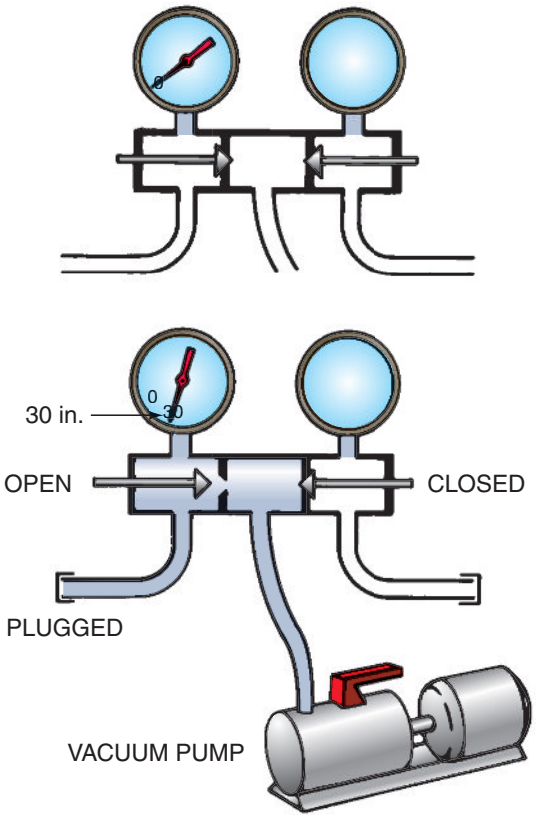


Figure 11.17 A large gauge is more accurate for monitoring systems that operate in a vacuum because the needle moves farther from 0 psig to 30 in. Hg.

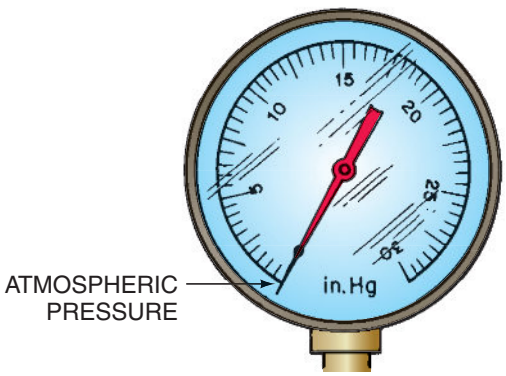
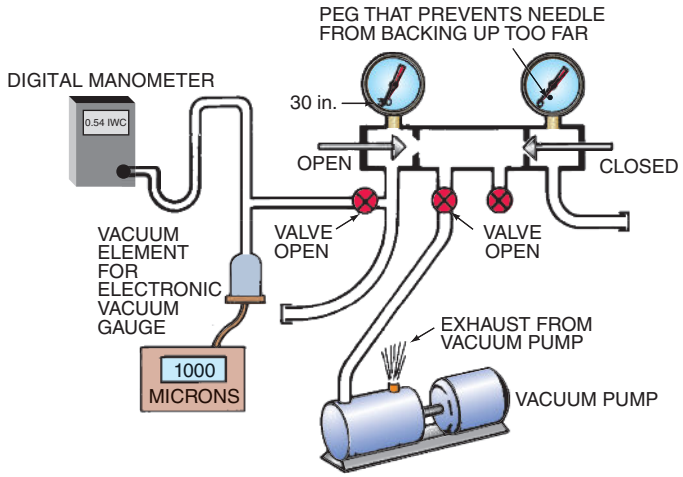


manometer can be compared to each other. The approximate relationship between microns and inches of water column, IWC, is as follows:

1000 microns = 0.54 IWC
2000 microns = 1.07 IWC
3000 microns = 1.6 IWC
4000 microns = 2.14 IWC
5000 microns = 2.7 IWC

Figure 11.18 The setup for checking an electronic manometer and an electronic micron gauge.



If the readings on the two instruments agree with each other, this simply means that either both instruments are calibrated or both instruments are not.

2. When the vacuum pump has evacuated the manifold and gauges, observe the readings. The micron gauge should read between 0 and 1000 microns.

11.4 ELECTRICAL TEST INSTRUMENTS

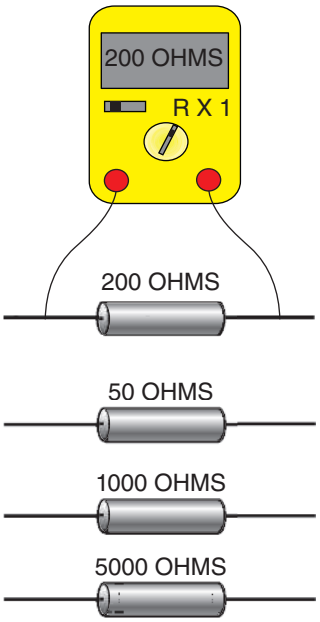
Electrical test instruments are not as easy to calibrate; however, they may be checked for accuracy. The technician must know that the ohm scale, the volt scale, and the ammeter scale are correct. The milliamp scale on the meter is seldom used and must be checked by the manufacturer or compared with another meter.

There are many grades of electrical test instruments. When electrical testing procedures must be very accurate, it pays to buy a good-quality instrument. If exact accuracy is not required, a less expensive instrument may be satisfactory. Electrical test instruments should be checked periodically (at least once a year). One way of doing this is to compare the instrument reading against known values.

The ohmmeter feature of a volt-ohm-milliammeter (VOM) can be checked by using several high-quality resistors of a known resistance. The actual resistance of a particular resistor will be within a percentage range, either above or below the rating of the component. Less expensive resistors, like those with a silver band, have a 10% tolerance, which means that a 100-ohm resistor will have an actual resistance between 90 and 110 ohms. More expensive resistors can have tolerances as low as 0.1% of the resistor's rating. A tolerance of 0.1% means that a 100-ohm resistor will have an actual resistance between 99.9 and 100.1 ohms.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 11.19 Checking an ohmmeter at various ranges with resistances of known values.



A resistor with a 2% or 5% tolerance is usually acceptable for the needs of the HVAC/R technician. Different values of resistors will allow you to test the ohmmeter at each end and at the midpoint of every scale on the meter, **Figure 11.19**. Always start the test by a zero adjustment check of the ohmmeter. **NOTE:** *If the meter is out of calibration to the point that it cannot be brought to the zero adjustment, check the batteries and change them if necessary. If the instrument will not read zero with fresh batteries, check the leads. The leads must be connected perfectly, particularly with digital meters. You may want to use the alligator clips on the end to ensure a perfect connection. Leads can become frayed internally. Good meter leads cost a little more, but they have many strands of very small wire for flexibility and will last longer and be more reliable. If the meter will not check at zero, send it to the experts. Do not try to repair it yourself. Be sure to start each test with a zero adjustment check of the ohmmeter.*•

The volt scale is not as easy to check as the ohm scale. A friend at the local power company or technical school may allow you to compare your meter to a high-quality bench meter. This is recommended at least once a year or whenever you suspect your meter readings are incorrect, **Figure 11.20**. It is satisfying to know your meter is correct when you call the local power company to report a low-voltage reading for a particular job.

The clamp-on ammeter is used most frequently for amperage checks. This instrument clamps around one conductor in an electrical circuit. Like the voltmeter, it can be compared with a high-quality bench meter, **Figure 11.21**. Some amount

Figure 11.20 A VOM being compared with a quality bench meter in the voltage mode.

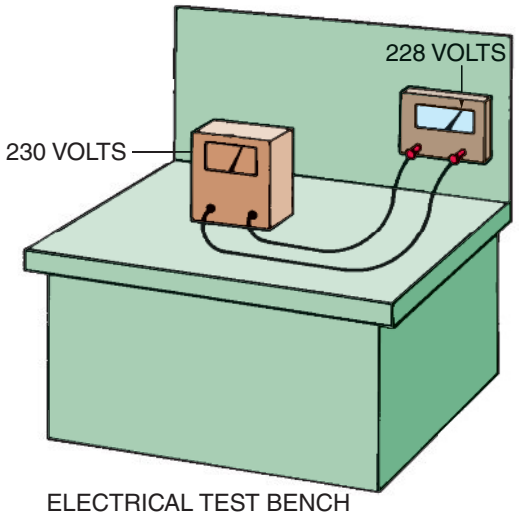


Figure 11.21 A clamp-on ammeter being compared with a quality bench ammeter.

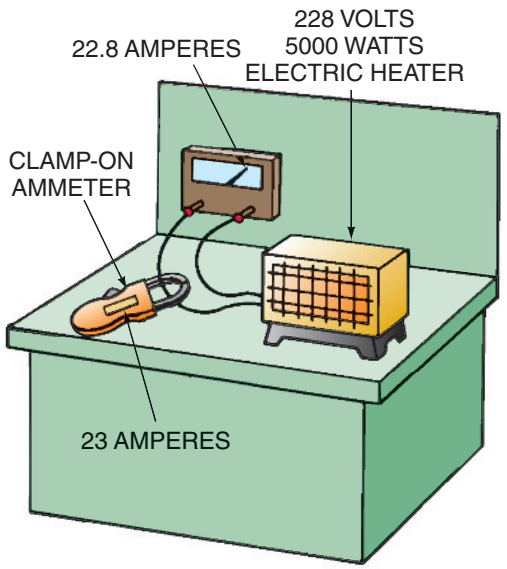


of checking can be done by using Ohm's law and comparing the amperage reading with a heater circuit of known resistance. For example, Ohm's law states that current (I) is equal to voltage (E) divided by resistance (R or Ω for ohms):

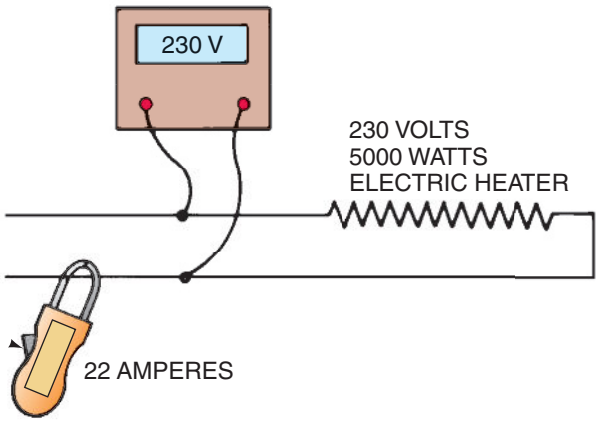
$$I = \frac{E}{R}$$

If a heater has a resistance of 10 Ω and an applied line voltage of 228 V, the amperage (current) on this circuit should be

$$I = \frac{228\ \text{V}}{10\ \Omega} = 22.8\ \text{A}$$

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 11.22 Using an electric heater to check the calibration of an ammeter.



Remember to read the voltage at the same time as the amperage, **Figure 11.22.** You will notice small errors because the resistance of the electric heaters will change when they get hot. The resistance will be greater, and the exact ampere reading will not compare precisely to the calculated one. But the purpose is to check the ammeter. If it is off by more than 10%, send it to the repair shop.

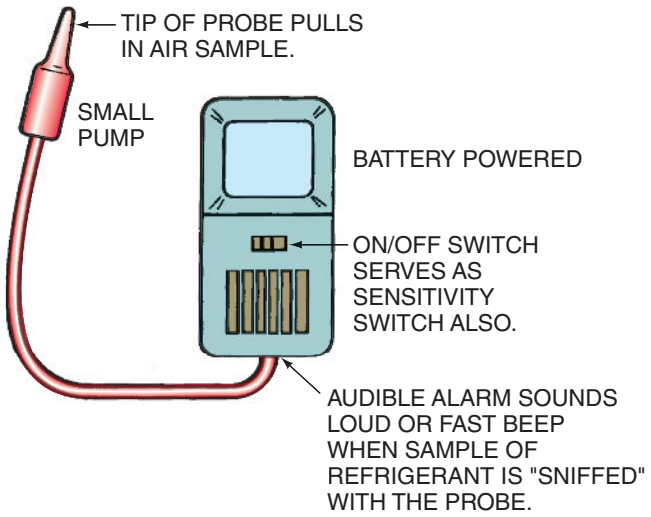
NOTE: *It is important to note that Ohm's law, as written, will hold for DC-powered circuits that are used to operate resistive-type loads. When there is an AC power supply, a power factor must be used to correct the calculated values. For example, it is not uncommon for a 115-volt circuit to produce one-half of the power that was calculated. Refer to Unit 12, "Basic Electricity and Magnetism," for more on this topic.*•

11.5 ELECTRONIC REFRIGERANT LEAK DETECTION DEVICES

Electronic leak detectors can detect leak rates as low as 1/4 oz per year. The detector samples air; if the air contains refrigerant, the detector either sounds an alarm or lights the probe end. These devices are typically battery-powered. Some units may have a pump to pull the sample across the sensing element, and some have the sensing element located in the head of the probe, **Figure 11.23**. Some electronic leak detectors can be adjusted to compensate for background refrigerant. Some equipment rooms may have many small leaks, and a small amount of refrigerant may be in the air all the time. Unless the detector has a feature that accounts for this background refrigerant, it will constantly indicate a leak.

No matter what style of leak detector you use, you must be confident that the detector will actually detect a leak. Remember that the detector only indicates what it samples.

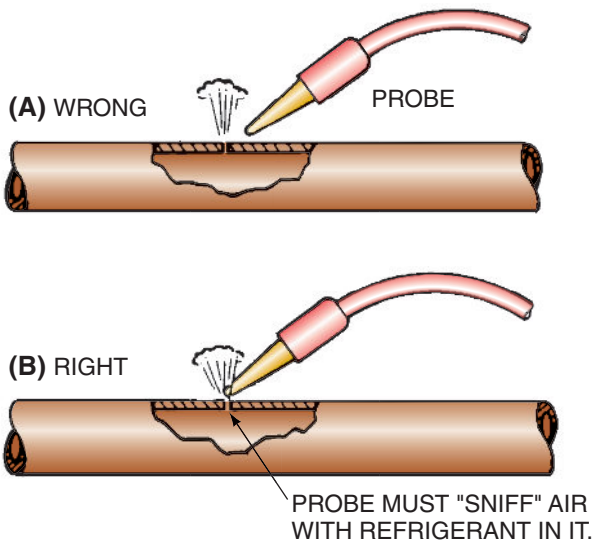
Figure 11.23 Electronic leak detectors.



If the detector is in the middle of a refrigerant cloud and the sensor senses air, it will not sound an alarm or light up. For example, the probe of a leak detector can pass by a pinhole leak in a pipe. The sensor is sensing air next to the leak, not the leak itself, **Figure 11.24**.

Some manufacturers furnish a reference leak canister, which is used to confirm the correct operation of the leak detector. **NOTE:** *Never spray pure refrigerant into the sensing element. Damage will occur.*• If you do not have a reference leak canister, a gauge line under pressure from a refrigerant cylinder can be loosened slightly, and the refrigerant can be fanned

Figure 11.24 (A) This electronic leak detector is not sensing refrigerant escaping from the small pinhole in the tubing. This is because the refrigerant is spraying past the detector's sensor. (B) In this position, the sensor will detect the leaking refrigerant.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

to the electronic leak detector sensing element. Doing it this way mixes air with the refrigerant to dilute it.

11.6 FLUE-GAS ANALYSIS INSTRUMENTS

Flue-gas analysis instruments analyze products of combustion from fossil-fuel–burning equipment, such as oil and gas furnaces and boilers, to determine the combustion efficiency of the appliance. These instruments are normally sold in kit form with a carrying case, and can be of either the "electronic," **Figure 11.25**, or "wet kit" variety, **Figure 11.26**. **SAFETY PRECAUTION:** *The red fluid, potassium hydroxide, in the "wet kit" must not be allowed to contact any tools or other instruments. It is acidic and can cause severe burns! The chemicals are intended to stay within the container or the instrument to which they belong. A valve at the top of the instrument is a potential leak source and should be checked periodically. It is best to store and transport the kit in the upright position so that if the valve does develop a leak, the chemical will not run out of the instrument.* •

Figure 11.25 An electronic combustion efficiency analyzer.

Source: Bacharach Inc. Pittsburgh, PA, USA

Figure 11.26 A "wet" combustion efficiency test kit.

Photo by Bill Johnson

Flue-gas instruments are expensive, precision devices that deserve special care and attention. The draft gauge, on the left side of **Figure 11.26**, for example, is highly sensitive. The kit should only be hauled around in a truck when you intend to use it. The potassium hydroxide in the wet kit should be changed according to the manufacturer's guidelines, which is roughly after 200 tests. A calibration check of wet kits is not necessary because they are direct-reading instruments and cannot be calibrated. The only adjustment to be made is the zero adjustment on the sliding scale, **Figure 11.27**, which is adjusted at the beginning of the flue-gas test. The thermometer in the kit, **Figure 11.28**, is used to measure very high temperatures, up to 1000°F. There is no easily available reference point for it except the boiling point of water, 212°F, which may be used as the reference even though it is near the bottom of the scale, **Figure 11.29**. Electronic combustion analyzers are easier to use than wet kits, but should be calibrated annually.

Figure 11.27 The zero adjustment on the sliding scale of the flue-gas analysis kit.

Figure 11.28 High temperature thermometer.

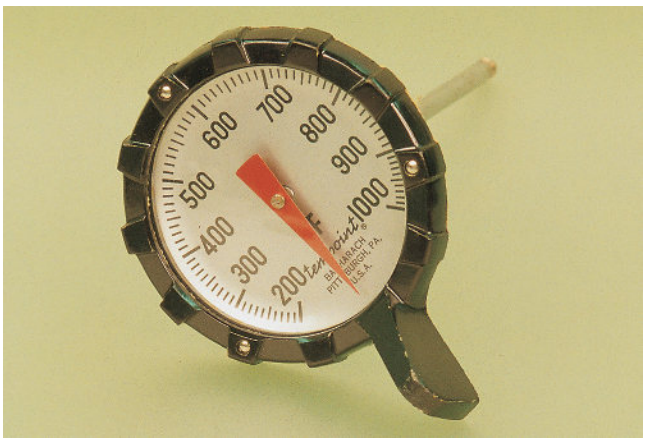

Photo by Bill Johnson

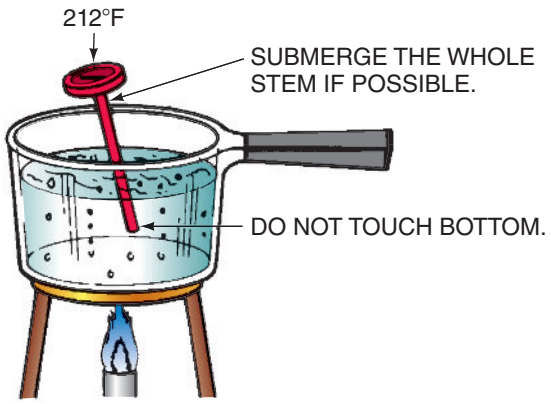
Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 11.29 A flue-gas thermometer being checked in boiling water.



In order to have the instrument calibrated, it needs to be sent to the manufacturer. Turnaround time is usually 2 or 3 weeks, so it is a good idea to have backup instruments at the ready.

11.7 GENERAL MAINTENANCE

Any instrument with a digital readout will have batteries, and these must be maintained. *Buy the best batteries available; inexpensive batteries may cause problems. A good battery will not leak acid on the instrument components if it is left unattended and goes dead.*

The instruments you use extend your senses; the instruments, therefore, must be maintained so that they can be believed. Airplane pilots sometimes have a malady called vertigo. They become dizzy and lose their orientation and relationship with the horizon. Suppose the pilot were in a storm and being tossed around, even upside down at times. The pilot can be upside down and have a sensation that the plane is right side up and climbing. The plane may be diving toward the earth while the pilot thinks it is climbing. Instruments must be believable, and the technician must have reference points to maintain faith in the instruments.

SUMMARY

- Reference points for all instruments should be established to give the technician confidence.
- The three easily obtainable reference points for temperature-measuring instruments are ice and water at 32°F, body temperature at 98.6°F, and water boiling temperature at 212°F.
- Make sure that the temperature-sensing element reflects the actual temperature of the medium used as the standard.
- Pressure-measuring instruments must be checked above and below atmospheric pressure. There are no good reference points below atmospheric pressure, so a vacuum pump pulling a deep vacuum is used as the reference.
- Flue-gas analysis kits need no calibration except for the sliding scale on the sample chamber.

REVIEW QUESTIONS

1. What does “calibrating an instrument” mean?
2. Three reference points that may be used to check temperature-measuring instruments are _____, _____, and _____.
3. True or False: All instruments can be calibrated.
4. Temperature-measuring instruments may be designed to measure the temperature of vapors, _____, and _____.
5. Glass stem thermometers are being replaced by _____ thermometers.
6. True or False: To check the temperature leads of an electronic thermometer for low temperatures, they should be stirred in a container of crushed ice, water, and a tablespoon of salt.
7. Accuracy of a thermometer is more important in the _____ temperature ranges.
8. True or False: Pressure test instruments measure pressures only above atmospheric pressure.
9. True or False: A pressure gauge can be checked by connecting it to a cylinder of refrigerant with a known temperature and comparing the pressure reading with that on a temperature/pressure relationship chart.
10. What should a gauge manifold reading indicate when opened to the atmosphere?
11. Describe how the ohmmeter feature of a VOM can be checked.
12. Describe how amperage readings are taken with a clamp-on ammeter.
13. Good-quality electronic leak detectors can detect leak rates down to approximately _____ ounce(s) per year.
14. What are three instruments that a flue-gas analysis kit might contain?

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

BASIC ELECTRICITY AND MAGNETISM

OBJECTIVES

After studying this unit, you should be able to

- describe the structure of an atom.
- identify atoms with a positive charge and atoms with a negative charge.
- explain the difference between conductors and insulators.
- describe how magnetism is used to produce electricity.
- state the differences between alternating current and direct current.
- list the units of measurement for electricity.
- explain the differences between series and parallel circuits.
- state three forms of Ohm's law.
- state the formula for determining electrical power.
- describe a solenoid.
- explain inductance.
- describe the construction of a transformer and how voltage is induced in a secondary circuit.
- describe how a capacitor works.
- describe a sine wave.
- state the reasons for using proper wire sizes.
- describe the physical characteristics and the function of several semiconductors.
- describe procedures for making electrical measurements.

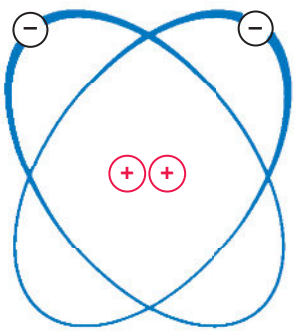
SAFETYCHECKLIST

- ✔ Before using any piece of electrical test equipment, become completely familiar with the instrument's features and carefully read the manufacturer's literature.
- ✔ Avoid becoming part of an electric circuit.
- ✔ Use non-conducting ladders, such as fiberglass or wood.
- ✔ Wear rubber-soled work boots to insulate yourself from wet floors and help prevent serious injury from electric shock.
- ✔ When servicing electric circuits, de-energize the power supply whenever possible.
- ✔ Be sure to follow lockout/tagout procedures to ensure your safety on the job.
- ✔ Be aware that some pieces of HVAC/R equipment have more than one power source. Be sure they are all de-energized before working on the equipment.
- ✔ Make certain that your electrical test instruments are in good working order.
- ✔ Make certain all system capacitors are properly discharged before working on equipment.
- ✔ Be sure to inspect the cords on all power tools. Do not use power tools that have damaged cords.
- ✔ Never cut the ground prong off a power cord under any circumstances.
- ✔ Never jump out safety devices.
- ✔ Make certain that the conductors used in a circuit are sized properly and protected by fuses and circuit breakers that are rated for the conductor size.

12.1 ATOMIC STRUCTURE

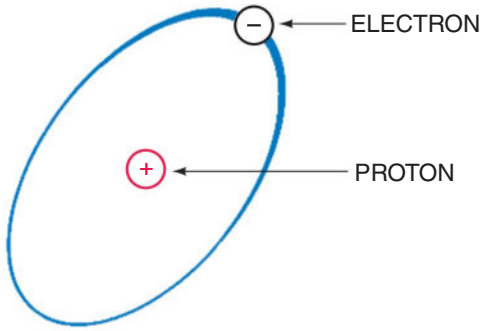
To understand the theory of how electric current flows, you must understand something about matter and what it is made of. Matter is made up of atoms, which are the smallest amounts of a substance that can exist. Atoms are made up of protons, neutrons, and electrons. The number of electrons in an atom is the same as the number of protons. Protons and neutrons are located at the center (or nucleus) of the atom. Protons have a positive charge. Neutrons have no charge and have little or no effect as far as electrical characteristics are concerned. Electrons have a negative charge and orbit around the nucleus, in a manner very similar to the way the planets orbit around the sun. Electrons move around the nucleus in different shells, which are at different distances from the nucleus of the atom. Although electrons in the same orbit are the same distance from the nucleus, they do not follow the same orbital paths, **Figure 12.1.**

Figure 12.1 The orbital paths of electrons.



Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 12.2 A hydrogen atom with one electron and one proton.



The hydrogen atom is simple to illustrate because it has only one proton and one electron, **Figure 12.2**. Not all atoms are as simple as the hydrogen atom, as they contain many electrons, protons and neutrons. Copper, for example, which is commonly used to construct electric circuits, has 29 protons and 29 electrons, **Figure 12.3**. Some of the electron orbits in a copper atom are farther away from the nucleus than others, and each orbit has the ability to hold a different number of electrons. The formula that is used to determine how many electrons can occupy each shell is:

$$\text{Number of Electrons} = 2s^2$$

where "s" is the shell number. So, in the case of copper, the first shell can hold 2 electrons (2×1^2), the second shell can hold 8 electrons (2×2^2), and the third shell can hold 18 electrons (2×3^2). The fourth shell can hold up to 32 electrons, 2×4^2, but there is only 1 electron left over, so the fourth shell is occupied by the one remaining electron. It is this single electron in the outermost orbit or shell that makes copper a good conductor of electricity.

The goal of an atom is to become as stable as possible. Being stable refers to having either a completely full or a completely empty outermost shell. Since the copper atom has only one electron in its outer shell, the atom can become stable if it is able to give up this outermost, or *valence*, electron. The term valence electrons refers to the electrons in the outermost, or valence, shell. For this reason, the copper atom, and other metallic elements and substances as well, are eager to give up their "loose" electrons. Since electric current is described as the flow of electrons, metallic substances facilitate current flow by not holding onto their valence electrons tightly and by allowing them to move freely from atom to atom.

12.2 MOVEMENT OF ELECTRONS

When sufficient energy or force is applied to an atom, the outer electrons become free and can move from atom to atom. When electrons leave an atom, the atom will contain more protons than electrons. As a result, since protons are positively charged, the atom will have a net positive charge, **Figure 12.4(A)**. The atom the electron joins will contain more electrons than protons, so it will have a net negative charge, **Figure 12.4(B)**.

The "law of charges" states that like charges repel each other and unlike or opposite charges attract each other. So, two protons (or electrons) will repel each other, while a proton and an electron will be attracted to each other. An electron in an atom with a surplus of electrons (negative charge) will be attracted to an atom with a shortage of electrons (positive charge). An electron entering an orbit with a surplus of electrons will tend to repel an electron already there and cause it to become a free electron.

Figure 12.3 A copper atom with 29 protons and 29 electrons.

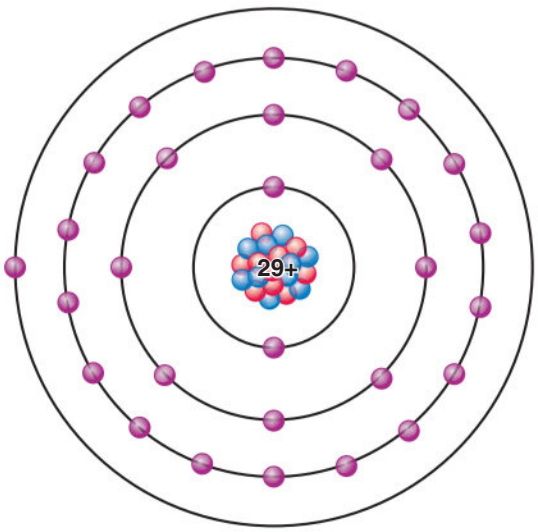


Figure 12.4 (A) This atom has two protons and one electron. It has a shortage of electrons and a positive charge. (B) This atom has two protons and three electrons. It has an excess of electrons and a negative charge.

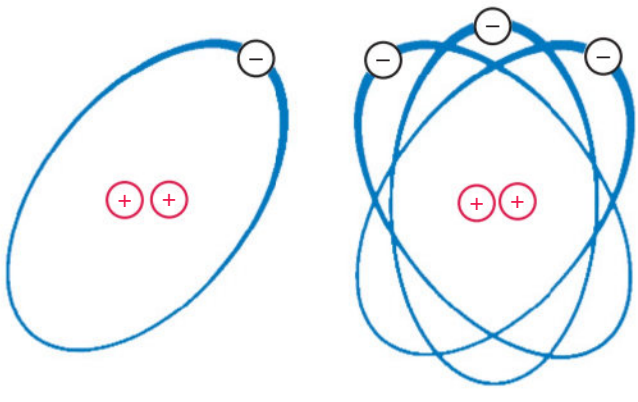

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

12.3 CONDUCTORS

Good conductors of electricity are those with few electrons in the outer orbit, or valence shell. Copper, silver, and gold are good conductors, and each has one electron in the outer orbit. Other metallic substances, such as mercury and aluminum, are also good conductors, even though they have two and three electrons, respectively, in their outermost electron shells. Information regarding the amount of current that can safely flow through a conductor is provided by the American Wire Gauge, AWG. Thicker wires or conductors can carry more current safely than thinner wires or conductors. Good conductors of electricity are typically also good conductors of heat.

12.4 INSULATORS

Insulators, unlike conductors, do not allow the free flow of electrons, and are often described as the opposite of conductors. Insulators are substances that are made up of atoms with several electrons in their outermost shell, making them poor conductors. The valence electrons are difficult to free, making it very difficult for the electrons to move from one atom to another. Glass, rubber, and plastic are examples of good insulators. Generally speaking, metallic substances make much better conductors and non-metallic substances make better insulators.

12.5 ELECTRICITY PRODUCED FROM MAGNETISM

Electricity can be produced in many ways, for example, from chemicals, pressure, light, heat, and magnetism. The electricity that air-conditioning and heating technicians are more involved with is produced by magnetism.

Magnets are common objects with many uses. They have poles, usually designated as the north (N) pole and the south (S) pole, and they also have fields of force, or magnetic lines of force. **Figure 12.5** shows the lines of the field of force around a permanent bar magnet. This field causes the like poles of two magnets to repel each other and the unlike poles to attract each other.

Figure 12.5 A permanent magnet with lines of force.

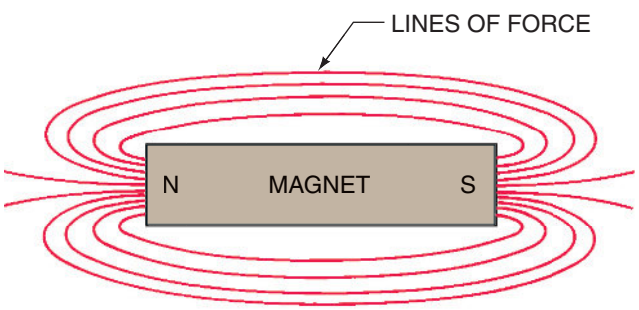

Figure 12.6 The movement of wire up and down cuts the lines of force, generating voltage, which in turn facilitates current flow.

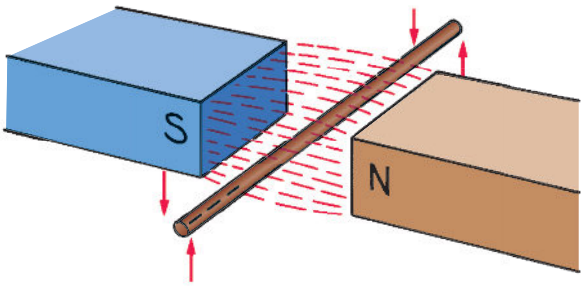

If a conductor, such as a copper wire, crosses the lines of force, the outer electrons in the atoms in the wire are freed and begin to move from atom to atom. This movement of electrons results in an excess of electrons on one end of the conductor and a deficiency of electrons on the other. This difference in charge is what we will later describe as voltage, or electrical potential. It is this electrical potential that causes electric current to flow. It does not matter if the wire moves or if the magnetic field moves. It is only necessary that the conductor cross through the lines of force, **Figure 12.6**. This movement of electrons in one direction produces current. The current is an impulse transferred from one electron to the next. For example, if you pushed a golf ball into a tube already filled with golf balls, one would be ejected instantly from the other end, **Figure 12.7**. The energy of electromagnetic waves travels in a similar manner at speeds up to 300,000 km/s, or 186,000 miles/s. The electrons themselves do not travel through a wire at speeds even close to this. The electrons flowing through a battery-powered lamp move at a speed of about 3 inches per hour!

An electrical generator has a large magnetic field and many turns of wire crossing the lines of force. The wires are in the form of coils that are rotated within the magnetic field. A large magnetic field will produce more current than a smaller magnetic field, and many turns of wire passing through a magnetic field will produce more current than a few turns of wire. The magnetic force field for generators is usually produced by electromagnets. Electromagnets have characteristics similar to those of permanent magnets and are discussed later in this unit. **Figure 12.8** shows a simple generator. Large industrial generators and power plants can use the force of water flow, wind, or steam to rotate the coils of wire within the magnetic field.

12.6 CURRENT

DIRECT CURRENT

Direct current (DC) travels in one direction. Because electrons have a negative charge and travel to atoms with a positive charge, DC is considered to flow from negative to positive. DC voltage is generated primarily by chemical reactions and is commonly known as the battery-power source used in wireless and portable devices. Direct current can also be created from alternating current (AC) power sources by utilizing solid-state or electronic circuits referred to as rectifiers. Rectifiers are discussed in more detail later on in this unit.

ALTERNATING CURRENT

Alternating current (AC) is a continually and rapidly reversing current. The charge at the power source (generator) is continually changing direction; thus, the current continually reverses itself. Most electrical energy generated for public use is AC. It is much more economical to transmit electrical energy long distances in the form of AC, as the transmission losses are very low compared to those associated with DC. The voltage of this type of current can be readily changed, so it has many more uses. DC still has many applications, but it is usually obtained by changing AC to DC or by producing the DC locally where it is to be used.

12.7 UNITS OF ELECTRICAL MEASUREMENT

Electromotive force (emf), or voltage (V), is used to indicate the potential difference between two charges. When an electron surplus builds up on one side of a circuit and a shortage of electrons exists on the other side, a difference in potential, or emf, is created. This potential difference is referred to as voltage. The unit used to measure this force is the **volt**. The **ampere** is the unit used to measure the quantity of electrons moving past a given point in a specific period of time (electron flow rate). When 6.24×10^{18} electrons pass a given point per second, we say that 1 ampere of electric current is flowing. One coulomb is defined as 6.24×10^{18} electrons. So, we can say that 1 ampere is equal to a current flow of 1 coulomb of electrons per second. *Amperage* and *ampere(s)* are sometimes termed "amp(s)" for short. The abbreviation for ampere is A.

All materials oppose or resist the flow of an electrical current to some extent. In good conductors this opposition or resistance is very low. In poor conductors the resistance is high. The unit used to measure resistance is the ohm. The symbol for ohm is the Greek letter Omega, Ω. A resistance of 1 ohm is present when a force of 1 volt causes a current of 1 ampere to flow in an electric circuit.

Volt = Electrical force or pressure (V)
Ampere = Quantity of electron flow rate (A)
Ohm = Resistance to electron flow (Ω)

12.8 THE BASIC ELECTRIC CIRCUIT

An electric circuit must have a power source, a load or device to consume the power, as well as a complete conductive path to and from the power source. There is also generally a means for starting and stopping the current flow through the circuit. **Figure 12.9** shows an electrical generator for the source, a complete conductive path, a light bulb for the load, and a switch for opening and closing the circuit.

Figure 12.9 An electric circuit.

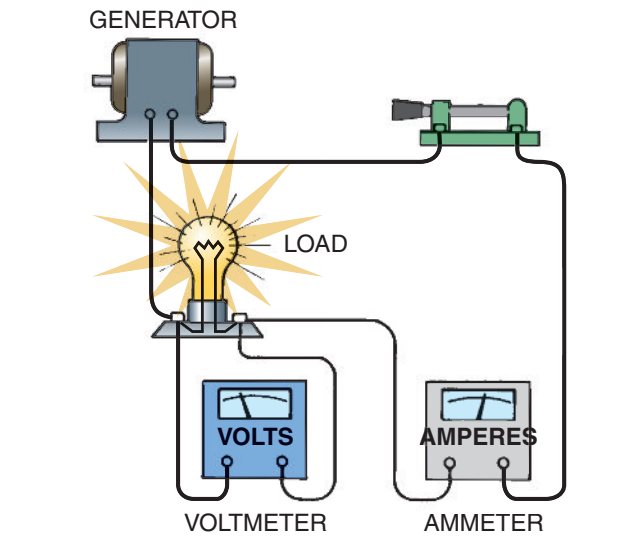
Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The generator produces the electrical potential, or voltage, by passing many turns of wire through a magnetic field. The wire provides the path for the electricity to flow to the bulb and complete the circuit. The electrical energy is converted to heat and light energy by the bulb. The switch is used to open and close the circuit. When the switch is open, no current will flow. When it is closed, the bulb element will produce heat and light because current is flowing through it.

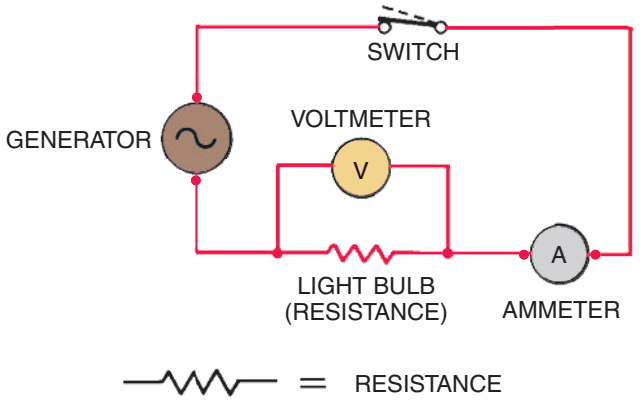
12.9 MAKING ELECTRICAL MEASUREMENTS

Electrical measurements can be made in the circuit illustrated in **Figure 12.9** to determine the voltage (emf) being supplied to the circuit and the amount of current (amperes) flowing in the circuit. To make the measurements, **Figure 12.10(A)**, a voltmeter is connected across the terminals of the bulb without interrupting the circuit. The ammeter is connected directly into the circuit so that all the current flows through it. **Figure 12.10(B)** illustrates the same circuit using symbols. Commonly used electrical symbols can be found in **Figure 12.11**. Voltmeters are used to measure the potential difference between two points in an electric circuit and are therefore connected in parallel to the portion of the circuit between those points. The internal resistance of the voltmeter is very high so that the meter does not alter the current flow or the potential difference between the points being evaluated.

Figure 12.10 (A) Voltage is measured across the load (in parallel). Amperage is measured in series. (B) The same circuit as in Figure 12.10 (A), illustrated with symbols.



(A)



(B)

Ammeters are used to measure the intensity of current flow in a circuit or a particular branch in a circuit, so they are wired in series with the circuit being evaluated. Since we do not want the meter to affect the circuit operation, current, or voltage, the internal resistance of an ammeter is very low. **NOTE:** *Connecting ammeters in series with a load can be dangerous. Series ammeter connections are most commonly found on bench test equipment, where the ammeter is permanently installed in the wiring to the bench test location. Service technicians working in the HVAC/R field will use a clamp-on-type ammeter that does not require the user to alter the circuit connections.* •

Often a circuit will contain more than one resistance or load. These resistances may be wired in series or in parallel, depending on the application or use of the circuit. **Figure 12.12** shows three loads in series, both shown pictorially and with symbols. **Figure 12.13** illustrates three loads wired in parallel. In circuits where devices are wired in series, all of the current passes through each load. When two or more loads are wired in parallel, the current is divided among the loads. This is explained in more detail later in this unit. Power-passing devices such as switches are wired in series with the devices or loads they are controlling. Most resistances or loads (power-consuming devices) that air-conditioning and heating technicians work with are wired in parallel.

Figure 12.14 illustrates how a voltmeter is connected to measure each of the resistances. The voltmeter is in parallel with each resistance. The figure also shows the ammeter; it is wired in series in the circuit. An ammeter that can be clamped around a single conductor to measure the rate of current flow is shown in **Figure 12.15**. This is convenient because it is often difficult to disconnect a circuit to connect the ammeter in series. This type of ammeter is usually called a clamp-on type since it simply clamps around the conductors in the circuit. This type of meter is discussed in more detail in Section 12.19, "Electrical Measuring Instruments."

12.10 OHM'S LAW

In the early 1800s, the German scientist George S. Ohm did considerable experimentation with electrical circuits. He determined that a relationship exists among the voltage, current, resistance, and power in an electrical circuit.

Photo by Eugene Silberstein

This relationship is called Ohm's law, which is described below. Letters are used to represent the different electrical factors.

E or V = Voltage (emf)
I = Amperage (current)
R = Resistance (load)

The "E" stands for electromotive force, the "V" stands for voltage, the "I" stands for intensity of current, and the "R" stands for resistance. Ohm's law appears in three common forms. The voltage equals the amperage times the resistance:

$$E = I \times R$$

The amperage equals the voltage divided by the resistance:

$$I = \frac{E}{R}$$

The resistance equals the voltage divided by the amperage:

$$R = \frac{E}{I}$$

Figure 12.16 shows a convenient way to remember these formulas.

Figure 12.16 To determine the formula for the unknown quantity, cover the letter that represents the unknown.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

In **Figure 12.17**, the resistance of the heating element can be determined as follows:

$$R = \frac{E}{I} = \frac{120\ \text{V}}{3\ \text{A}} = 40\ \Omega$$

In **Figure 12.18**, the voltage across the resistance can be calculated as follows:

$$E = I \times R = 2\ \text{A} \times 60\ \Omega = 120\ \text{V}$$

Figure 12.19 indicates the voltage to be 120 V and the resistance to be 20 Ω. The formula for determining the current flow is

$$I = \frac{E}{R} = \frac{120\ \text{V}}{20\ \Omega} = 6\ \text{A}$$

Figure 12.17 The resistance of the heating element can be determined by using the voltage and amperage indicated.

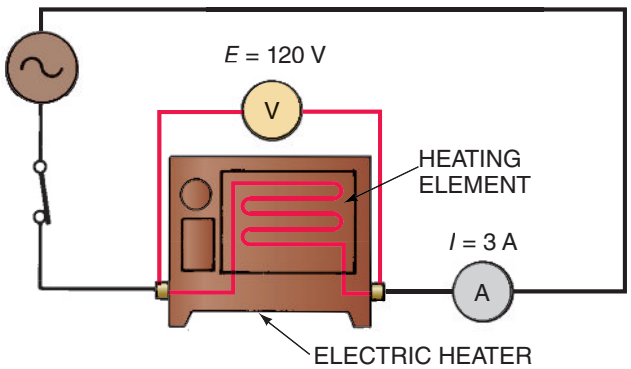

Figure 12.18 The voltage across the resistance can be calculated using the information in this diagram.

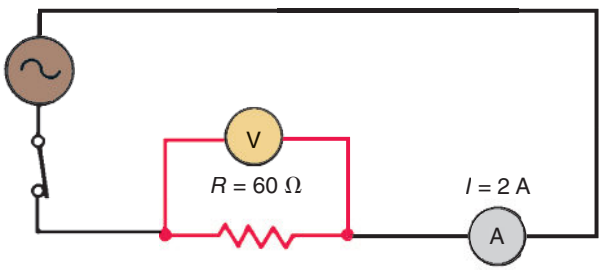

Figure 12.19 Voltage is 120 V and the resistance is 20 Ω. The amperage of the circuit can be determined using this information.

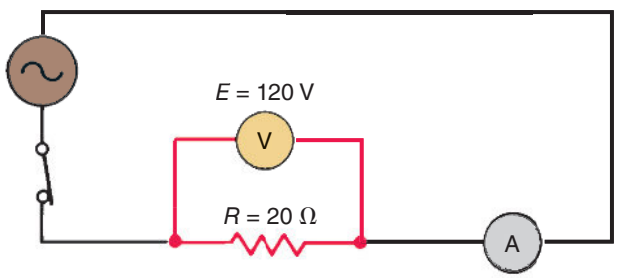

In series circuits with more than one resistance, simply add the resistances together to find the total resistance of the circuit. In **Figure 12.20**, there is only one path for the current to follow (a series circuit), so the resistance is 40 Ω (20 Ω + 10 Ω + 10 Ω). The amperage in this circuit will be

$$I = \frac{E}{R} = \frac{120\ \text{V}}{40\ \Omega} = 3\ \text{A}$$

The resistances, in ohms, of the individual loads can be determined by disconnecting the resistance to be measured from the circuit and reading the resistance with an ohmmeter, as illustrated in **Figure 12.21**. **NOTE:** *Ohmmeters are to be used only on circuits that are deenergized. Also, be sure that the component being evaluated is disconnected from the circuit to avoid inaccurate or false readings.* •

SAFETY PRECAUTION: *Do not use any electrical measuring instruments without specific instructions from a qualified person. Follow the manufacturer's instructions. The use of electrical measuring instruments is discussed in Section 12.19.* •

Figure 12.20 The current in a series circuit has only one possible path to follow.

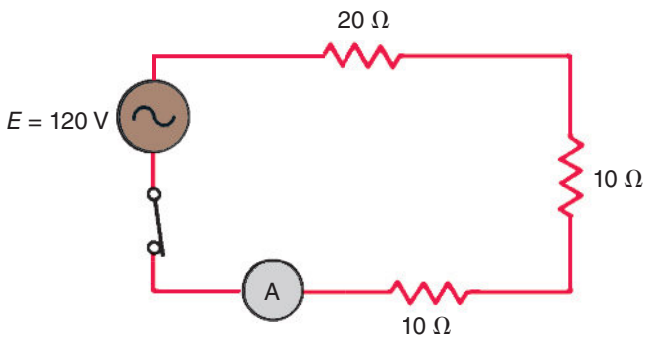

Figure 12.21 To determine the resistance of a circuit component, turn off the power and disconnect the component from the circuit. Then, check the component with an ohmmeter.

12.11 CHARACTERISTICS OF SERIES CIRCUITS

In series circuits,

- the voltage is divided across the different resistances. The mathematical formula is as follows:

$$E_{total} = E_1 + E_2 + E_3 + \ldots$$

  This means that the total voltage being supplied to the circuit will be equal to the sum of the voltages that are measured across each device in the circuit.
- the total current flows through each resistance or load. The mathematical formula is as follows:

$$I_{total} = I_1 = I_2 = I_3 = \ldots$$

  Simply stated, this means that the current flowing in a series circuit will be the same no matter where in the circuit the amperage is being measured. The current flowing through the first circuit device is the same as the current flowing through the second circuit device, and so on.
- the resistances are added together to obtain the total resistance. The formula for calculating total resistance in a series circuit is as follows:

$$R_{total} = R_1 + R_2 + R_3 + \ldots$$

12.12 CHARACTERISTICS OF PARALLEL CIRCUITS

In parallel circuits,

- the total voltage is applied across each circuit branch. The mathematical formula is as follows:

$$E_{total} = E_1 = E_2 = E_3 = \ldots$$

  This means that the total voltage being supplied to the circuit will be the same voltage that is supplied to branch 1, which will be the same as the voltage being supplied to branch 2, and so on.
- the current is divided between the different circuit branches according to their individual resistances, and the total current is equal to the sum of the currents in each branch. The mathematical formula is as follows:

$$I_{total} = I_1 + I_2 + I_3 + \ldots$$

- the total equivalent resistance of a parallel circuit will always be less than the value of the lowest resistance. As more and more resistive paths or branches are added to the parallel circuit, the total resistance of the circuit gets lower and lower.

Calculating the total resistance in a parallel circuit requires a different procedure than simply adding them together, as in a series circuit. A parallel circuit allows current flow along two or more paths at the same time. This type of circuit applies equal voltage to all loads. The general formula used to determine total resistance in parallel circuits is as follows:

For two resistances

$$R_{total} = \frac{R_1 \times R_2}{R_1 + R_2}$$

For more than two resistances

$$R_{total} = \frac{1}{\frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3} + \cdots}$$

The total resistance of the circuit in **Figure 12.22** is determined as follows:

$$R_{total} = \frac{1}{\frac{1}{10\ \Omega} + \frac{1}{20\ \Omega} + \frac{1}{30\ \Omega}}$$

$$= \frac{1}{0.1 + 0.05 + 0.033}$$

$$= \frac{1}{0.183}$$

$$= 5.46\ \Omega$$

Notice that the total resistance of 5.46 Ω is lower than the lowest individual resistance in the circuit. Another way to look at the resistance calculation is as follows:

$$\frac{1}{R_{total}} = \frac{1}{R_1} + \frac{1}{R_2} + \frac{1}{R_3}$$

$$\frac{1}{R_{total}} = \frac{1}{10\ \Omega} + \frac{1}{20\ \Omega} + \frac{1}{30\ \Omega}$$

$$\frac{1}{R_{total}} = \frac{6}{60} + \frac{3}{60} + \frac{2}{60}$$

$$\frac{1}{R_{total}} = \frac{11}{60}$$

$$R_{total} = \frac{60}{11}$$

$$R_{total} = 5.64\ \Omega$$

Figure 12.22 The total resistance of this circuit can be determined using the information in the diagram.

To determine the total current draw, use Ohm's law:

$$I = \frac{E}{R} = \frac{120\ \text{V}}{5.46\ \Omega} = 22\ \text{A}$$

We can confirm this value for the total current in the circuit by determining the current flow through the individual loads or resistances and then adding them up. The current flow through the 10-Ω resistance is determined here:

$$I_{10} = E \div R$$

$$I_{10} = 120\ \text{V} \div 10\ \Omega = 12\ \text{A}$$

The current flow through the 20-Ω resistance is determined here:

$$I_{20} = E \div R$$

$$I_{20} = 120\ \text{V} \div 20\ \Omega = 6\ \text{A}$$

The current flow through the 30-Ω resistance is determined here:

$$I_{30} = E \div R$$

$$I_{30} = 120\ \text{V} \div 30\ \Omega = 4\ \text{A}$$

By adding these three individual branch currents together, we get

$$I_{\text{total}} = I_1 + I_2 + I_3$$

$$I_{\text{total}} = 12\ \text{A} + 6\ \text{A} + 4\ \text{A}$$

$$I_{\text{total}} = 22\ \text{A}$$

12.13 ELECTRICAL POWER

Electrical power (P) is measured in watts. A **watt (W)** is the power used when 1 ampere flows with a potential difference of 1 volt. Therefore, power can be determined by multiplying the voltage and the circuit amperage together.

$$\text{Watts} = \text{Volts} \times \text{Amperes}$$

or

$$P = E \times I$$

The consumer of electrical power pays the electrical utility company according to the number of kilowatts (kW) used for a certain time span, usually billed as kilowatt hours (kWh). A kilowatt is equal to 1000 W. To determine the power being consumed, divide the number of watts by 1000:

$$P\ (\text{in kW}) = \frac{E \times I}{1000}$$

In the circuit shown in **Figure 12.22**, the power consumed can be calculated as follows:

$$P = E \times I$$

$$P = 120\ \text{V} \times 22\ \text{A} = 2640\ \text{W}$$

$$\text{kW} = P \div 1000$$

$$\text{kW} = 2640\ \text{W} \div 1000 = 2.64\ \text{kW}$$

If the circuit in **Figure 12.22** is in operation for one hour, 2.64 kWh of energy have been consumed.

12.14 MAGNETISM

Magnetism was briefly discussed earlier in the unit to explain how electrical generators are able to produce electricity. Magnets are classified as either permanent or temporary. Permanent magnets are used in only a few applications that air-conditioning and refrigeration technicians would work with, such as electronically commutated motors (ECM), but electromagnets, a type of temporary magnet, are used in many electrical components of air-conditioning and refrigeration equipment.

A magnetic field is generated around a wire whenever an electrical current is flowing through it, **Figure 12.23**. If the wire or conductor is formed into a loop, the strength of the magnetic field will be increased, **Figure 12.24**, and if the wire is wound into a coil, an even stronger magnetic field will be created, **Figure 12.25**. This coil of wire carrying an electrical current is called a **solenoid**. This solenoid or electromagnet will attract or pull an iron bar into the coil, **Figure 12.26**. If an iron bar is inserted permanently in the coil, the strength of the magnetic field will be increased even more.

The magnetic field can be used to perform a number of tasks including generating electricity and causing electric motors to operate. The magnetic attraction can also open and

Figure 12.23 This cross section of a wire shows a magnetic field around the conductor.

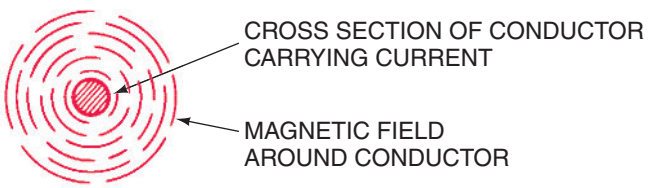

Figure 12.24 The magnetic field around a loop of wire. This is a stronger field than that around a straight wire.

close electrical contacts and valves, as in the case of many controls and switching devices, such as solenoids, relays, and contactors, **Figures 12.27(A)–(C)**. **Figure 12.28** is a cutaway view of a solenoid.

12.15 INDUCTANCE

As mentioned previously, when current flows through a conductor, a magnetic field is produced around the conductor. In an AC circuit, the current is continually changing direction. This causes the magnetic field to continually build up and collapse. When these lines of force build up and collapse, they cut through the wire or conductor and produce an emf, or voltage that opposes the existing voltage in the conductor.

In a straight conductor, the induced voltage is very small and is usually not considered, **Figure 12.29**. However, if a

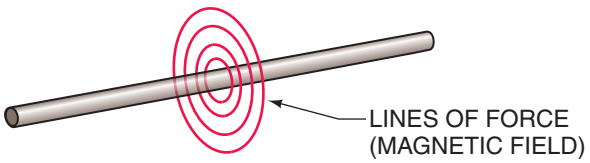

Figure 12.30 A conductor formed into a coil with lines of force.

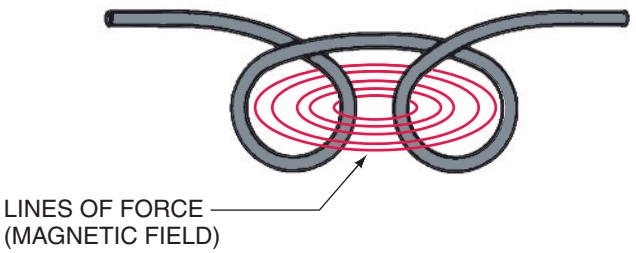

Figure 12.31 Electrical symbols for a coil.

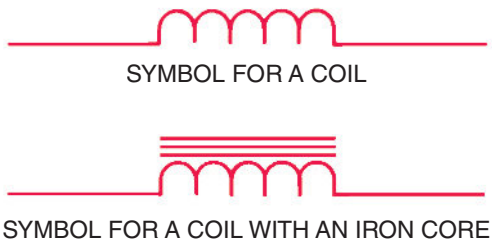
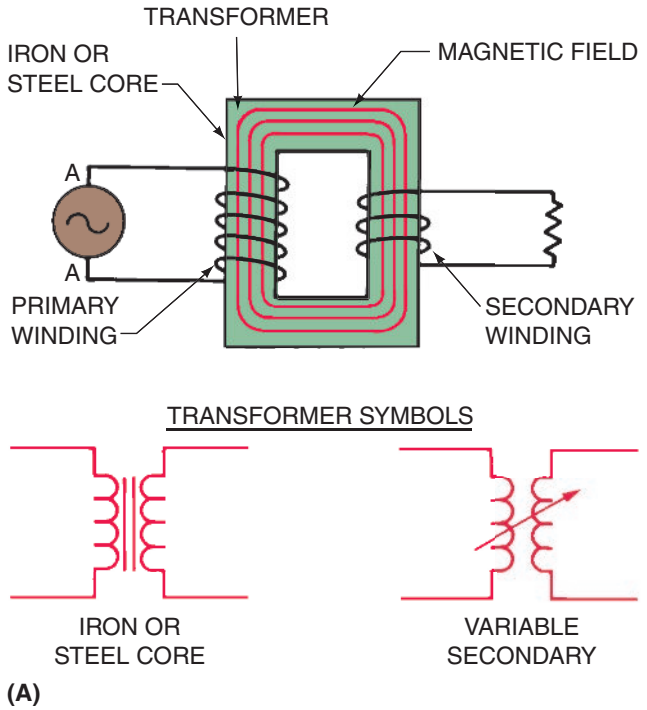


conductor is wound into a coil, the lines of force overlap and reinforce each other, **Figure 12.30**, which develops an emf or voltage that is strong enough to provide opposition to the existing voltage. This opposition is called **inductive reactance** and is a type of resistance in an AC circuit. Coils and transformers are examples of components that produce inductive reactance. **Figure 12.31** shows symbols for the electrical coil. Electric motors have coils of wire in them and are, therefore, referred to as inductive loads. Inductive loads primarily generate a magnetic field, unlike resistive loads such as incandescent light bulbs and electric heaters that generate primarily light and/or heat.

12.16 TRANSFORMERS

Transformers are electrical devices that produce voltage in a second circuit through electromagnetic induction. In **Figure 12.32(A)**, a voltage applied to the primary winding at A-A will produce a magnetic field around the steel or iron core. This AC current causes the magnetic field to continually build up and collapse as the current reverses. This will cause the magnetic field around the core in the secondary winding to cut across the conductor wound around it, inducing an electric voltage in the secondary winding. If this induced

Figure 12.32 (A) Voltage applied across terminals produces a magnetic field around an iron or steel core. (B) A transformer.



(A)

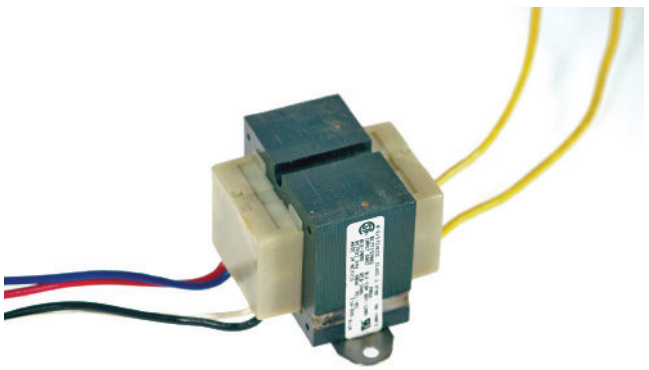


Photo by Bill Johnson

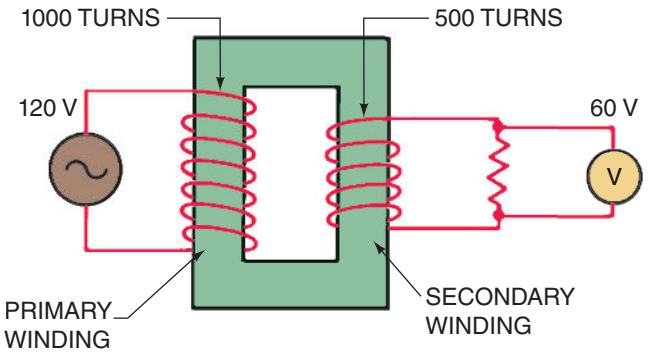
(B)

voltage is then connected to a separate, otherwise complete, circuit, current will flow in that circuit.

Transformers, **Figure 12.32(B)**, have a primary winding, a core usually made of thin plates of steel laminated together, and a secondary winding. There are step-up and step-down transformers. A step-down transformer contains more turns of wire in the primary winding than in the secondary winding. The voltage at the secondary is directly proportional to the number of turns of wire in the secondary (as compared to the number of turns in the primary) winding. For example, **Figure 12.33** shows a transformer with 1000 turns in the primary winding and 500 turns in the secondary winding.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 12.33 A step-down transformer.

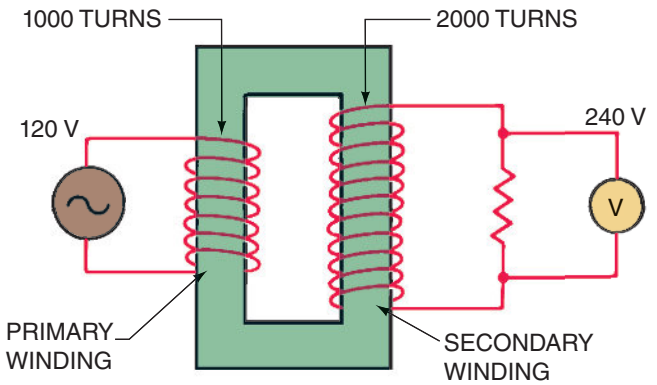


When a voltage of 120 V is applied to the primary, the voltage induced in the secondary is 60 V. (Actually, the secondary voltage is slightly lower than 60 V due to some loss into the air of the magnetic field and because of resistance in the wire.)

A step-up transformer has more windings in the secondary than in the primary. This causes a larger voltage to be induced in the secondary. In **Figure 12.34**, with 1000 turns in the primary, 2000 in the secondary, and an applied voltage of 120 V, the voltage induced in the secondary is roughly double, or approximately 240 V. The same power (watts) is available at the secondary as at the primary (except for a slight loss). If the voltage produced at the secondary winding is reduced to one-half that at the primary, the current capacity nearly doubles. Step-up transformers are commonly used to generate sparks to ignite air/fuel mixtures in heating applications.

Step-up transformers are also used at generating stations to increase voltage to more efficiently deliver electrical energy over long distances to substations or other distribution centers. At the substation, the voltage is reduced by a step-down transformer for ultimate distribution to the end users of the power. At a residence, the voltage may be reduced to 240 V or 120 V. Additional step-down transformers may be used with air-conditioning and heating equipment to produce the 24 V commonly used in thermostats and other control devices.

Figure 12.34 A step-up transformer.



12.17 CAPACITANCE

A **capacitor** is a device in an electric circuit that stores electrical energy for later use. A simple capacitor is composed of two plates with insulating material between them, **Figure 12.35**. This insulating material, referred to as a dielectric, can be air, paper, or other nonconductive material. The capacitor can store a charge of electrons on one plate. When the plate is fully charged in a DC circuit, no current will flow until there is a path back to the positive plate, **Figure 12.36**. When the path is available, the electrons will flow to the positive plate until the negative plate no longer has a charge, **Figure 12.37**. At this point, both plates are neutral.

In an AC circuit, the voltage and current are continually changing direction. As the electrons flow in one direction, the capacitor plate on one side becomes charged. As the current and voltage reverse, the charge on the capacitor becomes greater than the source voltage, and the capacitor begins to discharge through the circuit, and the opposite plate becomes charged. This continues through each AC cycle.

A capacitor has **capacitance**, which is the amount of charge that can be stored. The capacitance is determined by the following physical characteristics of the capacitor:

1. Distance between the plates, in meters
2. Surface area of the plates, in square meters
3. Dielectric material between the plates

Figure 12.35 A capacitor.

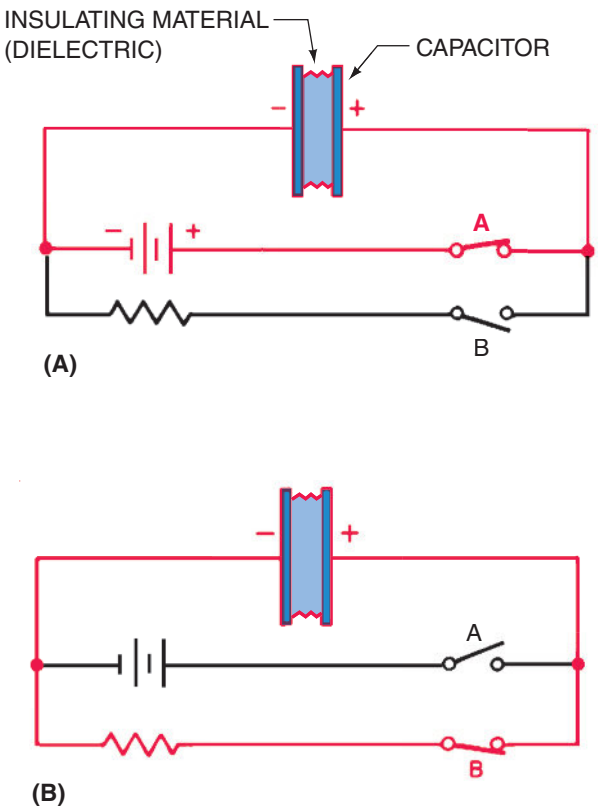
Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 12.37 (A) Electrons will flow to the negative plate from the battery. The negative plate will charge until the capacitor has the same potential difference as the battery. (B) When the capacitor is charged, switch A is opened, switch B is closed, and the capacitor discharges through the resistor to the positive plate. The capacitor is then completely discharged and has no charge.



Capacitors are rated in farads. However, farads represent such a large amount of capacitance that the unit microfarad is normally used, which is one-millionth (0.000001) of a farad. The symbol for micro is the Greek letter μ (mu) and the symbol for farad is the capital letter F, so a microfarad is represented as μF. Capacitors can range from 2 or 3 microfarads up to several hundred microfarads.

The formula for capacitance is given by

$$C = \varepsilon_0 KA/D$$

where ε_0 is a constant that is equal to 8.84×10^{-12} (0.00000000000884), K = the dielectric constant, A is the area of the capacitor's plates in square meters (m^2), and D is the distance between the plates in meters. Common dielectrics are air, paper, and glass and the dielectric constants for these materials are as follows:

Dielectric Constant for Air = 1.0

Dielectric Constant for Paper = 3.5

Dielectric Constant for Glass = 3

Figure 12.38 This meter is set to the appropriate scale to measure capacitance. The MFD stands for microfarads and the electrical symbol for a capacitor can also be seen.

Photo by Eugene Silberstein

If we had a capacitor that had a paper dielectric, and 0.33 square meters of plates that are separated by 0.000002 meters, the capacitance can be calculated as:

$$C = \varepsilon_0 KA/D$$

$$C = (8.84 \times 10^{-12})(3.5)(0.333\ m^2)/0.000002\ m$$

$$C = 5 \times 10^{-6}\ \text{Farads, or 5 microfarads}$$

Although the calculation shown above looks complicated, the great news is that HVAC/R service technicians do not make these calculations. This work is done when the capacitor is designed. Service technicians can, however, check a particular capacitor to be sure that it is working properly. Many pieces of electrical test equipment have a feature that allows the technician to check capacitors, **Figure 12.38**. By setting the meter to the microfarad, μFd, setting and connecting the meter's test leads across the capacitor, the technician can read the capacitor's capacitance on the meter's display.

A capacitor opposes current flow in an AC circuit similar to a resistor or to inductive reactance. This opposition or type of resistance is called **capacitive reactance.** The capacitive reactance depends on the frequency of the power supply and the microfarad rating of the capacitor. Two types of capacitors used frequently in the air-conditioning and refrigeration industry are the start and run capacitors used on electric motors, **Figure 12.39**.

Figure 12.39 A start capacitor, left, and a run capacitor, right.

12.18 IMPEDANCE

We have learned that there are three types of opposition to current flow in an AC circuit. There is pure resistance, inductive reactance, and capacitive reactance. The total effect of these three is called *impedance*. The voltage and current in a circuit that has only resistance are in phase with each other. The voltage leads the current across an inductor and lags behind the current across a capacitor. **Figures 12.57** and **12.58** in Section 12.20, "Sine Waves," illustrate these conditions. Inductive reactance and capacitive reactance can cancel each other. Impedance is a combination of the opposition to current flow produced by these characteristics in a circuit.

12.19 ELECTRICAL MEASURING INSTRUMENTS

A multimeter is an instrument that measures voltage, current, resistance, and, on some models, temperature. It is a combination of several meters and can be used for making AC or DC measurements in several ranges. It is the instrument used most often by heating, refrigeration, and air-conditioning technicians. Often, a digital multimeter, the **volt-ohm-milliammeter (VOM)**, is used, such as the one in **Figure 12.40**. This meter measures AC and DC voltages, direct current (DC), and resistance. Some meters have the ability to measure AC amperage, such as the meter shown in **Figure 12.15**. Meters have different features depending on the manufacturer.

Most meters have a function switch and a range switch. The function switch allows the user to set the meter to the electrical characteristic (voltage, current, or resistance) that is being measured. The range switch allows the user to "tell the meter" what the expected reading should be, **Figure 12.41**. For example, when measuring the potential of a 2-V battery, it would be a good idea to set the meter to the 6 VDC range, **Figure 12.42**. If, however, the technician was measuring a much higher DC voltage, he might choose to set the meter to the 600 VDC range, **Figure 12.43**. If uncertain about the magnitude of the measurement, it is always best to start at the highest range; it can always be lowered later on. When taking voltage readings or when making resistance measurements, the test leads must be plugged into the meter, **Figure 12.44**.

To check the voltage in the AC circuit in **Figure 12.45**, follow these steps:

1. Turn off the power.
2. Set the function switch to read AC Voltage.

Figure 12.40 A volt-ohm-milliammeter (VOM).

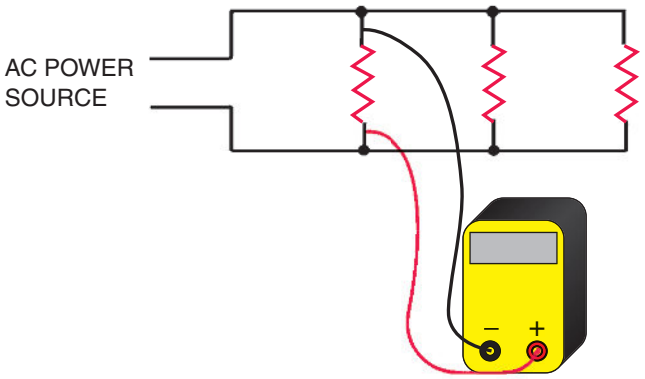
Figure 12.45 Connecting test leads across a load to check voltage.



3. Push the range button until the desired range appears on the meter's display.
4. Plug the black test lead into the common (–) jack and the red test lead into the positive (+) jack.
5. Connect the test leads across the load as shown in **Figure 12.45**.
6. Turn on the power.
7. Read the voltage on the meter's display.

To determine the resistance of a load, disconnect the load from the circuit. Make sure all power is off while doing this. If the load is not entirely disconnected from the circuit, the voltage from the battery of the ohmmeter may damage the meter's internal solid-state components. Then do the following:

1. Set the meter's function switch to read resistance.
2. Plug the test leads into the meter.
3. Connect the test leads to the device being tested.
4. Observe the reading on the meter's display.

The ammeter has a clamping feature that can be placed around a single wire in a circuit, and the current flowing through the wire can be read as amperage from the meter, **Figure 12.46**.

Figure 12.46 Measuring amperage by clamping the jaws of the meter around the conductor.

Photo by Eugene Silberstein

SAFETY PRECAUTION: *Do not perform any of the preceding or following tests in this unit without approval from an instructor or supervisor. These instructions are simply a general introduction to meters. Be sure to read the operator's manual for the particular meter available to you.* •

It is often necessary to determine voltage or amperage readings to a fraction of a volt or ampere, **Figure 12.47**. Many styles and types of meters are available for making these types of electrical measurements.

Electrical troubleshooting is performed one step at a time. **Figure 12.48** is a partial wiring diagram of a furnace's blower circuit. The blower motor does not operate because of an open motor winding. The technician could make the following voltage checks to determine where the failure is.

1. This is a 115 VAC circuit. The technician would set the VOM selector switch to the appropriate AC voltage scale. One of the meter's test leads (black) is connected to a neutral terminal, N, at the power source, while

Figure 12.47 Units of voltage and amperage.

VOLTAGE
1 volt = 1000 millivolts (mV)
1 volt = 1,000,000 microvolts (μV)

AMPERAGE
1 ampere = 1000 milliamperes (mA)
1 ampere = 1,000,000 microamperes (μA)
Note that the symbol for micro or millionths is μ.

Figure 12.48 Partial wiring diagram of furnace's blower circuit.

the other test lead (red) is connected to the line-side power source terminal, L1. Meter "A" reads 115 VAC indicating that voltage is being supplied to the circuit, **Figure 12.49**.

2. The positive (red) lead is then moved to the load side of the service switch at point 3, Meter "B" in **Figure 12.50.** Meter "B" reads 115 VAC indicating that power is passing through the service switch. If the meter reading was 0 VAC, this would indicate that the service switch is open or the wiring between L1 and the switch is defective.
3. The positive (red) lead is then moved to the load side of the fuse at point 5. Service switch at point 3, Meter "C" in **Figure 12.51.** Meter "C" reads 115 VAC indicating that power is passing through the fuse. If the meter reading was 0 VAC, this would indicate that the fuse is bad or the wiring between points 3 and 4 is defective.
4. The positive (red) lead is then moved to the load side of the fan switch at point 7, Meter "D" in **Figure 12.51.** Meter "D" reads 115 VAC indicating that power is passing through the fan switch. If the meter reading was 0 VAC, this would indicate that the fan switch is open or the wiring between points 5 and 6 is defective.
5. The positive (red) lead is then moved to the line side of the motor at point 8, Meter "E" in **Figure 12.52.** This meter reads 115 VAC indicating that power is being supplied to the motor.

   To ensure there is power through the wire on the neutral side of the motor, the neutral meter probe is moved to the neutral side of the motor at point 9 leaving the positive probe on the line side of the motor. The reading should be 115 V, indicating that current is flowing through the neutral wire and that 115 VAC is being supplied to the motor, **Figure 12.53**.

Figure 12.49 Measuring the voltage between L1 and neutral indicates that power is being supplied to the circuit.

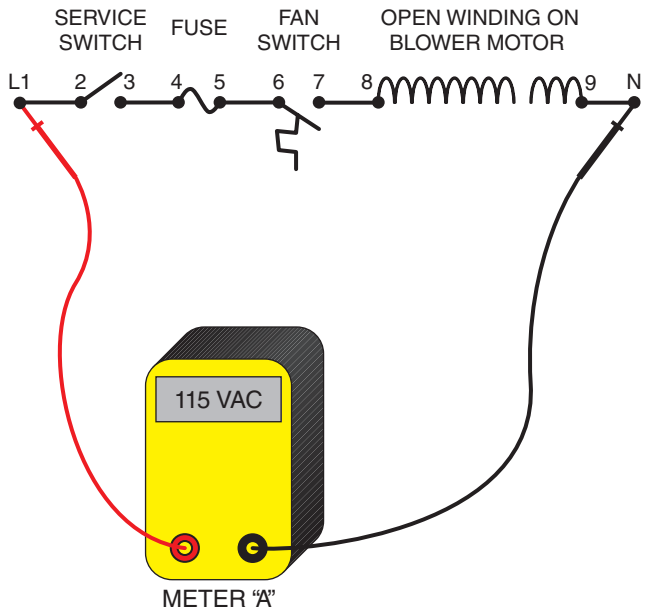

Figure 12.50 A reading of 115 VAC indicates that the service switch is in the closed position and power is passing from L1 to terminal 3.

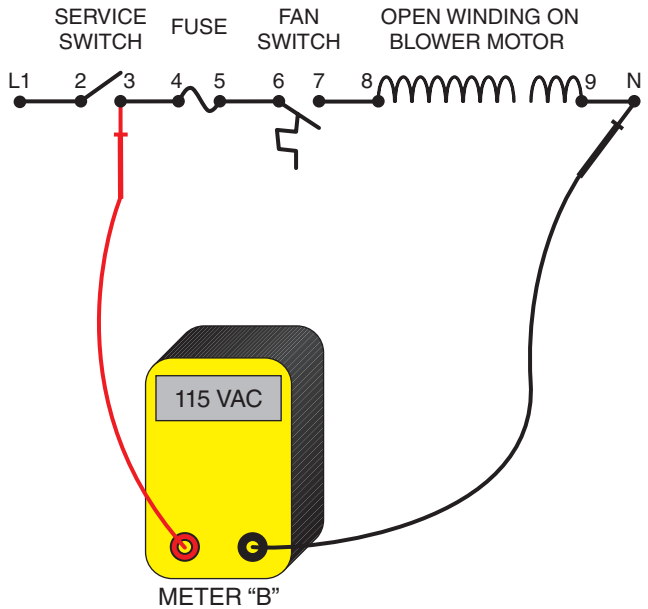

Figure 12.51 A reading of 115 VAC on Meter "C" indicates that power is passing through the fuse and a similar reading on Meter "D" indicates that power is also being passed though the fan switch. There is potential (voltage) between terminals 7 and N.

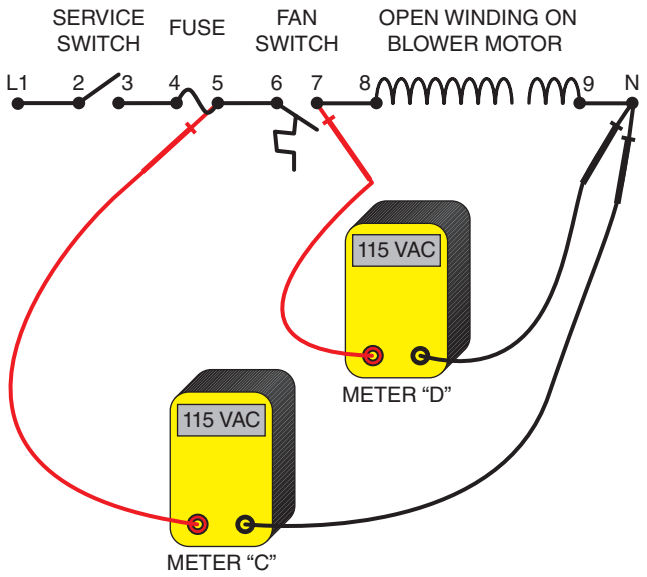

All of the checks above read 115 VAC, but the motor does not run. It would be appropriate to conclude that the motor is defective.

The motor winding can be checked with an ohmmeter. The motor winding must have a measurable resistance for it

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 12.52 A reading of 115 VAC on Meter "E" indicates that there is power being supplied to the motor at point 8.

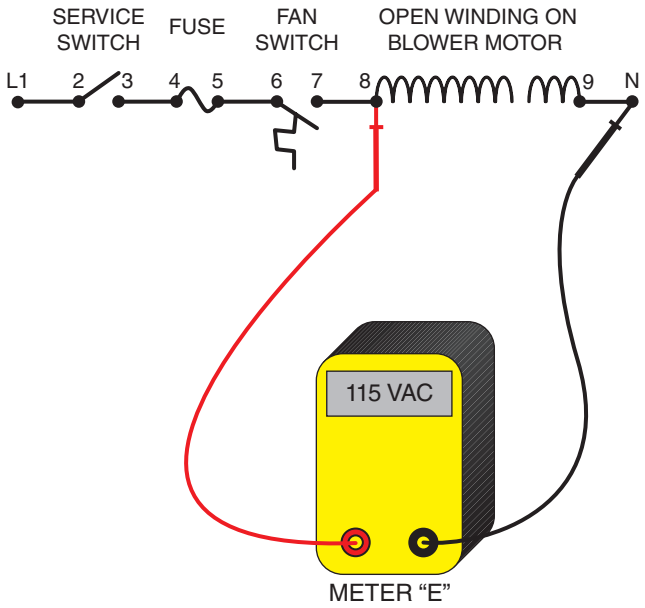

Figure 12.53 Connecting the voltmeter, Meter "F", between terminals 8 and 9 and obtaining a reading of 115 VAC indicates that the wiring between terminal 9 and N is good and that the motor winding is being powered.

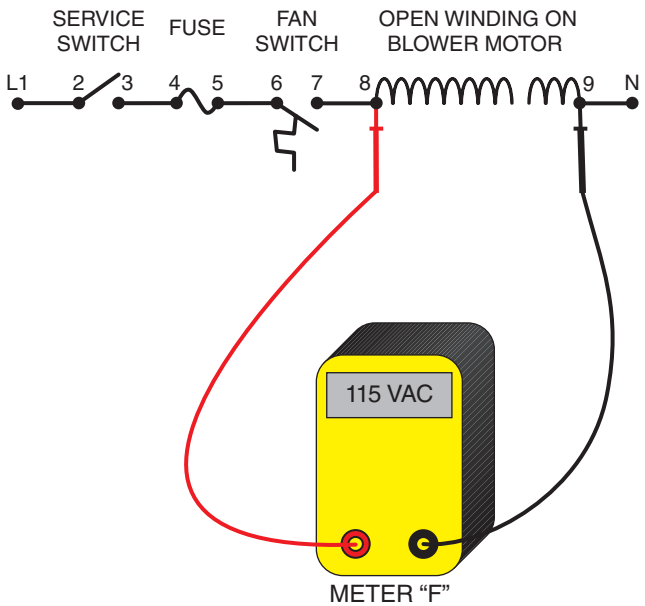
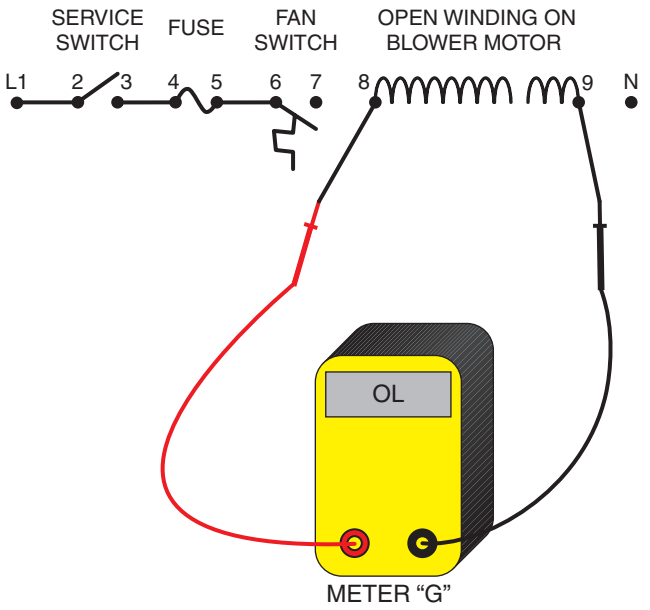


to function properly. To check this resistance, the technician may do the following, **Figure 12.54**:

1. Turn off the power source to the circuit.
2. Disconnect the terminals on the motor from the circuit.
3. Set the meter selector switch to read resistance (ohms).

Figure 12.54 The resistance of the motor winding is checked by shutting off the power to the motor and removing the winding from the electric circuit to be sure that the resistance readings obtained are accurate.



4. Touch the meter probes together to verify that the test leads are good and that the reading on the meter's display indicates a resistance value very close to zero ohms.
5. Touch one meter probe to one motor terminal and the other to the other terminal. The Meter "G" reads infinity. On digital meters, infinite resistance is often displayed as "OL" which stands for "open line" or "open lead." This is the same reading you would get by holding the meter probes apart in the air. There is no circuit through the windings, indicating that they are open.

Most analog (non-digital) ammeters do not read accurately in the lower amperage ranges, such as in the 1-ampere-or-below range. However, a standard clamp-on ammeter can be modified to accurately measure low amperages. For instance, transformers are rated in volt-amperes (VA). A 40-VA transformer is often used in the control circuit of combination heating and cooling systems. These transformers produce 24 V and can carry a maximum of 1.67 A. This is determined as follows:

$$\text{Output in amperes} = \frac{\text{VA rating}}{\text{Voltage}}$$

$$I = 40\text{VA}/24\text{V}$$

$$= 1.67\ \text{A}$$

Figure 12.55 illustrates how the clamp-on ammeter can be used with 10 wraps of wire to multiply the amperage reading by 10. To determine the actual amperage, divide the amperage indicated on the meter by 10.

12.20 SINE WAVES

As mentioned earlier, alternating current continually reverses direction. An oscilloscope is an instrument that measures the amount of voltage over a period of time and can display this voltage on a screen as a waveform. There are many types of waveforms, but we will discuss the one refrigeration and air-conditioning technicians encounter the most, the sine wave, **Figure 12.56**.

The sine wave displays the voltage of one cycle through 360°. In the United States and Canada, the standard voltage in most locations is produced with a frequency of 60 cycles per second. Frequency is measured in hertz. Therefore, the standard frequency in this country and Canada is 60 Hz. **Figure 12.56** shows a complete sine wave as it might be observed on an oscilloscope's display screen. At the 90° point, the voltage reaches its peak (positive); at 180° it is back to 0; at 270° it reaches its negative peak; and at 360° it is back to 0. If the frequency is 60 Hz, this cycle would be repeated

Figure 12.56 A sine wave displayed on an oscilloscope.

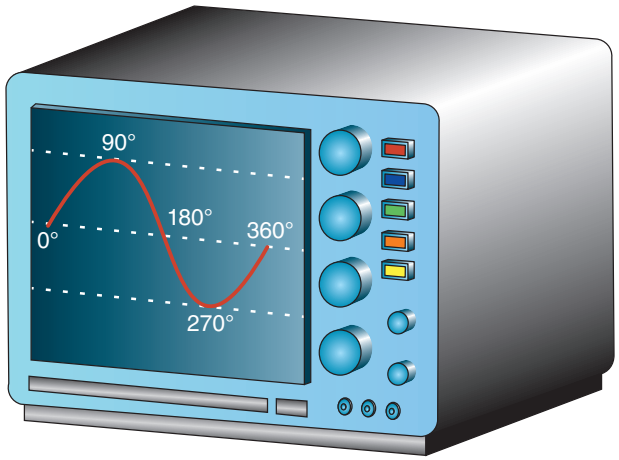

Figure 12.57 Peak and peak-to-peak AC voltage values.

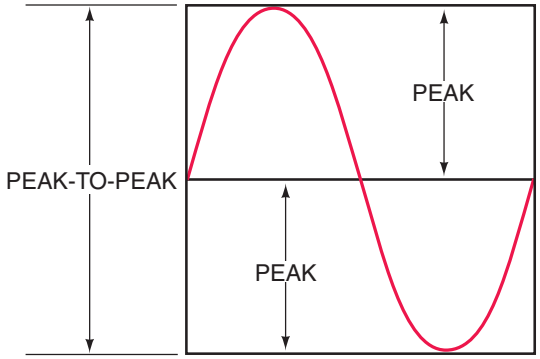

60 times every second. The sine wave is a representation of an alternating current cycle.

Figure 12.57 shows the peak and peak-to-peak values. As the sine wave indicates, the voltage is at its peak value only briefly during the cycle. Therefore, the peaks of the peak-to-peak values are not the effective voltage values. The effective voltage is the RMS voltage, **Figure 12.58**. The RMS stands for root-mean-square value. This is the alternating current value measured by most voltmeters and ammeters. The RMS voltage is 0.707 × the peak voltage. If the peak voltage were 170 V, the effective voltage measured by a voltmeter would be 120 V (170 V × 0.707 = 120.19 V).

Sine waves can illustrate a cycle of an AC electrical circuit that contains only a pure resistance, for example, a circuit with electrical heaters. In a pure resistive circuit such as this, the voltage and current will be in phase, **Figure 12.59**; notice that the voltage and current reach their negative and positive peaks at the same time.

Sine waves can also illustrate a cycle of an AC electrical circuit that contains a fan relay coil, which will produce an inductive reactance. The sine wave will show the current lagging the voltage in this circuit, **Figure 12.60**.

Figure 12.61 shows a sine wave illustrating an AC cycle of a purely capacitive circuit. In this case the current leads the voltage.

Figure 12.58 The root-mean-square (RMS) or effective voltage value.

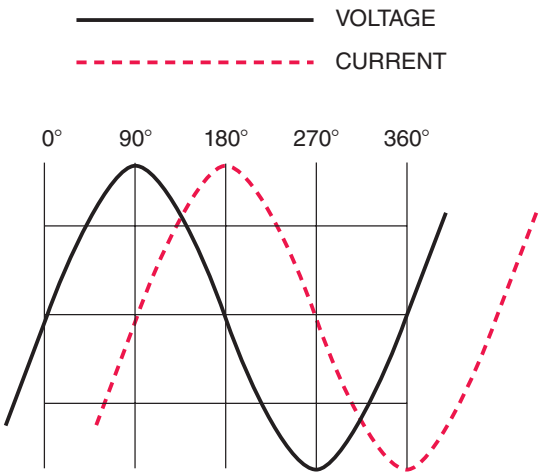

Figure 12.61 This sine wave represents a capacitive AC cycle with the voltage lagging the current by 90 degrees. The voltage and current are out of phase.

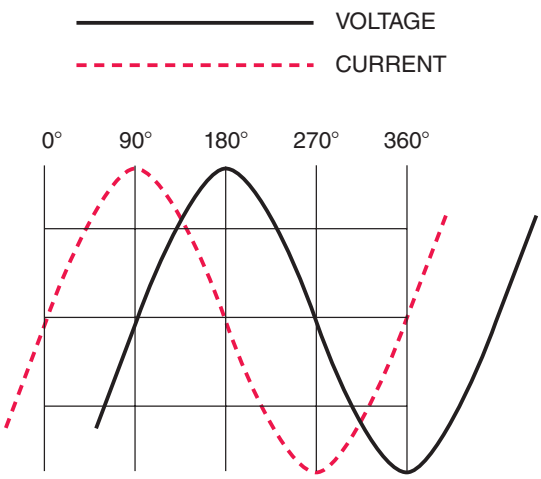

12.21 WIRE SIZES

All conductors have at least some resistance. The resistance depends on the conductor material, the cross-sectional area of the conductor, its temperature, and its length. A conductor with low resistance allows more current to flow through it than a conductor with high resistance.

The proper wire (conductor) size must always be used. The size of a wire is determined by its diameter, or cross section, **Figure 12.62**. A large-diameter wire has lower resistance and has more current-carrying capacity than a small-diameter wire. **SAFETY PRECAUTION:** *If a wire is too small for the current passing through, it will overheat and possibly burn the insulation and cause a fire.*• Standard copper wire sizes are identified by American Standard Wire Gauge (AWG) numbers and measured in circular mils. (A circular mil is the area of a circle 1/1000 in. in diameter.) Temperature is also considered because resistance increases as temperature increases. Increasing wire-size numbers indicate *smaller* wire diameters and greater resistance. For example, number 12 wire is smaller than number 10 wire and has less current-carrying capacity.

The technician should not select the size of a conductor nor install the wire unless licensed to do so. The technician should, however, be able to recognize an undersized conductor and bring it to the attention of a qualified person. As mentioned previously, an undersized wire may cause voltage to drop, breakers or fuses to trip, and conductors to overheat.

The conductors are sized by their amperage-carrying capacity. This is called **ampacity**. **Figure 12.63** contains a small part of a chart from the *National Electrical Code®* (*NEC®*) and a partial footnote for one type of conductor. As shown, this chart and the footnote should not be used to determine a wire size; it is included here only to familiarize you with the way in which it is presented in the *NEC*. The footnote actually reduces the amount of amperes for the number 12 and number 14 wire listed in the *NEC* table in **Figure 12.63**. The reason is that number 12 and number 14 wire are used in residential houses where circuits are often overloaded unintentionally by the homeowner. The footnote exception simply adds more protection. The following discussion is an example of a procedure that might be used for

Figure 12.62 Cross section of a wire.

Figure 12.63 This section of the *National Electrical Code®* shows an example of how a wire is sized for only one type of conductor. It is not the complete and official position, but a representative example.

WIRE SIZE	AMPACITY
	60°C (140°F)
AWG or kcmil	Types TW, UF
COPPER	
18	—
16	—
14*	20
12*	25
10*	30
8	40
6	55
4	70
3	85
2	95
1	110

***Small Conductors.** Unless specifically permitted in (e) through (g), the overcurrent protection shall not exceed 15 amperes for No. 14, 20 amperes for No. 12, and 30 amperes for No. 10 copper.

calculating the wire size for the outdoor unit of a heat pump, **Figure 12.64**.

The outdoor unit is a 3½-ton unit (the 42A in the model number means 42,000 Btu/hr or 3½ tons). The electrical data show that the unit compressor draws 19.2 FLA (full-load amperage) and the fan motor draws 1.4 FLA, for a total of 20.6 FLA. The specifications round this up to an ampacity of 25. In other words, the conductor must be sized for 25 amperes. According to the *NEC*, the wire size would be 10. The specifications for the unit indicate that a maximum fuse or breaker size would be 40 A. This difference allows for the compressor's locked-rotor amperage (LRA) draw at start-up. If the circuit were wired and protected to accommodate only 10 A of current, the circuit breaker would trip every time the compressor started. Some manufacturers state the ampacity and the recommended wire size in the directions or print this information on the unit's nameplate.

12.22 CIRCUIT PROTECTION DEVICES

SAFETY PRECAUTION: *Electric circuits must be protected from current overloads. If too much current flows through the circuit, the wires and components will overheat, resulting in damage and possible fire. Circuits are normally protected with fuses or circuit breakers.*•

FUSES

A **fuse** is a simple device used to protect circuits from overloading and overheating. Most fuses contain a strip of metal that has a higher resistance than the conductors in the circuit. This strip also has a relatively low melting point. Because of its higher resistance, it will heat up faster than the conductor. When the current exceeds the rating on the fuse, the strip melts and opens the circuit. Fuses are one-time devices and must be replaced when the strip or element melts. The cause for the circuit overload must be identified and corrected before replacing the fuse.

PLUG FUSES. Plug fuses have either an Edison base or a type S base, **Figure 12.65(A)**. Edison-base fuses are used in older installations and may be used for replacement only. Type S fuses can be used only in a type S fuse holder specifically designed for the fuse; otherwise, an adapter must be used, **Figure 12.65(B)**. Each adapter is designed for a specific amperage rating, and these fuses cannot be interchanged. The amperage rating determines the size of the adapter. Plug fuses are rated up to 125 V and 30 A.

DUAL-ELEMENT PLUG FUSES. Many circuits have electric motors as the load or part of the load. Motors draw more current when starting and can cause a plain (single-element) fuse to burn out or open the circuit. Dual-element fuses are frequently used in this situation, **Figure 12.66**. One element in the fuse will melt when there is a large overload, such as a short circuit. The other element will melt and open the circuit when there is a smaller current overload lasting more than a few seconds. This allows for the higher starting current of an electric motor.

CARTRIDGE FUSES. The ferrule cartridge fuse is used for 230-V to 600-V service up to 60 A, **Figure 12.67(A)**. Knife-blade cartridge fuses can be used, **Figure 12.67(B)**, from 60 A to 600 A. A cartridge fuse is sized according to its amperage rating to prevent the use of a fuse with an inadequate rating. Many cartridge fuses have an arc-quenching material around the element to prevent damage from arcing in severe short-circuit situations, **Figure 12.68**.

CIRCUIT BREAKERS

A circuit breaker can function as a switch as well as a means for opening a circuit when a current overload occurs. Most modern installations in houses and many commercial and industrial installations use circuit breakers rather than fuses for circuit protection. Circuit breakers protect the circuit in two ways. One is a bimetal strip that heats up with a current overload and trips the breaker, opening the circuit. The other is a magnetic coil that causes the breaker to trip and open the circuit when there is a short circuit or other excessive current overload over a short period of time, **Figure 12.69**.

GROUND FAULT CIRCUIT INTERRUPTERS (GFCI)

SAFETY PRECAUTION: *Ground fault circuit interrupters (GFCI) help protect individuals against shock in addition to providing current overload protection. The GFCI,* **Figure 12.70**, *detects even a very small current leak to a ground, which may not be detected by a conventional circuit breaker. Under certain conditions, this leak may cause an electrical shock. The leak will cause the GFCI to open the circuit.*•

Circuit protection is essential to avoid overloading the conductors in the circuit. If one of the circuit power-consuming devices were to cause an overload due to a short circuit, the circuit protector would stop the current flow

Figure 12.69 (A) A circuit breaker. (B) Cutaway view of the breaker.

(A) (B)

before the conductor became overloaded and hot. Remember, a circuit consists of a power supply, the conductor, and the power-consuming device. The conductor must be sized large enough that it does not operate beyond its rated temperature, typically 140°F (60°C) while in an ambient of 86°F (30°C). For example, a circuit may be designed to carry a load of 20 A. As long as the circuit is drawing less than this amperage, overheating is not a potential hazard. If the amperage in the circuit is gradually increased, the conductor will begin to become hot, **Figure 12.71**. Proper understanding of circuit protection is a lengthy process. More details can be obtained from the *NEC* and from further study of electricity.

12.23 SEMICONDUCTORS

Technological advances in the fields of semiconductors and solid-state component design have brought about major changes in the electrical devices and controls found in HVAC/R systems. Semiconductor-based components are generally small and lightweight and can be mounted in circuit boards, **Figure 12.72.** In this section we describe some of the individual solid-state devices and some of their uses. Refrigeration and air-conditioning technicians do not replace solid-state components on circuit boards, but they should have some knowledge of these components and should be able to determine when one or more of the circuits in which they are used are defective. In most cases, when a component is defective the entire board will need to be replaced.

Common semiconductor materials are silicon and germanium. In their pure form, semiconductors, as their name implies, do not conduct electricity very well. This is because pure silicon and germanium atoms each have four valence electrons and bond together to form crystals that hold onto their electrons tightly, **Figure 12.73.** Each silicon atom shares its four valence electrons with its neighboring atoms, while the neighboring atoms do the same. This allows each atom to have, in effect, a full outermost electron shell. To be of value, however, semiconductors must conduct electricity in some controlled manner. To accomplish this, impurities are added to the crystal-like structures of the silicon or germanium. This process is called *doping*. One type of doping involves adding small amounts of boron or gallium to the silicon. Since boron and gallium atoms each have three valence electrons, the addition of this impurity creates a hole in the material where an electron should be, **Figure 12.74.** Because the hole replaces an electron

Figure 12.73 A representation of a silicon crystal. Each silicon atom has 4 valence electrons that are shared with the surrounding atoms. The surrounding atoms also share their electrons to nearby silicon atoms. Notice that the center silicon atoms have 8 electrons, indicated by red circles, in the electron orbit.

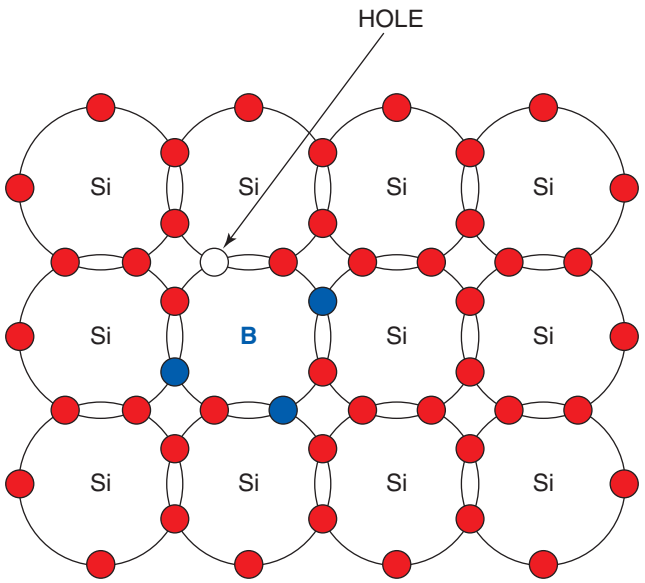
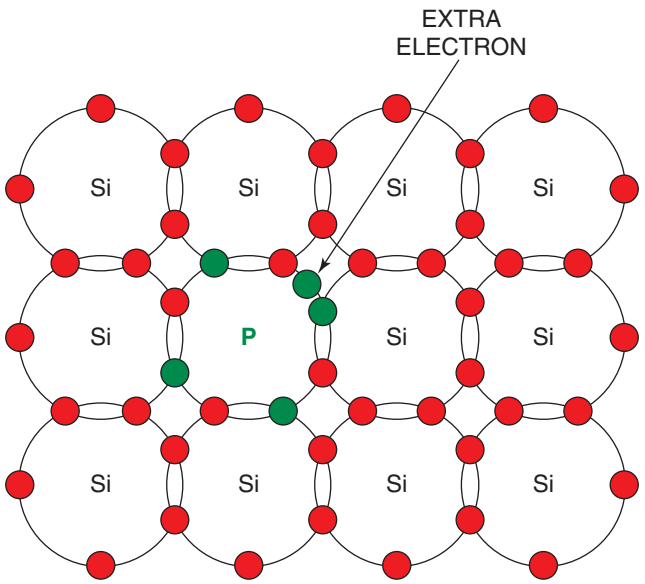
Figure 12.74 Silicon doped with boron, which has three valence electrons, indicated by the blue circles. Notice the hole that is present, creating P-type material.



(which has a negative charge), the material has fewer electrons, or a net result of a positive charge. This is called *P-type* material. A different type of doping involves adding small amounts of phosphorus or arsenic to the silicon. Since phosphorous and arsenic atoms each have five valence electrons, the addition of this impurity creates an excess of electrons, giving the semiconductor a negative charge, **Figure 12.75**. This creates what is referred to as N-type material. When a voltage is applied to a P-type material, electrons fill the holes and move from one hole

Figure 12.75 Silicon doped with phosphorous, which has five valence electrons, indicated by the green circles. Notice the extra electron that is present, creating N-type material.



to the next, still moving from negative to positive. This makes it appear that the holes are moving in the opposite direction (from positive to negative) as the electrons move from hole to hole. N-type material has an excess of electrons that move from negative to positive when a voltage is applied.

Solid-state components are made from various combinations of N-type and P-type substances. The manner in which the materials are joined together, the thickness of the materials, and other factors determine the type of solid-state component and its electronic characteristics.

DIODES

Diodes are simple solid-state devices. They consist of P- and N-type material connected together. When this combination of P- and N-type material is connected to a power source one way, it will allow current to flow and is said to have forward bias. When reversed, it is said to have reverse bias and no current will flow. **Figure 12.76** is a drawing of a simple diode; **Figure 12.77** is a photo of two types of diodes. One of the connections on the diode is called the cathode and the other the anode, **Figure 12.78**. If the diode is to be connected to a battery so as

Figure 12.76 A pictorial diagram of a diode.

Figure 12.79 A simple diagram with a diode indicating forward bias.

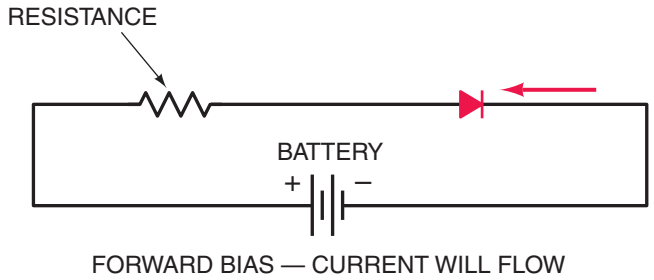

Figure 12.80 A circuit with a diode indicating reverse bias.

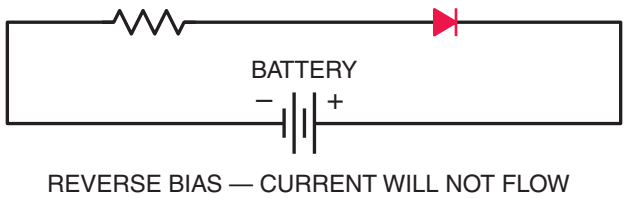

to have forward bias (current flow), the negative terminal on the battery should be connected to the cathode, **Figure 12.79**. Connecting the negative terminal of the battery to the anode will produce reverse bias (no current flow), **Figure 12.80**.

RECTIFIERS

A diode can be used as a solid-state rectifier, changing AC to DC. A component rated for less than 1 A is normally termed a diode. A similar component rated above 1 A is called a rectifier. A rectifier allows current to flow in one direction. Remember that AC flows first in one direction and then reverses, **Figure 12.81(A)**. The rectifier allows the AC to flow in one direction but blocks it from reversing, **Figure 12.81(B)**. Therefore, the output of a rectifier circuit is in one direction, or direct current. This is called a half-wave rectifier because it allows only

Figure 12.81 (A) A full-wave AC waveform. (B) A half-wave DC waveform.

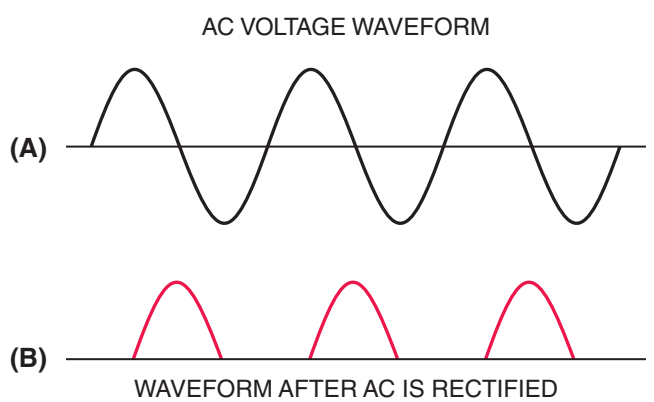

Figure 12.82 A diode rectifier circuit.

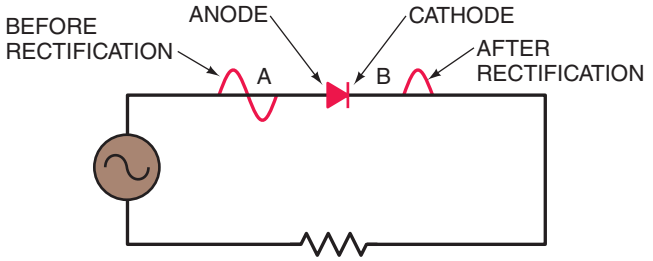

Figure 12.83 A full-wave bridge rectifier.

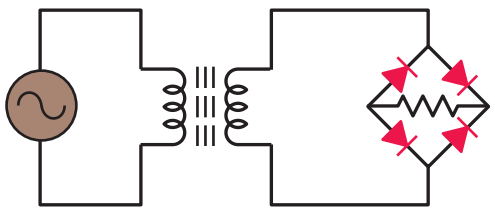

that part of the AC moving in one direction to pass through. **Figure 12.82** illustrates a rectifier circuit. Waveform "A" in **Figure 12.82** shows the AC before it is rectified and Waveform "B" in **Figure 12.82** shows the AC after it is rectified. Full-wave rectification can be achieved by using a more complicated circuit such as the one in **Figure 12.83**. This is a full-wave bridge rectifier, which is commonly used in the industry.

SILICON-CONTROLLED RECTIFIER. Silicon-controlled rectifiers (SCRs) consist of four semiconductor materials bonded together. These form a PNPN junction, **Figure 12.84(A)**; **Figure 12.84(B)** illustrates the schematic symbol. Notice that the schematic is similar to that for the diode except for the gate. The gate is the control for the SCR. The SCR is used

to control devices that may use large amounts of power, for example, to control the speed of motors or to control the brightness of lights. **Figure 12.85** is a photo of a typical SCR.

TRANSISTORS

Transistors are made of three pieces of N-type and P-type semiconductor materials sandwiched together. Transistors are either of the NPN or PNP type. **Figure 12.86** shows diagrams and **Figure 12.87** shows the schematic symbols for

Figure 12.86 Drawings of NPN and PNP transistors.

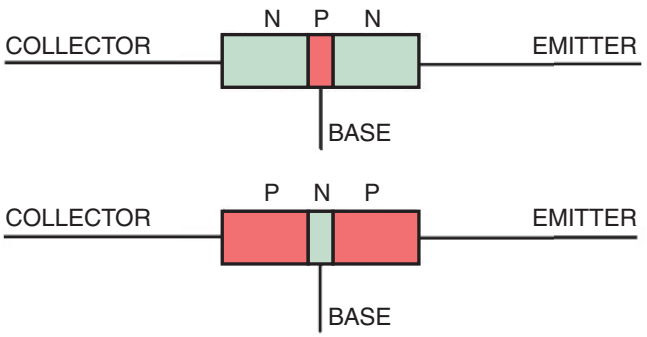

Figure 12.87 Schematic drawings of NPN and PNP transistors.

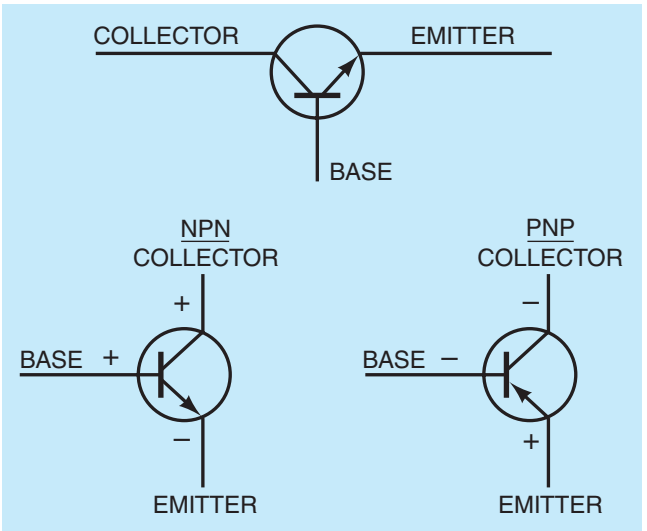

Figure 12.88 Typical transistors.

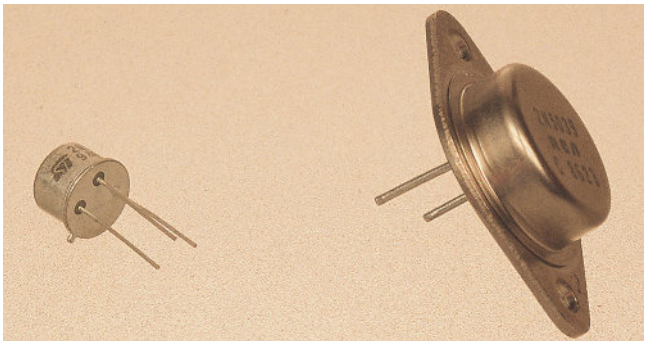

Photo by Bill Johnson

the two types. As the symbols show, each transistor has a base, a collector, and an emitter. In the NPN type, the collector and the base are connected to the positive; the emitter is connected to the negative. The PNP transistor has a negative base and collector connection and a positive emitter. The base must be connected to the same polarity as the collector to provide forward bias. **Figure 12.88** is a photo of typical transistors.

The transistor may be used as a switch or as a device to amplify an electrical signal. One application of a transistor in an air-conditioning control circuit would be to amplify a small signal to provide enough current to operate a switch or relay. Current will flow through the base-emitter and through the collector-emitter. The base-emitter current is the control, and the collector-emitter current produces the action. A very small current passing through the base emitter may allow a much larger current to pass through the collector-emitter junction. A small increase in the base-emitter junction can allow a much larger increase in the current flow through the collector-emitter.

THERMISTORS

A thermistor is a type of resistor that is sensitive to temperature, **Figure 12.89**. The resistance of a thermistor

Figure 12.89 A thermistor.

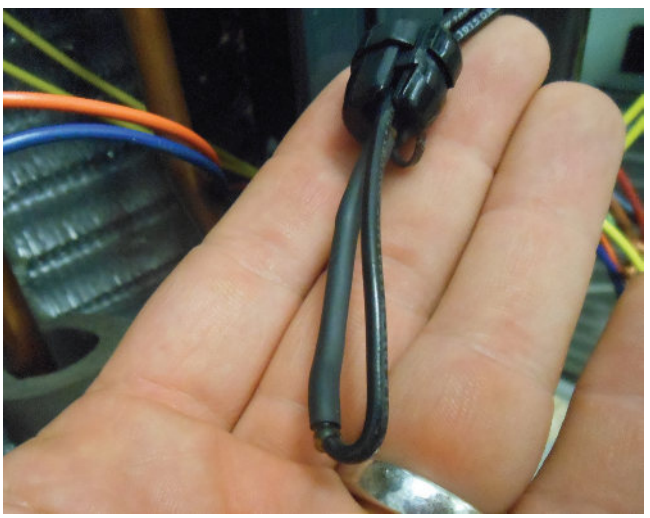

Photo by Eugene Silberstein

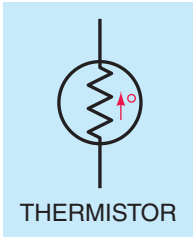
Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 12.90 The schematic symbol for a thermistor.



changes with a change in temperature. A positive temperature coefficient (PTC) thermistor causes the resistance of the thermistor to increase when the temperature increases. A negative temperature coefficient (NTC) thermistor causes the resistance to decrease with an increase in temperature. **Figure 12.90** illustrates the schematic symbol for a thermistor.

One thermistor application is to provide motor overload protection. The thermistor is embedded in the windings of a motor. When the winding temperature exceeds a predetermined amount, the thermistor resistance changes. This change in resistance is detected by an electronic circuit that causes the motor circuit to open. Another application is providing start assistance in a PSC (permanent split-capacitor) electric motor. This thermistor, a positive temperature coefficient device, allows full voltage to reach the start windings during start-up of the motor. The thermistor heats during start-up and creates resistance, turning off power to the start winding at the appropriate time. This does not give the motor the starting torque that a start capacitor does, but it is advantageous in some applications because of its simple construction and lack of moving parts.

DIACS

The diac is a two-directional electronic device that can operate in an AC circuit; its output is AC. It is a voltage-sensitive switch that operates in both halves of the AC waveform. When a voltage is applied, it will not conduct (act as an open switch) until the voltage reaches a predetermined level. Assuming this predetermined level to be 24 V, when the voltage in the circuit reaches 24 V, the diac will begin to conduct or fire. Once it fires it will continue to conduct even at a lower voltage. Diacs are designed to have a higher cut-in voltage and lower cut-out voltage. If the cut-in voltage is 24 V, and assuming that the cut-out voltage is 12 V, in this case the diac will continue to operate until the voltage drops below 12 V—at which time it will cut off. **Figure 12.91** shows two schematic symbols for a diac. **Figure 12.92** illustrates a diac in a simple AC circuit. Diacs are often used as switching or control devices for triacs.

Figure 12.91 Schematic symbols for a diac.

Figure 12.92 A simple diac circuit.

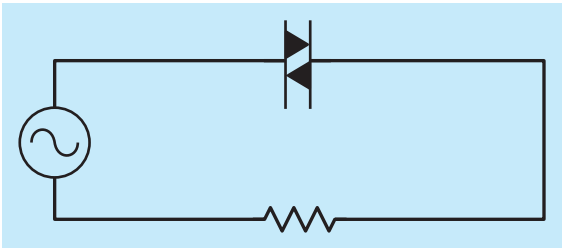


Figure 12.93 The schematic symbol for a triac.

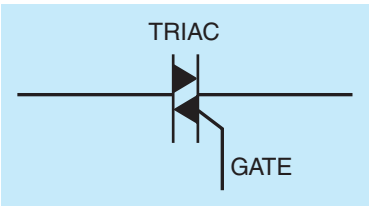


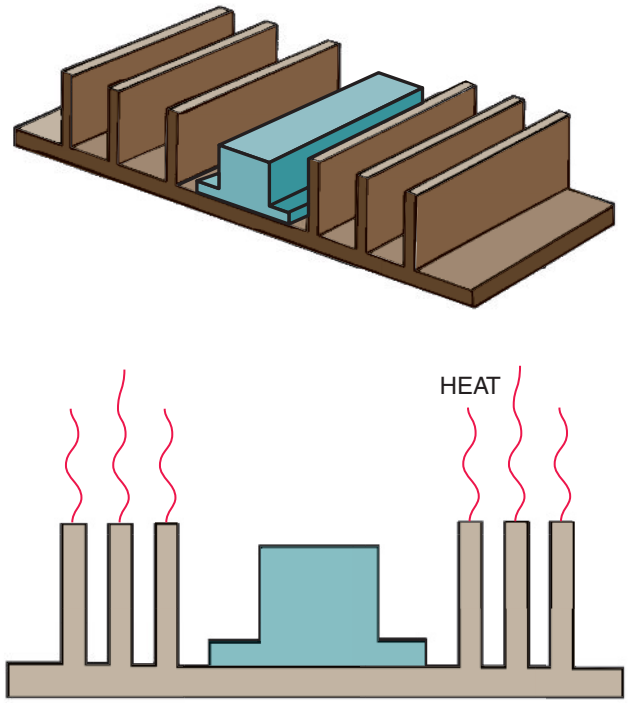
TRIACS

A triac is a switching device that will conduct on both halves of the AC waveform; its output is AC. **Figure 12.93** shows the schematic symbol for a triac. Notice that it is similar to the diac but has a gate lead. A pulse supplied to the gate lead can cause the triac to fire or to conduct. Triacs were developed to provide better AC switching. As mentioned previously, diacs often provide the pulse to the gate of the triac. A common use of a triac is as a motor speed control for AC motors.

HEAT SINKS

Some solid-state devices may appear a little different from others of the same type. This is due to the differing voltages and currents they are rated to carry and the purposes for which they are designed and used. Some produce much more heat than others and will operate only at the rating specified if kept within a certain temperature range. Heat that could change the operation of the device or destroy it must be dissipated. This is done by adhering the solid-state component to an object called a *heat sink* that has a much greater surface area, **Figure 12.94**. Heat will travel from the device to the object with the large surface area, allowing the excess heat to be dissipated into the surrounding air.

Figure 12.94 One type of heat sink.



PRACTICAL SEMICONDUCTOR APPLICATIONS FOR TECHNICIANS

This has been a short introduction to semiconductors. We have provided enough information so that you will have some idea of the purpose of these control devices and encourage you to pursue the study of these components because solid-state electronics are being used extensively to control the systems you will be working with. Each manufacturer has a control sequence procedure that you must use to successfully check their controls. Make it a practice to attend seminars and factory schools in your area to increase your knowledge of all segments in this ever-changing field. Unit 15, "Troubleshooting Basic Controls," contains many exercises that involve reading electrical schematic drawings.

SUMMARY

- Atoms are made up of protons, neutrons, and electrons.
- Protons have a positive charge, and electrons have a negative charge.
- Electrons travel in orbits around the protons and neutrons.
- When an atom has a surplus of electrons, it has a negative charge. When the atom has a deficiency of electrons, it has a positive charge.
- Electricity can be produced by using magnetism. A conductor cutting through magnetic lines of force produces electricity.
- Direct current (DC) is an electrical current moving in one direction.
- Alternating current (AC) is an electrical current that is continually reversing.
- Volt = electrical force or pressure.
- Ampere = quantity of electron flow.
- Ohm = resistance to electron flow.
- Voltage (E) = Amperage (I) × Resistance (R). This is Ohm's law.
- In series circuits, the voltage is divided across the resistances, the total current flows through each resistance, and the resistances are added together to obtain the total resistance.
- In parallel circuits, the total voltage is applied across each resistance, the current is divided between the resistances, and the total resistance is less than that of the smallest resistance.
- Electrical power is measured in watts, $P = E \times I$.
- Inductive reactance is the resistance caused by the magnetic field surrounding a coil in an AC circuit.
- A step-up transformer increases the voltage and decreases the current. A step-down transformer decreases the voltage and increases the current.
- A capacitor in an AC circuit will continually charge and discharge as the current in the circuit reverses.
- A capacitor has capacitance, which is the amount of charge that can be stored.
- Impedance is the opposition to current flow in an AC circuit from the combination of resistance, inductive reactance, and capacitive reactance.
- A multimeter often used is the VOM (volt-ohm-milliammeter).
- A sine wave displays the voltage of one AC cycle through 360°.
- **SAFETY PRECAUTION:** *Properly sized conductors must be used. Larger wire sizes can carry more current than smaller wire sizes without overheating.*
- **SAFETY PRECAUTION:** *Fuses and circuit breakers are used to interrupt the current flow in a circuit when the current is excessive.*

- Semiconductors in their pure state do not conduct electricity well, but when they are doped with an impurity, they form an N-type or P-type material that will conduct in one direction.
- Diodes, rectifiers, transistors, thermistors, diacs, and triacs are examples of semiconductors.

REVIEW QUESTIONS

1. The _____ is that part of an atom that moves from one atom to another.
   A. electron
   B. proton
   C. neutron
2. When this part of an atom moves to another atom, the losing atom will have a _____ charge.
   A. negative
   B. positive
   C. neutral
3. State the differences between AC and DC.
4. Describe how a meter would be connected in a circuit to measure the potential difference across a light bulb.
5. Describe how an amperage reading would be taken using a clamp-on or clamp-around ammeter.
6. Describe how the total resistance in a series circuit is determined.
7. Ohm's law for determining voltage is _____.
8. Ohm's law for determining amperage is _____.
9. Ohm's law for determining resistance is _____.
10. Sketch a circuit with three loads wired in parallel.
11. Describe the characteristics of the voltage, amperage, and resistances when there is more than one load in a parallel circuit.
12. If there were a current flowing of 5A in a 120-V circuit, what would the resistance be?
    A. 25 Ω
    B. 24 Ω
    C. 600 Ω
    D. 624 Ω
13. If the resistance in a 120-V circuit was 40 Ω, what would the current be in amperes?
    A. 4800A
    B. 48A
    C. 4A
    D. 3A
14. Electrical power is measured in
    A. amperes.
    B. volts.
    C. watts.
    D. ohms.
15. The formula for determining electrical power is _____.
16. Describe how a step-down transformer differs from a step-up transformer.
17. What are the three types of opposition to current flow that impedance represents?
18. Why is it important to use a properly sized wire in a particular circuit?
19. What does forward bias on a diode mean?
20. The unit of measurement for the charge a capacitor can store is the
    A. inductive reactance.
    B. microfarad.
    C. ohm.
    D. joule.

UNIT 13

INTRODUCTION TO AUTOMATIC CONTROLS

OBJECTIVES

After studying this unit, you should be able to

- describe the function of a bimetal device.
- make general comparisons between different bimetal applications.
- describe the rod and tube.
- describe fluid-filled controls.
- describe partial liquid/partial vapor-filled controls.
- distinguish among the bellows, diaphragm, and Bourdon tube.
- explain how thermocouples function.
- explain the thermistor.

SAFETYCHECKLIST

- ☑ Pressure switches are often connected directly to the refrigerant circuit, so removing them could result in the complete loss of refrigerant from the system. Be aware of how these devices are connected and whether or not they can be removed from the system safely without releasing the refrigerant charge.
- ☑ Some older controls contain mercury, which is toxic. Be sure to follow all local and federal laws and guidelines when discarding devices that contain mercury.
- ☑ Be sure to understand how a particular control operates before attempting to service or repair it.

13.1 TYPES OF AUTOMATIC CONTROLS

The heating, air-conditioning, and refrigeration field requires many types of automatic controls to start, stop, and adjust various components in response to the needs of the system. Some items that need to be controlled are the flow of electricity through circuits and the flow of various fluids (liquids and gases) through the piping, duct, and distribution systems. For example, modulating controls are used to vary the speed of a blower motor to increase or decrease the amount of airflow through a duct system.

Controls can be classified as electrical, mechanical, electromechanical, electronic or digital, and pneumatic. Pneumatic controls are discussed in Unit 16. Electrical controls are electrically operated and are typically used to control electrical devices. Mechanical controls are often operated by pressure or temperature and used to control fluid flow. Electromechanical controls are driven by pressure or temperature to provide electrical functions or they are driven by electricity to control fluid flow. Electronic controls use electronic circuits and devices to perform the same functions that electrical and electromechanical controls perform. Electronic, or digital, controls are becoming much more common, even on the smallest of systems.

The automatic control of a system is intended to maintain stable or constant conditions without excessive human interference, while also protecting people and equipment. The system must regulate itself within the design boundaries that have been established. If the equipment is allowed to operate outside of its design boundaries, the system components may become damaged, human comfort may be sacrificed and, in extreme cases, personal injury can result. The main purpose of the HVAC/R industry is to control space or product conditions by controlling temperature, humidity, air quality, and air cleanliness.

13.2 DEVICES THAT RESPOND TO THERMAL CHANGE

Automatic controls in the HVAC/R industry usually provide some method of controlling temperature. Temperature control is used to maintain space or product temperature and to protect equipment from damaging itself. When used to control temperature, the control is called a **thermostat**; when used to protect equipment, it is known as a safety device. Devices, such as thermostats, that open and close their contacts during the *normal* operation of the system are referred to as operational controls. Safety devices, on the other hand, are typically normally closed devices that open their contacts only when the device senses system conditions that are outside of the desired, or safe, operating range. A good example of both applications is a household refrigerator. The refrigerator maintains the space temperature in the fresh food section at about 35°F. When food is placed in the box and stored for a long time, it becomes the same temperature as the space. If the space temperature is allowed to go much below 35°F, the food begins to freeze. Foods such as eggs, tomatoes, and lettuce are not edible after being frozen.

The thermostat, **Figure 13.1**, automatically stops and starts the refrigeration cycle thousands of times over the 15- or 20-year life expectancy of the appliance. Without

(B)

an automatic control such as the thermostat, the appliance owner would have to manually turn the unit on and off in an effort to maintain the refrigerator at the desired temperature.

The compressor in the refrigerator has a protective device that keeps it from overloading and damaging itself, **Figure 13.2(A)**. This device is called an overload. This automatic overload control is designed to open its contacts in the event that an overload or power problem might damage the compressor. One such example would be when the power goes off and comes right back on while the refrigerator is running. The overload control will open its contacts and prevent the compressor from operating until it is ready to go back to work again. Overloading often occurs when the refrigerator's low-torque, fractional-horsepower compressor motor tries to start against unequal system pressures. The motor would go into a locked rotor situation and draw locked rotor amperage (LRA). The overload control would then open the electrical circuit and protect the compressor. After the compressor goes through a cool-down period, the control resets and closes the circuit when, hopefully, system pressures are nearing equalization and the motor can start safely.

The system overload control may be electrical, thermal, or a combination of both. An electrical overload happens when the electric circuit is drawing more current than it is designed for, due to an electrical problem such as a short circuit, improper electrical connections, or a faulty electrical component. A thermal system overload may occur if a specific electrical or mechanical component is not cooled properly, resulting in overheating. System overloads may also be due to mechanical reasons, causing too much current that in turn produces excess heat. For example, restricted airflow through a condensing coil of a central air conditioner would produce high head pressure, requiring the compressor motor to work harder. **Figure 13.2(B)** shows one combination control, a small heater located under the bimetallic element of a compressor overload control. When either an electrical or thermal overload occurs, the heater warps the bimetallic element and opens the circuit.

Some common automatic control devices are

- Temperature controls in household refrigerator fresh and frozen food compartments
- Temperature controls in residential and office cooling and heating systems
- Water heater temperature controls
- Electric oven temperature controls
- Garbage disposal overload controls
- Fuses and circuit breakers that control current flow in home electric circuits

Automatic controls in the air-conditioning and refrigeration industry monitor temperatures. Some controls that respond to temperature changes are used to monitor electrical overloads by sensing temperature changes in the wiring circuits. This response is usually a change in dimension or electrical characteristic of the control-sensing element.

13.3 THE BIMETAL DEVICE

The **bimetal** device is probably the most common device used to detect thermal change. In its simplest form, it consists of two unlike metal strips—often brass and steel—attached back to back. Each of these metals has a different rate of expansion and contraction when heated or cooled, **Figure 13.3**. When the device is heated, the brass expands faster than the steel, which causes the device to warp. The motion of the bimetal strip is then used to perform some useful task. Bimetal controls can be attached to an electrical component or valve to stop, start, or modulate electrical current or fluid flow, **Figure 13.4**. Bimetal controls are limited in application by the amount of warp that can be accomplished with a temperature change. For example, when the device is heated, the bimetal strip bends a certain amount per degree of temperature change, **Figure 13.5**.

To make bimetal devices practical over a wider temperature range, the strip is lengthened. A longer strip is normally coiled into a circle, shaped like a hairpin, wound into a helix, or formed into a worm shape, **Figure 13.6**. The movable end of the coil or helix can be attached to a pointer to indicate

Figure 13.3 A basic bimetal strip made of two unlike metals such as brass and steel fastened back to back.

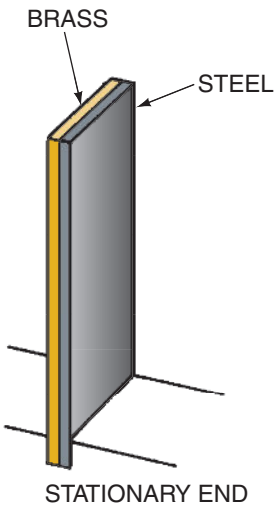

Figure 13.5 This bimetal is straight at 70°F. The brass side contracts more than the steel side when cooled, causing a bend to the left. On a temperature rise, the brass side expands faster than the steel side, causing a bend to the right. The degree of bending is predictable per degree of temperature change. The longer the strip, the greater the bend.

temperature, a switch to stop or start current flow, or a valve to modulate fluid flow. One basic control application is shown in **Figure 13.7.**

ROD AND TUBE

The **rod and tube** is another type of control that uses two unlike metals and the difference in thermal expansion and contraction. The rod and tube could more accurately be

Figure 13.7 Movement of the bimetal strip due to changes in temperature opens or closes electrical contacts.

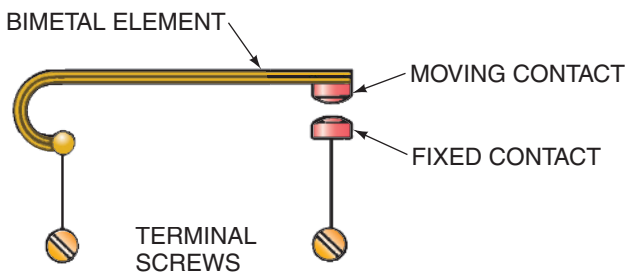

Figure 13.8 The rod and tube.

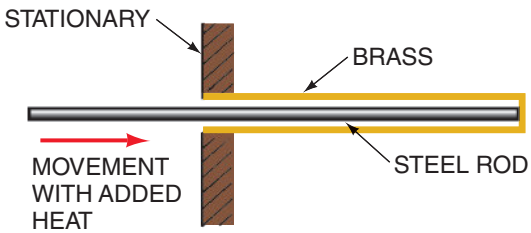

called the "rod *in* tube." It has an outer tube of metal with a high expansion rate and an internal rod of metal with a low expansion rate, **Figure 13.8.** Used for years in residential gas water heaters, the tube, which is inserted into the tank, provides very accurate sensing of water temperature. As the tank water temperature changes, the tube pushes the rod and opens or closes the gas valve to start or stop the heating of the water in the tank, **Figure 13.9.**

Heat motor valves are another application of the rod and tube device. A small heater is wrapped around the tube portion of the mechanism. When voltage is applied, the tube heats up and expands, which pulls the rod and opens the valve for water flow. When the heat is removed, the tube shrinks and closes the valve, **Figure 13.10.**

Figure 13.9 The rod-and-tube type of control consists of two unlike metals, with the faster-expanding metal enclosed in a tube, and is normally inserted in a fluid environment such as a hot water tank.

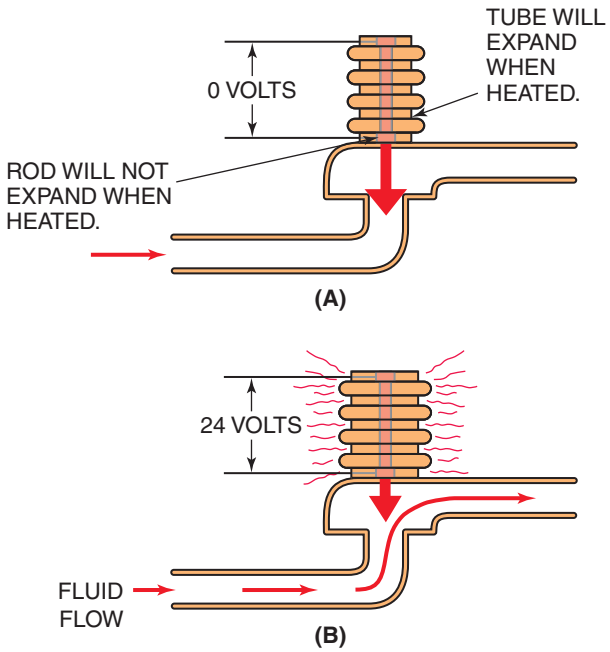
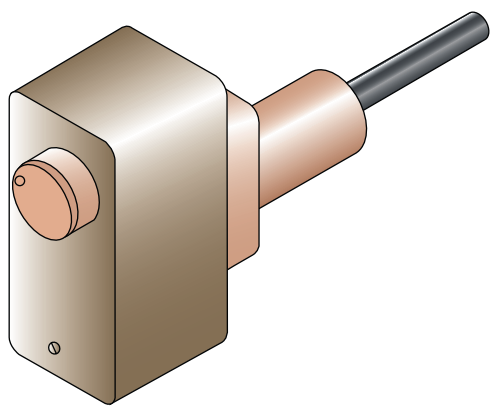
Figure 13.10 This heat motor valve is used to control the flow of water. (A) When it receives a 24-V signal, an electrical heater heats the tube, which expands, pulling the rod. (B) When the rod moves, it pulls the seat off the valve.



Another common application for the rod and tube type of control is in a duct-mounted limit control, **Figure 13-11.** This type of device will "lock out" or prevent an air conditioning system's blower from operating in the event the return air temperature gets too high, such as when there is a fire. This device is mounted to the return duct of an air conditioning system, and the sensing element penetrates into the duct through drilled holes. If the sensing element gets too hot, the rod pushes a set of electrical contacts open to de-energize the blower motor. When used in this manner, the device will need to be manually reset once the problem has been identified and resolved.

Figure 13.11 A rod and tube device used to sense return air temperature and de-energize the blower in the event of a fire.



SNAP-DISC

The **snap-disc** is another type of bimetal device used to sense temperature changes in some applications. This control is treated apart from the bimetal because its snap characteristic gives it a quick open-and-close feature. Some sort of snap-action feature has to be incorporated into all controls that stop and start electrical loads, **Figure 13.12.**

Figure 13.12 The snap-disc is another variation of the bimetal concept. It is usually round and fastened on the outside. When heated, the disc snaps to a different position. (A) Open circuit. (B) Closed circuit.

13.4 CONTROL BY FLUID EXPANSION

Fluid expansion is another way to sense temperature change. A thermometer, for example, can be described as a column of temperature-sensitive fluid rising and falling within a hollow stem in response to a sensed temperature or level of heat intensity. The level of the liquid in the hollow stem of the thermometer is determined by the temperature of the liquid in the thermometer's bulb. The liquid in the thermometer must rise and fall because it has no place else to go. When heated, the liquid in the thermometer expands, and so it has to rise up in the tube; when it cools, it naturally falls down the tube. This same idea can be used to transmit a signal to a control device, indicating that a temperature change is occurring. The lines or tubes that transmit these signals are referred to as transmission lines.

The liquid rising up the transmission line or tube has to act on some device to generate usable motion. One such device is the **diaphragm**, which is a thin, flexible metal (typically steel) disc with a large area. Pressure changes underneath the disc cause it to flex up and down, **Figure 13.13**. When a bulb is filled with liquid and connected to a diaphragm by piping, the temperature of the bulb can be transmitted to the diaphragm by the expanding liquid. In **Figure 13.14,** a bulb filled with mercury is placed in the pilot light flame of a gas furnace to ensure that a pilot light is present to ignite the gas burner before the main gas valve is opened. The pilot light is very hot, so only the sensing bulb is located in the pilot light flame. Both the mercury-filled tube and mercury-filled diaphragm are sensitive to temperature changes.

Figure 13.13 The diaphragm is a thin, flexible, movable membrane (brass, steel, or other metal) used to convert pressure changes to movement. This movement can stop, start, or modulate controls.

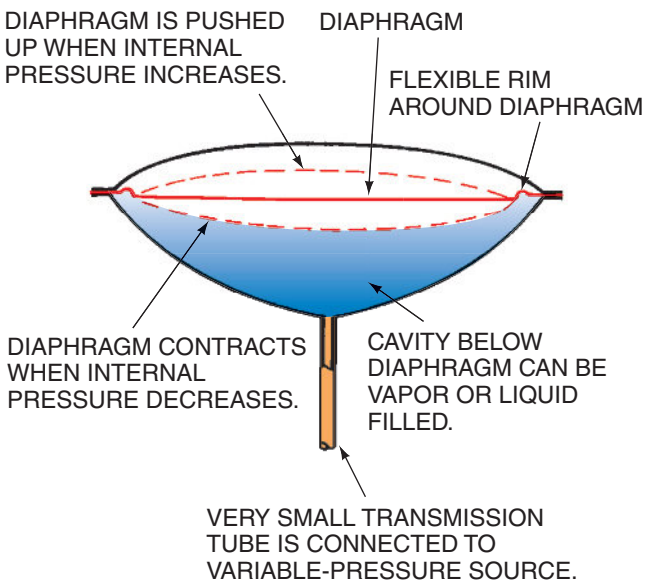

Figure 13.14 The bulb in or near the flame is filled with mercury. Heating the bulb causes the mercury to expand, move up the transmission tube, and flex out the diaphragm. This proves that a pilot flame is present to ignite the main burner.

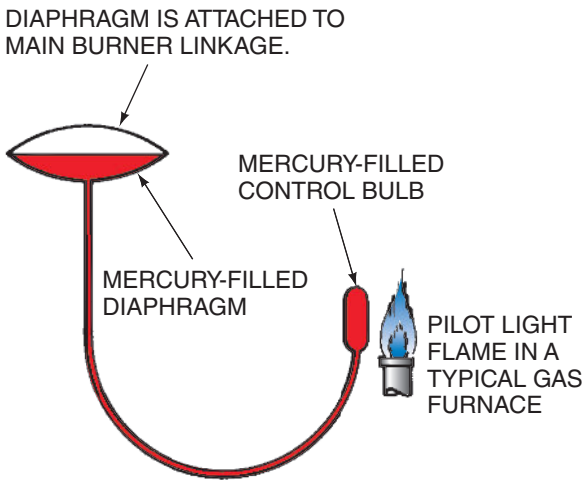

More accurate control at the actual bulb location is achieved by using a bulb partially filled with a liquid that will boil and make a vapor, which is then transmitted to the diaphragm at the control point, **Figure 13.15**. The liquid is much more sensitive to temperature change than the vapor that is used to transmit the pressure. An R-134a walk-in refrigerated box is an example of how this works. (**Figure 13.16** presents a progressive explanation of this example.) The box temperature is maintained by shutting the refrigeration

Figure 13.15 A large bulb partially filled with a volatile liquid, one that boils and creates vapor pressure when heated. An increase in vapor pressure forces the diaphragm to move outward. When cooled, the vapor condenses and the diaphragm moves inward.

(B)

system off when its temperature reaches 35°F and starting it up when the box temperature reaches 45°F. A control with a remote bulb is used to regulate the box temperature. The bulb is located inside the box, and the control is located outside the box so that it can be adjusted. A pressure gauge is installed (for illustration purposes) in the bulb to monitor the pressures as the temperature changes. At the point that the unit needs to be cycled off, the bulb temperature is 35°F, which corresponds to a pressure of 30 psig for R-134a. (Refer to **Figure 3.15** for the temperature/pressure chart for R-134a.) A control mechanism that operates on a diaphragm can open an electrical circuit and stop the unit at this point. When the

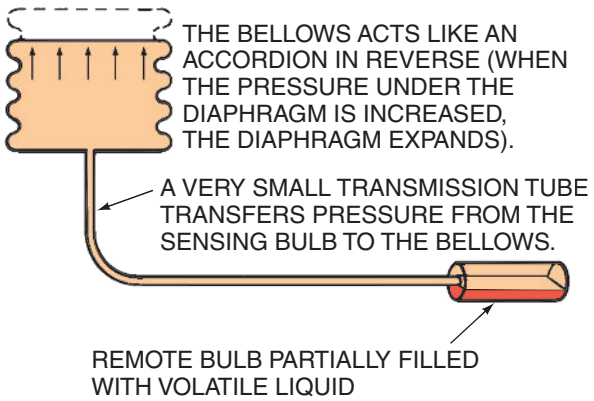
Figure 13.17 The bellows is employed where more movement per degree is desirable. This control would normally have a partially filled bulb with vapor pushing up in the bellows section.



cooler temperature rises to 45°F, the pressure inside the control is 40 psig and it is time to restart the unit. The same mechanism that stops the refrigeration system can be used to close the electrical circuit and restart it.

A diaphragm travels a limited amount but has a great deal of power during its movement. The travel of a liquid-filled control is limited, however, by the degree to which the liquid in the bulb expands in the temperature range within which it is working. When more travel is needed, another device, called a **bellows**, can be used. The bellows is much like an accordion—it has a lot of internal volume and a lot of travel, **Figure 13.17**. Normally, the bellows is used with a vapor inside instead of a liquid. The Bourdon tube is often used in the same manner as the diaphragm and the bellows to monitor fluid expansion, in this case to indicate temperature. The Bourdon tube straightens out with an increase in vapor pressure. This movement moves a needle on a calibrated dial to indicate temperature, **Figure 13.18**.

Controls employing partially filled bulbs are widely used in the industry because they are reliable, simple, and economical. This type of control has been around since the industry began, and it has many configurations. **Figure 13.19** shows some remote bulb thermostats.

The descriptions of these mechanisms have been simplified and are not practical because each electrical switch must also have a snap action built into it. As explained earlier, when an electric circuit is closed or opened, but especially when opened, an electrical arc occurs. This arc is a small version of an electric welding arc. Electrons are flowing and will try to keep flowing when the switch is opened, creating the arc, **Figure 13.20**. Every time a switch is opened, wear takes place. Every switch has a lifetime, so to speak. That lifetime is a certain number of openings; after that the switch will fail. The faster the opening, the longer the switch will last. There are many types of snap-action mechanisms. Some switches use an over-center device to accelerate the opening. Some use a puddle of mercury to create the quick action, and some may use a magnet. See **Figure 13.21** for some examples of snap-action mechanisms.

13.5 THE THERMOCOUPLE

The **thermocouple** does not use expansion to control thermal change; instead, it uses electrical principles. The thermocouple consists of two unlike metals joined together at one end (usually wire made of unlike metals such as iron and constantan), **Figure 13.22**. When heated on the fastened end, an electrical current flow is started due to the temperature difference between the two ends of the device, **Figure 13.23**. Thermocouples can be made of many different unlike metal combinations, and each one has a different characteristic. Each

Figure 13.18 This remote bulb is partially filled with liquid. When heated, the expanded vapor is transmitted to a Bourdon tube that straightens out with an increase in vapor pressure. A decrease in pressure causes the Bourdon tube to curl inward.

(B)

thermocouple has a *hot* junction and a *cold* junction. The hot junction, as the name implies, reaches a higher temperature than the cold junction. This difference in temperature is what starts the current flowing. Heat will cause an electrical current to flow in one direction in one metal and in the opposite direction in the other. When these metals are connected, they form an electrical circuit, and current will flow when heat is applied to one end of the device.

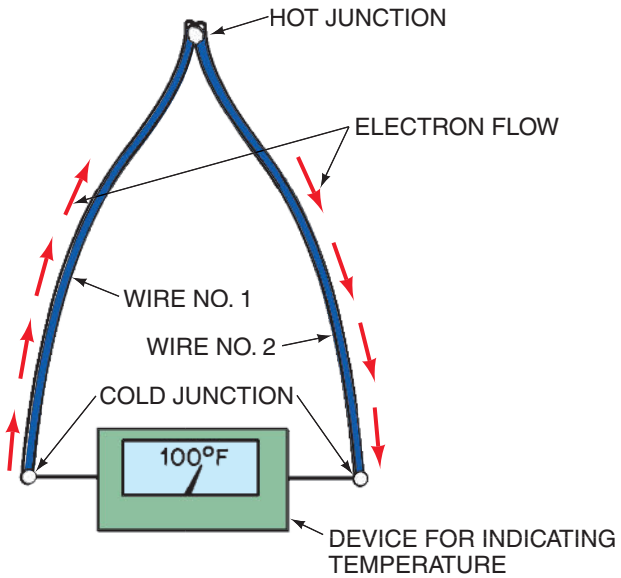
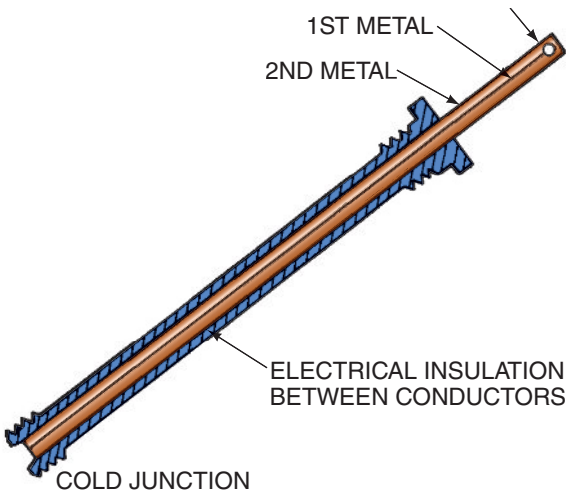
Figure 13.22 A thermocouple used to detect a pilot light in a gas-burning appliance.

Courtesy Robertshaw Controls Company

Figure 13.23 The thermocouple on the top is made of two wires of different metals welded together at one end. It is used to indicate temperature. The thermocouple on the bottom is a rigid device and is used to detect a pilot light.





Tables and graphs for various types of thermocouples show how much current flow can be expected under different conditions for hot and cold junctions. The current flow can be monitored by an electronic circuit and used for many temperature-related applications, such as a thermometer, a thermostat to stop or start a process, or a safety control,

Figure 13.24 This thermocouple senses whether the gas furnace pilot light is on.

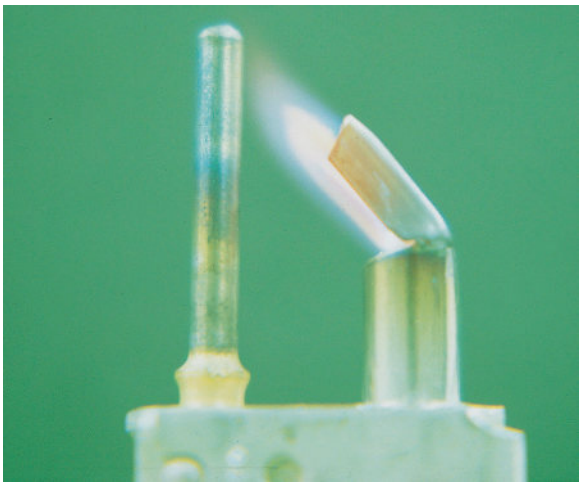


Photo by Bill Johnson

Figure 13.24. The thermocouple has been used extensively for years in gas furnaces for safety purposes to detect the pilot light flame. This application is found on older pieces of equipment, since it works best with standing pilot systems, which are, for the most part, not being produced anymore. The changeover to intermittent pilots (pilot lights that are extinguished each time the burner goes out and relit each time the room thermostat calls for heat) and other newer types of ignition is the main reason for the phaseout of older standing pilot technology.

Pilot-light thermocouples have an output voltage of about 20 to 30 millivolts (DC), all that is needed to control a safety circuit to prove there is flame, **Figure 13.25.**

Figure 13.25 A thermocouple and control circuit used to detect a gas flame. When the flame is lit, the thermocouple generates voltage. This voltage energizes an electromagnet that holds the gas valve open. When the flame is out, the thermocouple stops generating electricity and the valve closes. Gas is not allowed to flow.

Figure 13.28 A thermistor application.

Photo by Bill Johnson

Multiple thermistors can be wired in series with each other to provide a higher output voltage and, when configured like this, are called **thermopiles**, **Figure 13.26**, The thermopile is used as the only power source on some gas-burning equipment. This type of equipment has no need for power other than the control circuit, so the power supply is very small (about 500 millivolts). The thermopile has also been used in remote areas to operate radios using the sun or heat from a small fire.

13.6 ELECTRONIC TEMPERATURE-SENSING DEVICES

The **thermistor** varies its resistance to current flow based on its temperature. Thermistors are incorporated into solid state circuit boards and respond to small temperature changes. The changes in current flow in the device are monitored by special electronic circuits that can stop, start, and modulate machines or provide a temperature readout, **Figure 13.27** and **Figure 13.28**.

Thermistors are usually made of cobalt oxide, nickel, or manganese and from a few other materials. These materials are mixed and milled in very precise proportions and then hardened for durability. A thermistor can have either a positive or a negative coefficient of resistance. If the thermistor increases its resistance as the temperature increases, it has a positive temperature coefficient (PTC) of resistance. If it decreases its resistance as the temperature increases, it has a negative temperature coefficient (NTC) of resistance. Also, some thermistors can double their resistance with as little as 1 degree of temperature change.

Thermistors are used in solid-state motor protectors, motor-starting relays, room thermostats, electronic expansion valves, duct sensors, micron gauges for vacuum pumps, heat pump controls, and in many other control schemes. **Figure 13.29** shows how a PTC thermistor assists in starting a **permanent split-capacitor (PSC)** motor. At the instant of start, the PTC thermistor has a very low resistance, which

Figure 13.29 A PTC thermistor wired in parallel with a run capacitor. This increases motor starting torque on this permanent split-capacitor (PSC) motor.

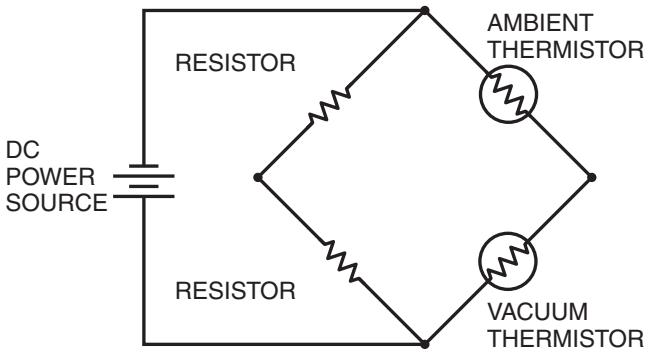
allows a large inrush of current to help increase the starting torque of the motor. However, after a fraction of a second, the thermistor's resistance increases because its temperature increases from the high starting current. Now the thermistor is like an open circuit, and the motor is running like a normal PSC motor.

Thermistors can also be used in a bridge circuit when measuring the vacuum in a refrigeration system, **Figure 13.30**. One thermistor is placed in the vacuum, while the other is placed in the outside ambient. As the vacuum gets deeper and deeper, the heat cannot be as easily transferred away from the thermistor placed in the vacuum because fewer molecules are surrounding it. This difference in resistance of the two thermistors can now be sensed by the bridge circuit and calibrated into microns for vacuum measurement.

Figure 13.30 A bridge circuit showing thermistors used for micron readings when a vacuum is being measured.



SUMMARY

- A bimetal element consists of two unlike metal strips, such as brass and steel, fastened back to back.
- Bimetal strips warp with temperature changes and can be used to stop, start, or modulate electrical current flow and fluid flow when used with different mechanical, electrical, and electronic helpers.
- The travel of the bimetal device can be extended by coiling it. The helix, worm shape, hairpin shape, and coil are the names given to an extended bimetal.
- The rod and tube is another version of the bimetal device.
- Fluid expansion is used in a thermometer to indicate temperature and to operate controls that are totally filled with liquid.
- The temperature/pressure relationship is the basis of some controls that are partially filled with liquid.
- A diaphragm is used to move a control mechanism when either liquid or vapor pressure is applied.
- A diaphragm has very little travel but much power.
- The bellows is used for more travel and is normally filled with vapor.
- The Bourdon tube is sometimes used like the diaphragm or bellows.
- A thermocouple generates electrical current flow when heated at the hot junction. This current flow can be used to monitor temperature changes to stop, start, or modulate electrical circuits.
- A thermistor is an electronic device that varies its resistance to electrical current flow on the basis of temperature changes.
- Positive temperature coefficient (PTC) thermistors increase in resistance as the temperature increases. Negative temperature coefficient (NTC) thermistors decrease in resistance when the temperature increases.

REVIEW QUESTIONS

1. What is the device that consists of two unlike metal strips that are attached and have a different rate of expansion and contraction?
   A. Thermistor
   B. Thermocouple
   C. Diaphragm
   D. Bimetal
2. What are some applications of the bimetal strip?
3. How can the bimetal strip be extended to have more travel per degree of temperature change?
4. What two metals can be used in the bimetal device or the rod and tube?
5. A thin, flexible metal disc with a large surface area is a _____.
6. An accordion-type device with a large internal volume that has a lot of travel is referred to as a _____.
7. What is the difference between a bellows and a diaphragm?
8. Which type of fluid is normally found in a bellows?

9. Which of the following is a device consisting of two unlike metals fastened at one end that, when heated on the fastened end, produces a DC current?
   A. Thermocouple
   B. Thermistor
   C. Diaphragm
   D. Bimetal
10. How can a thermocouple be used to verify that a gas flame is present?
11. Define a thermistor.
12. What does a thermistor do that makes it different from a thermocouple?
13. What do the terms PTC and NTC mean with regard to thermistors?
14. Draw and explain how a PTC thermistor assists with increasing the starting torque of a motor.

UNIT 14

AUTOMATIC CONTROL COMPONENTS AND APPLICATIONS

OBJECTIVES

After studying this unit, you should be able to

- discuss space temperature control.
- describe the mercury control bulb.
- describe system overshoot and temperature swing.
- describe the difference between low- and high-voltage controls.
- identify some commonly used low- and high-voltage controls.
- name two ways motors are protected from high temperature.
- describe the difference between a diaphragm and a bellows control.
- state the uses of pressure-sensitive controls.
- describe a high-pressure control.
- describe a low-pressure control.
- discuss the range and differential of a control.
- describe pressure transducers.
- describe a pressure relief valve.
- describe the functions of mechanical and electromechanical controls.

SAFETYCHECKLIST

- ☑ The subbase for a line-voltage thermostat is attached to an electrical outlet box. If an electrical arc due to overload or short circuit occurs, it is enclosed in the conduit or box. Do not consider this a low-voltage device.
- ☑ The best procedure to use when encountering a hot compressor is to shut off the compressor with the space temperature thermostat "off" switch and return the next day. This gives the compressor time to cool and keeps the crankcase heat on.
- ☑ If the above is not possible or feasible and the compressor must be cooled quickly, turn the power off and cover electric circuits with plastic before using water to cool the compressor. Do not stand in this water when you make electrical checks.
- ☑ When used as safety controls, pressure controls should be installed in such a manner that they are not subject to being isolated or valved off by the service valves.
- ☑ The high-pressure control provides safety for equipment and surroundings. It should not be tampered with.
- ☑ A gas pressure switch is a safety control and should never be bypassed except for troubleshooting and then only by experienced service technicians.
- ☑ A pressure relief valve is a safety device that is set at the factory; this setting should not be changed or tampered with.
- ☑ Exercise extreme caution when working with control devices that contain mercury. Mercury is toxic! Be sure to follow all local and federal laws and guidelines when disposing these devices.

This unit describes how various controls look and operate. Recognizing a control, understanding its function and what component it influences are vitally important. This will help eliminate confusion when reading a wiring diagram or troubleshooting a system. It will be easier to see a control on a circuit diagram and then recognize it on the equipment once the technician becomes familiar with its description, function, and appearance.

14.1 TEMPERATURE CONTROLS

Temperature is controlled in many ways and for many reasons. For instance, space temperature is controlled for comfort. The motor-winding temperature in a compressor motor is controlled to prevent heat-related damage to the motor. The motor could overheat and damage could occur from the very power that operates it. Both types of controls require some device that will sense temperature, with some type of sensing element, and respond accordingly. The space temperature control is an operating control or operational device, while the motor temperature control serves as a safety device.

The space temperature control has two different actions, depending on whether the heating or cooling mode is needed. In winter, the control must *break a circuit* to stop the heat when the space temperature rises to a particular set point. In summer, the conditions are reversed: The control must *make a circuit* and start the cooling when the temperature rises to a certain point. The heating thermostat opens on a rise in temperature, and the cooling thermostat closes on a rise in temperature. **NOTE:** *In both cases the control is functioning on a rise. This terminology is important because it is commonly used in the industry.* • The motor temperature cut-out performs the same circuit action as the heating thermostat. It opens the circuit on a rise in motor temperature and stops the motor. The

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

heating thermostat and a motor-winding thermostat may operate the same way under the same conditions, but they do not physically resemble each other, **Figure 14.1**.

Another difference between the two thermostats is the medium they sense. The motor-winding thermostat must be in close contact with the motor winding. It is fastened to the winding itself. The space temperature thermostat is mounted on a wall and responds to random air currents passing over it. Another important design concept is the current-carrying characteristics of the various controls. In the space temperature application, the stopping or starting of a heating system, such as a gas or oil furnace, involves stopping and starting low-voltage (24-V) components and line-voltage (115-V or 230-V) components. The gas or oil furnace normally has a low-voltage gas valve or relay and a line-voltage blower motor.

There is no firm rule for using one voltage or another in any specific application. However, the stopping and starting of a 3-hp compressor requires a larger switching mechanism than the one used to control a simple gas valve. A 3-hp compressor could operate with a running amperage of 18 A and a starting amperage of 90 A, whereas a simple gas valve might draw only 0.5 A. If a bimetal were large enough to carry the current for a 3-hp compressor, the control would be so large that it would be slow to respond to temperature changes. This is one reason for using low-voltage controls to stop and start high-voltage components.

Residential systems usually have low-voltage control circuits. There are four reasons for this:

1. Economy
2. Safety
3. More precise control of relatively still air temperature
4. In many states, there is no need for an electrician's license to install and service low-voltage wiring

The low-voltage thermostat receives its voltage from the residential power supply that is reduced to 24 V with a small transformer usually furnished with the equipment, **Figure 14.2**. On an air-conditioning system, for example, the control transformer is typically located within the air handler.

Figure 14.1 Both thermostats open on a rise in temperature, but they serve two different purposes. (A) The motor-winding thermostat measures the temperature of iron and copper while in close contact with the motor windings. (B) The space thermostat measures air temperature from random air currents.

14.2 LOW-VOLTAGE SPACE TEMPERATURE CONTROLS

The low-voltage space temperature control (thermostat) normally regulates other controls and does not carry much current—seldom more than 2 A. The thermostat consists of the following components:

- Electrical contacts
- Heat Anticipator
- Cold Anticipator
- Thermostat cover
- Thermostat assembly
- Subbase

ELECTRICAL CONTACTS

In *older* low-voltage thermostats, the mercury bulb is probably the most common component used to make and break electric circuits. The mercury bulb is inside the thermostat, **Figure 14.3**. It consists of a glass bulb filled with an inert gas (a gas that will not support oxidation) and a small puddle of mercury free to move from one end to the other. **NOTE:** *New thermostats that are being installed do not contain mercury. When replacing older thermostats that contain mercury, be sure to handle them carefully to avoid breaking the glass bulb.*

Figure 14.3 (A) A wall thermostat with the cover off and the mercury bulb exposed. (B) A detail of the mercury bulb. Note the very fine wire that connects the bulb to the circuit.

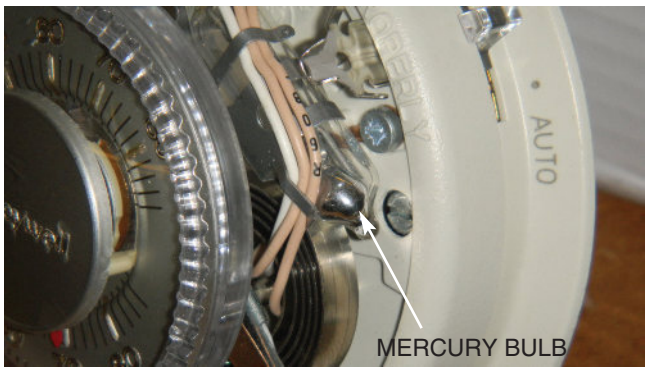

Photo by Eugene Silberstein

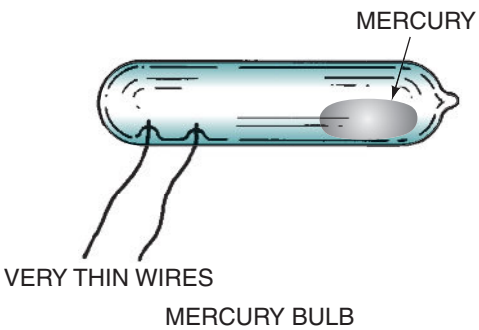
(A)



(B)

Figure 14.4 New, smart thermostats utilize digital circuitry and control strategies.

Photo by Eugene Silberstein

The mercury bulb is fastened to the movable end of a bimetal strip, so it is free to rotate with the movement of the bimetal. The wires that connect the mercury bulb to the electrical circuit are very thin, so they will have little effect on the movement of the bulb. The mercury cannot be in both ends of the bulb at the same time, so when the bimetal rolls the mercury bulb to a new position, the mercury rapidly makes or breaks the electric current flow. This is called *snap* or *detent action*. Devices that contain mercury bulbs must be mounted level to ensure proper operation and temperature control. *Mercury is dangerous to the environment! When disposing of devices that contain mercury, be sure to comply with all local and federal laws!*

New thermostats, **Figure 14.4**, use electronic circuitry instead of mercury bulbs to control circuit operation. These thermostats do not utilize bimetal strips to sense changes in temperature and are not position-sensitive like the devices that contain mercury.

HEAT ANTICIPATOR

The **heat anticipator** is a small resistor, which is usually adjustable, located close to the bimetal sensing element. It is used to cut off the heating equipment prematurely, **Figure 14.5**. Consider that when an oil or a gas furnace has heated a home to just the right cut-off point, the furnace itself, weighing several hundred pounds, could be hot from running a long time. When the combustion is stopped, the furnace still radiates a great amount of heat. The heat left in the furnace is enough to drive the house temperature past the comfort point. The blower is allowed to run to dissipate this heat.

The heat anticipator is located inside the thermostat to cut the furnace off early to dissipate heat before the space temperature rises to an uncomfortable level, **Figure 14.6**. The temperature rise of the room above the set point of the

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Figure 14.5 The heat anticipator as it appears in an actual thermostat.

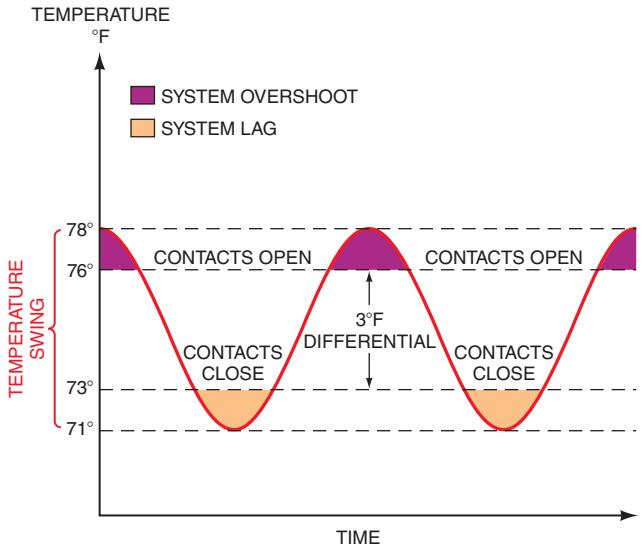
thermostat is called **system overshoot**. The heat anticipator gives off a small amount of heat and causes the bimetal to become warmer than the room temperature. If there was no heat anticipator, the thermostat would open its contacts when its bimetal reaches the setpoint of, for example, 73°F. However, the furnace blower will still move the residual heat from the heat exchanger into the room for a few minutes before it shuts off, resulting in overshoot. If the thermostat has a differential of 3°F, the thermostat might be set at 73°F, but the furnace might cycle off at 76°F. Now, taking the system overshoot into account, the room might get as warm as 78°F. The heat anticipator helps reduce this condition. When the system cycles on, a similar situation arises.

Let us say that the thermostat is set for the furnace to come on at 73°F. However, the temperature of the room may fall below 73°F because the heat source in the furnace must first warm the heat exchanger before the blower comes on and delivers heat to the room. Otherwise, objectionable colder air would be delivered to the room. The temperature drop of the heated room below the set point of the thermostat

Figure 14.7 Unanticipated thermostat cycles showing system lag and system overshoot causing a large temperature swing.



is referred to as **system lag**. System lag may cause the room to drop in temperature to 71°F before heated air is delivered to the room.

As you can see, even though the thermostat was set to close at 73°F and open at 76°F, the room temperature could fall as low as 71°F and rise as high as 78°F. This causes a large room **temperature swing** of 7°F (78°F − 71°F) from system lag and system overshoot. **Figure 14.7**, which has been exaggerated for illustrative purposes, illustrates system lag and system overshoot.

It is obvious from the figure that there needs to be some means to reduce system overshoot and cause the thermostat to open its contacts earlier, allowing the residual heat in the furnace to be delivered to the heated space. This is where the

Figure 14.6 The heat anticipator is usually a wirewound, slide-bar-type variable resistor.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

heat anticipator comes into play. The heat anticipator actually fools the bimetal of the thermostat into opening its contacts sooner by placing a small heat load on it. This causes the temperature sensed by the thermostat to be slightly higher than the room temperature when the thermostat contacts are closed. The thermostat will thus open sooner, and system overshoot will be reduced.

The heat anticipator is wired in series with the heating contacts so that current will flow through it any time the thermostat contacts are closed. For the thermostat to control properly, the heat given off by the anticipator must be the same regardless of the current flow through it. Ohm's law says that power in watts is $W = I^2R$. For different values of I (current), different values of R (resistance) will be required to produce the same amount of heat in watts in the anticipator. The designer of the thermostat has precalculated how much resistance will produce the right amount of heat for proper operation.

In order to properly set the heat anticipator (on non-digital thermostats that have one), the technician must determine what the current flow is through the heating control circuit when the furnace is operating in a *steady-state condition*. Furnace steady-state conditions occur when the furnace is fired and operating. Using an AC ammeter to measure the current between the R and W terminals of the thermostat's subbase, **Figure 14.8**, is the most accurate way to measure the current through the heat anticipator. When the steady-state current is determined, the technician should adjust the heat anticipator to that current. If the heat anticipator is ever set at a higher amperage setting than what it is supposed to be, the smaller resistance in the anticipator would dissipate less heat to the thermostat's bimetal and greater system overshoot would occur. Heat anticipators do not eliminate system overshoot and temperature swings; they simply make them smaller and less objectionable in terms of human comfort. Directions that come with a thermostat showing how to set the anticipator should be followed.

Electronic or microelectronic thermostats have different anticipation circuits. Usually, these thermostats have a built-in factory microprocessor with software that will determine the cycle rate. A factory-installed thermistor wired into an electronic circuit can also determine the cycle rate. In either case, there is no need for the technician to set the anticipator on these types of thermostats.

Given the technological advances in HVAC/R controls, along with the reduced cost of these hi-tech devices, it is wise to replace older, non-programmable, analog thermostats with newer models. Digital, programmable thermostats have the potential to save the end-user large amounts of energy and money. Some new "smart" thermostats, such as the one shown in **Figure 14.4**, are able to learn the behavior and comfort requirements of the occupants and adjust the system accordingly to meet these needs automatically.

COLD ANTICIPATOR

A cooling system needs to be started just a few minutes early to allow the air-conditioning system to get up to capacity

Figure 14.8 (A) An analog AC ammeter measuring current through the heating control circuit. Often, 10 turns of wire wrapped around an ammeter will give a more accurate reading. Do not forget to divide by 10. (B) Digital ammeters can read small amperages without the wire turns.

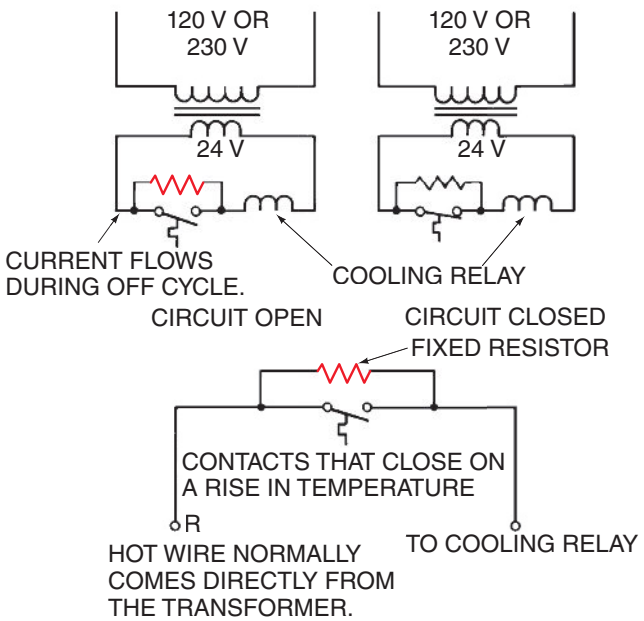
when needed. If the air-conditioning system is not started until it is needed, it would take 5 to 15 min before it would produce to full capacity, which is enough time to cause a temperature rise in the conditioned space. The cold anticipator causes the system to start early, to compensate for this capacity lag. Normally, the cold anticipator is a high-resistance device that is not adjustable in the field, **Figure 14.9**. It is wired in parallel with the mercury-bulb cooling contacts and is energized during the off cycle, **Figure 14.10**. A small heat load is put on the thermostat's bimetal by the anticipator when the thermostat's contacts are opened. This will fool the bimetal and keep it at a temperature slightly above room temperature. This causes the thermostat contacts to close a few minutes early, reducing the cooling system's lag.

Figure 14.10 The cold anticipator is wired in parallel with the cooling contacts of the thermostat. This allows the current to flow through it during the off cycle.



Because the cold anticipator has a high resistance, it will drop most of the voltage when wired in series with another power-consuming device like the cooling relay coil in **Figure 14.10**. This will prevent the cooling relay coil from being energized when the thermostat contacts are open. The cold anticipator is, however, giving off heat for the thermostat's bimetal to sense when the thermostat is open. When the thermostat's contacts close, the cold anticipator is shunted out of the circuit, which allows the cooling relay to be energized and cooling to begin.

THERMOSTAT COVER

The thermostat cover is intended to be decorative and protective. A thermometer is usually mounted on it to indicate the surrounding (ambient) temperature. The thermometer is functionally separate from any of the controls and would serve the same purpose if it were hung on the wall next to the thermostat. Thermostats come in many shapes, **Figure 14.11**.

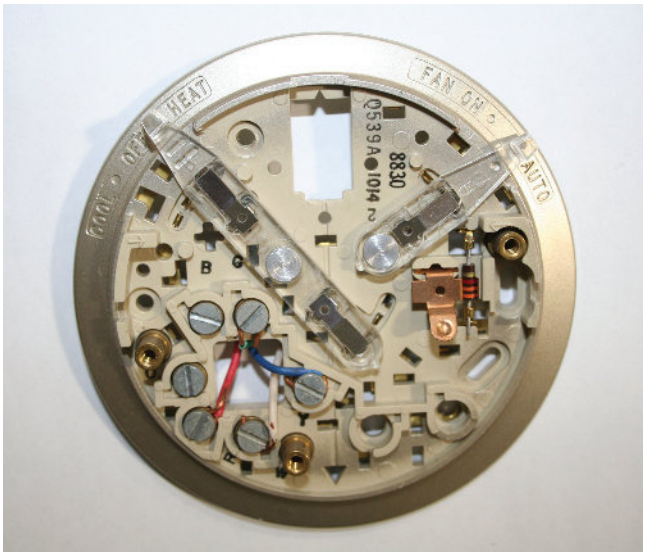
Figure 14.12 The subbase normally mounts on the wall, and the wiring is fastened inside the subbase on terminals. When the thermostat is fastened to the subbase, electrical connections are made between the two. In some thermostats, the subbase contains the selector switches, such as FAN ON-AUTO and HEAT-OFF-COOL.



Courtesy Ferris State University. Photo by John Tomczyk.

THERMOSTAT ASSEMBLY

The *thermostat assembly* houses the thermostat components already mentioned and is normally mounted on a subbase fastened to the wall. This assembly could be called the brain of the system. In addition to mercury bulbs, sensors, circuitry, and anticipators, the thermostat assembly includes the levers, buttons, and slide switches that are used to adjust the temperature and, in many cases, program the device.

THE SUBBASE

The **subbase**, which is usually separate from the thermostat, contains the selector switching levers, such as the FAN ON-AUTO switch or the HEAT-OFF-COOL switch, **Figure 14.12**. The subbase is important because the thermostat is mounted to it. The subbase is first mounted on the wall, then the interconnecting wiring is attached to the subbase. When the thermostat is attached to the subbase, the electrical connections are made between the two components. Often, cold anticipators are located on the subbase of the thermostat.

14.3 LINE-VOLTAGE SPACE TEMPERATURE CONTROLS

Sometimes it is desirable to use line-voltage thermostats to stop and start equipment. Some self-contained pieces of equipment do not need remote thermostats. To add a remote thermostat would be an extra expense and would only increase the potential for trouble. The window air conditioner is a good example of this. It is self-contained and needs no remote thermostat. If it had a remote thermostat, the window unit would no longer be a plug-in appliance, since it would require the installation of the thermostat. Note that the remote-bulb-type thermostat is normally used with the bulb located in the return airstream, **Figure 14.13**. The fan usually runs all the time and keeps a steady stream of room return air passing over the bulb, which provides more sensitivity.

Figure 14.13 The window air conditioner has a line-voltage thermostat that starts and stops the compressor. On some models with energy-saving modes, the thermostat cycles both the compressor and the fan motor.

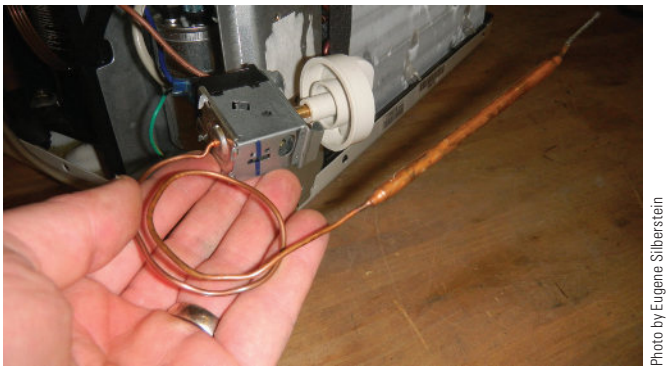


Photo by Eugene Silberstein

The line-voltage thermostat is used in many types of installations. The household refrigerator, reach-in coolers, and free-standing package air-conditioning equipment are just a few examples. All of these have something in common—the thermostat is a heavy-duty type and may not be as sensitive as the low-voltage type. When replacing these thermostats, an exact replacement or one recommended by the equipment manufacturer should be used.

The line-voltage thermostat must be matched to the voltage and current that the circuit is expected to use. For example, a reach-in cooler for a convenience store has a compressor and fan motor that need to be controlled. The combined running-current draw for both components is 16.2 A at 115 V (15.1 A for the compressor and 1.1 A for the fan motor). The locked-rotor amperage for the compressor is 72 A. (Locked-rotor amperage is the inrush current that the circuit must carry until the motor starts turning. The inrush is not considered for the fan because it is so small.) This is a 3/4-hp compressor motor. A reliable, long-lasting thermostat chosen to operate this equipment should have a control rated at 20 A running current and 80 A locked-rotor current, **Figure 14.14**.

Usually, thermostats are not designed to handle more than 25 A because they would physically be too large. This limits the size of the compressor that can be started directly with a line-voltage thermostat to about 1.5 hp on 115 V or 3 hp on 230 V. Remember, the same motor would draw exactly half of the current when the voltage is doubled. When larger current-carrying

capacities are needed, a motor starter is normally used with a line-voltage thermostat or a low-voltage thermostat. Line-voltage thermostats usually consist of the switching mechanism, the sensing element, the cover, and the subbase.

Figure 14.15 Silver-coated line-voltage contacts. (A) Closed. (B) Open.

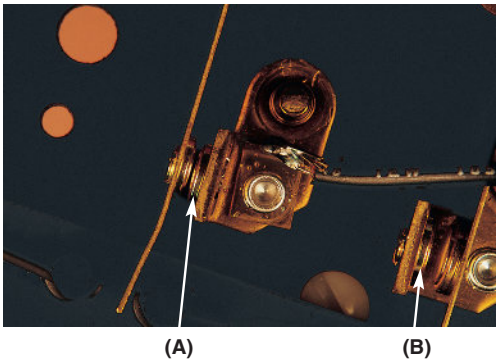

Photo by Bill Johnson

THE SWITCHING MECHANISM

Some line-voltage thermostats use mercury as the contact surface, but most switch contacts are constructed from a silver-coated base metal. The silver helps conduct current at the contact point. The silver contact point takes the real load in the circuit and is the component in the control that wears first, **Figure 14.15**.

THE SENSING ELEMENT

The sensing element is normally a bimetal, a bellows, or a liquid-filled remote bulb, **Figure 14.16**, located where it can

Figure 14.16 Bimetal, bellows, and remote-bulb sensing elements used in line-voltage thermostats. The levers or knobs used to adjust these controls are arranged to apply more or less pressure to the sensing element to vary the temperature range.

Figure 14.17 A line-voltage, wall-mounted thermostat.

Photo by Eugene Silberstein

sense the space temperature. If sensitivity is important, a low-velocity air stream should cross the element. The levers or knobs used to adjust the thermostat are attached to the main thermostat.

THE COVER

Because of the line voltage nature of the controls, the cover is usually attached with some sort of fastener to discourage easy entrance, **Figure 14.17**. If the control is applied to room space temperature, such as in a building, a thermometer may be mounted on the cover to read the room temperature. If the control is used to control a box space temperature, such as a reach-in cooler, the cover might be just a plain protective cover.

SUBBASE

When the thermostat is used for room space temperature control, there must be some way to mount it to the wall. A subbase that fits on an electrical outlet box is usually used. The wire leading into a line-voltage control is normally a high-voltage wire routed between points in a conduit. The conduit is connected to the box that the thermostat is mounted on. **SAFETY PRECAUTION:** *If an electrical arc due to overload or short circuit occurs, it is enclosed in the conduit box. This reduces fire hazard,* **Figure 14.18.**•

As mentioned, as far as function is concerned, a room thermostat for the purpose of controlling a space-heating system is the same as a motor temperature thermostat. They both open or interrupt the electrical circuit on a rise in temperature. However, the difference in the appearance of the two controls is considerable. One control is designed to sense the temperature of slow-moving air, and the other is designed to sense the temperature of the motor winding. The winding has much more mass, and the control must be in much closer contact to get the desired response.

14.4 SENSING THE TEMPERATURE OF SOLIDS

A key point to remember is that any sensing device indicates or reacts to the temperature of the sensing element. A thermometer indicates the temperature of the bulb at the end of the thermometer, not the temperature of the substance in which it is submerged. If it stays in the substance long enough to reach the temperature of the substance, an accurate reading will be achieved, **Figure 14.19**.

To accurately determine the temperature of solids, the sensing element must reach the temperature of the object as soon as practical. It can be difficult to get the rounded bulb of a thermometer close enough to a flat piece of metal so that it accurately measures the temperature of the metal. Only a fraction of the bulb will touch the flat metal at any time,

Figure 14.18 (A) The box for a line-voltage, wall-mounted thermostat. (B) A remote bulb thermostat with flexible conduit. In both cases, the interconnecting wiring is covered and protected.

Figure 14.19 The mercury thermometer rises or falls depending on the expansion or contraction of the mercury in the bulb. The bulb is the sensing device.

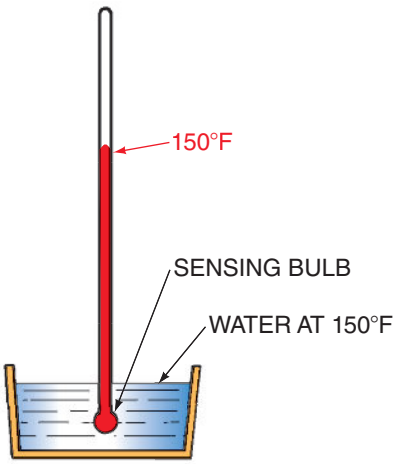

Figure 14.20 Only a fraction of the mercury-bulb thermometer can touch the surface of the flat iron plate at one time. This leaves most of the bulb exposed to the surrounding temperature.

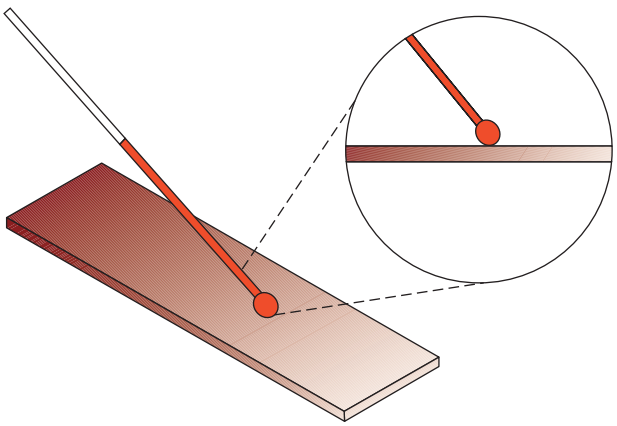

Figure 14.20. This leaves most of the area of the bulb exposed to the surrounding (ambient) air. Placing insulation over the thermometer to hold it tightly on the plate and to shield the bulb from the ambient air helps give a more accurate reading. A gum-type substance can be used to hold the thermometer's bulb against the surface and insulate it from the ambient air, **Figure 14.21**. A more permanent installation may require a well in which to insert the thermometer, **Figure 14.22**.

Most sensing devices will have similar difficulties in reaching the temperature of the substance to be sensed. Some are designed to fit the target surface. The external motor temperature-sensing element is a good example. Because it is a bimetal, among other reasons, it can be manufactured flat to fit close to the motor housing, **Figure 14.23**. This control is

Figure 14.21 An example of temperature sensing often used for field readings. The insulating gum holds the bulb against the metal and insulates it from the ambient air.

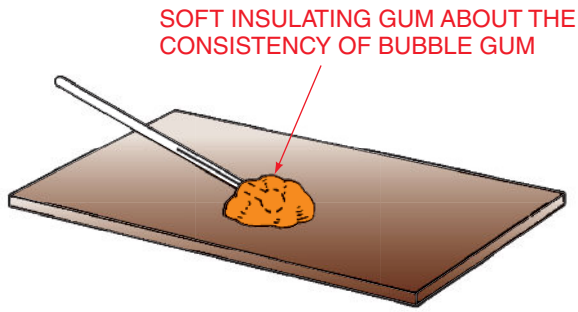

Figure 14.22 An example showing how a well for a thermometer is designed. The well is fastened to the metal plate so that heat will conduct both into and out of the bulb.

normally mounted inside the terminal box of the motor or compressor to shield it from the ambient temperature.

The protection of electric motors is important in the HVAC/R industry because motors are the prime movers of refrigerant, air, and water. Motors, especially the compressor motor, are the most expensive components in the system. They are normally made of steel and copper and need to be protected from heat and from an overload that will cause heat. All motors build up heat as a normal function of work. The electrical energy that passes to the motor is intended to be converted to magnetism and work, but some of it is converted to heat. All motors have some means of detecting and dissipating this heat under normal or design conditions. If the heat becomes excessive, it must be detected and dealt with. Otherwise, the motor will overheat and be damaged.

Motor high-temperature protection is usually accomplished with some variation of the bimetal device or the thermistor. The bimetal device can either be mounted on the outside of the motor, usually in the terminal box, or be embedded in the windings themselves, **Figure 14.24**. The section on motors later covers in detail how these devices actually protect the motors. The thermistor type is normally embedded in the windings. This close contact with the windings gives fast, accurate response, but it also means that the wires must be brought to the outside of the compressor, which involves extra terminals in the compressor terminal box, **Figure 14.25**. **Figures 14.26** and **14.27** show wiring diagrams of temperature protection devices.

Because of its size and weight, a motor can take a long time to cool after overheating. If the motor is an open type, a fan or moving airstream can be used to cool it more quickly. If the motor is inside a compressor shell, it may be suspended from springs inside the shell, which means that the actual motor and the compressor may be hot and hard to cool even though the shell does not feel hot. **Figure 14.28** shows a method often used to cool a hot compressor. There is a vapor space between the outside of the shell and the actual heat source, **Figure 14.29**. **SAFETY PRECAUTION:** *The unit must have time to cool. If you are in a hurry, set up a fan, or even cool the compressor with water, but do not allow water to get into the electric circuits. DO NOT try to cool a cast-iron compressor with cold water. The shock may cause a casting failure. Turn the power off and cover electric circuits with plastic before using water to cool a hot compressor. Be careful when restarting. Use an ammeter to look for overcurrent and gauges to determine the charge level of the equipment.*•

Figure 14.24 A bimetal motor temperature-protection device.

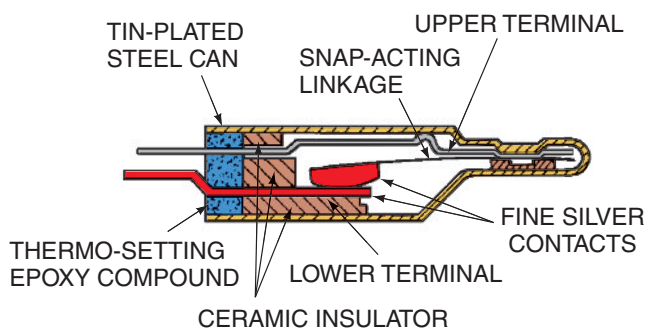

Figure 14.25 A terminal box on the side of the compressor. It has more terminals than the normal run and start of the typical compressor. The additional terminals are for internal motor protection.

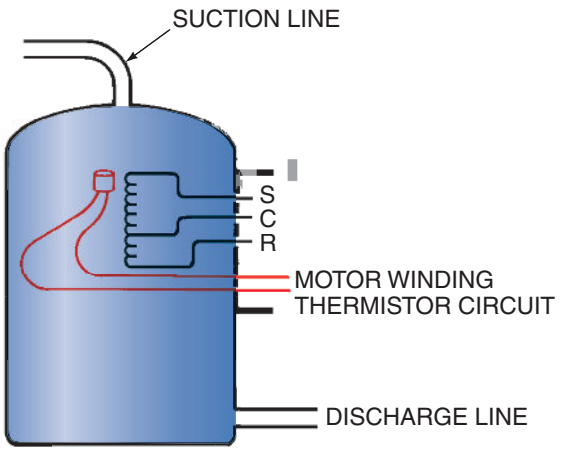

Most hermetic compressors are cooled by suction gas. If there is a refrigerant undercharge, the system superheat will be high and the temperature of the suction gas reaching the compressor will be high as well. Compressor motor overheating is very likely to occur.

SAFETY PRECAUTION: *The best procedure when a hot compressor is encountered is to shut off the compressor with the space temperature thermostat switch and return the next day. This gives the compressor enough time to cool and keeps the crankcase heat on. Many service technicians have diagnosed an open winding in a compressor that was only hot, and they later discovered that the winding was open because of internal thermal protection.*•

14.5 MEASURING THE TEMPERATURE OF FLUIDS

The term *fluid* applies to both the liquid and vapor states of matter. Liquids are heavy and change temperature very slowly. For example, it takes 1 Btu of heat energy to change the temperature of 1 pound of water 1°F, but it only take 0.24 Btu of heat energy to change the temperature of 1 pound of air 1°F. The sensing element must be able to reach the temperature of the medium to be measured as soon as practical. Because liquids are contained in vessels (or pipes), the measurement can be made either by contact with the vessel or by some kind of immersion. When a temperature is detected from the outside of the vessel by contact, care must be taken that the ambient temperature does not affect the reading.

Figure 14.26 Line-voltage bimetal sensing devices under hot and normal operating conditions. (A) Permanent split-capacitor motor with internal protection. Note that a meter would indicate an open circuit if the ohm reading were taken at the C terminal to either start or run if the overload thermostat were to open. There is still measurable resistance between start and run. (B) The same motor, except that the motor protection is on the outside. Note that it is easier to troubleshoot the overload, but it is not as close to the winding for fast response.

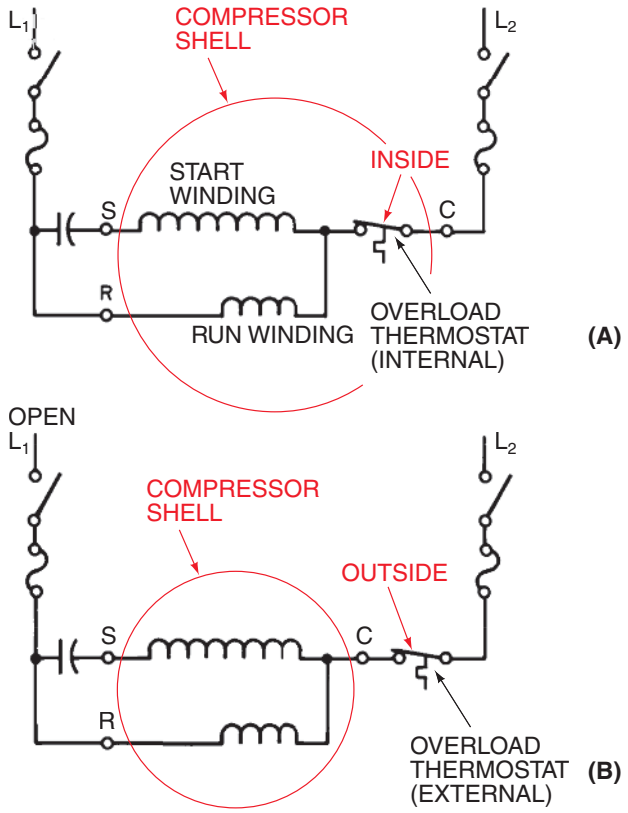

Figure 14.27 The thermistor type of temperature-monitoring device uses an electronic monitoring circuit to check the temperature at the thermistor. When the temperature reaches a predetermined high, the monitor interrupts the circuit to the contactor coil and stops the compressor.

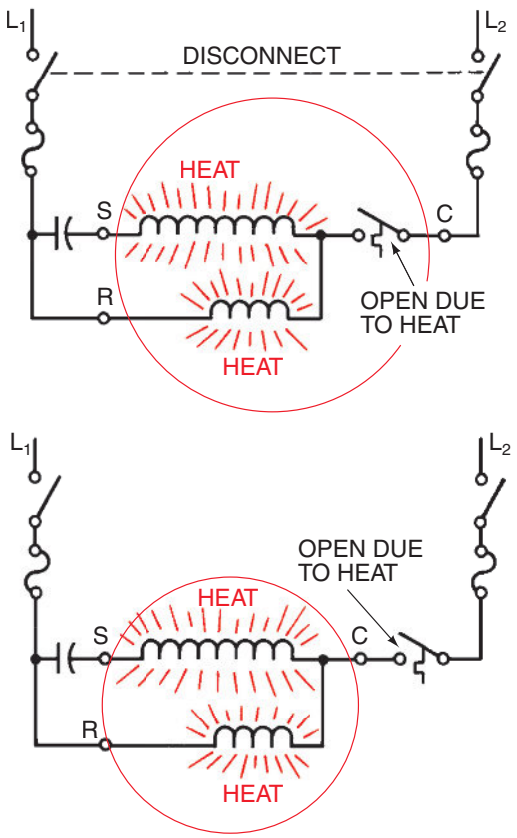

Figure 14.28 Ambient air is used to cool the compressor motor in the fan compartment.

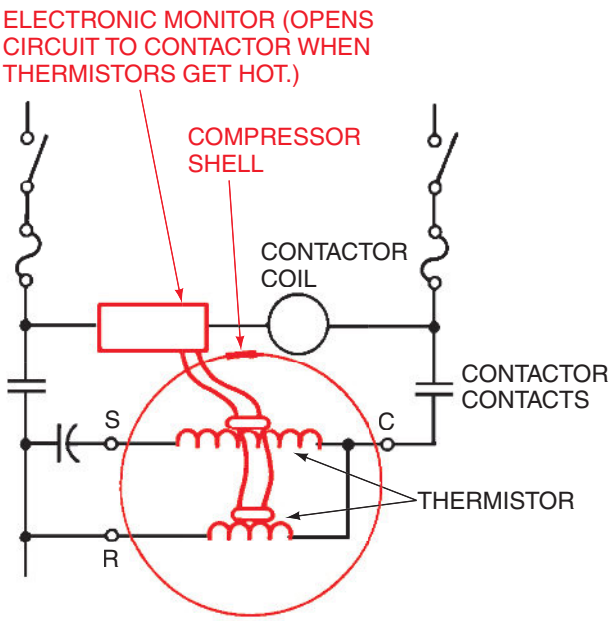

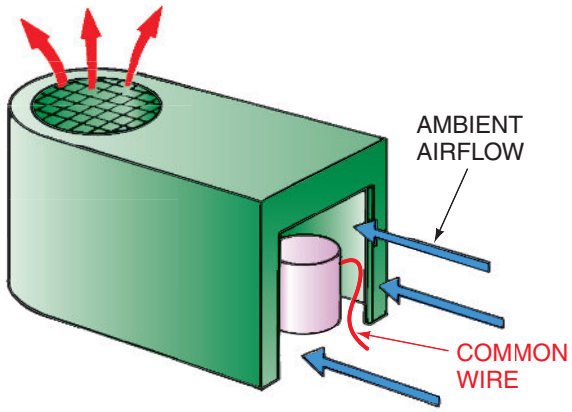

THE COMPRESSOR COMPARTMENT DOOR IS REMOVED AND THE FAN IS STARTED. THIS MAY BE ACCOMPLISHED BY REMOVING THE COMPRESSOR'S COMMON WIRE AND SETTING THE THERMOSTAT TO CALL FOR COOLING.

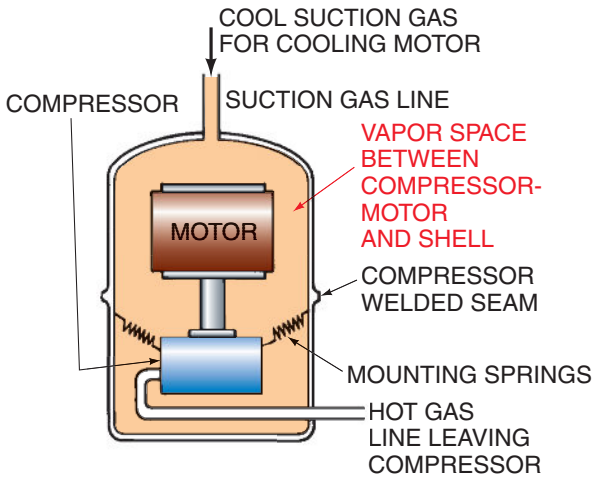
Figure 14.29 The compressor and motor are suspended in vapor space in the compressor shell. The vapor conducts heat slowly.



A good example of readings being affected by ambient temperature is a thermostatic expansion valve's sensing bulb that is used to control the operation of the valve. The sensing bulb must sense refrigerant gas temperature accurately to keep liquid from entering the suction line. Often, the technician will strap the sensing bulb to the suction line in the correct location but fasten it incorrectly. The technician may forget to insulate the bulb from the ambient temperature when it needs to be. In this case, the bulb will sense the ambient temperature and average it in with the line temperature. Since the ambient temperature is higher than the temperature of the refrigerant in the suction line at the outlet of the evaporator, the pressure in the bulb will be higher than desired. This will push the thermostatic expansion valve open. Make sure when mounting a sensing bulb to a line for a contact reading that the bulb is making the very best possible contact, **Figure 14.30**. Brass or copper mounting straps, not plastic, should be used to secure sensing bulbs to the suction line or anywhere else freezing temperatures occur. Brass and copper are much stronger than plastic and can withstand the freezing and thawing cycles, which will prevent breakage from expansion when moisture gets in between the suction line and the sensing bulb and freezes.

Figure 14.30 The correct way to get good contact with a sensing bulb and the suction line. The bulb is mounted on a straight portion of the line with a strap that holds it securely against the line.

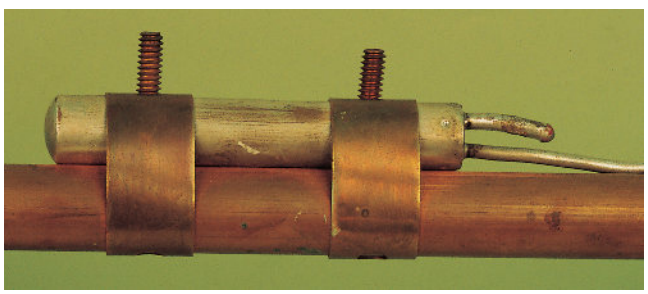


Photo by Bill Johnson

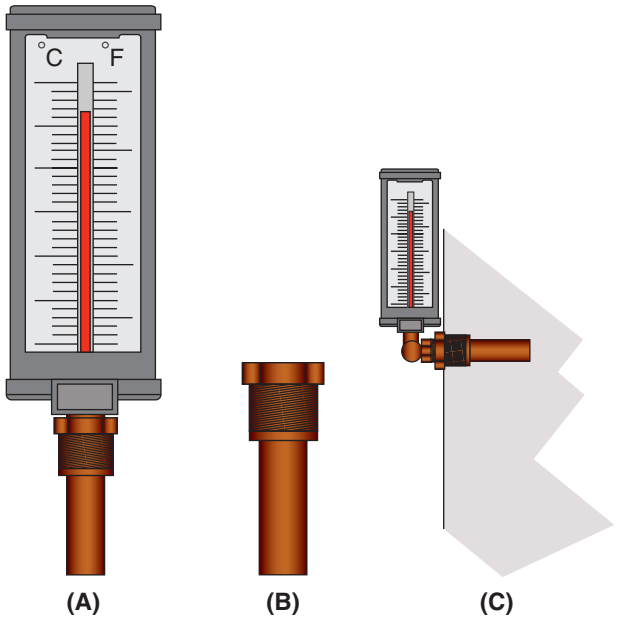
Figure 14.31 (A) A thermometer that is designed be mounted in a well. (B) A well that can be connected to a piece of equipment or installed in a piping circuit. (C) A thermometer installed in a well on a piece of equipment.



When a temperature reading is needed from a larger pipe in a permanent installation, different arrangements are made. A well can be installed into the pipe so that a thermometer or controller-sensing bulb can be inserted into it, **Figure 14.31**. The well must be matched to the sensing bulb to get a good contact fit, or the reading will not be accurate. Sometimes, for troubleshooting purposes, it is desirable to remove the thermometer from the well and insert an electronic thermometer with a small probe. The inside diameter of the well is much larger than the probe, but it can be packed so that the probe is held firm against the well for an accurate reading, **Figure 14.32**.

Figure 14.32 The well is packed to get the probe against the wall of the well. A method for obtaining a leaving-water temperature reading from a small boiler.

Figure 14.33 A snap-disc temperature sensor that can be used to sense air temperature in ductwork and furnaces.

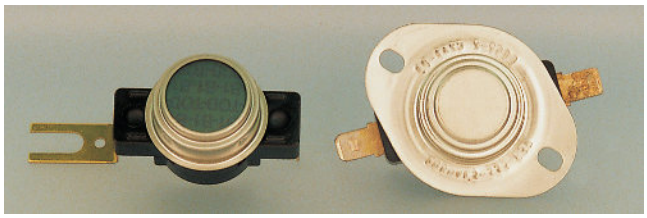

Photo by Bill Johnson

Sensing temperature in fast-moving airstreams such as ductwork and furnace heat exchangers is usually done by inserting the sensing element into the actual airstream. A bimetal device such as the flat-type snap-disc or the helix coil is usually used. **Figure 14.33** shows a snap-disc. Refer to **Figure 13.6b** to see the configuration of a helix coil.

14.6 PRESSURE-SENSING DEVICES

Pressure-sensing devices are normally used when measuring or controlling the pressure of refrigerants, air, gas, and water. They are sometimes strictly pressure controls, or they can be used to operate electrical switching devices. The terms **pressure control** or **pressure switch** are often used interchangeably in the field. The actual application of the component should indicate if the device is being used to control a fluid or to operate an electrical switching device.

Pressure controls contain a bellows, a diaphragm, or a Bourdon tube to create movement when the pressure being sensed by the device changes. Pressure switches can be used to stop and start electrical loads, such as motors, **Figure 14.34**, but they can also be attached to switches or valves, **Figure 14.35**. When used as a switch, the bellows, Bourdon tube, or diaphragm is attached to the linkage that operates the electrical contacts. The electrical contacts are the components that actually open and close the electrical circuit. The electrical contacts either open or close with snap action on a rise in pressure, **Figure 14.36**. The pressure setting at which the control interrupts the electrical circuit is known as the **cut-out**. The point or pressure setting at which the electrical circuit is made is known as the **cut-in**. The difference in the two settings is known as the **differential**.

Pressure controls can either open or close on a rise in pressure and are classifies as "open on pressure rise" or "close on pressure rise" devices. **Figure 14.37** shows the electrical symbols for some commonly used pressure switches. The pressure control can also sense a pressure differential and be designed to open or close a set of electrical contacts, depending on the sensed pressure difference. Refer to Section 14.10 for an example of the oil pressure safety switch, which is a pressure differential switch.

Figure 14.34 The electrical circuit of a refrigeration compressor with a high-pressure control. This control has a normally closed circuit that opens on a rise in pressure.

Figure 14.38 The relief valve on a boiler acts as a safety control.

Photo by Bill Johnson

Pressure switches can function as operational devices or safety controls. A pressure relief valve, **Figure 14.38**, is a safety control and will open if the pressure in a hot water system reaches unsafe levels. Once the pressure has dropped below the rated cut-out pressure setting, the valve will close automatically. A water-regulating valve, **Figure 14.39**, is an operational device. This type of valve is commonly found on water-cooled condensers and will open and close in order to maintain the high side pressure of an air-conditioning or refrigeration system within an acceptable range. This type of valve has a spring pressure that pushes against the high side pressure of the air-conditioning system. If the high side pressure is too low, the spring pressure pushes the valve closed and the high side pressure will increase. If the high side pressure is too high, the high side pressure pushes the valve open and more water flows through the condenser to lower the high side pressure. When used to control fluid flow, the pressure controls are normally attached directly to the valve.

The pressure control can operate either at low pressures (even below atmospheric pressure) or high pressures, depending on the design of the control mechanism. Pressure controls are easily recognized by the small tubes or transmission lines connected to them. These lines are connected to the system at the point where the pressure is being sensed.

The high-pressure and low-pressure controls in refrigeration and air-conditioning equipment are the two most

Figure 14.37 These symbols show how pressure controls connected to switches appear on control diagrams. Symbols (A) and (B) indicate that the circuit will make a rise in pressure. Symbol (A) indicates the switch is normally open when the machine does not have power to the electrical circuit. Symbol (B) shows that the switch is normally closed without power. Symbols (C) and (D) indicate that the circuit will open on a rise in pressure. Symbol (C) is normally open, and (D) is normally closed.

widely used pressure controls in this industry. Some controls are automatic reset, **Figure 14.40**, and some must be reset manually, **Figure 14.41**. Some pressure switches are adjustable, **Figure 14.42**, and some are not. The pressure switch in **Figure 14.40** is not adjustable. In some pressure controls, the high-pressure and the low-pressure controls are built into one housing. These are called dual-pressure controls, **Figure 14.43**. Pressure controls are usually located near the compressor on air-conditioning and refrigeration equipment.

SAFETY PRECAUTION: *When used as safety controls, pressure controls should be installed in such a manner that they are not subject to being valved off, or otherwise isolated from the system.*•

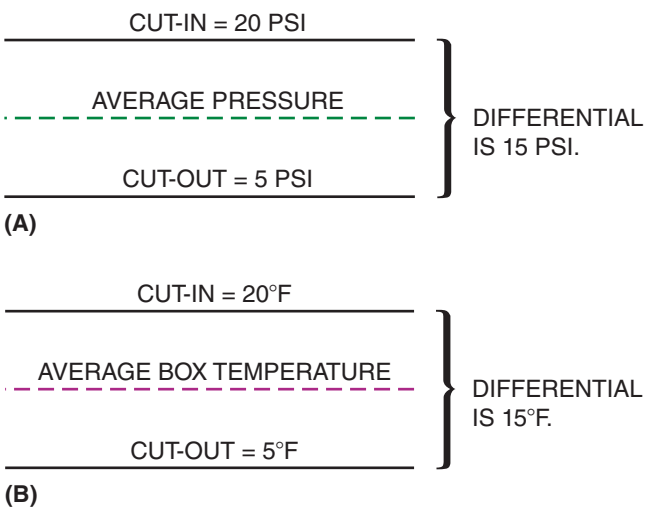
In the HVAC/R field, both pressure and temperature controls incorporate cut-out, cut-in, and differential adjustments. As mentioned earlier, the cut-out of a control interrupts or opens the electric circuit. The cut-in closes the electric circuit, and the differential is the difference between the cut-in and cut-out points. This logic can be represented in the following formula:

$$\text{Cut-in} - \text{Cut-out} = \text{Differential}$$

Another way to write the equation is:

$$\text{Cut-in} - \text{Differential} = \text{Cut-out}$$

Figure 14.44 Cut-in, cut-out, and differential points shown in a graphical format for (A) a pressure controller and (B) a temperature controller.



If a pressure control has a cut-in of 20 psi and a cut-out of 5 psi, the differential would be 15 psi (20 psi – 5 psi). **Figure 14.44** shows this in graphical form. Note that this control language can be used for both pressure and temperature controls. Some control manufacturers refer to the cut-out as the "low event" and the cut-in as the "high event."

As you can see, the differential controls the pressure or temperature difference between the cut-in and cut-out settings. The differential adjustment is usually not easily accessible to the owner or operator when making a temperature or pressure change with the control. It is usually protected or locked up by some sort of mechanism that takes time and knowledge to access. In most cases, only a service technician can make an adjustment to the control's differential. If the differential is set too low, the compressor motor or other power-consuming devices it is controlling may short cycle. Short cycling can overheat motor windings and prematurely wear and pit electrical contacts. On the other hand, if the differential is set too high, the motor may never shut off and may consume large amounts of power. Some differential controls can be nonadjustable and built into the control as a fixed differential. Most high-pressure controls and inexpensive box thermostats are nonadjustable.

Changing the cut-in setting without changing the differential will automatically change the cut-out setting, **Figure 14.45**. The **range** of the control is increased and so is the average box temperature. In the figure, the beginning range is from 5°F to 20°F. By changing the cut-in adjustment of the control to cut in at 25°F, the cut-out point is automatically moved to 10°F because the differential stays constant at 15°F. Notice that both the cut-in and cut-out temperatures are higher, but the difference between the two temperatures (differential) does not change. This gives the control a new range, from 10°F to 25°F. It also increases the average box temperature. The range provides for the

Figure 14.45 A change in the cut-in adjustment by 5°F in (B) will automatically change the cut-out setting by 5°F. This changes the range. Notice that the differential is the same in both examples (A) and (B).

correct minimum and maximum pressures or temperatures when it is controlled automatically by a controller. There must be a range of temperatures because it is very difficult to control the box temperature of a refrigerated case at one exact temperature.

The cut-in adjustment of a control is often referred to as the range adjustment because changing the cut-in causes both the cut-out and cut-in (range of the control) to change, as in **Figure 14.45**. If the differential of the control is changed, the range of the control will also be changed because the differential is the distance between the two settings. The range (cut-in) adjustment spring always acts directly on the control bellows that operates the temperature- or pressure-control electrical switch. The differential adjustment or spring is usually set to the side of the bellows and adds resistance to the mechanism that the bellows of the control is acting on. This action makes it either easier or harder for the electrical contact points to open or close, **Figure 14.36**. Applications and more detailed examples of cut-in, cut-out, and differential settings will be covered in Unit 25, "Special Refrigeration System Components."

There are some electronic pressure controls on the market, **Figure 14.46**. They often have small, on-board microprocessors that are hardwired to an electronic pressure transducer. These versatile electronic controls have easy-to-read digital liquid crystal displays. Some of their features include the following:

- Selectable pressure ranges
- Anti-short–cycling devices
- Remote pressure transducer (easily mounted)
- Wiring harness (no capillary tubes)
- Lockable touch pads (prevents tampering)
- Ability to open contacts on an increase or decrease in pressure

14.7 PRESSURE TRANSDUCERS

Pressure transducers are devices that measure pressure and then convert the sensed pressure into an electronic signal that is then processed by a microprocessor. Two modern pressure transducers are shown in **Figure 14.47**. Most pressure transducers today are capacitive-type pressure transducers. They are usually constructed of a durable, compact housing containing two closely spaced parallel plates, **Figure 14.48**, The parallel plates are generally made of some sort of metal and are electrically isolated from each other with an insulator, usually air or a vacuum, referred to as a dielectric. However, the plates can be made of other materials. One of the metallic plates is stationary; the other acts like a diaphragm that slightly flexes when pressure is applied to its surface. A slight mechanical flexing of the movable plate caused by the applied pressure will change the gap between the plates. This creates a capacitor that varies its capacitance as more or less pressure is applied to the flexible plate or diaphragm. The change in capacitance is sensed by solid-state linear comparative circuitry that is usually linked to a microprocessor. The solid-state circuit analyzes the signal and then amplifies its proportional output signal. Capacitive-type pressure transducers can sense pressures in the ranges of 0.1 in. of water column, IWC, (0.0036 psig) to 10,000 psig. Older and less accurate pressure transducers can operate on the strain gauge principle or simply off a mechanical linkage mechanism.

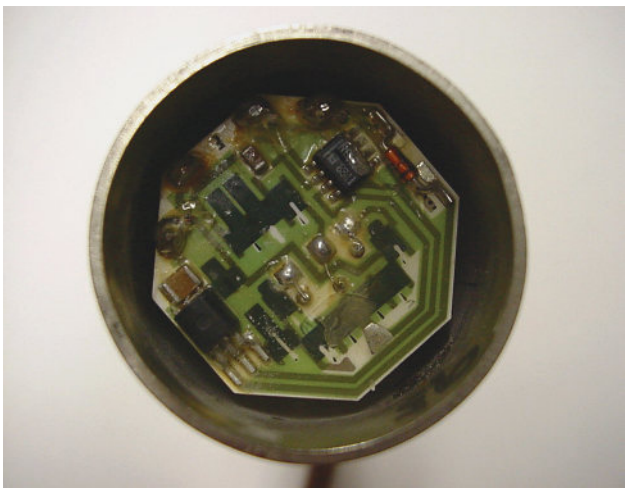
Figure 14.50 Solid-state circuitry in the head of the pressure transducer.



Courtesy Ferris State University. Photo by John Tomczyk

Figure 14.49 shows a working pressure transducer connected to the common suction line of a parallel compressor system. The transducer will sense the common suction pressure in the suction line and convert this signal to a voltage signal for a microprocessor to analyze. This signal is used to cycle different-size compressors on and off to more accurately match the heat loads on the refrigerated cases in the store. There is also solid-state circuitry in the head of the transducer, as shown in **Figure 14.50**. The transducer usually has three wires connected to it. Two wires provide the input voltage, which is usually a DC voltage, and the other wire is the output signal, which can also (but not always) be a DC voltage. The three wires usually originate from a microprocessor board, which is ribbon-cabled to an input/output board, **Figure 14.51**. The transducer senses pressure and converts the signal to an output voltage signal that is processed by the microprocessor board, which operates relays that either start or stop power-consuming devices.

14.8 HIGH-PRESSURE CONTROLS

The high-pressure control (switch) on an air conditioner stops the compressor if the pressure on the high side becomes excessive. In the wiring diagram this control appears as a normally closed control that opens on a rise in pressure. The manufacturer may set the upper limit of operation for

a particular piece of equipment and furnish a high-pressure cut-out control to ensure that the equipment does not operate above these limits. High-pressure controls on HVAC/R equipment usually have a built-in differential that often ranges from 50 psig to 100 psig. For example, if the control opens at a pressure of 400 psig, it will usually reset itself (close contacts) at a pressure between 300 and 350 psig.

A reciprocating compressor is known as a positive displacement device. When it has a cylinder full of vapor, it has to pump out the vapor or stall. If a condenser fan motor on an air-cooled piece of equipment burns out and the compressor continues to operate, very high pressures will occur. **SAFETY PRECAUTION:** *The high-pressure control is one method of ensuring safety for the equipment and the surroundings. Some compressors are strong enough to burst a pipe or a container. On semihermetic compressors, pressures can often increase to the point of blowing out a head gasket or a valve plate gasket. The results can be a large refrigerant loss and spoiled product. The overload device in the compressor offers some protection, but it is really secondary because it does not directly respond to pressures. The motor overload device may also be a little slow to respond to pressure.*•

14.9 LOW-PRESSURE CONTROLS

The low-pressure control (switch) is commonly used in the air-conditioning field as a low-charge protection device, **Figure 14.52**. In commercial refrigeration applications, low-pressure controls are also used to cycle compressors on and

Figure 14.52 The low-pressure control. Photo by Bill Johnson

Photo by Bill Johnson

off in response to evaporator pressures that indirectly control box temperatures. They can also be used in ice makers to initiate the harvest cycle. When equipment loses some of the refrigerant from the system, the pressure on the low-pressure side of the system will fall. Manufacturers may set a minimum pressure below which the equipment will not operate. This is the point at which the low-pressure control cuts off the compressor. These settings vary from manufacturer to manufacturer, so their recommendations should be followed.

Special care must be taken when installing a low-pressure control on systems that are equipped with capillary tube metering devices. The capillary tube allows system pressures to equalize during the off cycle. If the low-pressure control is not carefully applied, the device can cause the compressor to short cycle. The capillary tube is a fixed-bore metering device and has no shutoff valve action. To prevent a short cycle, some equipment has a time-delay circuit that will not allow the compressor to restart for a predetermined time period.

It is undesirable to operate a system without an adequate charge for two good reasons:

1. The compressor motors used most commonly in the industry, particularly in air-conditioning, are cooled by the refrigerant. Without this cooling action, the motor will build up heat when the charge is low. The motor temperature cut-out is used to detect this condition and often takes the place of the low-pressure cut-out by sensing motor temperature.
2. If the refrigerant escapes from a leaking system, the system may very well operate in a vacuum. When a vessel is in a vacuum, the atmospheric pressure is greater than the vessel pressure. This causes the atmosphere to be sucked into the system, where it is sometimes hard to detect. The reference point is atmospheric pressure. If air in the

system is not removed, it will be pumped through the evaporator and the compressor. Because air is a noncondensable gas, it will not condense as refrigerant will and will take up valuable volume in the condenser and cause unwanted high head pressures. These higher head pressures cause high compression ratios and low efficiencies. The compressor's discharge temperature will elevate to a point where oil may break down. Also, the combination of oxygen and moisture in the air, excess heat, and the refrigerant will create an oil sludge and acid formations.

14.10 OIL PRESSURE SAFETY CONTROLS

The oil pressure safety control (switch) is used to ensure that the compressor has oil pressure when operating, **Figure 14.53**. If there is not sufficient oil pressure, the control will open its contacts and de-energize the compressor. Used on larger compressors, this control has a different sensing arrangement than the high- and low-pressure controls, which are single-diaphragm or single-bellows controls used to compare atmospheric pressure with the pressures inside the system.

Figure 14.53 Two views of an oil pressure safety control. This control satisfies two requirements: the effective measurement of net oil pressure and how to get the compressor started to build oil pressure.

(B)

The oil pressure safety control is a pressure differential control. It measures a difference in pressure to determine if positive oil pressure is present. The compressor crankcase pressure (where the oil pump suction inlet is located) is the same as the compressor suction pressure, **Figure 14.54**. The suction pressure will vary from the off or standing reading to the actual running reading. For example, a system using R-22 as the refrigerant may have the pressure readings similar to 125 psig while standing, 70 psig while operating, and 20 psig during a low-charge situation. A plain low-pressure cut-out control would not function at all of these levels, so a control had to be devised that would sensibly monitor pressures under all of these conditions. Most compressors need at least 30 psig of actual oil pressure for proper lubrication. This means that whatever the suction pressure is, the oil pump discharge pressure has to be at least 30 psig above the oil pump inlet pressure, because the oil pump inlet pressure is the same as the suction pressure. For example, if the suction pressure is 70 psig, the oil pump outlet pressure must be 100 psig. This difference in the suction pressure and the oil pump outlet pressure is called the **net oil pressure**.

In the basic low-pressure control, there is pressure under a diaphragm or bellows and atmospheric pressure on the other side. The atmospheric pressure is considered a constant because it does not vary by more than a small amount. The oil pressure control uses a double bellows—one bellows opposing the other to detect the net or actual

Figure 14.54 The oil pump suction pressure is actually the suction pressure of the compressor. This means that the true oil pump pressure is the oil pump discharge pressure minus the compressor suction pressure. For example, if the oil pump discharge is 130 psig and the compressor suction pressure is 70 psig, the net oil pressure is 60 psig. This is usable oil pressure.

oil pressure. These bellows are positioned opposite to each other, either physically or by linkage. The pump inlet pressure is under one bellows, and the pump outlet pressure is under the other bellows. The bellows with the higher pressure is the pump outlet bellows, and it overrides the bellows with the lower pressure. This override in effect is the net pressure, and the bellows is attached to a linkage that can stop the compressor when the net pressure drops for a predetermined time.

When the compressor is off, the net oil pressure is zero and, under these conditions, the compressor should not be allowed to start. This is a catch-22 situation since we need the compressor to operate in order to build up oil pressure and we need oil pressure to allow the compressor to operate. A time delay is therefore built into the control to allow the compressor to get started, build up the necessary oil pressure, and prevent unnecessary cut-outs when the oil pressure varies for only a moment. The time delay is normally about 90 sec and is accomplished by means of a heater circuit and a bimetal device or electronic circuitry.

NOTE: *The manufacturer's instructions should be consulted when working with any compressor that has an oil safety control,* **Figure 14.55**.•

Oil safety controls can also incorporate a pressure transducer for sensing the combination of oil pump discharge pressure and suction (crankcase) pressure, **Figure 14.56**. The difference between the two pressures (net oil pressure) is measured by the transducer, which has two separate sensing ports. As shown in **Figure 14.57**, the pressure transducer is mounted directly in the oil pump and is connected to an electronic controller by wires. The pressure transducer transforms a pressure signal to an electrical signal for the electronic controller to process. One advantage of an electronic oil safety controller over a mechanical bellows-type controller is that it eliminates capillary tubes; thus, there is less chance of refrigerant leaks. Also, the electronic clock

Figure 14.55 The oil pressure control is used to protect the compressor by ensuring adequate lubrication. The oil pump that lubricates the compressor is driven by the compressor crankshaft. Therefore, a time delay is necessary to allow the compressor to start up and build oil pressure.

and circuitry are much more accurate and reliable. A more detailed explanation of both the mechanical bellows and the electronic oil safety controllers, with accompanying circuitry, will be covered in Unit 25, "Special Refrigeration System Components."

14.11 AIR PRESSURE CONTROLS

Air pressure switch sensors need a large diaphragm to sense the very low pressures in air systems. Mounted on the outside of the diaphragm is a small switch (microswitch) capable only of stopping and starting control circuits. Air pressure controls (switches) are used in several applications.

1. Ice buildup on the outdoor coil of a heat pump will cause an air pressure drop through the coil. When a predetermined pressure drop is detected, there is sufficient ice buildup and a defrost cycle is needed. When used in this manner, the air pressure control is an operating control, **Figure 14.58**. Not all manufacturers use air pressure as an indicator for defrost.
2. When electric heat is used in a remote duct as terminal heat, an air switch (sail switch) is sometimes installed to ensure that the blower is passing air through the duct before heat is allowed to be generated. Thus, this control is a safety switch and should be treated as such, **Figure 14.59**. The switch has a very lightweight and sensitive sail. When air is passing through the duct, the sail is blown out to an approximately horizontal position, which allows the heat source to be activated. When the blower stops, the sail rises, ensuring that the heat source is turned off.
3. Air switches or sail switches are also used to prove that the combustion blower motor is operating before energizing the main gas valve for ignition.

14.12 GAS PRESSURE SWITCHES

Gas pressure switches are similar to air pressure switches but usually smaller. They detect the presence of gas pressure in gas-burning equipment before burners are allowed to ignite. **SAFETY PRECAUTION:** *This is a safety control and should never be bypassed except for troubleshooting and then only by experienced service technicians.*•

14.13 SWITCHLESS DEVICES THAT CONTROL FLUID FLOW

The pressure relief valve can be considered a pressure-sensitive device. It is used to detect excess pressure in any system that contains fluids (water or refrigerant). Boilers, water heaters, hot water systems, refrigerant systems, and gas systems all use pressure relief valves, **Figure 14.60**. This device can be either pressure- and temperature-sensitive (called a p & t valve) or just pressure-sensitive. The p & t valves are normally used in water heaters. The type considered here is the pressure-sensitive type.

The pressure relief valve can usually be recognized by its location. On boilers it is often placed at the highest

REFRIGERANT RELIEF VALVE

(B)

point on the boiler. **SAFETY PRECAUTION:** *This valve is a safety device that must be treated with the utmost respect. Some have levers on top that can be raised to check the valve for flow. Most have a visible spring that pushes the seat downward toward the system's pressure. A visual inspection reveals that the spring holds the seat against the valve body. The valve body is connected to the system, so, in effect, the spring is holding the valve seat down against the system pressure. When the system pressure becomes greater than the spring tension, the valve opens and relieves the pressure and then reseats.* **SAFETY PRECAUTION:** *The pressure setting on a relief valve is set at the factory and should never be tampered with. Normally, the valve setting is sealed or marked on the valve in some manner so that the correct replacement valve can be selected.* Most relief valves automatically reset. After they relieve, they seat back to the original position. A seeping or leaking relief valve should be replaced. **SAFETY PRECAUTION:** *Never adjust or plug the valve. Doing this can be extremely dangerous.*

14.14 WATER PRESSURE REGULATORS

Two types of water pressure regulators are commonly used: the pressure regulating valve for system pressure and the pressure regulating valve for head pressure control in water-cooled refrigeration systems. Air-conditioning and refrigeration systems operate at lower pressures and temperatures when water-cooled, but the water circuit requires a special kind of maintenance. At one time water-cooled equipment was in widespread use. Because it is easy to maintain, air-cooled equipment has now become dominant. Therefore, although water pressure valves are still present in air-conditioning and refrigeration equipment, they are not as common as they once were.

Water pressure regulating valves are used in two basic applications.

1. They reduce supply water pressure to the operating pressure in a hot water heating system. This type of valve has an adjustment screw on top that increases the tension on the spring regulating the pressure, **Figure 14.61**. A great many boilers in home or business hydronic systems use circulating hot water at about 15 psig. The supply water may have a working pressure of 75 psig or more, which must be reduced to the system working pressure. If the supply pressure were to be allowed into the system, the boiler pressure relief valve would open. The water-regulating valve is installed in the supply water makeup line that adds water to the system when some

leaks out. Most water-regulating valves have a manual valve arrangement that allows the service technician to remove the valve from the system and service it without stopping the system. Most systems also have a manual feedline to allow the system to be filled by bypassing the water-regulating valve. **SAFETY PRECAUTION:** *Care must be taken not to overfill the system.*•

2. The water-regulating valve controls water flow to the condenser on water-cooled equipment to regulate head pressure. This valve takes a pressure reading from the high-pressure side of the system and uses it to control the water flow in order to establish a predetermined head pressure, **Figure 14.39**. For example, if an ice maker were to be installed in a restaurant where the noise of the fan would be objectionable, a water-cooled ice maker could be used. This might be a "wastewater" type of system in which the cooling water is allowed to go down the drain. In the winter the water may be very cool, and in the summer the water may get warm. In other words, the ice maker may have a winter need and a summer need. The water-regulating valve would modulate the water in both cases to maintain the required head pressure. An added benefit when the system is off for any reason is that the head pressure is reduced and the water flow is stopped until needed again. All of this is accomplished without an electrical connection.

   The water-regulating valve is controlled by two pressures: the high-side pressure of the refrigeration system and the spring pressure on the water-regulating valve itself. The high-side pressure pushes to open the valve and the valve's spring pressure pushes to close the valve. If the high-side pressure is too high, the valve opens to push more water through the condenser. If the head pressure is too low, the spring pressure on the valve acts to close the valve so less water is pushed through the condenser.

14.15 GAS PRESSURE REGULATORS

The gas pressure regulator is used in all gas systems to reduce the gas transmission pressure to usable pressure at the burner. The gas pressure at the street in a natural gas system could be 5 psig, and the burners could be manufactured to burn gas at 3.5 in. WC (this is a pressure-measuring system that indicates how high the gas pressure can push a column of water). **SAFETY PRECAUTION:** *Street pressure must be reduced to the burner design. This is done with a pressure-reducing valve that acts like the water pressure regulating valve in the boiler system,* **Figure 14.62.**• A device on top of the valve can be used by qualified personnel to adjust the gas pressure. A propane tank can have as much as 150 psig in pressure that needs to be reduced to the burner design pressure of 11 in. WC. A pressure regulator is normally located on the tank, **Figure 14.63**.

14.16 MECHANICAL AND ELECTROMECHANICAL CONTROLS

A water pressure regulating valve is an example of a mechanical control. The valve maintains a preset water pressure in a boiler circuit without electrical contacts or connections, **Figure 14.61**. It acts independently from any of the other controls, yet the system depends on it as part of the team of controls that make the system function trouble-free. The

Figure 14.64 This high-pressure control is considered an electromechanical control.

Photo by Eugene Silberstein

technician must be able to recognize and understand the function of each mechanical control. This may be more difficult than it is for electrical controls because control diagrams do not always describe mechanical controls as well as they do electrical controls.

Electromechanical controls convert a mechanical movement into some type of electrical activity. A high-pressure switch is an example of an electromechanical control. The switch contacts are the electrical part, and the bellows or diaphragm is the mechanical part. The mechanical action of the bellows is transferred to the switch to stop a motor when high pressures occur, **Figure 14.64**. Electromechanical controls normally are shown on the electrical diagram with a symbol adjacent to the electrical contact describing what the control does, **Figure 14.65**. The symbols are supposed to be standard; however, old equipment still in service and installed long before standardization was considered will require imagination and experience to understand the intent of the manufacturer.

14.17 MAINTENANCE OF MECHANICAL CONTROLS

Mechanical controls are used to control the flow of fluids such as water, refrigerant, liquids and vapors, or natural gas. The fluids flowing through the controls must be contained within the system, but the diaphragms, bellows, and gaskets that are typically part of the controls are subject to leakage after long-time use.

Water is one of the most difficult substances to contain and is likely to leak through even the smallest of openings. All water-regulating valves should be inspected for leaks by looking for wet spots or rust streaks. Water circulating in a system will also leave mineral deposits in the piping and valve seats or mechanisms. For example, a water-regulating valve for a hot water system, **Figure 14.39** is subject to problems that may cause water leaks or control set-point drift. Some valves are made from brass to prevent corrosion and some are made of cast iron. The cast-iron ones are less expensive but rust may bind the moving parts. Mineral deposits or rust inside a valve can prevent the valve from moving up and down to feed water, which might result in overfeeding or underfeeding the system. Water valves also have a flexible diaphragm that moves every time the valve functions. The diaphragm is subject to deterioration from flexing and age. If the diaphragm leaks, water will escape to the outside and drip on the floor.

Because pressure relief valves on boilers are a safety control, they are constructed of material that will not corrode. These valves must move freely to ensure that they will not stick shut and lose their function. A valve that is stuck shut may cause an explosion. Many technicians from time to time pull the lever on the top of safety relief valves and let them relieve a small amount of steam or hot water. This ensures that the valve port is free from deposits that may prevent it from functioning. On some occasions, the valve may not seat properly when the lever is released and the valve may seep. Pulling the lever again will usually clear this up by blowing out any trash in the valve seat. If a valve cannot be stopped from leaking, it must be replaced. The fact that pulling the lever may start a leak is the reason many technicians do not "test" relief valves.

14.18 MAINTENANCE OF ELECTROMECHANICAL CONTROLS

Electromechanical controls have both a mechanical and an electrical action. When water is involved, many of the same procedures used to maintain mechanical controls should be followed. Inspect for leaks. Electromechanical pressure controls are often connected to the system with transmission

lines that resemble the capillary tube metering device. This small-diameter tube, usually made of copper, is the cause of many leaks in refrigeration systems because of misapplication or poor installation. Consider the example of a low- or high-pressure control. These devices are located near the compressor, but the transmission lines or control tubes must be routed between the control and the compressor to properly sense system pressures. The control must be mounted securely to the frame and the control tube routed in such a manner that it does not touch the frame or any other component. If the control tubes are installed improperly, leaks can result. The vibration of the compressor will vibrate the control tube and rub a hole in the tube or one of the refrigerant lines if they are not kept separate.

The electrical section of the control will usually have a set of contacts or a mercury switch to stop and start some component in the system. The electrical contacts are often enclosed and cannot be viewed, so visual inspection is not possible. When a problem occurs, look for frayed wires or burned wire insulation adjacent to the control. The mercury in mercury switches may be viewed through the clear glass enclosure. If the mercury becomes dark, the tube is allowing oxygen to enter the space where the mercury makes and breaks the electrical contact and oxidation is occurring. In this case, the switch should be replaced because the switch may conduct across the oxidation and so be closed at all times. This could prevent a boiler from shutting off, allowing overheating to occur.

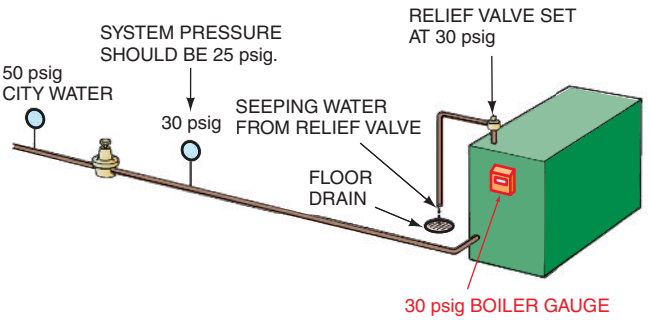
14.19 SERVICE TECHNICIAN CALLS

SERVICE CALL 1

A customer calls indicating that the boiler in the equipment room at a motel has hot water running out and down the drain all the time. Another service company has been performing service at the motel for the last few months. *The problem is that the water-regulating valve (boiler water feed) is out of adjustment. Water is seeping from the boiler's pressure relief valve,* **Figure 14.66**.

The technician arrives at the motel, parking alongside the building so as not to block the front door or the motel's registration parking areas. When the property manager comes into the office to greet the technician, the technician introduces himself and hands him his company's business card. After asking some preliminary questions about the system, the technician and the manager go to the boiler room. Once there, the tech notices that, as the customer said, water is seeping out of the relief valve pipe that terminates in the drain. This is heated water, causing a very inefficient situation The needle on the boiler gauge is in the red; the pressure

Figure 14.66 This illustration indicates how one control can cause another to look defective. The water pressure regulating valve adjustment had been changed by mistake, allowing more than operating pressure into the system. The water pressure regulating valve is designed to regulate the water pressure down to 25 psig. The valve is necessary to allow water to keep the system full automatically should a water loss develop due to a leak.



is 30 psig. No wonder the valve is relieving the pressure; it is too high. The boiler is hot, but the technician cannot tell if it is too hot. The burner is not operating, so the technician decides that this may be a pressure problem instead of a temperature problem.

The technician looks for and finds the water pressure regulating valve, which is in the supply water line entering the boiler. Actually, this valve keeps the supply water pressure from reaching the boiler and feeds water into the system when there is a loss of water due to a leak. The supply water pressure could easily be 75 psig or more. The boiler working pressure is 30 psig with a relief valve setting of 30 psig. If the supply water were allowed directly into the boiler, it would push the pressure past the design pressure of the system, which must be less than 30 psig. If the pressure were above this, it would cause the pressure relief valve to relieve the pressure and dump water from the system until the pressure is lowered.

The technician shuts off the water valve leading to the boiler makeup system and bleeds some water from the system until the pressure at the boiler is down to 15 psig. He then adjusts the water regulating valve to a lower pressure and opens the supply water valve to allow water to enter the system. The technician can hear water entering through the water regulating valve. In a few minutes, the water stops entering. The pressure in the system is now adjusted to 18 psig and all is well.

In this example the problem is that a mechanical automatic control is causing another control to show that the system has problems. If left unexamined, the problem might seem to be that the relief valve is defective because water is seeping out of it. This is not the case; the relief valve is doing its job. The water regulating valve is at fault.

The technician shows the motel manager what the problem was, how it was corrected, and completes the paperwork before leaving for another call. The technician makes a point

of thanking the manager for choosing to let his company service the equipment and asks that his company be called for future service and repairs.

SERVICE CALL 2

A customer in a service station calls to say the hot water boiler in the equipment room is blowing water out from time to time. A technician is quickly dispatched to the job because of the potential hazard. *The problem is the gas valve will not close. The boiler is overheating. The relief valve is relieving water periodically.* The season is mild, so the boiler has a small load on it.

Because the relief valve is relieving intermittently, a periodic pressure buildup in the boiler might be to blame. If the problem were the same as in Service Call 1, where a constant, bleeding relief occurred, the water regulating valve or the relief valve might be suspect. This is not the case.

The technician speaks with the lead mechanic at the service station since the manager is out to lunch. Once at the boiler, the technician reads the gauge; it is in the red and about to relieve again. The technician then looks at the flame in the burner section, notices that it is not a full flame but small, and decides that the gas valve may be stuck open, allowing fuel to enter the burner all the time. The in-line gas hand valve is shut off to put out the flame so the technician can investigate the problem.

A check with a voltmeter shows no voltage at the gas valve terminals, so the thermostat is trying to shut the gas off. The valve must be stuck open. Before replacing the gas valve, the technician calls the office, reports his findings, and gets approval to replace the part. This was very important, since the service station manager is not available.

The technician obtains a new gas valve and installs it. The boiler is started up and allowed to run. It is cold after being off for some time for the gas valve change, so it takes a while for it to get up to temperature. The set point of the thermostat is 190°F and the gas valve shuts off when this temperature is reached.

These service calls are examples of how a trained technician might approach service problems. Technicians develop their own approaches to problems. The point is that no diagram was consulted. A technician either must have prior knowledge of the system or must be able to look at the system and make accurate deductions based on a knowledge of basic principles.

Each control has distinguishing features that indicate its purpose. There are hundreds of controls and dozens of manufacturers (some of whom are out of business). If a technician has no information as to what a control does, the manufacturer should be consulted. If this is impossible, speaking with someone who has experience with the equipment would likely be helpful. In general, when examined from the proper perspective, the design parameters of the control can provide clues. For example, what maximum temperature or pressure is practical? What minimum temperature or pressure is practical? Ask these questions when running across a strange control.

Solutions for the following service calls are not provided here. Please discuss the solutions with your instructor.

SERVICE CALL 3

A residential customer reports that a heating system was heating until early morning, but for no apparent reason it stopped. The furnace, a gas-fired appliance located in the basement, seems to be hot, but no heat is coming out of the air outlets.

The technician arrives at the house, making certain to park on the street, not in the driveway. When the customer answers the doorbell, the technician introduces himself and the company he represents and tells the homeowner why he is there. The technician asks the homeowner for details regarding her concerns. From the description he believes the problem may be with the blower. The technician first checks to see if there is power at the furnace and notices that although the furnace is hot to the touch, no heat is coming out of the duct. Further investigation shows that the blower is not running.

The technician knows there is power to the furnace because it is hot and the burner ignites from time to time. The problem must be in the blower circuit. A voltage check shows that there is 115 VAC between points A and J, as well as 115 VAC between points K and L. The blower motor is not running. See the diagram in **Figure 14.67** for direction.

What is the problem and the recommended solution?

SERVICE CALL 4

A customer calls to say that the central air-conditioning system in their small office building will not cool. When the service technician arrives he turns the thermostat to COOL and sets the thermostat to a temperature that is lower than the present temperature in the space. The indoor blower motor starts. This indicates that control voltage is present and will send power on as requested for cooling. Only recirculated air is coming out of the ducts.

The technician checks the outside unit, notices that it is not running, and removes the control panel cover to see what controls will actually prevent the unit from starting, which will give some indication of what the possible problem may be. Use the diagram in **Figure 14.68**.

The technician installs pressure gauges to obtain the system pressures. New air-conditioning systems use R-410A. If the system were standing at 80°F, the system should have 235 psig of pressure, according to the temperature/pressure chart for R-410A at 80°F.

Figure 14.67 This diagram can be used for Service Call 3.

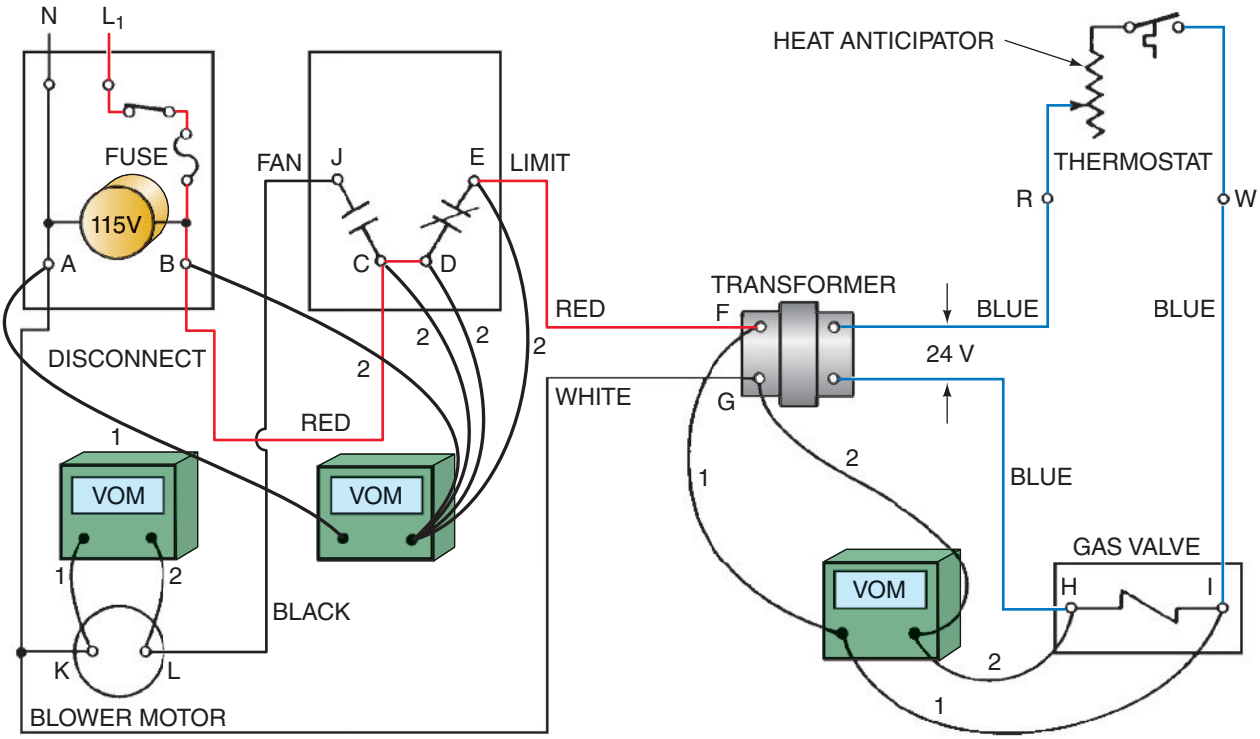

Figure 14.68 This diagram can be used for Service Call 4.

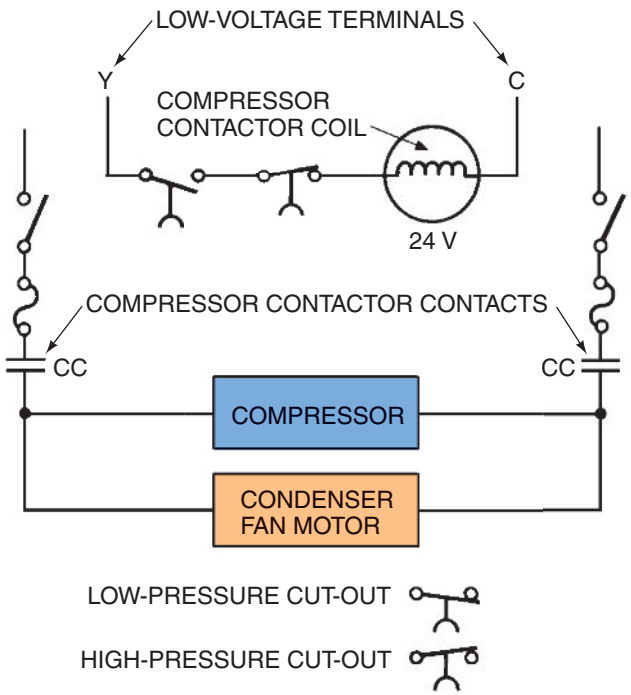

NOTE: *Care should be used in the standing pressure comparison. Part of the unit is inside, at 75°F air, and part of the unit is outside. Some of the liquid refrigerant will go to the coolest place if the system valves will allow it to.*

The gauge reading may correspond to a temperature between the indoor and outdoor temperature but not less than the cooler temperature. Some systems use fixed-bore metering devices that allow the system pressures to equalize and the refrigerant to migrate to the coolest place in the system.

In this example the pressure in the system is 105 psig, the refrigerant is R-410A, and the temperature is about 80°F. A typical pressure control setup may call for the control to interrupt the compressor when the system pressure gets down to 42 psig and to make the control start the compressor when the pressure rises back to a temperature corresponding to 70°F.

What is the problem and the recommended solution?

The foregoing typical service problems show how a service technician might arrive at the correct diagnosis, using the information at hand. Always save and study the manufacturer's literature. There is no substitute for having access to the manufacturer's specifications.

SUMMARY

- Space temperature controls can be either low-voltage or line-voltage types.
- Low voltage is normally used for residential heating and cooling controls.
- Heating thermostats normally have a heat anticipator circuit in series with the thermostat contacts.
- Cooling thermostats may have a cooling anticipator in parallel with the thermostat contacts.
- Line-voltage thermostats are normally rated up to 20 A because they are used to switch high-voltage current.
- Low-voltage thermostats will normally carry only 2 A of current.
- To get a correct temperature reading on a flat or round surface, the sensing element (either mercury bulb, remote bulb, or bimetal) must be in good contact with the surface and insulated from the ambient air.
- Some installations have wells in the substance to be sensed in which the sensor can be placed.
- Motors have both internal and external types of motor temperature-sensing devices.
- The internal type of motor temperature-sensing device can be either a bimetal or a thermistor inserted inside the motor windings.
- Some sensing elements are inserted into the fluid stream. Examples are the fan or limit switch on a gas, oil, or electric furnace.
- All temperature-sensing elements change in some manner with a change in temperature: The bimetal warps, the thermistor changes resistance, and the thermocouple changes voltage.
- Pressure controls normally are operated either by a diaphragm, Bourdon tube, or bellows.
- Pressure controls can operate at high pressures, low pressures, and even below atmospheric pressure (in a vacuum) and can detect differential pressures.
- **SAFETY PRECAUTION:** *Gas pressure must be reduced before it enters a house or place of business.*
- Some purely mechanical controls are water regulating valves, pressure relief valves, and expansion valves.
- Some electromechanical controls are low-pressure cut-out, high-pressure cut-out, and thermostats.
- Keep and study manufacturers' literature.

REVIEW QUESTIONS

1. Why is a low-voltage thermostat normally more accurate than a high-voltage thermostat?
2. The three kinds of switching mechanism used in low-voltage thermostats are _____, _____, and _____.
3. What does a heat anticipator do?
4. What does a cold anticipator do?
5. Define system overshoot when dealing with thermostats.
6. True or False: The temperature drop below the thermostat's set point is referred to as system lag.
7. What is meant by the steady-state condition with regard to setting a heating anticipator?
8. Describe the method a service technician should follow when measuring the current that normally travels through a heating anticipator.
9. Explain how microelectronic or electronic thermostats handle system overshoot and system lag.
10. Describe how a bimetal functions.
11. What component steps down the voltage to the low-voltage value?
12. Low voltage is desirable for residential control voltages because of _____, _____, _____, and _____.
13. What is the maximum amperage usually encountered by a low-voltage thermostat?
14. A heating thermostat _____ on a rise in temperature.
15. A cooling thermostat _____ on a rise in temperature.
16. What two types of switches are normally found in the subbase of a low-voltage thermostat?
17. When is a line-voltage thermostat used?
18. What is the maximum amperage generally encountered in a line-voltage thermostat?
19. Why is a line-voltage thermostat mounted on an electrical box that has conduit connected to it?
20. What is the principle of operation for most externally mounted overload protection devices?
21. Describe a method for speeding up the cooling of an open motor.
22. Describe two methods for cooling an overheated compressor.
23. How can an electronic thermometer be used in a well to obtain an accurate response?
24. A temperature-sensing device used in measuring airflow is the _____.
25. How does a thermocouple change with a temperature change?

26. True or False: Pressures below atmospheric pressure cannot be detected.
27. Name one function of the low-pressure control.
28. Which is true of a high-pressure control?
    A. It closes on a rise in pressure.
    B. It opens on a fall in pressure.
    C. It is located on the evaporator.
    D. It protects the compressor from high pressures.
29. Name two types of water pressure control.
30. Why should a safety control not be adjusted if it has a seal to prevent tampering?
31. True or False: If the differential of a motor control is set too small, the motor may short cycle.
32. True or False: A change in the differential setting will automatically change the cut-in point of the control.
33. True or False: A change in the differential of a control will always change the range of the control.
34. True or False: Changing the cut-out adjustment without changing the differential adjustment will automatically change the cut-in setting.
35. Explain what is meant by the range of a temperature control or pressure control.

UNIT 15

TROUBLESHOOTING BASIC CONTROLS

OBJECTIVES

After studying this unit, you should be able to

- describe and identify power- and non-power-consuming devices.
- describe how a voltmeter is used to troubleshoot electrical circuits.
- identify some typical problems in an electrical circuit.
- describe how an ammeter is used to troubleshoot an electrical circuit.
- describe how a voltmeter is used to troubleshoot an electrical circuit.
- recognize the components in a heat-cool electrical circuit.
- follow the sequence of electrical events in a heat-cool electrical circuit.
- differentiate between a pictorial and a line-type electrical wiring diagram.

SAFETYCHECKLIST

- ✔ When troubleshooting electrical malfunctions, disconnect electrical power unless power is necessary to make appropriate checks. Lock and tag the panel where the disconnect is made, and keep the only available key on your person.
- ✔ When checking continuity or resistance, turn off power and disconnect both leads from the component being checked.
- ✔ Ensure that meter probes come in contact with only the intended terminals or other contacts.
- ✔ Make certain that all electrical connections are tight.
- ✔ Make certain that all unused wires are properly capped to prevent them from coming into contact with other conductors or with the metal casing of the equipment.

15.1 INTRODUCTION TO TROUBLESHOOTING

Each control must be evaluated as to its function (major or minor) in the system. Recognizing the control and its purpose requires that you understand its use in the system. Studying the purpose of a control before you take action will save a great deal of troubleshooting time. Look for pressure lines going to pressure controls and temperature-activated elements on temperature controls. Determine if the control stops and starts a motor, opens and closes a valve, or provides some other function. As mentioned previously, controls are either electrical, mechanical, or a combination of electrical and mechanical. (For now, electronic controls are considered the same as electrical controls.)

Electrical devices can be considered as power-consuming or non-power-consuming so far as their function in the circuit is concerned. Power-consuming devices use power and have either a magnetic coil or a resistance circuit. They are more commonly referred to as *loads*. Non-power-consuming devices pass power on to power-consuming devices. Non-power-consuming, or power-passing, devices are commonly referred to as *switches*. They are used to simply pass power to the loads that are ultimately being controlled.

Both power-consuming and power-passing devices are wired in series with the power supply. Multiple loads are often wired in parallel with each other, and the switches that are used to control each load are connected in series with that load. If multiple switches are to be used to control the operation of a single load, the switches are wired in series with each other and in series with the load being controlled.

The concepts of the load and switch can be easily clarified using a simple light bulb circuit with a switch. The light bulb in the circuit is the load and actually consumes the power, whereas the switch passes the power to the light bulb. The object is to wire the light bulb to both sides (hot and neutral) of the power supply, **Figure 15.1**. This will then ensure that a complete circuit will be established. The switch is a power-passing device and is wired in series with the light bulb. For any power-consuming device to consume power, it must have a potential voltage across it. A potential voltage is the voltage indicated on a voltmeter between two power legs (such as line 1 to line 2) of a power supply. This can be thought of as electrical pressure in a home; for example, the light bulb has to be wired from the hot leg (the wire that has a fuse or breaker in it) to the neutral leg (the grounded wire that actually is wired to the earth ground).

The following statements may help you understand electron flow in an electrical circuit. We have taken some liberties in this unit in explaining electrical circuits, but this has been done to aid your understanding of the concepts involved.

1. It does not make any difference which way the current flows in an alternating current (AC) circuit when the object is to get the electrons (current) to a power-consuming device and complete the circuit.

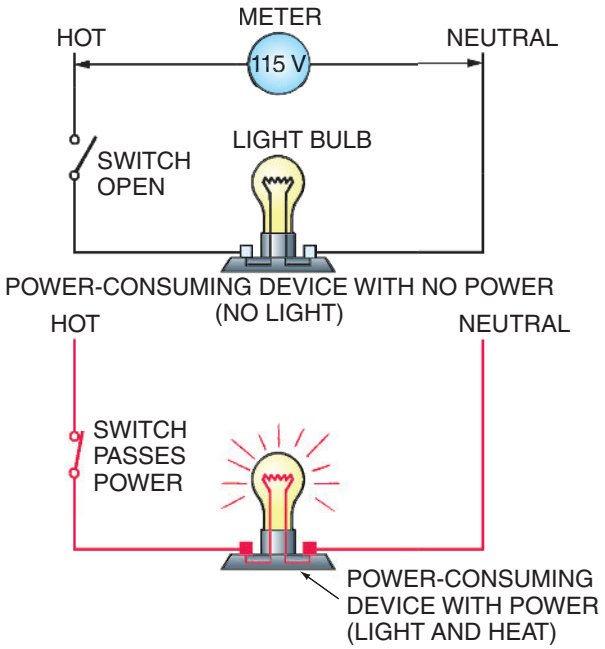
Figure 15.1 A power-consuming device (light bulb) and a non-power-consuming device (switch). The switch passes power to the light bulb.



2. The electrons may pass through many power-passing devices before getting to the power-consuming device(s).
3. Devices that do not consume power pass power.
4. Devices that pass power can be either safety devices or operating devices.

Suppose the light bulb mentioned above was to be used to add heat to a well pump to keep it from freezing in the winter. A thermostat is installed to prevent the bulb from burning all the time. A fuse must also be installed in the line to protect the circuit, and a switch must be wired to allow the circuit to be serviced, **Figure 15.2**. Note that the power now must pass through three power-passing devices to reach the light bulb. These three switches are connected in series with each other. The fuse is a safety control, and the thermostat turns the light bulb on and off. The switch is not a control but a service convenience device. Notice that all switches are on one side of the circuit. Let us suppose that the light bulb does not light up when it is supposed to. Which component is interrupting the power to the bulb: the switch, the fuse, or the thermostat? Or is the light bulb itself at fault? In this example, the thermostat (switch) is open, **Figure 15.3**.

Figure 15.2 When closed, the switch passes power to the fuse, then to the thermostat, and on to the light bulb.

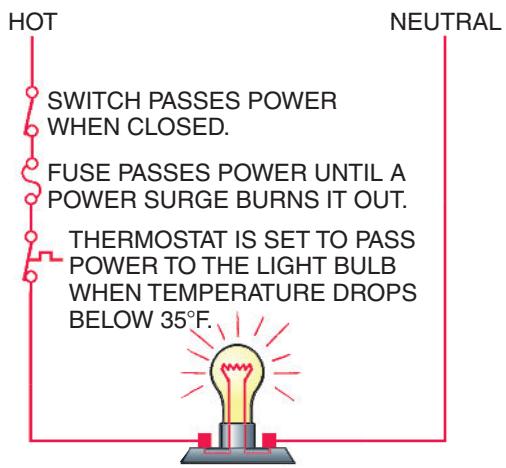


Figure 15.3 The troubleshooting procedure is to establish the main power supply of 115 V from the hot line to the neutral line. When this power supply is verified, the lead on the hot side is moved down the circuit toward the light bulb. The voltage is established at all points; when point 6 is reached, no voltage is present. The thermostat contacts are open.

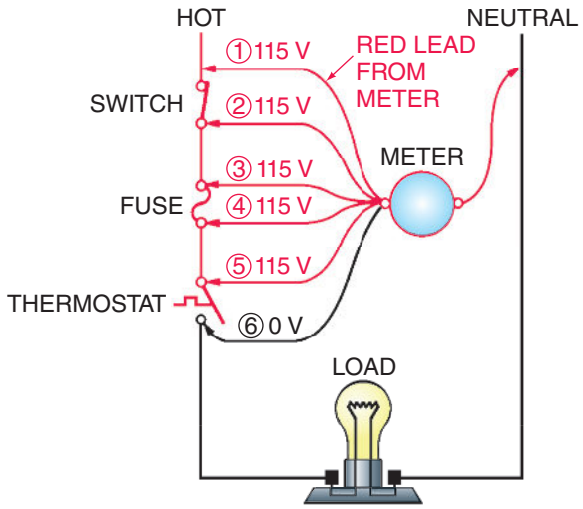

15.2 TROUBLESHOOTING A SIMPLE CIRCUIT

A voltmeter may be used to troubleshoot the circuit in the previous paragraph. Turn the voltmeter selector switch to a voltage setting higher than the voltage supply. In this case, the supply voltage should be 115 V, so the 250-V scale is a good choice. Follow the diagram in **Figure 15.3** as you read the following:

1. Place the red lead of the voltmeter on the hot line and the black lead on the neutral. The meter will read 115 V.
2. Place the red lead, the lead being used to find and detect power in the hot line, on the load side of the switch. (The "load" side of the switch is the side of the switch that the load is connected to. The other side of the switch, where the line is connected, is the "line" side of the switch.) The black lead should remain in contact with the neutral line. The meter will read 115 V.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

3. Place the red lead on the line side of the fuse. The meter will read 115 V.
4. Place the red lead on the load side of the fuse. The meter will read 115 V.
5. Place the red lead on the line side of the thermostat. The meter will read 115 V.
6. Place the red lead on the load side of the thermostat. The meter will read 0 V. There is no power available to energize the bulb. The thermostat contacts are open. Now ask the question, "Is the room cold enough to cause the thermostat contacts to make?" If the room temperature is below 35°F, the circuit should be closed; the contacts should be made.

NOTE: *The red lead was the only one moved. It is important to note that if the meter had read 115 V at the light bulb connection when the red lead was moved to this point, then further tests should have been made.* •

Another step is necessary to reach the final conclusion. Let us suppose that the thermostat is good and 115 V is indicated at point 6.

7. The red meter lead can now be moved to the terminal on the light bulb, **Figure 15.4**. Suppose it reads 115 V. Now, move the black lead to the light bulb terminal on the right. If there is no voltage, the neutral wire is open between the source and the bulb.

If there is voltage at the light bulb and it will not burn, the bulb is defective, **Figure 15.5**. *When there is a power supply and a path to flow through, current will flow.* The light bulb filament is measurable resistance and should be the path for the current to flow through.

The power supply used in the preceding example was 115 V with neutral as one side of the circuit. Neutral and earth ground are usually the same thing. With 115-V circuits, the technician need have only a ground source, such as a water pipe, for one side of the meter. When troubleshooting

Figure 15.4 The thermostat contacts are closed and 115 volts is the measurement when one lead is on the neutral and one lead is on the light bulb terminal (see position 7). When the black lead is moved to the light bulb at position 2, there is no voltage reading. The neutral line is open.

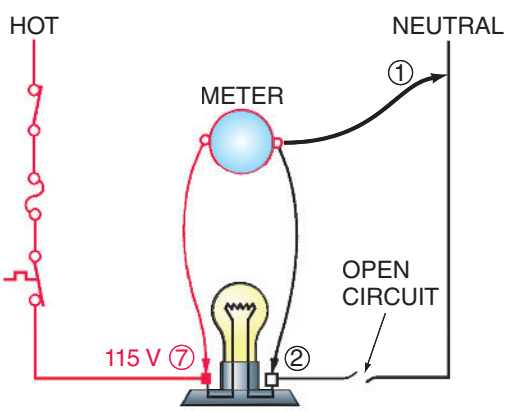

Figure 15.5 Power is available at the light bulb. The hot line on the left side and the neutral on the right side complete the circuit. The light bulb filament is burned out, so there is no current path through the bulb and no current flows through the circuit.

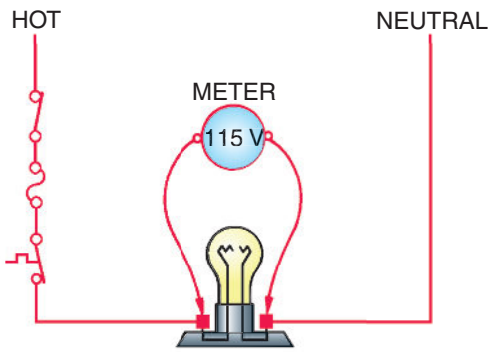

208-V or higher circuits, one meter lead must be placed on the other side of the line feeding the control circuit. This lead may be labeled line 1 and line 2, line 2 and line 3, or line 1 and line 3.

15.3 TROUBLESHOOTING A COMPLEX CIRCUIT

The following example is a progressive circuit that would be typical of a combination heating-cooling unit. Because each manufacturer may design its circuits differently, this circuit is not standard. However, although they may vary, they will be similar in nature.

The unit in this example is a package air conditioner with 1½ tons of cooling capacity and 5 kW of electric heat. It resembles a window air conditioner because all of the components are in the same cabinet. The unit can be installed through a wall or on a roof, and the supply and return air can be ducted to the conditioned space. The reason for using this unit as an example is that it comes in many sizes, from 1½ tons of cooling (18,000 Btu/h) to very large systems. The unit is popular with shopping centers because several roof units give a store good zone control. If one unit is not functioning, other units could help to hold the heating/cooling conditions steady. Also, all of the control components, except the room thermostat, are within the unit's cabinet. The thermostat is mounted in the conditioned space. The unit can be serviced without disturbing the conditioned space, **Figure 15.6**.

The first thing we will consider is the thermostat. The thermostat is not standard, but a version used for illustration purposes. It is a useable circuit that has been designed to illustrate troubleshooting. This thermostat is equipped with a selector switch for either HEAT or COOL. When the selector switch is in the HEAT position and heat is called for, the **electric heat relay** is energized. The fan must run in the

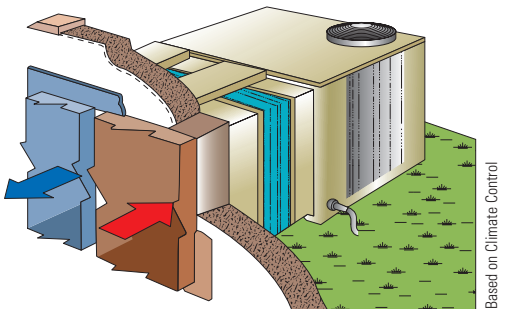
Figure 15.6 A small package air conditioner.



heating cycle and will be started and run in the high-voltage circuit. (This is discussed later in this unit.)

Figure 15.7 begins the control explanation and illustrates the simplest of thermostats, having only a set of heating contacts and a selector switch. Follow the power from the R terminal through the selector switch to the thermostat heat contacts and on to the W terminal. The W terminal destination is not universal but it is common. When the heat contacts are closed, we can say that the thermostat is calling for heat. The contacts pass power to the heat relay coil. Power for the other side of the heat relay coil comes directly from the control transformer. When this coil is energized (24 V), the heat should come on. The coil is going to close a set of contacts in the high-voltage circuit to pass power to the electric heat element.

It should be noted that the circuit in **Figure 15.7** has two switches and one load. The two switches are the manual heat switch and the other is the set of heat contacts. The manual heat switch is opened and closed by the operator of the equipment, hence the term *manual*. The other switch, the set of heat contacts, is an automatic switch that opens and closes its contacts depending on the temperature sensed by the

Figure 15.7 A simple thermostat with a HEAT OFF/HEAT ON position. The selector switch is closed, calling for heating. When the heat relay is energized, the heating system starts.

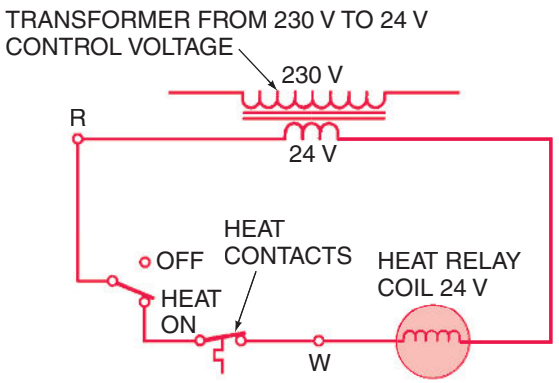


Figure 15.8 This is the same diagram as shown in Figure 15.7, but a heat anticipator has been added in series with the thermostat contacts. The selector switch is set for heat, and the thermostat contacts are closed, calling for heat.

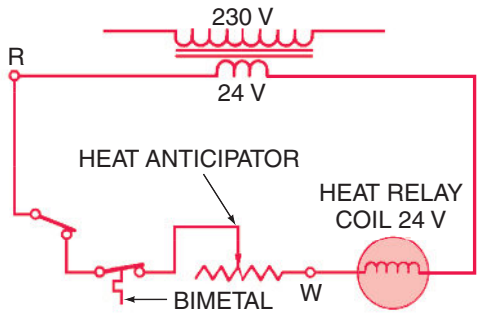

NOTE: THE HEAT ANTICIPATOR IS A VARIABLE RESISTANCE THAT IS DESIGNED TO CREATE A SMALL AMOUNT OF HEAT NEAR THE BIMETAL. THIS FOOLS THE THERMOSTAT INTO CUTTING OFF EARLY. THE FAN WILL CONTINUE TO RUN AND DISSIPATE THE HEAT REMAINING IN THE HEATERS.

contacts. In order for the heating system to be energized, both the manual switch and the automatic temperature-sensing switch must be in the closed position. If the occupied space is very cold but the manual heat switch is off, the heating system will not operate. Similarly, if the manual heat switch is on and the space is warm, the system will not operate. As with any circuit that has multiple switches connected in series with each other, all of the switches must be in the closed position in order to pass power to the load being controlled.

In **Figure 15.8** the heat anticipator is added to the circuit. The heat anticipator is in series with the heat relay coil and has current passing through it any time the heat relay coil is energized. The current passing through the anticipator creates a small amount of heat in the vicinity of the thermostat bimetal sensing element, which causes the bimetal to break the thermostat contacts early to dissipate the heat in the heat exchanger. This is done because the fan will blow hot air into the heated space for a short time after the heat relay is deenergized while cooling off the heat exchanger. If the contacts to the heater did not open until the space temperature was actually up to the cut-off point of the room thermostat, the extra heat would overheat the space; this is referred to as a system overshoot. The fan that moves the heat is stopped and started in the high-voltage circuit (discussed later in this unit).

Often the heat anticipator is a variable resistor and must be adjusted to the actual system. The current must be matched to the current used by the heat relay coil. All thermostat manufacturers explain this in the installation instructions for specific thermostats. Heat anticipators are covered in detail in Unit 14, "Automatic Control Components and Applications."

Figure 15.9 illustrates how a fan-starting circuit can be added to a thermostat. Notice the addition of the G terminal,

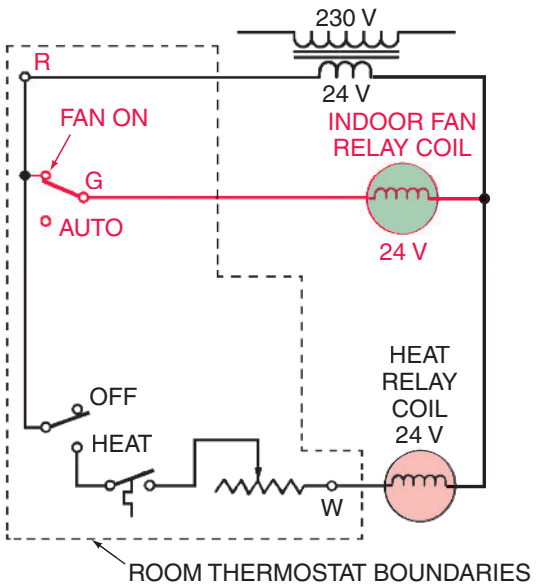
Figure 15.9 The addition of the fan relay to the thermostat allows the owner to switch the fan on for continuous operation. The fan must be operating during the heating cycle. (Automatic fan operation will be explained later in this unit.)



which is used to start the indoor fan. Although not universal, the G designation is common. Follow the power from the R terminal through the fan selector switch to the G terminal and on to the indoor fan relay coil. Power is supplied to the other side of the coil directly from the control transformer. When this coil has power (24 V), it closes a set of contacts in the high-voltage circuit and starts the indoor fan.

Figure 15.10 completes the circuitry in the thermostat by adding a Y terminal for cooling. Again, this is not the only letter used for cooling but it also is common. Follow the power from the R terminal down to the cool side of the selector switch through to the contacts and on to the Y terminal. When these contacts are closed, power will pass through them and go two ways:

- One path will be through the fan AUTO switch to the G terminal and on to start the indoor fan. The indoor fan has to run in the cooling cycle.
- The other path is straight to the cool relay. When the cool relay is energized (24 V), it closes a set of contacts in the high-voltage circuit to start the cooling cycle.

When the fan is switched to ON, the indoor fan will run all the time, even when the system switch is in the OFF position. This thermostat is equipped with a FAN ON or FAN AUTO position, so the fan can be switched on manually for air circulation when desired. When the fan switch is in the AUTO position, the fan will start on a call for cooling. When

Figure 15.10 (A) Cooling has been added to **Figure 15.9**. (B) The cooling circuit has a cooling anticipator in parallel with the cooling contacts. Current flows through the cooling anticipator during the OFF cycle. **NOTE:** *This is one of the few times that there are two loads connected in series with each other.*

the selector switch is in the cooling mode, the cooling system will start on a call for cooling. The indoor fan will start through the AUTO mode on the fan selector switch. The outdoor fan must run also, so it is wired in parallel with the compressor.

NOTE: *The cooling anticipator is in parallel with the cooling contacts. This means that current will flow through this anticipator when the thermostat is satisfied (or when the thermostat's circuit is open). The cool anticipator is normally fixed and nonadjustable. It causes the cooling cycle to start early, which enables the system to be up to capacity at the time the room warms to above the thermostat set point.* •

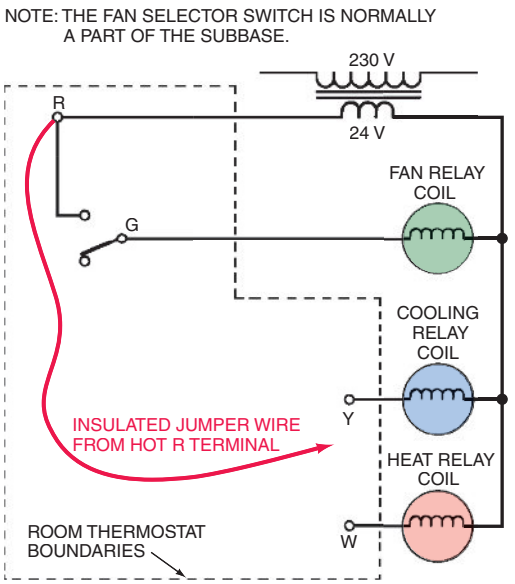
15.4 TROUBLESHOOTING THE THERMOSTAT

During equipment malfunction, the thermostat is often a misunderstood and frequently suspected component. But it does a straightforward job of monitoring temperature and distributing the power leg of the 24-V circuit to the correct components to control the temperature. Service technicians should remind themselves as they approach the job that "one power leg enters the thermostat and it distributes power where called." Every technician needs a technique for checking the thermostat for circuit problems.

It should be restated that the thermostat is nothing more than a set of switches. There is a manual selector switch that selects the mode of operation, which can be OFF, COOL, or HEAT, and the automatic temperature-sensing component. When the conditions are correct, the thermostat will pass power on through the device to the system components to be controlled. When the system is calling for heat, power will be passed to the heat relay. When the system is calling for cooling, power will be passed to the cooling relay and the indoor fan relay. If power enters the thermostat and does not pass through the device, either the thermostat is not calling for the desired mode of operation or there is a problem with the control.

One way to troubleshoot a thermostat on a heating and cooling system is to first turn the fan selector switch to the FAN ON position to see if the fan starts. If the fan does not start, the problem may be with the control voltage. Control voltage must be present for the thermostat to operate. Assume for a moment that the thermostat will cause the fan to come on when turned to FAN ON but will not operate the heat or cooling cycles. The next step may be to take the thermostat off the subbase and jump the circuit out manually with an *insulated jumper.* Jump from R to G, and the fan should start. Jump from R to W, and the heat should come on. Jump from R to Y, and the cooling should come on. If the circuit can be made to operate without the thermostat, the thermostat is defective, **Figure 15.11**. Jumping these circuits out one at a time is not a worry because only one leg of power comes

Figure 15.11 Terminal designation in a heat-cool thermostat subbase. The letters R, G, Y, and W are common designations. A jumper wire placed between R and G should start the indoor fan motor. A jumper wire placed between R and Y should start the cooling cycle. A jumper wire placed between R and W should start the heating cycle.



to the thermostat. Some more sophisticated thermostats may have a clock or indicator lights and may have the common side of the circuit wired to the thermostat, which means caution must be used. If all circuits were jumped out at one time in these thermostats, the heating and cooling would run at the same time. Of course, this should not be allowed to continue.

SAFETY PRECAUTION: *Jumping all circuits at once should be done only under the supervision of the instructor. Do not restart the air conditioner until 5 min have passed unless a hard-start kit is employed on the compressor. This allows the system pressures to equalize.* •

We have just covered what happens in the basic thermostat. The next step is to move into the high-voltage circuit and see how the thermostat's actions actually control the fan, cooling, and heating. We will again use the progressive circuit.

The first thing to remember is that the high voltage (230 V) is the input to the transformer. Without high voltage there is no low voltage. When the service disconnect is closed, the potential voltage between line 1 and line 2 is the power supply to the primary of the transformer. The primary input then induces power to the secondary winding of the transformer.

Figure 15.12 illustrates the high-voltage operation of the fan circuit. In the high-voltage circuit, the power-consuming device is the fan motor. The fan relay contact is in the line 1 circuit. It should be evident that the fan relay contacts have to be closed to pass power to the fan motor. These contacts close when the fan relay coil is energized

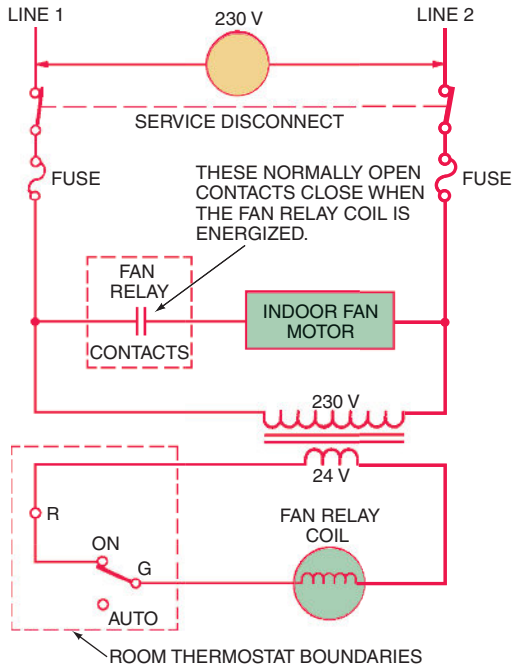
Figure 15.12 When the fan switch is turned to the ON position, a circuit is completed to the fan relay coil. When this coil is energized, it closes the fan relay contacts, passing power to the indoor fan motor.

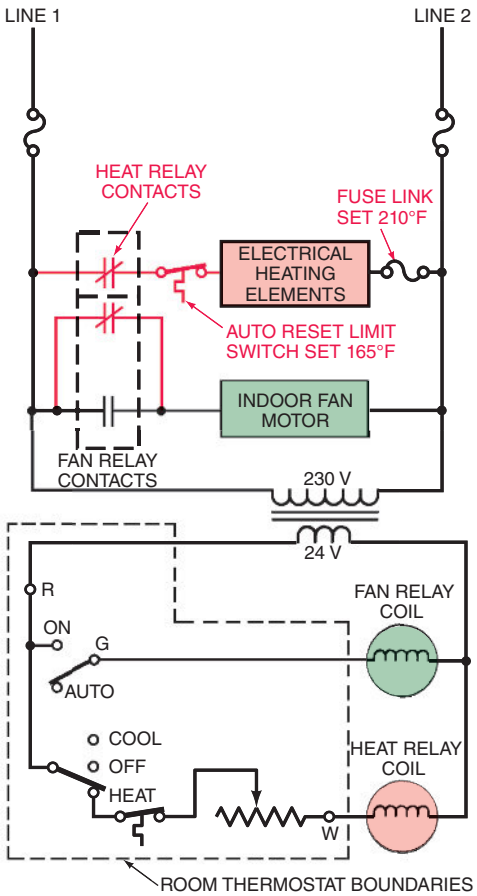


in the low-voltage control circuit. Although not drawn together, the fan relay coil in the low-voltage circuit causes the fan relay contacts in the line-voltage circuit to open and close. The magnetic field that is generated when current flows through the fan relay coil is the force that causes the relay contacts to close.

Figure 15.13 illustrates the addition of the electric heat element and the electric heat relay. The electric heat element and the fan motor are the power-consuming devices in the high-voltage circuit. When the HEAT-COOL selector switch is moved to the HEAT position in the low-voltage circuit, power is passed to the thermostat contacts. When there is a call for heat, these contacts close and pass power through the heat anticipator to the heat relay coil. This closes the two sets of contacts in the high-voltage circuit. One set starts the fan, and the other set passes power to the limit switch and then through the limit switch to the line 1 side of the heater. This limit switch (165°F) is the primary overheat safety control. The circuit is completed through the fuse link in line 2. The fuse link is the secondary overheat safety control (210°F).

In **Figure 15.14** cooling, or air-conditioning, has been added to the circuit. For this illustration the heating circuit was removed to reduce clutter and confusion. Three components have to operate in the cooling mode: the indoor fan, the compressor, and the outdoor fan. The compressor and the outdoor fan are wired in parallel and, for practical purposes, can be thought of as one component.

Figure 15.13 When the selector switch is in the HEAT position and the thermostat contacts close, the heat relay coil is energized. This action closes two sets of contacts in the heat relay. One set starts the fan because it is wired in parallel with the fan relay contacts. The other set passes power to the auto reset limit switch (set at 165°F). Power reaches the other side of the heater element through the fusible link. When power reaches both sides of the heating element, the heating system is functioning.



The line 2 side of the circuit goes directly to the three power-consuming components. Power for the line 1 side of the circuit comes through two different relays. The cooling relay contacts start the compressor and outdoor fan motor; the indoor fan relay starts the indoor fan motor. In both cases, the relays pass power to the components on a call from the thermostat.

When the thermostat selector switch is set to the COOL position, power is passed to the contacts in the thermostat. When these contacts are closed, power passes to the cooling relay coil. When the cooling relay coil is energized, the cooling relay contacts in the high-voltage circuit are closed. This passes power to the compressor and outdoor fan motor.

The indoor fan must run whenever there is a call for cooling. When power passes through the contacts in the thermostat, a circuit is made through the AUTO side of the selector switch to energize the indoor fan relay coil and start the

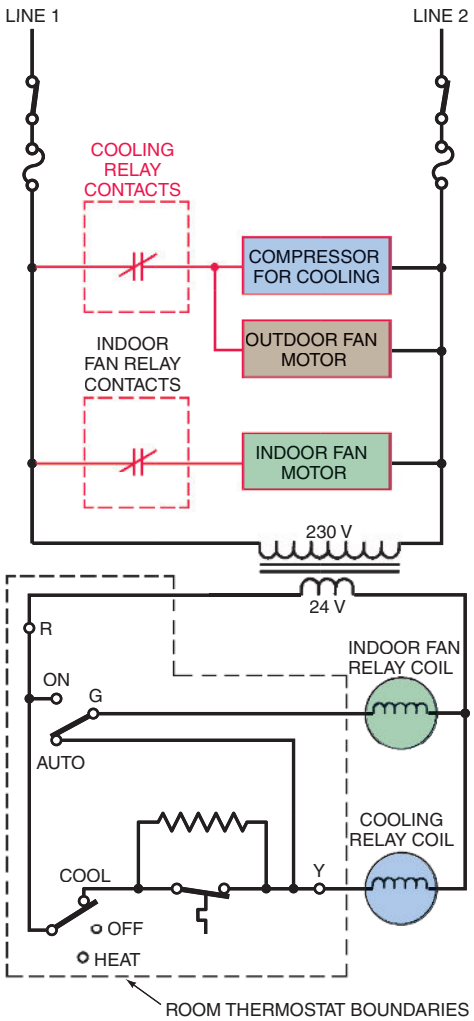
Figure 15.14 Addition of cooling to the system. When the thermostat selector switch is set to COOL and the thermal contacts close, the cooling relay coil is energized, closing the high-voltage contacts. These high-voltage contacts feed power to the compressor and condenser fan motor. Notice that the circuit in the thermostat starts the indoor fan motor through the AUTO position of the fan selector switch.



indoor fan. Note that if the fan selector switch is in the FAN ON position, the fan would run all the time and would still be on for cooling.

15.5 TROUBLESHOOTING AMPERAGE IN THE LOW-VOLTAGE CIRCUIT

Transformers are rated in **volt-amperes**, commonly called VA. This rating can be used to determine whether the transformer is underrated or drawing too much current. For example, it is quite common to use a 40-VA transformer for the low-voltage power source on combination cooling and heating equipment. This tells the technician that at 24 V, the maximum amperage the transformer can be expected to carry is 1.66 A. This is determined as follows:

$$\frac{40\,\text{VA}}{24\,\text{V}} = 1.66\,\text{A}$$

Older clamp-on ammeters will not readily measure such a low current with any degree of accuracy, so adjustments must be made to determine an accurate current reading. Using a jumper wire coiled 10 times (called a 10-wrap amperage multiplier), place the ammeter's jaws around the 10-wrap loop and place the jumper in series with the circuit, **Figure 15.15**. **The reading on the ammeter will have to be divided by 10.** For instance, if the cooling circuit coil amperage reads 7 A, it is really carrying only 0.7 A. Many digital clamp-on ammeters can read small amperages accurately and may not need a 10-wrap coil of wire around them. Refer to Unit 5, "Tools and Equipment," for an illustration of a modern digital clamp-on ammeter.

Some ammeters have attachments for readings in ohms and volts. The volt attachments can be helpful for voltage readings, but the ohm attachment should be checked to make sure that it will read in the range of ohms needed. Some of the

Figure 15.15 A clamp-on ammeter is used to measure the current draw in the 24-V control circuit.

ohmmeter attachments will not read very high resistance. For instance, they may show an open circuit on a high-voltage coil that has a considerable amount of resistance.

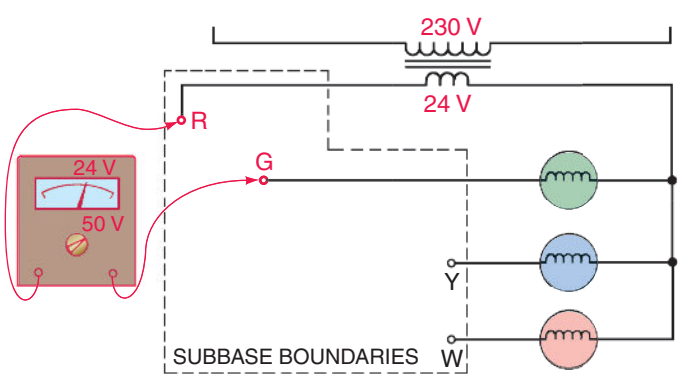
15.6 TROUBLESHOOTING VOLTAGE IN THE LOW-VOLTAGE CIRCUIT

The volt-ohm-milliammeter (VOM) has the capability of checking continuity, milliamps, and volts. The most common applications are checking voltage and continuity. The volt scale can be used to check for the presence of voltage, and the ohmmeter scale can be used to check for continuity. A high-quality meter will give accurate readings for each measurement.

Remember that any power-consuming device in the circuit must have the correct voltage applied to it in order to operate. The voltmeter, when set on the correct scale, can be applied to any power-consuming device for a voltage check by placing one probe on one side of the device and the other probe on the other side. When power is present at both points, the component should function. If not, a check of continuity through the device is the next step, using the ohmmeter. Again, keep in mind that when voltage is present and a path is provided, current will flow. If the flowing current does not cause the load to do its job, it is defective and will have to be changed.

The voltmeter cannot be used to much advantage at the actual thermostat because the thermostat is a closed device. When the thermostat is removed from the subbase, the method discussed earlier of jumping the thermostat terminals is usually more effective. With the thermostat removed from the subbase and the subbase terminals exposed, the voltmeter can be used in the following manner. Turn the voltmeter selector switch to the scale just higher than 24 V. Attach the voltmeter lead to the hot leg feeding the thermostat, **Figure 15.16**. This terminal is sometimes labeled R or V; there is no standard letter or number. When the other lead is placed on the other terminals one at a time, the circuits will be verified.

Figure 15.16 The VOM can be used at the thermostat location with the thermostat removed from the subbase.



For example, with one lead on the R terminal and one on the G terminal, the terminal normally used for the fan circuit, there will be a voltage reading of 24 V. The meter is reading one side of the line straight from the transformer and the other side of the line through the coil on the fan relay. In this case, the fan relay coil is not energized and simply acts as a coil of wire. It will now let the other line of the transformer feed through to the G terminal of the thermostat's subbase. This phenomenon is sometimes referred to as **voltage feedback**. The voltmeter now will be reading each side of the transformer, or 24 V. When the meter probe is moved to the circuit assigned to cooling (this terminal could be lettered Y), it reads 24 V. When the meter probe is moved to the circuit assigned to heating (sometimes the W terminal), 24 V again appears on the meter. The fact that the voltage reads through the coil in the respective circuits is evidence that a complete circuit is present.

15.7 TROUBLESHOOTING SWITCHES AND LOADS

Service technicians often encounter electrical problems when troubleshooting equipment. These problems are often nothing more than electrical switches that are either opened or closed. However, when power-consuming devices (electrical loads) are in series with these switches, matters can become complicated. Most of the time electrical switches are in series with one another and are relatively simple to troubleshoot electrically. The complications arise when these electrical switches are in parallel with one another.

Figure 15.17 shows a pressure switch in series with a motor (electrical load, or power-consuming device). In this case, the electrical load is a permanent split-capacitor (PSC) motor. The potential difference (voltage) between line 1 and line 2 is 230 V. This means that if the two leads of a voltmeter were placed between line 1 and line 2, it would read a voltage of 230 V. If a technician measured the voltage across the open switch, the voltmeter would also read a voltage of 230 V. This happens because line 1 ends at the left side of the open switch and line 2 simply bleeds through the run winding of the motor, through the closed overload, and ends at the right side of the switch. Since the motor is not running or consuming power, the windings are nothing but conductive wire for line 2 to bleed through. If a technician were to measure the voltage across the run winding (between R and C) of the PSC motor in **Figure 15.17**, the voltage would be 0 V because the motor winding is simply passing line 2 when it is not running. Line 2 would be at both the R and C terminals of the motor, and the potential difference or voltage difference between line 2 and line 2 is 0 V. However, if the technician references

Figure 15.17 Voltage readings for a switch in series with a motor.

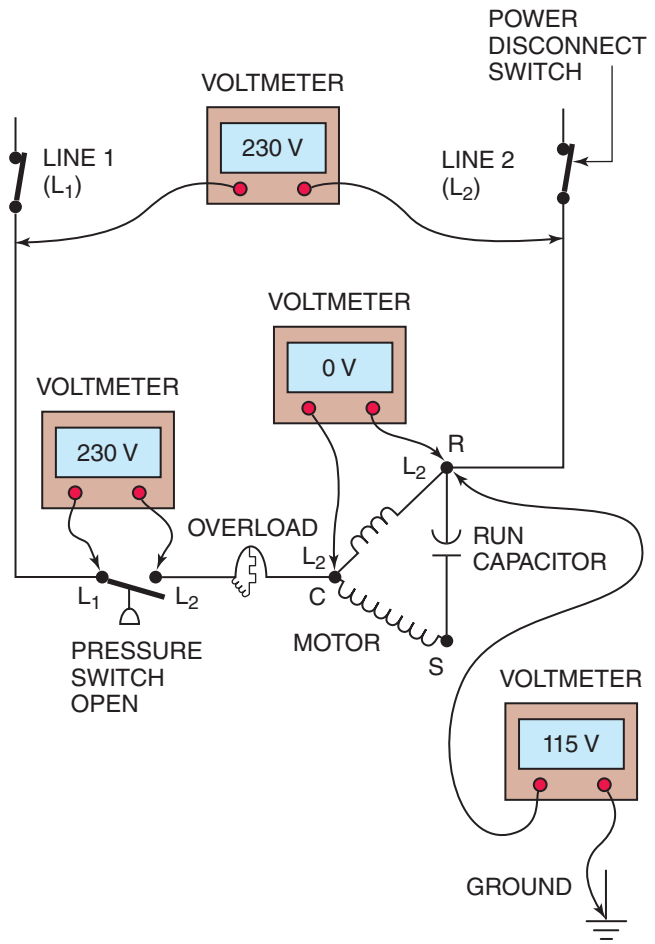

Figure 15.18 Voltage readings for a closed switch in series with an operating motor.

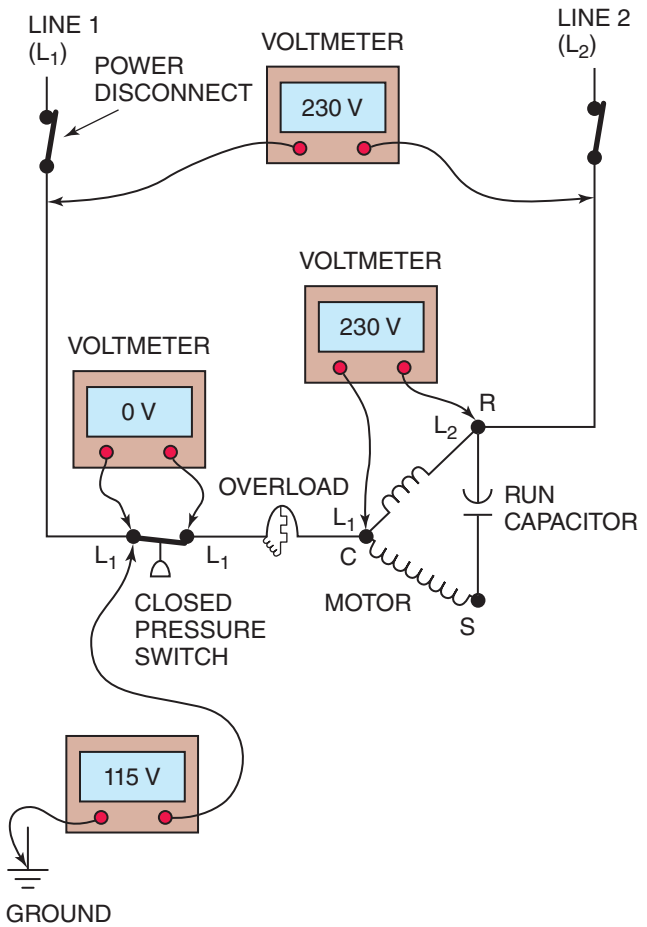

either the R or C terminal to ground, the voltage would be 115 V because line 2 relative to ground is 115 V.

In **Figure 15.18** the pressure switch is closed and the motor is running. The motor is now consuming power and would read 230 V across its run winding (terminals R and C) while it is running. A voltage measurement across the closed switch will read 0 V. This is because line 1 ends at the C terminal of the motor when it is running. The switch experiences line 1 at both its terminals, and the potential difference or voltage difference between line 1 and line 1 is 0 V. If a technician measures from one terminal of the switch to ground, the voltage reading will be 115 V. In **Figure 15.17** the voltmeter across the open switch reads 230 V, whereas in **Figure 15.18** the voltmeter across the closed switch reads 0 V. It is incorrect to conclude that open switches always read some voltage and closed switches always read zero voltage. The parallel switches in **Figure 15.19** will clarify this concept.

When the switches are in parallel, the technician faces a greater challenge. **Figure 15.19** shows two switches that are in parallel but at the same time in series with a motor

Figure 15.19 Voltage readings for two switches wired in parallel with each other. These switches are both wired in series with the operating motor.

(power-consuming device). The top switch is closed, but the bottom switch is open. A voltmeter across terminals A and B of the top switch will read 0 V because it is measuring a potential difference between line 1 and line 1. Since the motor is running, it has 230 V applied across the run winding (C and R terminals) of the PSC motor. However, a voltmeter across terminals C and D of the bottom switch will also read 0 V. This happens because line 1 actually extends to the common terminal of the motor when it is running. This would make terminals C and D of the bottom switch both line 1, and the voltage difference between line 1 and line 1 is 0 V. Actually, points A, B, C, and D are all line 1. This example is a scenario where both an open switch and a closed switch read 0 V. *When doing electrical troubleshooting with a voltmeter, technicians must ask themselves where line 1 and line 2 are, not whether the switch is open or closed.* Measuring across the same line with a voltmeter, whether it be line 1 or line 2, will always give 0 V. Measuring from line 1 to line 2 will always give the total circuit voltage, which in these examples was 230 V.

There will be times when a technician must switch to an ohmmeter and shut the electrical power off in order to solve the problem. In **Figure 15.20**, what would be the voltage between R and C if the run winding between R and C opened, causing the motor to stall and draw locked-rotor amperage (LRA)? This is, of course, before the overload has opened. Notice that a voltmeter placed across the R and C terminals of the motor (the opened winding) will again read 230 V. No matter if the motor is running properly or if it has an opened run winding, the voltage will still read 230 V across R and C. So, how does the service technician determine whether the run winding is opened or not? The answer is, with an ohmmeter. The service technician must shut the electrical power down and disconnect one wire from the R or C terminal of the motor, **Figure 15.21**. Disconnecting a wire will prevent electrical feedback from the ohmmeter's internal voltage source (battery) through another parallel electrical circuit. The technician must then place an ohmmeter across the R and C terminals of the motor. The measurement will read infinite ohms (∞) if the winding is open. This is the only way the service technician can tell whether the winding is opened or not.

Figure 15.20 A voltmeter reading 230 V across the run winding of a motor even when the run winding is open.

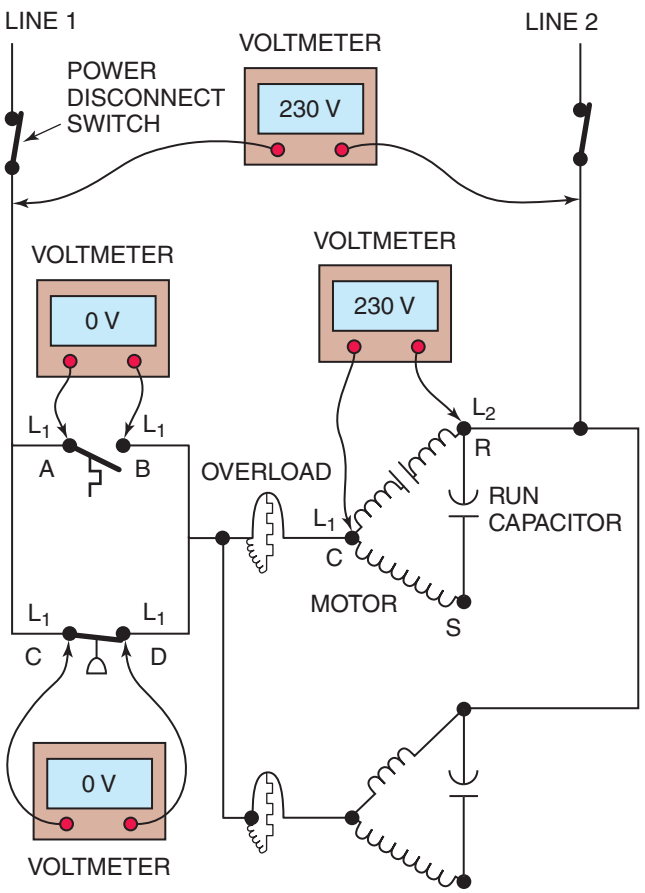

Figure 15.21 An ohmmeter reading of infinity (∞) across an open motor run winding. Notice that the wires have been disconnected from the R terminal.

Notice in **Figure 15.21** that the only potential current path exists between terminal C and terminal R. Even the run capacitor has been disconnected. In the event that the run capacitor had a short in it, the ohmmeter would read the resistance in the path through the run capacitor and the start winding, instead of the infinite resistance of the open path between terminals C and R. **Figure 15.22** shows a feedback circuit from the ohmmeter's battery if a wire is not disconnected from the motor terminals. In this case, the ohmmeter reading would be 3 ohms. This resistance comes from the resistance of the run winding in the feedback circuit of the PSC motor in parallel with it. This would fool the technician into thinking the winding was still good and not opened.

Figure 15.23 is a 230-V, single-phase electrical schematic of a typical commercial refrigeration system. The diagram includes a timer assembly with a defrost termination solenoid (DTS), evaporator fans, defrost heaters, a temperature-activated defrost termination/fan delay (DTFD) switch, a low-pressure control (LPC), a high-pressure control (HPC), a compressor contactor assembly, and a compressor/potential relay assembly. Although this diagram may look a little complicated, it is actually multiple series circuits connected to a single power supply. We will now examine each of these branch circuits individually. The system is drawn in the refrigeration mode and shows where line 1 (L_1) is in relation to line 2 (L_2) for ease of understanding the measured voltages.

The first load we will look at in this circuit is the timer motor. It can be seen from **Figure 15.24** that the timer motor is connected directly to the 230-V power supply. As long as the power to the system is on, there should be a reading of

Figure 15.22 A feedback circuit from the ohmmeter's battery when a wire is not disconnected from the motor being tested. The ohmmeter will now measure the 3 ohms of the run winding of the PSC motor that is wired in parallel with the motor being tested.

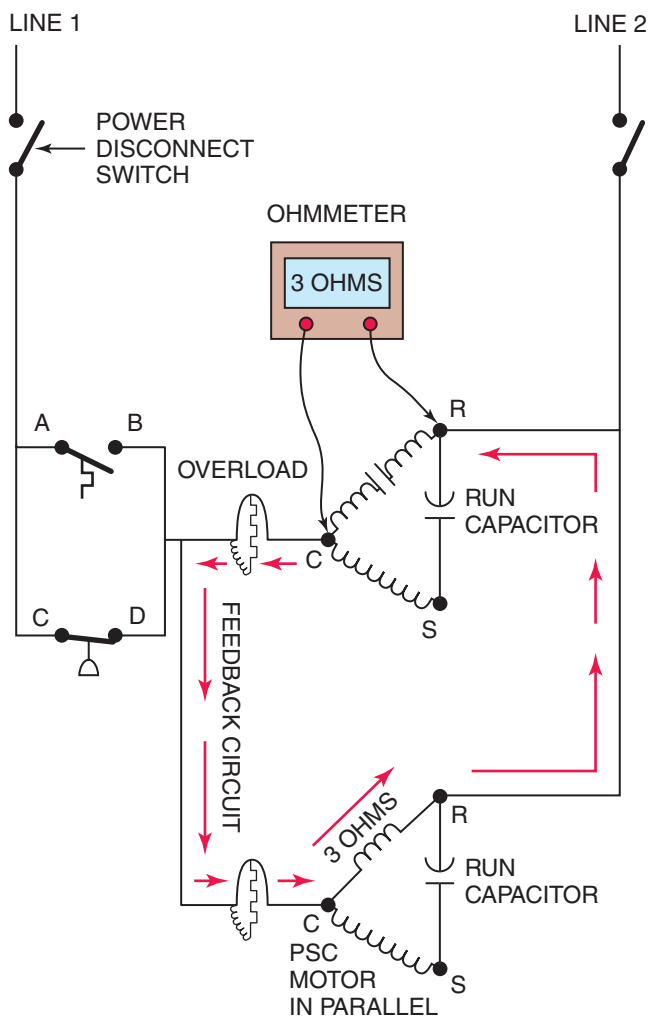

Figure 15.23 A 230-V electrical schematic of a typical refrigeration circuit showing relative positions of line 1 (L_1) and line 2 (L_2).

Figure 15.24 The timer motor circuit.

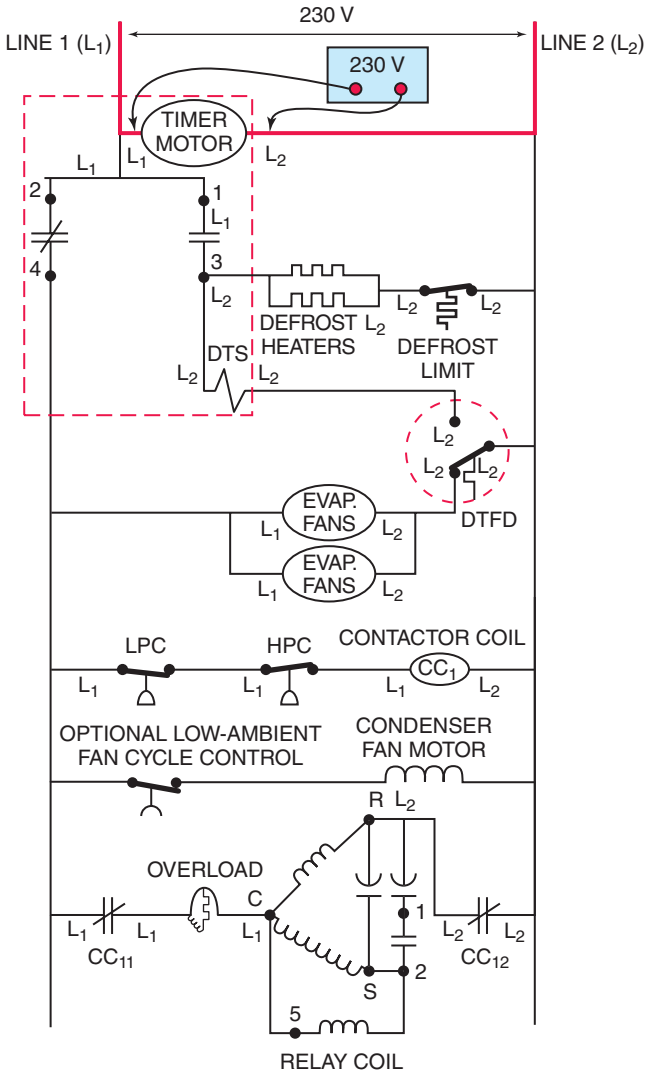

Figure 15.25 The defrost heater circuit.

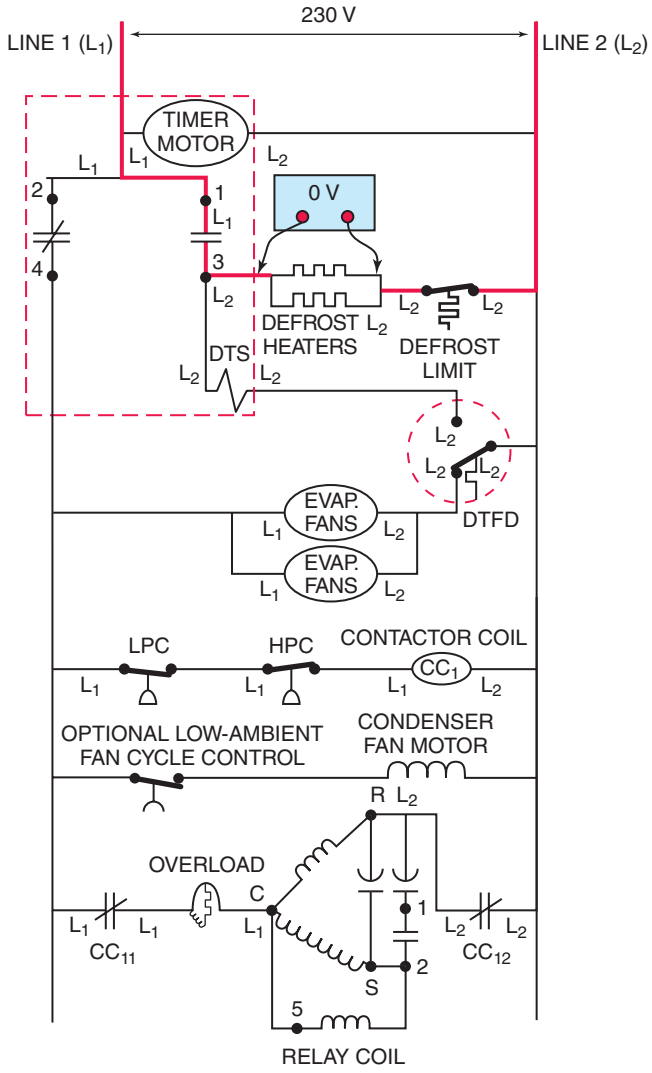

230 V across the timer motor. If the power is on and 230 V are not being supplied to the timer motor, there is a problem with the wiring that is connecting the power supply to the timer motor. If 230 V are being supplied to the timer motor—and the motor is not operating—there is a problem with the timer motor.

The next circuit we will examine is the defrost heater circuit, **Figure 15.25**. By starting at L_1 and tracing a path through the defrost heaters and back to L_2, we can see that there are a number of switches in series with the heaters. The first switch is the set of contacts that is located between contact points 1 and 3 on the timer, which is the component that is outlined with the dashed line. When the system is operating in the refrigeration mode, the heater contacts are in the open position, as we do not want them to be energized when the system is providing refrigeration. When the system goes into defrost, these contacts will close and the heaters will become energized as long as the second switch in the circuit and all interconnecting wiring is correct. The second switch in the circuit is the defrost limit switch. This is a safety device and will remain closed as long as the temperature it senses is below the safe operational limit. If the temperature rises too high, the limit switch will open and the heaters will be turned off. A reading of 230 V across the heaters indicates that the heaters are being powered. An amperage reading must then be taken to ensure that the heaters are indeed energized. If the heaters are being powered but the amperage draw of the heaters is 0 A, there is a problem with the heaters. A positive amperage reading in the heater circuit indicates that the heaters are energized.

The next circuit controls the operation of the defrost termination solenoid (DTS), **Figure 15.26**. Just as with the

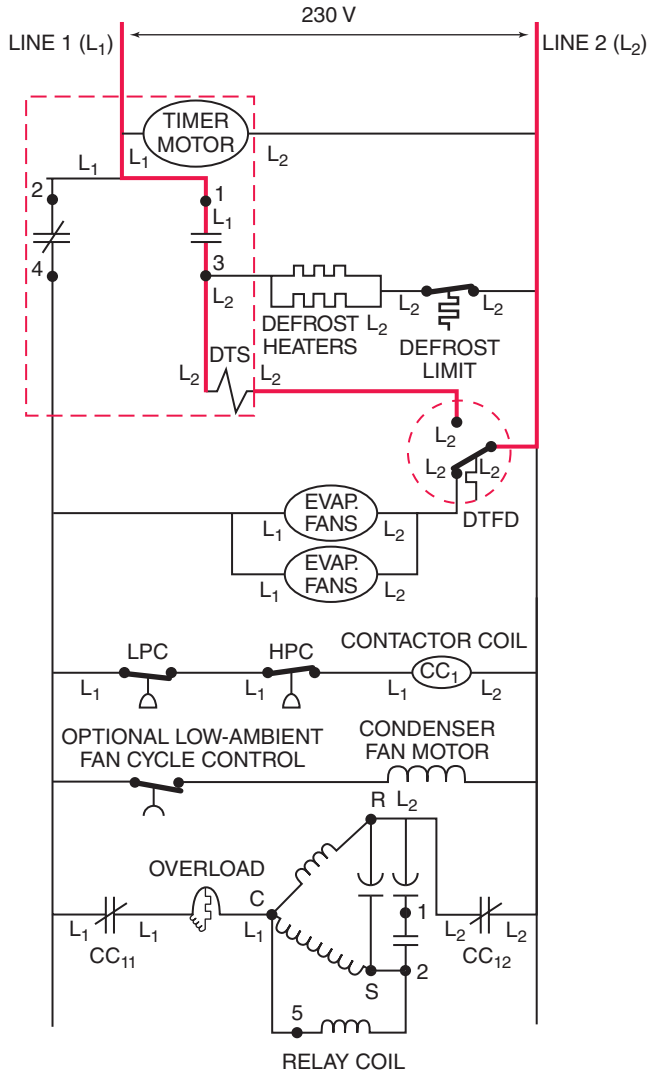
Figure 15.26 The defrost termination solenoid circuit.



defrost heaters, the defrost solenoid is controlled by a set of time-controlled contacts as well as a set of temperature-controlled contacts. It just so happens that the set of time-controlled contacts is the same set used to control the defrost heaters: the contacts between terminals 1 and 3 on the defrost timer. The temperature-controlled switch has a set of normally open and a set of normally closed contacts. The normally open set of contacts are sometimes referred to as the "HOT" contacts, and the normally closed set of contacts are often referred to as the "COLD" contacts. The temperature-controlled switch performs two functions:

- It takes the system out of defrost if all of the evaporator frost has been removed.
- It controls the evaporator fan motors so they can only operate when the evaporator is cold enough to provide refrigeration. This helps prevent an overload on the compressor's motor after defrost from high suction pressure due to a very warm evaporator.

In order for the defrost termination solenoid to be energized, the system must be in defrost and the temperature sensed by the defrost termination thermostat must be warm enough. When the DTS is energized, the closed contacts on the timer will open and the open contacts will close, putting the system back into the refrigeration mode.

The defrost termination solenoid is also often referred to as a "Z-coil." Taking amperage readings in the Z-coil circuit is difficult, as the coil is never energized for more than a fraction of a second. Here's why (let's say the system is in defrost):

- The set of contacts between terminal 1 and 3 is closed.
- There is frost on the evaporator coil, so the defrost termination/fan delay switch (DTFD) is in the position shown in **Figure 15.26**.
- So the Z-coil circuit is not energized.
- When the frost is melted, the DTFD changes its position and energizes the DTS.
- The instant the DTS is energized, it opens the closed contacts on the defrost timer and closes the open contact.
- This opens the very contacts that are energizing the DTS in the first place.

For this reason, it is possible to take voltage readings, but amperage readings will not prove to be very useful for troubleshooting purposes.

We will now take a look at the evaporator fan circuit, **Figure 15.27**. There are two control devices that cycle the evaporator fans on and off. One is a set of contacts on the defrost timer that is located between terminals 2 and 4 on the timer. These contacts are in the closed position when the system is in the refrigeration mode. The other control device is the defrost termination/fan delay switch. When the evaporator is cold enough for refrigeration, the DTFD will close the contacts in series with the evaporator fan motors. If there is no voltage being supplied to the evaporator fan motors, the technician should check for voltage across the timer contacts 2 and 4 as well as for voltage across the DTFD. A reading of line voltage across contacts 2 and 4 indicates that the system is not in the refrigeration mode, while a line-voltage reading across the DTFD is an indication that the evaporator coil temperature is too high for refrigeration.

The next part of the wiring diagram is the circuit that energizes and deenergizes the compressor contactor coil, **Figure 15.28**. In this circuit, the contactor coil is the load and there are three switches that are wired in series with this coil. The three power-passing devices are

- the set of defrost timer contacts between terminals 2 and 4;
- the low-pressure control; and
- the high-pressure control.

Figure 15.27 The evaporator fan motor circuit.

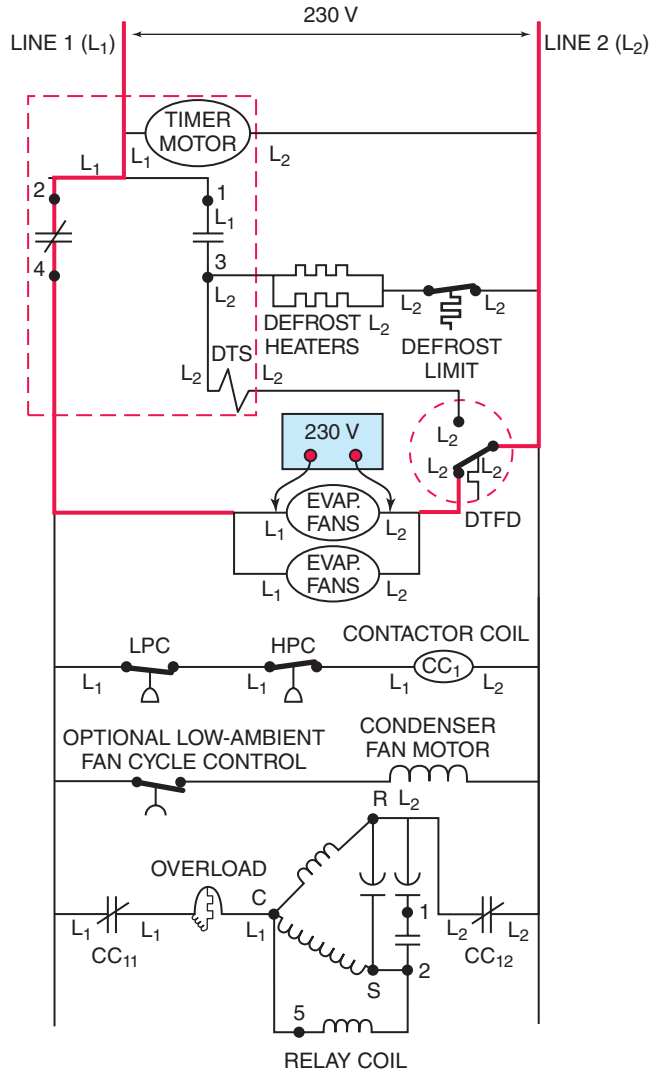

Figure 15.28 The contactor coil circuit.

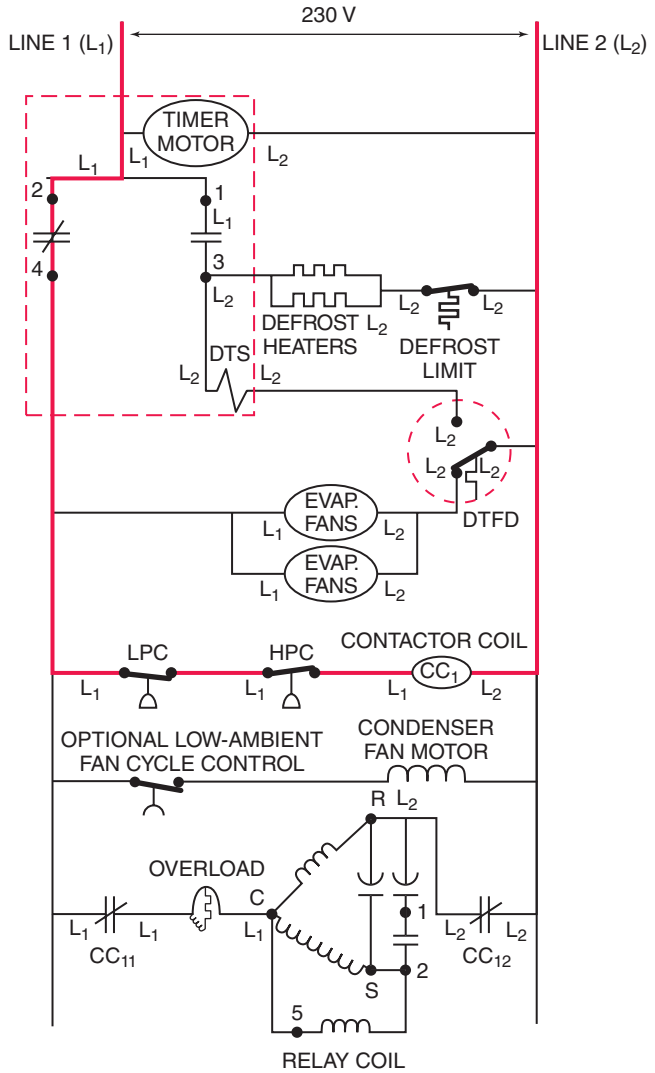

So, in order for the contactor coil to be energized, the system's defrost timer must be calling for refrigeration and the system pressures must be within the safe or desired operating range. If the system pressure is too low, the low-pressure control will open and deenergize the coil. If the high-side pressure is too high, the high-pressure switch will open and deenergize the coil, as well. If there is line voltage being supplied to the contactor coil, the voltage readings across each of the three switches in the circuit will be 0 V. A reading of 0 V across the contactor coil most likely indicates that one of the three switches is in the open position. For example, a 230-V reading across contacts 2 and 4 on the defrost timer indicates that the contacts are open and that the defrost timer is not calling for refrigeration.

The last circuit in this diagram is the compressor circuit, **Figure 15.29**. Once again, the load is wired in series with a number of switches. In this case, there are four sets of contacts that must be closed in order for the compressor to operate. The four switches are

- The set of defrost timer contacts between terminals 2 and 4
- The contactor contacts CC_{11}
- The contactor contacts CC_{12}
- The compressor overload.

We already know that in order for contacts 2 and 4 to be closed, the system has to be calling for refrigeration. The two sets of contactor contacts, CC_{11} and CC_{12}, are controlled by the contactor coil in the circuit branch we just discussed, **Figure 15.28**. The magnetic field generated by the contactor coil will cause these contacts to close. The last switch is the overload, which is a safety device. This device will open if there is excessive current flow in that circuit branch or if the compressor overheats. A voltage reading of 230 V across the overload indicates that there is an overcurrent,

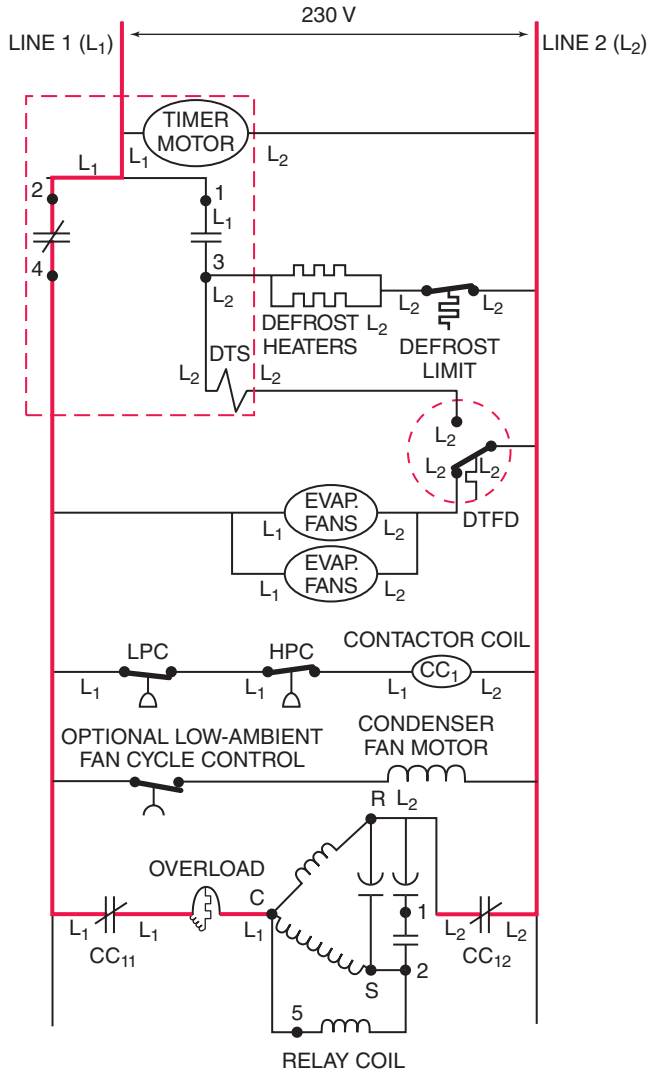
Figure 15.29 The compressor circuit.



overload, or overheating condition. The cause for this condition must be identified and corrected to put the system back into operation.

15.8 PICTORIAL AND LADDER DIAGRAMS

The previous examples were all about troubleshooting the basic circuit, which is recommended to start with. The control circuits that use circuit boards work much the same way. The same rules apply but with more emphasis on manufacturers' directions. The service technician must have a good mental picture of the circuit or a good diagram to work from. Two distinct types of diagrams are furnished with equipment: the **pictorial wiring diagram** and the **ladder wiring diagram**. Equipment may come with one or both diagrams.

The pictorial diagram is used to locate the different components in the circuit, **Figure 15.30**. **Figure 15.30(A)** is a pictorial diagram of an integrated furnace control (IFC) board for a two-stage gas furnace. It contains connections for an electronic air cleaner (EAC), a humidifier (HUM), line 1 and neutral, fan connections for heating and cooling, secondary connections for the 24-V transformer, a 12-pin connector plug, a low-voltage thermostat terminal board, flame and power status lights, and an ignition transformer. Also built into the board through the 12-pin connector is a flame sensor, limit, rollout, overtemperature switches, high- and low-pressure controls, and a heat-assisted limit control. A blower door switch is connected to the integrated furnace control through a 2-pin connector. The induced draft motor is connected to the board through a 3-pin connector. This diagram is organized just as the technician would see it with the panel door open. For example, if the flame and power status lights are in the upper left-hand corner of the diagram, they will be in the upper left-hand corner of the control board when the door is opened. This is useful when you do not know what a particular component looks like. Study the pictorial diagram in **Figure 15.30(A)** until you find a control and then locate it in the actual integrated furnace control board in **Figure 15.30(B)**. Notice that the pictorial diagram also gives wire colors to further verify the components.

The ladder diagram is the easier diagram to use for following the logic behind the circuit, **Figure 15.31**. Normally, the diagram need only be studied briefly to determine the circuit functions. Notice that the power-consuming devices are to the right of the diagram. Switches and controls are usually to the left in a ladder diagram. Most of the time, a technician must know what the sequence of events is for the IFC in order to follow the logic when the furnace is called on to ignite. A technical manual from the manufacturer will sometimes outline the sequence of events, which will assist the technician in troubleshooting. The manuals often come with the furnace, or the homeowner may have one from the day of purchase. If the technician does not have such a manual, an Internet search or phone call to the furnace manufacturer may be needed before going any further in troubleshooting. Often, one of the diagrams on the inside of the front cover of the furnace will assist the service technician in figuring out the sequence of events for the furnace.

Pictorial and ladder diagrams are examples of the way most manufacturers illustrate the wiring in their equipment, but each has its own way of illustrating points of interest. The only standard the industry seems to have established is the symbols used to mark the various components, but even these tend to vary from one manufacturer to another. Anyone studying electrical circuits could benefit by first using a colored pencil for each circuit. A skilled person can divide every diagram into circuits. The colored pencil will allow an unskilled person to make a start in dividing the circuits into segments.

The following service calls are examples of actual service situations. The problem and solution are stated at the beginning of the first three service calls so that you will have a

better understanding of the troubleshooting procedures. The last four service calls describe the troubleshooting procedures up to a point. Solutions for these service calls are not provided here. Please use your critical thinking abilities or class discussion to determine the solutions and discuss further with your instructor.

15.9 SERVICE TECHNICIAN CALLS

SERVICE CALL 1

A customer with a package air conditioner calls and tells the dispatcher that the unit is not cooling. *The problem is that the control transformer has an open circuit in the primary,* **Figure 15.32.**

Before approaching the house, the technician makes sure there is no dirt or grease on himself from the previous job. He quickly wipes his shoes clean with a rag kept in the service truck for this purpose. After ringing the doorbell, the technician maintains a distance from the door that is comfortable for the customer, politely introduces himself and his company, and maintains eye contact with the customer. The technician allows the customer to finish talking before replying. After asking permission to enter the living room where the thermostat is located, the technician puts on shoe covers to protect the customer's floors.

The technician turns the indoor fan switch on the indoor thermostat to the FAN ON position. The fan will not start, which possibly indicates there is no control voltage. There must be high voltage before there is low voltage. The technician then goes to the outdoor unit and, with the meter range selector switch set on 250 V, checks for high voltage. There is power.

The technician removes the cover from the control compartment (usually this compartment can be located easily because the low-voltage wires enter close by). A check for high voltage at the primary of the transformer shows that there is power. A check for power at the secondary of the low-voltage transformer indicates no power. The transformer must be defective.

To prove this, the main power supply is turned off. One lead of the low-voltage transformer is removed and the ohmmeter feature of the VOM is used to check the transformer for continuity. *Here the technician finds the primary circuit is open*. A new transformer must be installed.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 15.32 The control transformer has an open circuit.

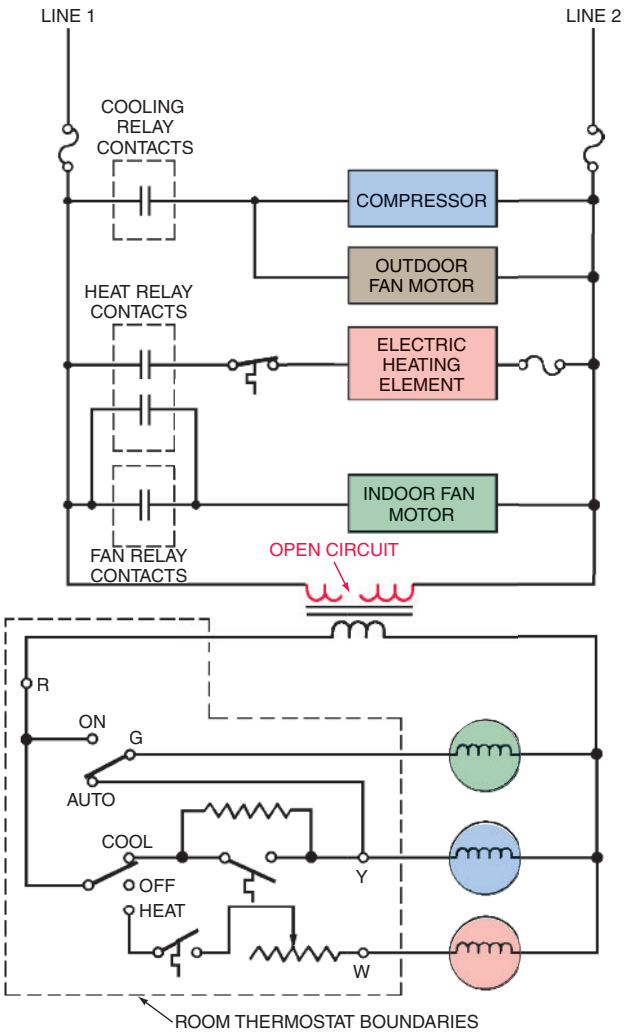

Figure 15.33 The cooling relay has an open circuit and will not close the cooling relay contacts. Notice that the indoor fan motor remains operational.

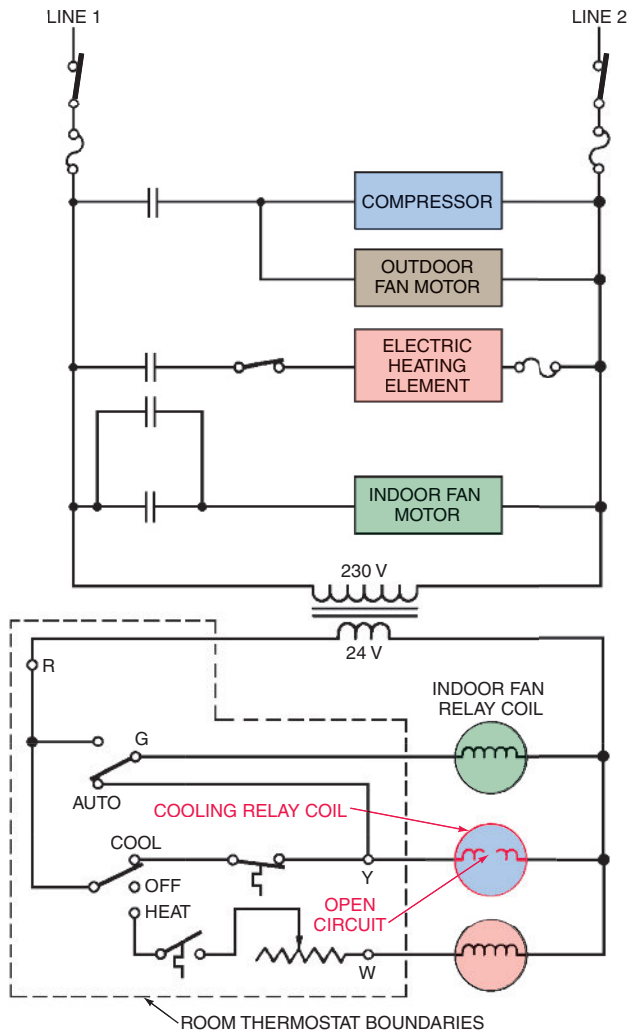


The technician installs the new transformer and turns the power on. The system starts and runs correctly. After double-checking his work, the technician cleans the work site and explains to the customer how the problem was found. The technician now gives the customer billing information with a work description and costs. The technician then lets the customer know that he is a valued customer and leaves after shaking hands.

SERVICE CALL 2

A customer calls with a "no cooling" complaint. *The problem is that the cooling relay coil is open,* **Figure 15.33**.

As the technician arrives at the customer's house, he makes sure he is not blocking the driveway with the service van; reviews the customer's name and complaint; makes sure his uniform is neat, clean, and tucked in; wipes down his shoes with a clean rag; then rings the doorbell and maintains a comfortable distance while introducing himself. The service technician politely listens to the customer, and once the problem is understood, covers his shoes with shoe covers to protect the paying customer's floors. The technician now heads over to the thermostat and tries the fan circuit. The fan switch is moved to FAN ON and the indoor fan starts. Then the thermostat is switched to the COOL position and the fan runs. This means that the power is passing through the thermostat, so the problem is probably not there. The thermostat is left in position to call for cooling while the technician goes to the outdoor unit. Since the primary for the low-voltage transformer comes from the high voltage, the power supply is established.

A look at the diagram shows the technician that the only requirement for the cooling relay to close its contacts is that its coil be energized. A check for 24 V at the cooling relay coil shows 24 V. The coil must be defective. To be sure, the

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

technician turns off the power, removes one of the leads on the coil, and uses the ohmmeter to check the coil. There is no continuity. It is open.

The technician replaces the whole contactor (it is less expensive to change the contactor from stock on the truck than to go to a supply house and get a coil), turns the power on, and starts the unit. It runs correctly. After cleaning up the work site, the technician clearly explains what the problem was and what work needed to be done. The technician then politely shows the customer the proper way to operate the system and gives the customer billing information, which includes work descriptions and costs. After letting the customer know that the service company values the business, the service technician thanks the customer and leaves the house.

SERVICE CALL 3

A customer complains of no heat. *The problem is the heat relay has a shorted coil that has overloaded the transformer and burned it out,* **Figure 15.34**.

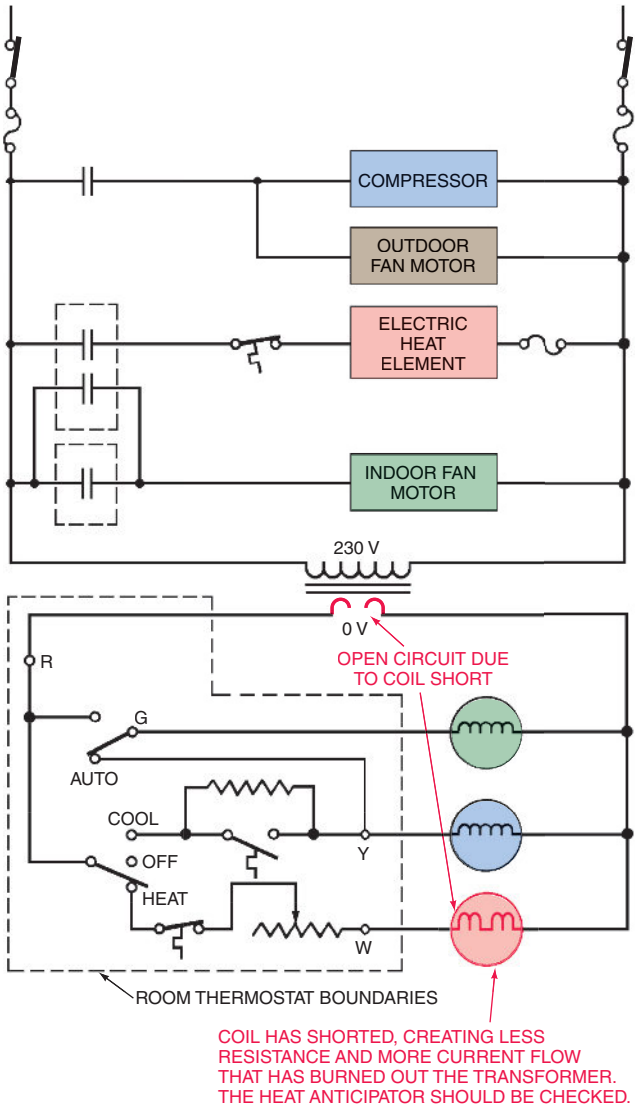
The service technician notices that his service van needs to be ran through an automatic car wash before going on this service call. Once the van is washed, the technician changes into a spare uniform set that is kept in the service van. After making sure his face is clean and his hair combed, the service technician proceeds to the call. Once invited into the house by the customer, the technician politely listens to the customer explain the symptoms of the problem. The technician remembers never to interrupt customers while they are talking. Once the customer is done, the service technician explains a technical topic using everyday language the customer can understand. The technician remembers not to make the customer feel inept about any technical topic being explained. After putting on protective shoe covers, the technician asks the customer's permission to enter the living room, where he tries to turn on the indoor fan at the thermostat. It will not run. There is obviously no current flow to the fan. This could be a problem in either the high- or low-voltage circuits.

The technician goes to the outdoor unit to check for high voltage and finds there is power. A check for low voltage shows there is none. The transformer must be defective. It has a burnt smell when it is removed. It is checked with the VOM and found to have an open secondary.

When the transformer is changed and the system is switched to HEAT, the system does not come on. The technician notices the transformer is getting hot. It appears to be overloaded. The technician turns off the power before a second transformer is damaged. The problem is to find out which circuit is overloading. Since the system was in the heating mode, the technician assumes for the moment it is the heat relay. The technician realizes that if too much current is allowed to pass through the heat anticipator in the room thermostat, it will burn also and a thermostat will have to be replaced.

The technician turns off the room thermostat to take it out of the circuit and then goes to the outdoor unit where the low-voltage terminal block is located. An ammeter is applied to the transformer circuit leaving the transformer. A 10-wrap coil of wire is installed to amplify the current reading. The power is turned on; no amperage is recorded. The problem must not be a short in the wiring.

Figure 15.34 A shorted heat relay causes the transformer to burn out.



The technician then jumps from R to W to call for heat. The amperage goes to 25 A, which is divided by 10 because of the 10 wrap. The real amperage is 2.5 A in the circuit. This is a 40-VA transformer with a rated amperage of 1.67 A (40/24 = 1.666). The heat relay is pulling enough current to overheat the transformer and burn it up in a short period of time. It is lucky that the room thermostat heat anticipator was not burned also.

The technician changes the heat relay and tries the circuit again; the average is only 5 A, divided by 10, or 0.5 A. This is correct for the circuit. The jumper is removed, and

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

the panels are put back in place. The system is started with the room thermostat and it operates normally. Once the work is double-checked, the technician cleans the job site. He explains the problem and solution to the customer in everyday language and gives a written work description and billing information to the customer and explains them politely. The service technician then thanks the customer and leaves the house.

Solutions for the following service calls are not provided here. Please discuss the solutions with your instructor.

SERVICE CALL 4

A customer calls and indicates that the air conditioner quit running after the cable TV repairman had been under the house installing TV cable.

When the technician enters the house it is obvious that the air conditioner is not running. The technician can hear the fan running, but it is hot inside. A check outside shows that the condensing unit is not running. The technician then proceeds through the following checklist. Use the diagram in **Figure 15.35** to follow the checkout procedure.

1. Low voltage is checked at the condenser; there is none.
2. The technician then goes to the room thermostat, removes it from the subbase, and jumps from R to Y; the condensing unit does not start.
3. Leaving the jumper in place, the technician then goes to the condenser, checks voltage at the contactor, and finds no voltage.

What is the problem and the recommended solution?

SERVICE CALL 5

A shoe store manager calls to report that the heat is off. This store has an electric heat package unit on the roof.

The service technician politely introduces himself and his company to the customer. While maintaining eye contact with the customer, the technician asks for the customer's account of the problem. The service technician should always make customers feel like they are helping to find the solution to the problem. Once all of the customer's questions are answered in everyday language the customer can understand, the technician puts on protective shoe covers and starts to troubleshoot. The technician uses the following checkout procedures to determine the problem. You can follow the procedure using the diagram in **Figure 15.36**.

1. The store manager says the system worked well until about an hour ago when the store seemed to be getting cold.

Figure 15.35 Use this diagram for the discussion of Service Call 4.

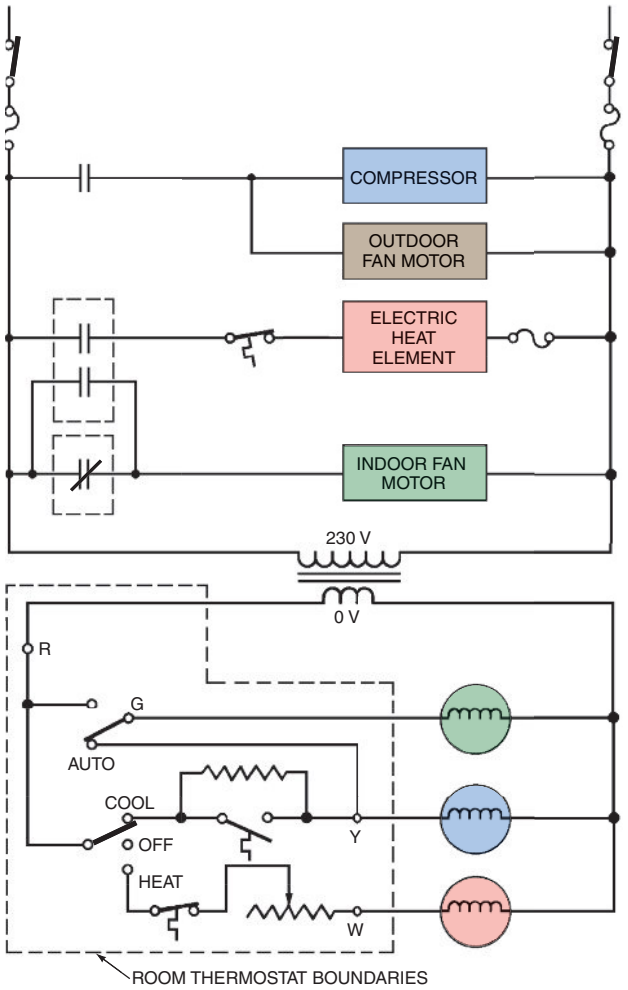

Figure 15.36 Use this diagram for the discussion of Service Call 5.

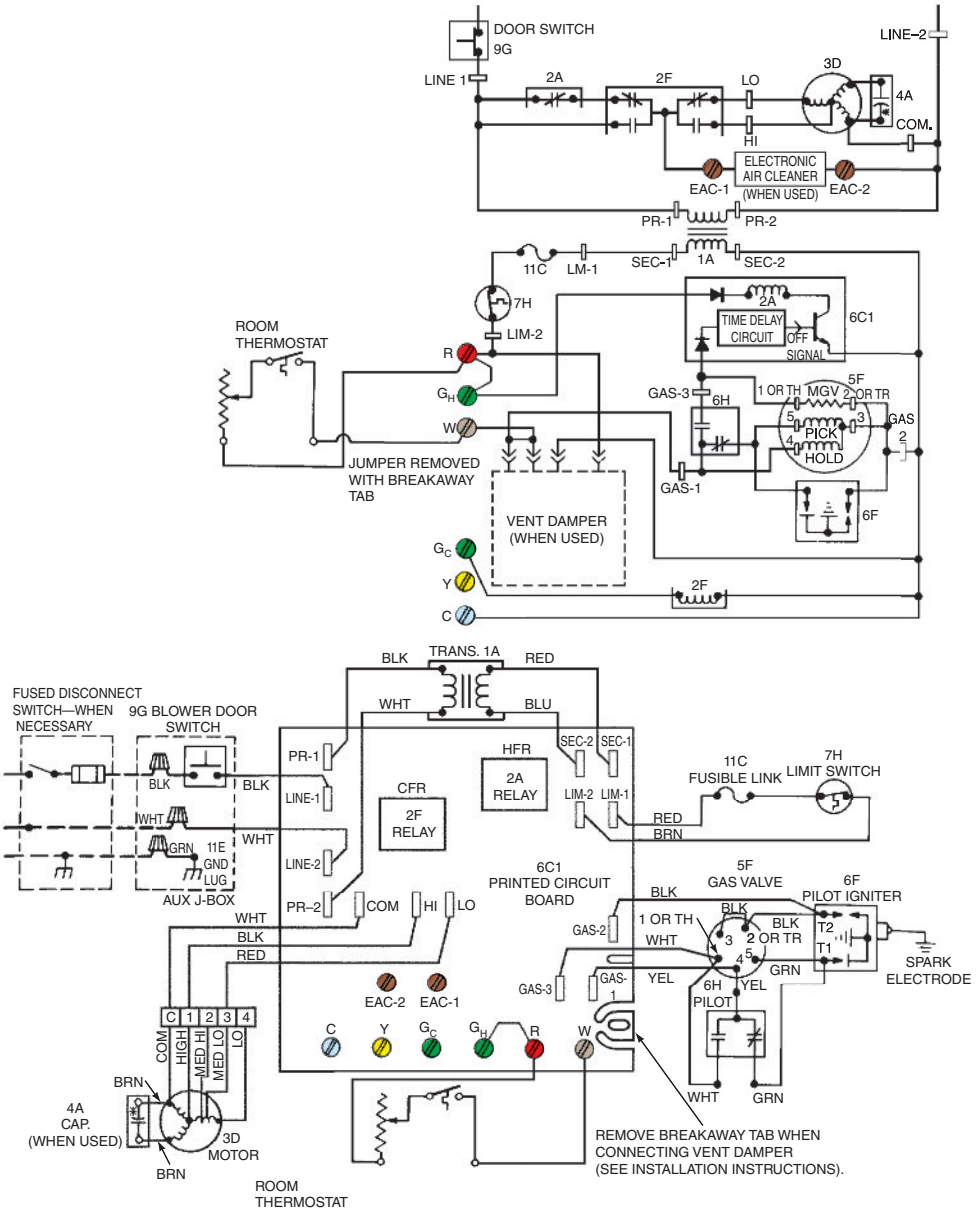
Figure 15.37 Use this diagram for the discussion of Service Call 6.



2. The technician notices that the set point on the room thermostat is 75°F, and the store temperature is 65°F.
3. The service technician now informs the store owner that he has to get onto the roof of the building. Once on the roof, the technician removes the low-voltage control panel. The voltage from C to R is 24 V and the voltage from C to W (the heat terminal) is 0 V. There is a 24-V power supply, but the heat is not operating.
4. The room thermostat is removed from the subbase, and a jumper is applied from R to W. The heating system starts.

What is the problem and the recommended solution?

SERVICE CALL 6

A customer calls on a very cold day and explains that the gas furnace just shut off and the house is getting cold. The system has a printed circuit board, **Figure 15.37**.

The technician arrives and checks the room thermostat. It is set at 73°F and the house temperature is 65°F. The thermostat is calling for heat. The fan is running, but there is no heat.

The technician removes the front door to the furnace, which stops the furnace fan because of the door switch (see 9G at the top of the diagram). The technician tapes down the door switch so he can troubleshoot the circuit.

The technician places one meter lead on SEC-2 (the common side of the circuit) and the other on SEC-1 and finds that there is 24 V. The meter lead on SEC-1 is then moved to the R terminal, and 24 V is found there. The lead is then moved to G_H, where the signal from the room thermostat passes power to the circuit board, and there is power.

The technician then removes the lead from G_H and places it on the GAS-1 terminal, where the technician finds 24 V.

What is the problem and the recommended solution?

SERVICE CALL 7

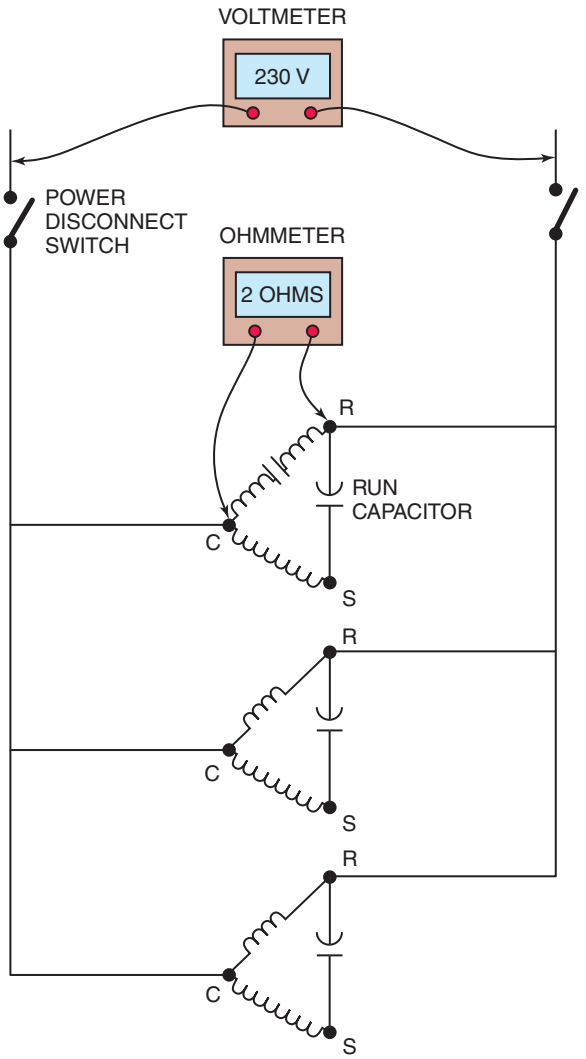
A service technician is called to a small market where the customer is complaining of products spoiling in a dairy case.

After introducing himself and his company and handing the store owner a business card, the service technician carefully listens to the owner's account of the problem. The technician then politely asks the customer some pertinent questions in clear, concise, everyday language. Even though the questions are somewhat technical, the technician tries to not make the customer feel inept about any technical topics. Once the store owner shows where the dairy cases are located, the technician starts working. The technician takes the box temperature of the dairy case with a thermometer and finds it to be 47°F. The case is supposed to be holding product at 35°F to 39°F. While measuring the temperature of the dairy case, the technician notices that there is no airflow on one side of the case. A quick inspection of the evaporator section and evaporator fans indicates that one of the three PSC evaporator fan motors is not operating.

The three fans are wired in parallel and operate off 230 V, **Figure 15.38**. The run winding of the inoperative PSC fan motor has burned open. The technician suspects that the inoperative fan motor probably has an open winding. The service technician then opens the power disconnect switch and places an ohmmeter across the run winding of the inoperative fan motor. The ohmmeter reads 2 ohms.

Did the service technician take the right steps when troubleshooting the open winding in the inoperative evaporator fan motor with the ohmmeter? Explain your answer.

Figure 15.38 The fan circuit for a dairy case showing three PSC motors in parallel with one another.



SUMMARY

- Electrical controls are divided into two categories: power-consuming and power-passing (non-power-consuming).
- One method of understanding a circuit is to understand that the power supply is the potential difference between two power legs.
- Devices or controls that pass power are known as safety, operating, or control devices.
- The light bulb controlled by a thermostat with a fuse in the circuit is an example of an operating device and a safety device in the same circuit.
- The fan relay, cooling relay, and heat relay are all power-consuming devices.
- The low-voltage relays start the high-voltage power-consuming devices.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- The voltmeter is used to trace the actual voltage at various points in the circuit.
- The ohmmeter is used to check for continuity in a circuit.
- The ammeter is used to detect current flow.
- The pictorial diagram has wire colors and destinations printed on it. It shows the actual locations of all components.
- The line or ladder diagram is used to trace the circuit and understand its purpose.

REVIEW QUESTIONS

1. Name three types of automatic controls.
2. Two categories of electric controls are _____ and _____.
3. What circuit is energized with the thermostat Y circuit?
4. The component in the system that is energized when the G terminal is energized is the _____.
5. The _____ terminal must be energized in the thermostat for the heat to start.
6. The hot circuit in the thermostat is the _____ terminal.
7. Is the heat anticipator in **series** or **parallel** with the thermostat contacts?
8. The cooling anticipator is wired
   A. in parallel with the cooling contact.
   B. next to the liquid line.
   C. in series with the cooling contact.
   D. inside the indoor unit.
9. Which anticipator is adjustable, **heat** or **cool**?
10. True or False: The indoor fan must always run during the cooling cycle.
11. True or False: When the control transformer is not working, the indoor fan will not run in the FAN ON position.
12. Which of the following should be turned off while working on the compressor circuit?
    A. The indoor unit fan
    B. The unit disconnect
    C. The thermostat
    D. The main power supply to the building
13. The _____ diagram is used to locate different components on the diagram in the unit.
14. To trace the circuits in the unit, the _____ diagram is used.
15. Describe how the amperage in a low-voltage circuit can be measured.
16. Explain why an ohmmeter, and not a voltmeter, should be used to assist in finding an opened run winding on a motor.
17. True or False: When using a voltmeter for troubleshooting, any time the technician measures across the same line (whether it be line 1 to line 1 or line 2 to line 2), the voltage will always be zero.
18. True or False: Open switches will always read voltage.
19. Explain why a service technician must always know where line 1 and line 2 are in relation to one another when voltage troubleshooting a schematic wiring diagram.

UNIT 16

ADVANCED AUTOMATIC CONTROLS—Direct Digital Controls (DDCs) and Pneumatics

OBJECTIVES

After studying this unit, you should be able to

- recognize advanced control terminology.
- demonstrate control applications.
- describe electronic control circuits.
- describe pneumatic control circuits.
- discuss a control loop.
- understand direct digital control systems.
- discuss sensitivity or gain in controls.

16.1 CONTROL APPLICATIONS

In the beginning of the HVAC/R industry, there was only manual control of all the components in a unit. For example, coal furnaces required a person called a "stoker" to put the coal in at the correct time to heat a structure. When the furnace was overfired, it was too hot. The windows had to be opened to release some of the heat. If the furnace was underfired, it took time to get the temperature up to a comfortable level. The first big improvement was the automatic stoker, which was a conveyor belt operated by a timer. Every so many minutes, it started up and ran for a prescribed length of time, dumping coal into the furnace. This method had no connection to the actual temperature of the heated space, but it eliminated a person from the process. As time passed, the process was improved by using a thermostat in the conditioned space. Then it was further improved with an outside thermostat that anticipated heating needs. All of these control methods would be considered primitive and unacceptable by today's standards. Today, we expect the temperature to be well within the bounds of comfort, summer and winter. This can be accomplished with modern systems and a small number of technicians, even in large buildings.

If you walked through a large modern building with the best control systems and noticed warm and cool spots, you would be correct in thinking that the temperature level should be much more even. Many buildings have adequate systems and control arrangements but do not have a staff of people who understand how to operate the controls. The control system must be thoroughly understood to be set up to operate correctly. Even after the system is correctly set up, the controls may drift out of calibration from time to time and have to be readjusted. Buildings are designed to be divided into zones and into different styles and sizes of office space. Walls are easily removed and new ones installed. Many times this is done with no regard to the heating and cooling system. It is not unusual to find the return air inlet in one office, the supply air outlet in another office, and the thermostat in yet another office. Sometimes construction workers put the thermostat in the ceiling while they are building walls and forget to remount it. All of this leads to unbalanced systems.

The accomplished technician should be able to look at the building blueprints and interpret the intentions of the control designer. Many control systems do not control as well as expected, but most will be satisfactory if set up correctly.

16.2 TYPES OF CONTROL SYSTEMS

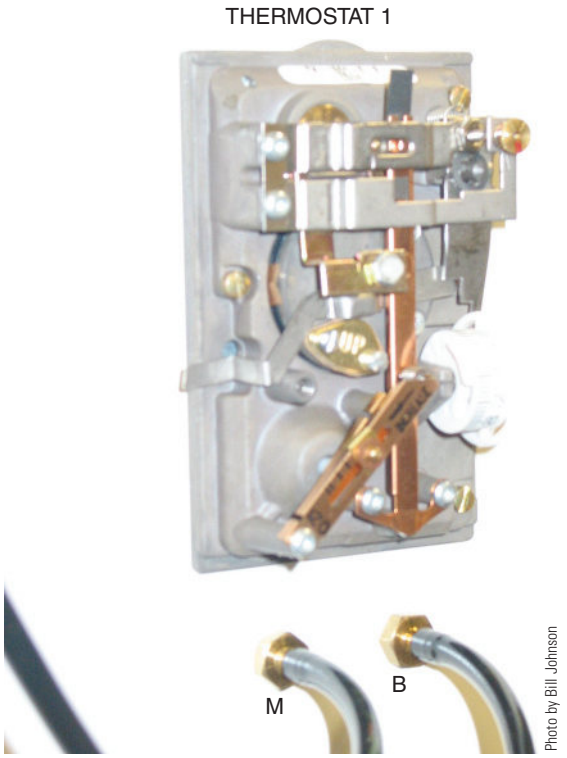
The very first control systems only stopped and started the components to be controlled. These controls were discussed in Unit 14, "Automatic Control Components and Applications." Control technology has been expanded not only to switch components on and off but also to modulate them. An example of modulation is the throttle on an automobile. Can you imagine a car that had only on and off as controls? You would be either accelerating at full speed or decelerating. The accelerator is properly used to slowly move up to the required speed and to slow down by applying less pressure to the gas pedal. Modern control systems can accomplish these same functions with automatic controls.

Control systems can be broken down into three basic components. These components make up a **control loop**. All control systems can be subdivided into control loops, no matter how many controls there are:

- The sensor measures the change in conditions.
- The controller controls an output signal to the controlled device. The sensor and controller are often in the same device.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 16.1 Typical pneumatic thermostat.



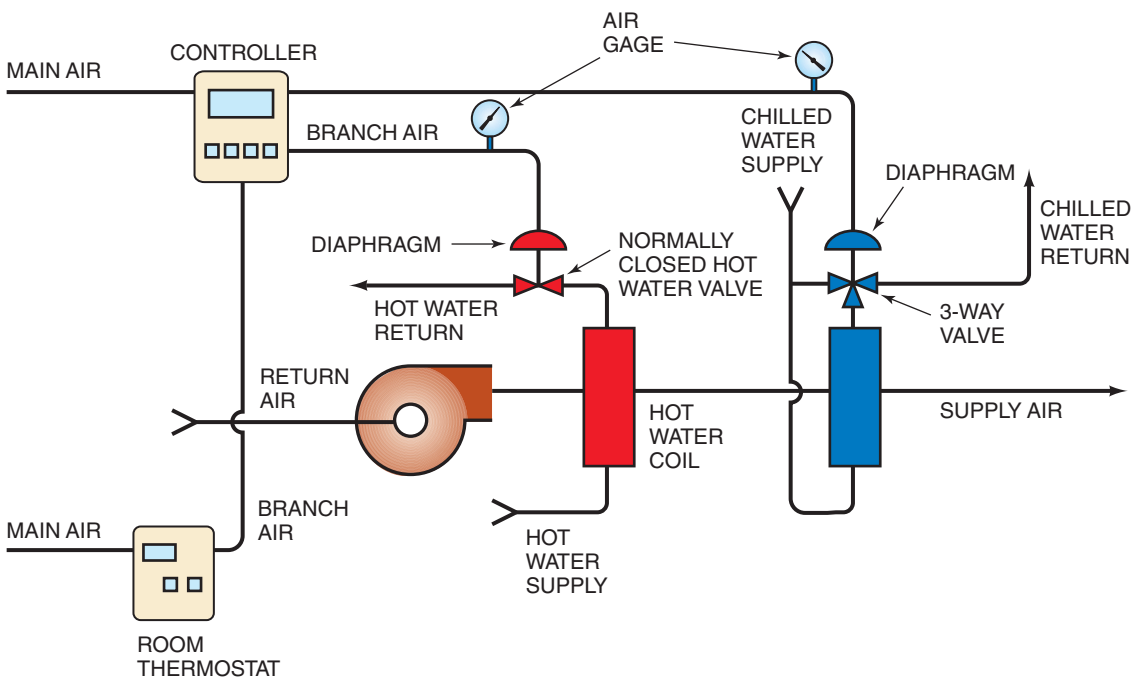
- The controlled device reacts to stop, start, or modulate the flow of water, air, or refrigerant to the system or the conditioned space.

The sensor is the device that responds to a change in conditions. In this field, the sensors respond to temperature, velocity of air, humidity, water level, and pressure. **Figure 16.1** shows the inside of a pneumatic room thermostat. The sensor sends a signal to the controller, which in turn sends the correct signal to the device to be controlled. The controller may be built into the sensor.

The controls that control the temperature in a home will serve as a simple example of a basic control loop. The wall thermostat may be located in the hall close to the return air where it senses the space temperature. When the temperature rises above the set point, for example to 75°F, the bimetal in the thermostat will move and cause the mercury contacts to close. This is the action of the sensor coupled to the controller. When the mercury contacts close, a 24-V signal goes to the compressor contactor (the controlled device), which passes power to the compressor and starts to cool the house. It will continue to run until the mercury contacts open the circuit to the compressor contactor.

The technician must understand that all systems can be divided into "control loops" and that they can be identified. A large building will have a control print that shows the basic control loops as individual loops, **Figure 16.2**. The legend that shows abbreviated words and symbols is at the beginning of the mechanical print section. You may drive past a 200-room motel and think you could never understand what

Figure 16.2 A building is divided into control loops for each area. One area may be larger than another, but the control loop may be the same.



Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. goes on inside to operate the air-conditioning and heating systems. When you look further, you will find that it is actually one plan that has been implemented 200 times. Each room is practically identical as far as the utilities are concerned. They each have the same sink, toilet, lights, and air-conditioning system. When you learn one of them, you have learned all of them because it is a control loop for a portion of the system. The control loop in an office building may be much the same. When you learn one area, you have a basic understanding of the next one.

The basic types of controls being installed today to control large systems are pneumatic and digital electronic controls. These systems can also be divided into control loops for the purpose of design, installation, and troubleshooting. Pneumatic control systems were used before electronic ones. Pneumatic controls are mechanical in nature and use air to transmit signals from the sensor controller to the controlled device. Electronic controls are quickly taking the place of pneumatic controls and are the controls of the future. However, many installations already set up and operating with pneumatic controls will be used for many years. Electronic control systems can be integrated into the pneumatic systems to employ the best features of both control systems.

16.3 PNEUMATIC CONTROLS

In the past, many buildings and industrial installations were supplied with pneumatic controls. A good mechanic can easily master these simple controls. The control signal is air, which is run in small pipes, typically 3/8 in. or 1/4 in. This eliminates the need for an electrical license and expertise in installing control wiring. Some advantages of pneumatic controls are as follows:

- They are simple to install and understand. A person with a mechanical background can soon adapt to them.
- They are safe and explosion-proof around combustible materials.
- They can be easily adapted to provide either on/off or modulating control functions.
- They are versatile and can perform many control sequences.
- They are very reliable.
- The installation cost may be lower than the cost of running long electrical lines and conduit.

The starting point for understanding pneumatic controls is to understand the air system that supplies the power to operate the controls. Most systems use a dedicated air compressor and tank with a rather elaborate filtering and drying system to supply the air. Pneumatic controls must have a permanent air supply that is **clean** and **dry**. The actual control portion of the system will have many components with small air passages called orifices, which are so small that they cannot tolerate a dirt particle or a drop of water. Because some of the controls have a constant bleed rate with air escaping all the time, the systems use air continuously. **Figure 16.3** shows a drawing of a typical dedicated single-compressor system for the air supply. Some systems have two compressors of the same capacity so that there is always a backup compressor. Either compressor can supply the total air requirements for

Figure 16.3 An air compressor system for a pneumatic control system.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

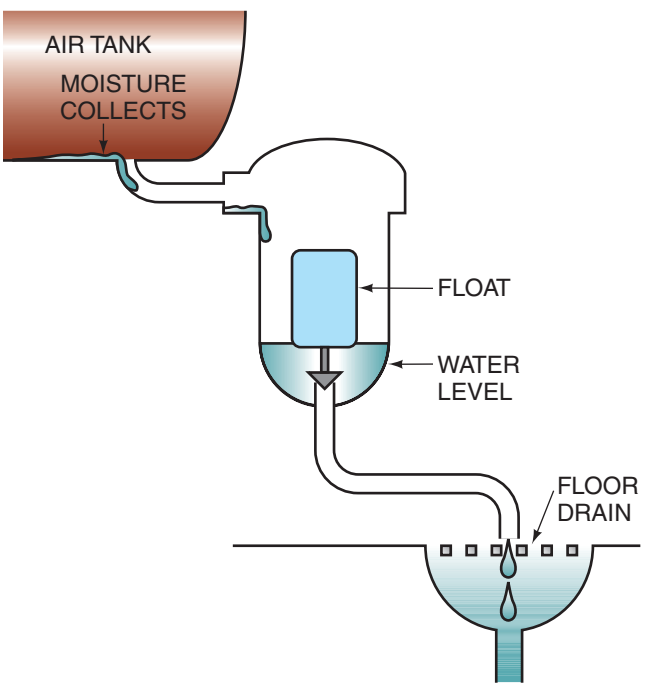
the entire system by running only about half the time. The second compressor operates when there is a great demand. Most system compressors provide 100 to 125 psig of air pressure to the storage tank and are controlled with a pressure switch. When the air pressure drops to about 75 psig, the compressor starts; when the pressure rises to about 100 or 125 psig, the compressor stops.

16.4 CLEANING AND DRYING CONTROL AIR

The cleaning of the air starts with the prefilter to the compressor. It is much like the air filter on an automobile. It may be a dry-type filter that filters all entering air. This must be kept clean, or pressure will drop, causing excess running times.

The air entering the compressor usually has moisture, or humidity, entrained in it. Most parts of the country have some humidity, and many states have high humidity, particularly in the summer. When air with high humidity is compressed from atmospheric pressure to 100 psig, the outlet air from the compressor into the storage tank may be 100% saturated with moisture. Often, the air passes through a small coil over which air from the blades on the compressor flywheel passes. This coil will condense some of the moisture to a liquid, where it will quickly drop to the bottom of the storage tank. The storage tank normally will have a float-operated automatic bleed valve that will drain water from the tank, **Figure 16.4**.

Figure 16.4 As water accumulates in the float chamber, the float rises and drains the water to the floor drain.



The remaining air in the storage tank normally will still have too much moisture to be used for control air, so it must be further dried. Usually one of four types of drier is used:

- Local water supply and coil
- Chilled water coil
- Desiccant driers
- Refrigerated air drier

The local water supply may be used if it is cold enough to remove the correct amount of moisture from the air. This is not likely in most applications. Chilled water from the refrigeration system may be used; however, if the chiller is not operating, the air may not be dried enough, and problems may occur. Desiccant driers use some of the same products that refrigerant driers use—silica gel or molecular sieve as an adsorbent, which removes moisture much like table salt attracts moisture. The desiccant may be regenerated by means of heat, so there must be two driers—one in operation and one being regenerated at all times. Regeneration may be accomplished with heated dry air. Using some portion of the dried air from the system that is in operation may be part of the process.

Refrigerated air driers are probably most common, **Figure 16.5**. These use a small refrigerated system that passes the compressed air through a refrigerated heat exchanger, which is operated below the dew point temperature of the compressed air. This condenses much of the moisture from the air, where it is automatically drained from the system with a float-operated drain device. When the water level rises in the float chamber, a valve is opened and the water goes down the drain.

When the air is dried, it may pass through another filter that is so fine that oil vapor or liquid cannot pass through it. This is a high-density filter to prevent any leftover particles from entering the control system. The system has virtually a zero tolerance for contaminants.

Figure 16.5 A small refrigerated air drier.

The control systems require an air supply that is usually no more than 20 psig. A pressure-reducing regulator is located in the line after the air-drying device. This pressure reducer or regulator reduces the air pressure from about 100 psig to 20 to 30 psig, **Figure 16.3**. A relief valve is located either in the pressure reducer or in the downstream side of the system to ensure that the control air pressure does not exceed about 30 psig. The reason for this is that the controls themselves are not rated for high pressure. High pressures will destroy the components.

16.5 CONTROL COMPONENTS

The 20-psig control air is used to position various components in the system. We will use a valve actuator assembly as an example. Remember that we will be working with an air pressure of 20 psig, that is, 20 pounds per square inch. Main air pressure is used in this example. This is important because we will use the 20 psig to open a valve with a large diaphragm that has a diameter of 4 in. This diaphragm has an area of 12.56 in^2 (area = $\pi \times r^2$, or $3.14 \times 2 \times 2 = 12.56$ in^2). When 20 psig of pressure is applied to the top of the diaphragm, there are 251.2 lb of force (12.56 $in^2 \times$ 20 psi = 251.2 pounds of force), **Figure 16.6**. The diaphragm is held in the upward location with a strong spring, and the air above the diaphragm overcomes the spring. Therefore, when the air pressure is released, the diaphragm will be repositioned to the upward location.

The diaphragm and its plunger can be fastened to any device that we want to move with the air pressure, such as a steam or water valve or a set of air dampers, **Figure 16.7**. We can move a rather large load with 251.2 lb of energy. The air pressure, which is the force, can be piped to the various components using small copper or plastic tubing. The 20-psig main air lines are typically run using 3/8-in. lines, and the branch control pressures are run with 1/4-in. lines. If you have ever watched a service station operator push an air valve and lift a 4000-lb car with the air lift, it is the same principle, only with about 100 to 125 psig of air pressure.

The pneumatic control components—the sensors such as thermostats, humidistats, pressure controls, relays, and switches—perform the same functions that other controls do. The components to be controlled are valves, dampers, pumps, compressors, and fans. These components work to control the conditioned space. There are as many combinations of

Figure 16.6 This diaphragm assembly can exert a pressure of up to 250 lb because 20 psi of air pressure is exerted on a 4-in. diaphragm.

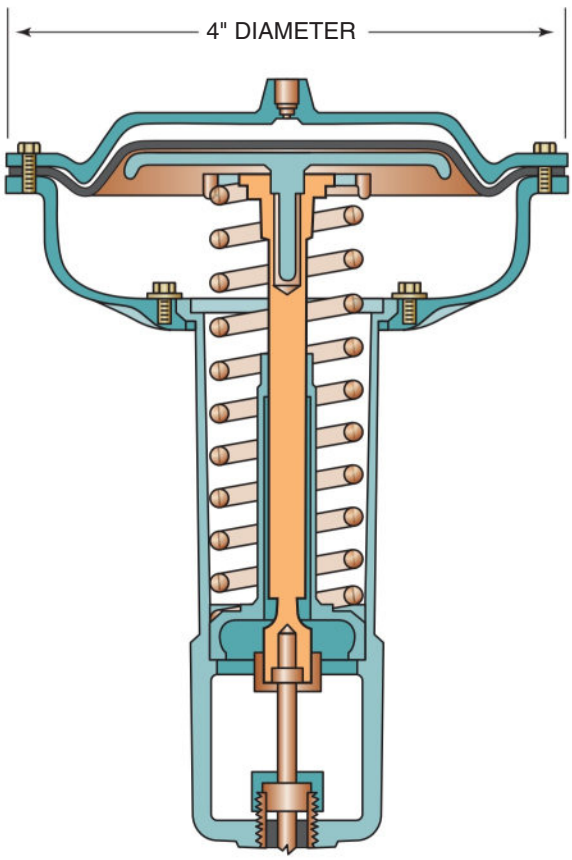

Figure 16.7 This diaphragm and plunger can be fastened to any number of devices that need to be positioned to control conditions.

Figure 16.8 This control loop is used to control room temperature.

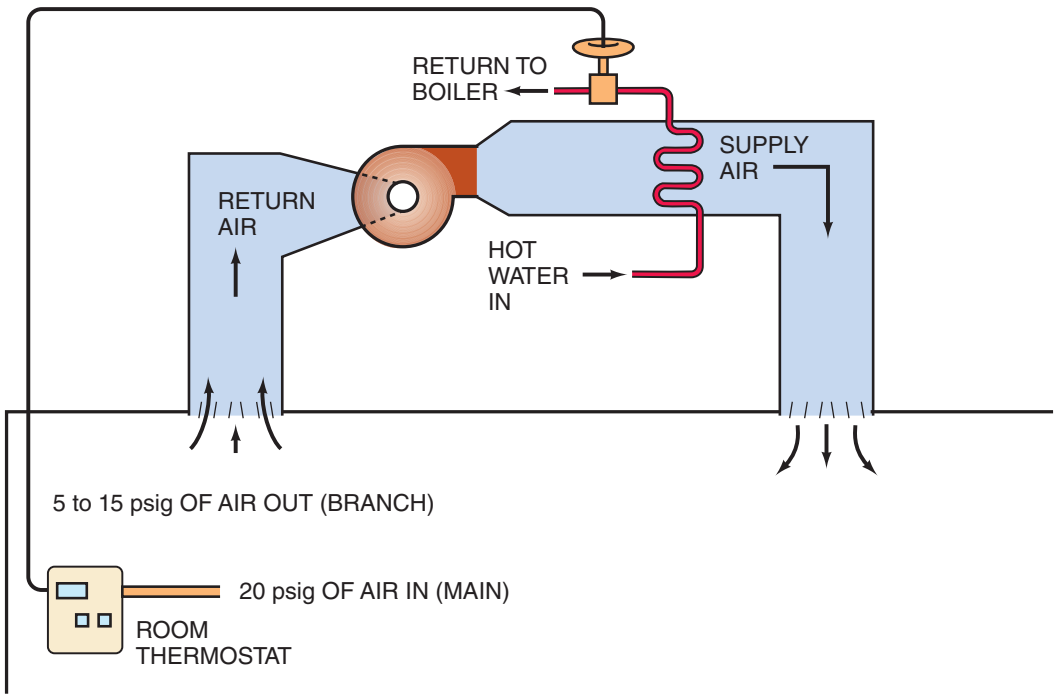

Figure 16.9 The electrical solenoid can only provide on/off control. This causes a swing in room temperature.

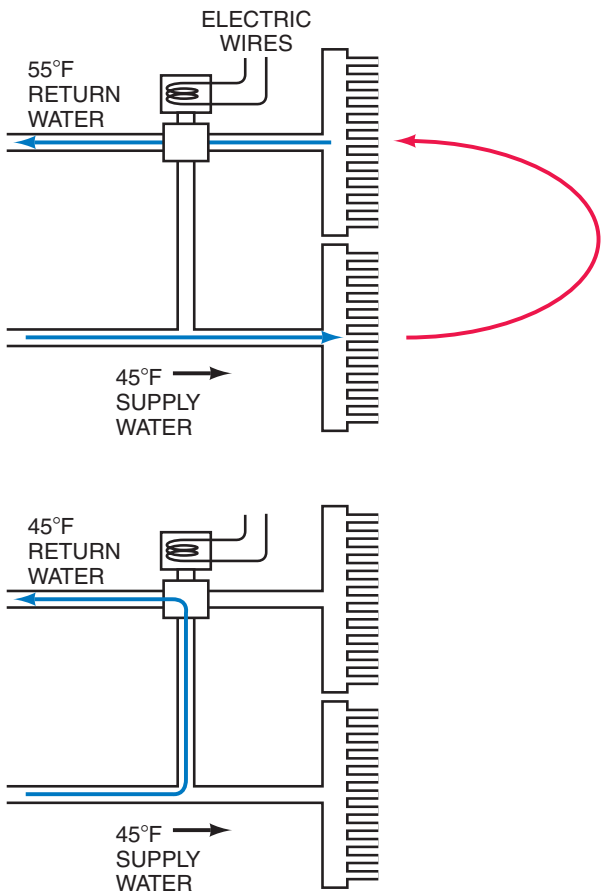

controls in various systems as there are systems. We will outline some basic processes.

The system in **Figure 16.8** can control the room temperature in many increments, depending on the sensitivity of the thermostat. This is a basic control loop: When the room conditions change and cause a change in the room thermostat, the outlet air changes and that changes the room thermostat. This is called a closed loop because all changes happen within the loop. This control setup is found in many office buildings and motels. When you change a thermostat and then hear air movement, it is a pneumatic control system that uses a normally closed diaphragm valve and air pressure to overcome the spring to allow hot water to pass to the coil. Many other applications use a normally open valve that is held closed by air pressure. When the room conditions call for heat, it allows air pressure to bleed off the diaphragm and open the valve. This is called reverse acting. It has the advantage that if the systems fail for any reason, the building will overheat rather than have no heat. This can be considered a safety feature in cold climates because it prevents building freezing conditions over a holiday.

The following is an example of how a room thermostat controls chilled water flow by modulating it to the room's needs. The output pressure positions the valve for the correct chilled water flow through the coil to maintain even temperatures in the conditioned space. With electric controls, only a solenoid valve may be used to divert water around the chilled water coil or through the coil, **Figure 16.9**. Pneumatic

controls can be used to position the valve for the correct water flow by modulating the air pressure to the valve that controls the water. The valve is the controlled device; the pneumatic device is the controller (controlled by the sensor). This high-air-volume valve may be located some distance from the room thermostat. A device called a **pilot positioner** is used to control the large volume of air. The pilot positioner receives the signal from the thermostat and regulates the air pressure to the air cylinder, which modulates the water valve anywhere from fully closed to fully open. The pilot positioner uses main air pressure, 20 psig, to move an air cylinder piston. The piston is held in the retracted position by a coil spring within the air cylinder body, and the shaft can only be moved with air pressure on the opposite side of the diaphragm, **Figure 16.10**.

The pilot positioner has a main air supply (the largest line) that is governed by the internal diaphragm, which enables it to handle the large volume of air required to fill the air cylinder chamber, **Figure 16.11**. The thermostat now uses a small volume of air, which can be piped a greater distance from the pilot positioner. **Figure 16.12** shows the pilot positioner and the air cylinder it operates. For example, suppose that the room thermostat calls for maximum cooling. It will provide 15 psig of air to the pilot positioner, and full water flow will occur through the coil, providing maximum cooling. When the room temperature gets close to the set point—for example, 75°F—the air pressure from the output of the thermostat, the branch line pressure into the pilot positioner, drops to 7 1/2 psig, **Figure 16.13**. The pilot positioner would, in turn, govern the main air to the valve. The spring would move the valve to halfway, reducing the water flow through the coil to 50%, **Figure 16.14**.

Figure 16.10 The air-operated cylinder is commonly used to control valves and dampers.

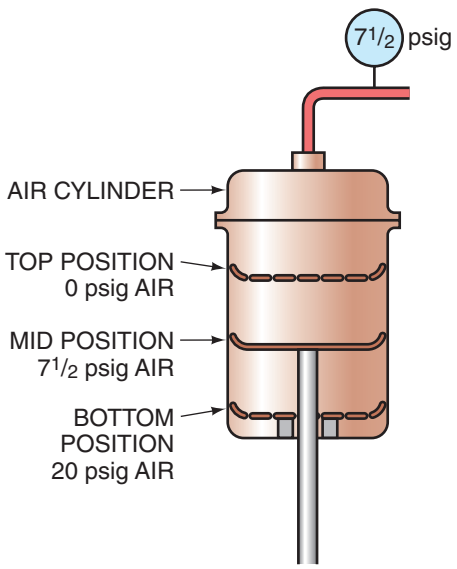

Figure 16.11 The pilot positioner in this system allows the thermostat to handle a very small amount of air from the pilot positioner, which governs a high volume of air to the cylinder.

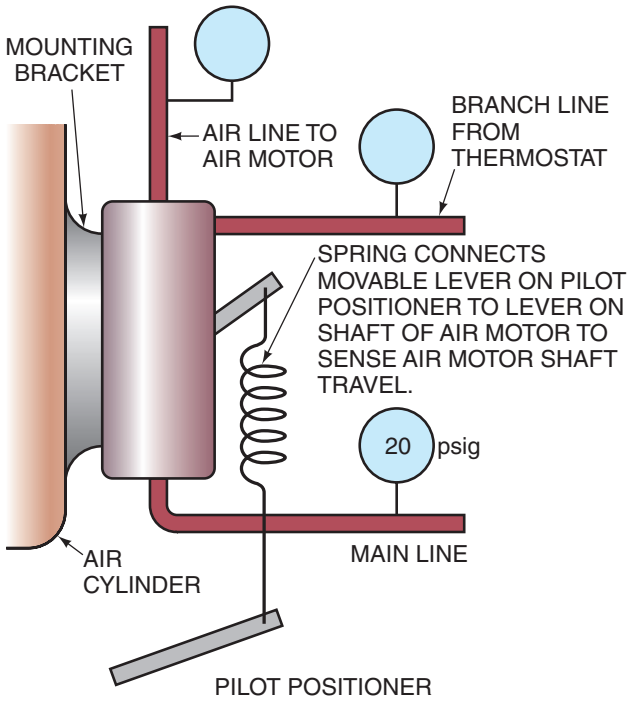

Figure 16.12 The room thermostat is supplying 15 psig of air to the pilot positioner, causing full stroke of the air motor. This will result in full water flow through the coil, providing maximum cooling. The room temperature is 78°F and the thermostat is set for 75°F.

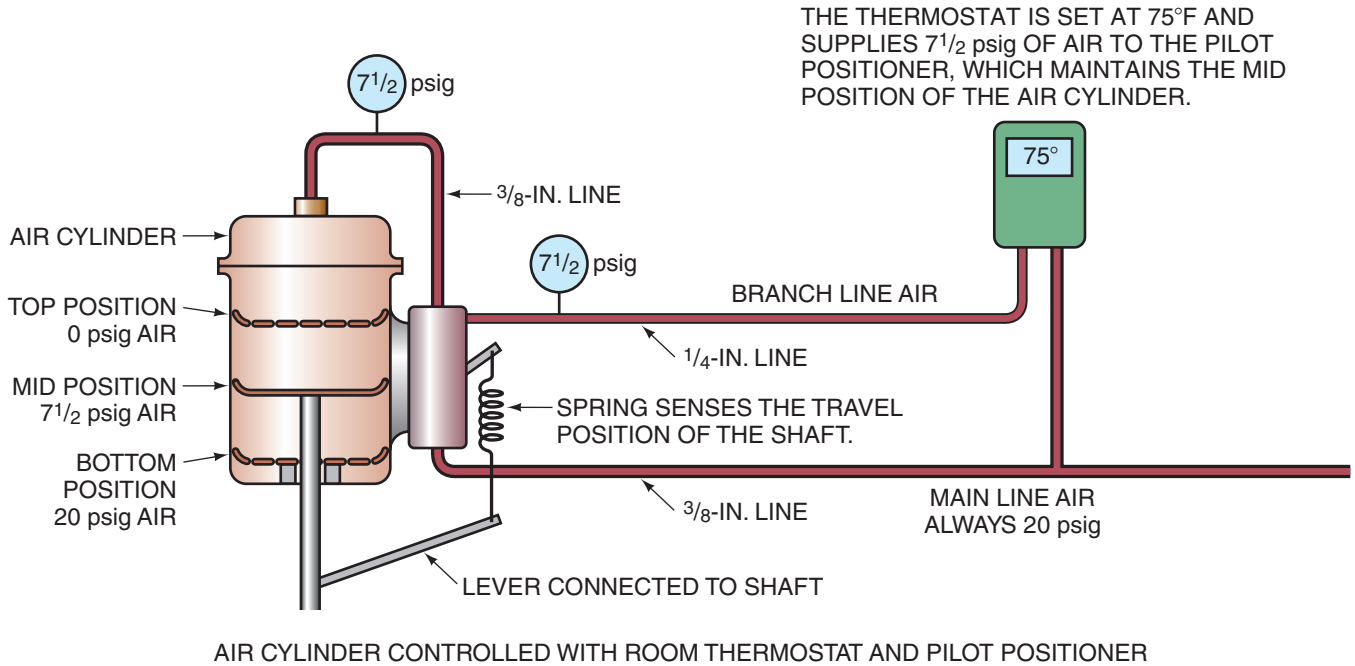
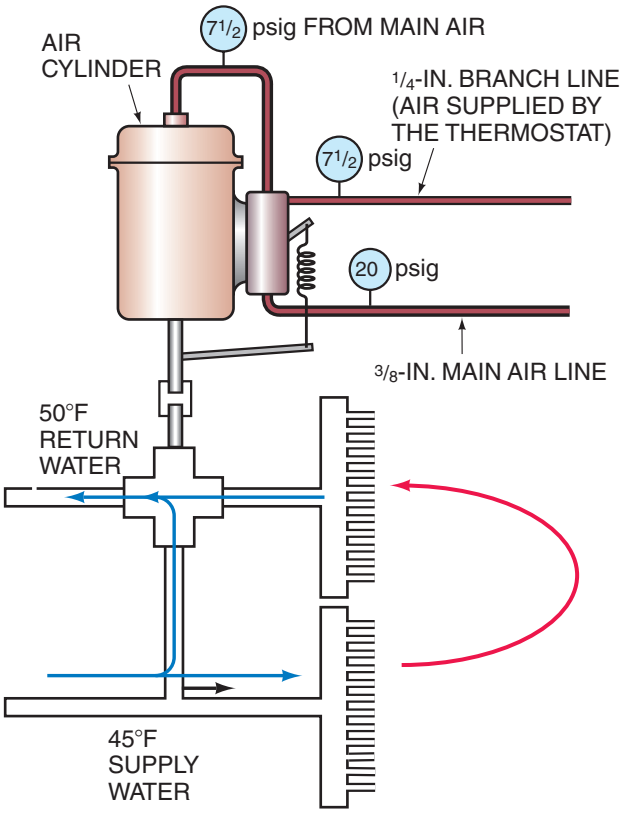
Figure 16.13 This shows the entire system.



AIR CYLINDER CONTROLLED WITH ROOM THERMOSTAT AND PILOT POSITIONER

Figure 16.14 The room thermostat is set to control the room temperature at 75°F. The room is at 75°F so the thermostat is sending 7 1/2 psig of air pressure to the pilot positioner. This positions the valve to allow 50% water flow through the coil.



When the room thermostat is satisfied at about 72°F, the valve will be positioned to completely bypass water around the coil and back into the return water to the chiller, **Figure 16.15**. This allows the thermostat to adapt the water flow to the room's needs, rather than an on/off flow. This is called **modulating flow**. Much like the accelerator on an automobile, it modulates the flow of fuel.

Notice in the preceding explanation that at 75°F we had 50% flow and a branch line pressure of 7 1/2 psig, and at 72°F we had no flow. The pressure should be 5 psig. When the temperature reaches 78°F, we should have 15 psig branch line pressure and full flow. We have a temperature difference of 78°F − 72°F = 6°F and an air pressure change of 10 psig. The **sensitivity**, or **gain** as it is sometimes called, is 1.67 psig per °F (10 psig/6°F = 1.67 psig per °F temperature change). When there is 1°F temperature change, the thermostat will change the branch line pressure 1.67 psig, a variable called for in the design of the application. If sensitivity is too great, the control may have a tendency to hunt, back and forth, as if it cannot find equilibrium or a steady state. If sensitivity is too little, there will be a noticeable difference in the room temperature that will not be much better than on/off control. The job application dictates what the sensitivity should be; the previous example is typical for cooling applications. The three-way valve is used in the cooling application to maintain a constant water flow through the chiller. If a building has 20 chilled water coils similar to the one in the example and they all bypass water, there is still water flow through the chiller, and the chiller will shut off due to low load.

Figure 16.15 The room temperature is now 72°F. The room thermostat is satisfied and has an output of 5 psig. The valve is now bypassing all water around the coil. If the room temperature drops much more, heating will be required. A hot water coil may then be allowed to provide heat in a similar manner.

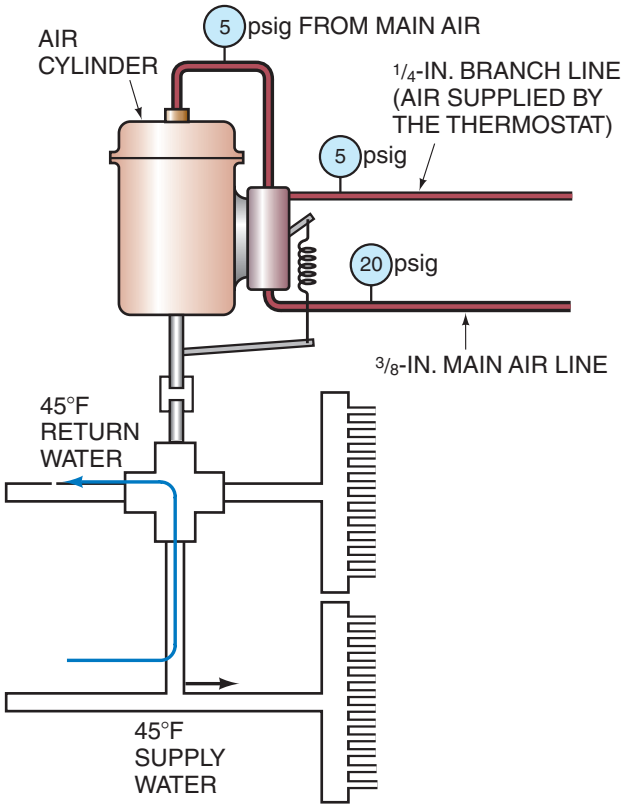

Figure 16.16 A thermometer, a gauge, and an Allen wrench are the tools used by the pneumatic control technician to make control adjustments.

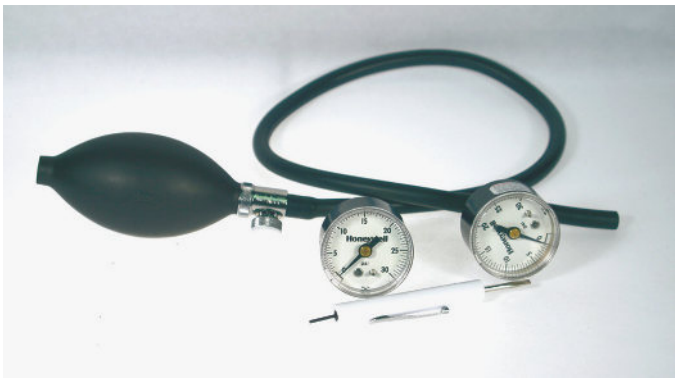

Photo by Bill Johnson

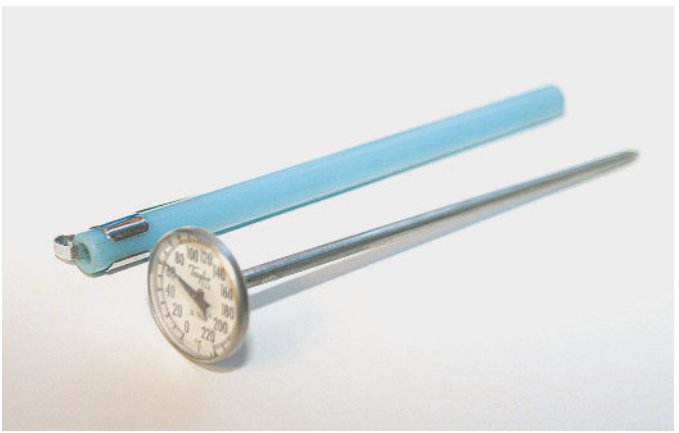

Photo by Bill Johnson

The tools of the pneumatic technician are a pressure gauge that can be plugged into the various control points, an Allen wrench to make adjustments, and a good pocket thermometer, **Figure 16.16**. The pressure gauge has a quick-connect fitting that will fit the particular brand of pneumatic control, available from the manufacturer. Many technicians carry fittings for each brand.

The technician may be called on to check a room thermostat for calibration. Leaving the pocket thermometer in the air long enough to adjust to the air temperature and detect the temperature in the vicinity (ambient air temperature) of the thermostat, the technician then records the air pressure at the thermostat. Suppose the air temperature is 75°F, the thermostat is set for 75°F, and the air pressure is 3 psig. The thermostat indicates that cooling should be occurring, but the air pressure does not call for cooling. The thermostat has drifted out of calibration. The thermostat can be adjusted to call for 7 1/2 psig under this condition and cooling will start.

Pneumatic controls may be used to switch electrical circuits, or electrical circuits may be used to switch pneumatic control circuits on or off. The pneumatic device that is used to switch electrical circuits is called a pneumatic-electric (PE) device. **Figure 16.17** shows a PE switch that is much like a pressure control except that it operates at much lower pressures. The electric device used to switch pneumatic devices on and off is called an electric-pneumatic (EP) device.

Many different types of pneumatic controls and arrangements are possible, but they all operate using the principles described. Pneumatic controls can be recognized by the air pressure line going to them. When they change conditions or positions, you will often hear the air bleeding from the control. Technicians who have pneumatic controls in their maintenance program should attend any pneumatic control classes available, try to watch a seasoned technician, and ask a lot of questions. The control sequence provided by the building blueprint is invaluable for showing how the building controls are supposed to function. Control manufacturers are very cooperative with regard to supplying duplicate diagrams and material on their controls. Many times, when the building blueprint has been lost, the original control company or architect will have a control blueprint on file.

16.6 DIRECT DIGITAL CONTROLS (DDCs)

Electronic controls have taken over the majority of today's control systems. These controls, commonly called **direct digital controls (DDCs)**, have the advantage of being able to operate on very low voltages. In some states the control wiring may be installed without an electrical license. DDCs can also be modulated like pneumatic controls. They are much more compact than pneumatic controls; however, they do the same sort of duty. They may need to open, close, or modulate a water valve, steam valve, or an air damper in an airstream. They can also modulate motor speeds, as will be seen in Unit 17, "Types of Electric Motors".

DDC is a control process in which a microprocessor, acting as a digital controller, constantly updates a **database** of internal information. Through **sensors**, the microprocessor updates this information by watching and monitoring information from an external **controlled environment** or conditioned space. The microprocessor then continually produces corrections and outputs this corrected information back to the controlled environment. The controlled environment could be controlled by an array of **controlled output devices**, such as dampers, fans, variable-frequency drives (VFDs), cooling coil valves, heating coil valves, relays, and motors—to name a few. The sensors can sense many things like pressure, temperature, light, humidity, velocity, or flow rate. They can also do a status check to see if something is energized or running or not running. A conventional control system (pneumatic, electric, or electro-mechanical) works very similarly to a DDC system except that digital (binary) information can be processed much faster and is much more accurate at all times and under all conditions. Binary information consists of nothing but zeros and ones (0 or 1) and often represents one of two elements in opposition to each other, such as on/off, high/low, or yes/no.

The DDC system actually changes or conditions a signal in three steps, **Figure 16.18**. The following is an explanation of the three steps:

- The input information from sensors is converted from analog (modulating) to a digital (on/off) binary format. **Signal converters**, usually housed internally inside the controller, convert the information from either analog to digital (A/D) or digital to analog (D/A) format, **Figure 16.18**. This allows the microprocessor or digital controller to read the incoming data.
- Control commands (algorithms) stored in the digital controller's central processing unit (CPU) are performed by the microprocessor with this newly converted digital data.
- The correct output response of the microprocessor or digital controller is reconverted from digital data to analog data for analog output devices. Digital data is the output

Figure 16.18 Three-step procedure for conditioning a signal on a DDC control system.

of the digital controller when the controlled output device is digital. This allows the appropriate controlled output devices to recognize the controller's output signals and respond accordingly.

Figure 16.19 shows this process in graphical form. The digital controller (microprocessor) will address each **control point** in the system through an input/output (I/O) card. The signal then passes through an analog/digital converter, which gives the signal a binary value. This allows the digital controller to understand the input signal and will allow the internal instructions (**algorithms**) stored in its memory to act upon the information. The controller's output response is converted from digital to analog format through a digital-to-analog converter. Notice that the signal is now back into its original analog format. The signal can now be sent to the controlled devices, however, control output devices today can receive either analog or digital signals. So digital controllers can be programmed to send the output signal that is appropriate to the device under control.

The microprocessor or digital controller must remember its tasks, what information is available for its use, what this information does, and the results of what it has done. The digital controller must also remember a number of rules and mathematical functions for controlling the system. **Memory** is the part of the digital controller where this information is stored. An algorithm (program of instructions) resides in the memory of the digital controller and serves as the instructions or step-by-step operations sequence for how the digital controller should act (take action) on the data received from the inputs. The controlled output devices can now implement this action and make changes to the controlled environment. The following lists some of the major advantages a DDC control system has over a traditional control system:

- Speed and accuracy
- Ability to control many control sequences simultaneously
- Ability to manage many control loops simultaneously
- Repeatable control of system set points
- Operating functions of the controller adjustable through software
- Ability to automatically adapt to changing conditions in the controlled environment

DDC controls are being used worldwide to reduce energy costs. Current trends in DDC technology are toward smaller, modular, stand-alone DDC panels, **Figure 16.20**. Today, with microprocessor-based controls located right on the equipment being controlled, component failure does not put at risk an entire building's HVAC/R system. The systems are said to be intelligent, self-compensating, self-maintaining, and self-diagnosing.

Basically, a control system, no matter how complex, consists of the following:

- Sensors
- Controller
- Controlled devices

Sensors are devices that can measure some type of environmental parameter or a controlled variable and convert this parameter to a value that the controller can understand. Sensors can measure parameters such as the following:

- Temperature
- Pressure
- Humidity
- Light
- Position
- Moisture
- Velocity
- Enthalpy
- Conductivity

Since a sensor measures the current values of controlled variables, it is the most critical element of a control system, **Figure 16.21**. For accurate control, a change in a controlled variable must be

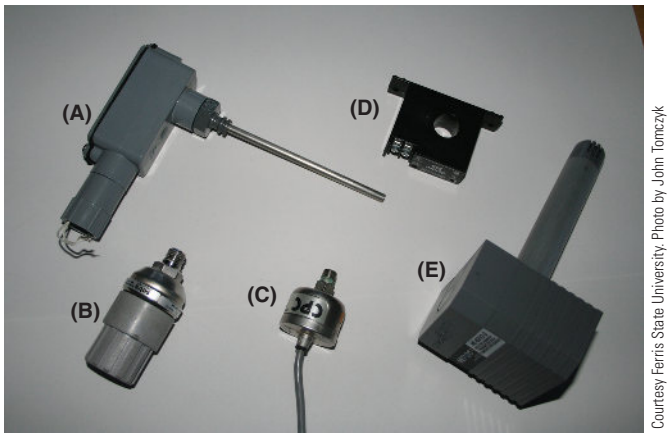
- sensed or measured;
- transmitted to a controller for interpretation; and
- acted on to elicit the correct response from the controlled output device.

Sensors can be divided into two basic categories. They are

- active sensors.
- passive sensors.

Passive sensors send information back to the controller in terms of resistance (ohms). A typical temperature sensor is a 1000-Ω nickel sensor. This sensor converts temperature to resistance. The resistance is measured by the controller and is translated back to temperature. Passive sensors are typically

Figure 16.21 Sensors for a DDC controller. (A) Thermistor (analog). (B) and (C) Pressure transducers (analog). (D) Current sensor (digital). (E) Humidity sensor (analog).



Courtesy Ferris State University. Photo by John Tomczyk

less expensive than other types of sensors. One disadvantage is that they are limited in how far they can be located from the controller because of the resistance of the wire connecting the sensor to the controller. **Active sensors** send information back to the controller in terms of milliamps (mA) or volts. The sensor converts the input signal at the sensor to mA or volts before being sent to the controller, which then measures mA or volts. These sensors are not affected by the length of wire to the controller. Typical output signals sent back to the controller from the active sensors are 0–10 V or 4–20 mA.

Sensors have both **binary** (**digital**) and **analog** inputs to the controller. Digital inputs report back to the controller as one of two opposing conditions. Examples of digital inputs are the following:

- Yes/no
- Open/closed
- On/off
- Start/stop

In the HVAC/R field, digital or binary inputs can be a set of contacts that are either open or closed or a motor that is either on or off. They can be used as indicators of status, proof, safety, and limits.

Analog inputs have a range of values over any given time period, **Figure 16.22**. Examples of analog inputs are the following:

- Temperature
- Pressure
- Humidity
- Flow
- Light

In the HVAC/R field, analog inputs can measure room temperature, discharge air temperature, return air temperature, mixed air temperature, outdoor air temperature, chilled

(B)

water temperature, hot water temperature, static pressure, chilled water flow, outdoor air humidity, return air humidity, or light levels—to name a few. Probably the most recognized analog inputs to a controller are thermistors and resistance temperature devices (RTDs). Thermistor sensors measure temperature using silicone instead of a metal. However, the thermistor does not establish a linear relationship between resistance and temperature, **Figure 16.23(A)**. So the digital controller has to be able to handle this type of sensor. RTDs, on the other hand, have a more linear and predictable output resistance whenever their temperature changes. The controller has to analyze a much more linear temperature/resistance-to-voltage relationship, **Figure 16.23(B)**.

Controlled output devices can be either analog or digital. When analog, the final control device has a range of operation such as "full open to full close" or "full speed to stop." Analog output devices are typically operated with either a 0–10-V or a 4–20-mA signal range. The controller has to be able to handle one of these two outputs or both. Typical analog outputs in the HVAC/R field are valves, dampers, and VFDs (variable-frequency drives) that control motor speed.

Digital or binary output devices have two states of operation—such as on/off, open/closed, start/stop, and yes/no, **Figures 16.24(A)** and **(B)**. Binary outputs are simply an electronic switch (triac) that is operated by the controller. Examples of binary outputs in the HVAC/R fields are fans (start/stop), pumps (start/stop), direct-expansion (DX) cooling (on/off), and gas heat (on/off)—to name a few.

Any time there is a group of control devices interconnected in such a way that they control a single process at a certain desired condition, a control loop is said to exist. An example of this is a group of sensors, controllers, valve actuators, dampers, VFDs, and signal converters. Processes controlled by a control loop in the HVAC/R fields are usually comfort-related. Certain control loops can maintain temperature, pressure, lighting, flow rates, or humidity at a certain **set point**. Others simply make sure a process or control point never exceeds a predetermined system design limit. The difference between the two loops will be discussed later in this section.

The information that any control loop handles starts with the sensors. The sensors pass the information on to the controller, which alters the information and sends it to the final control device. Control loops can only maintain one pressure, temperature, humidity, or lighting value. So it would take four control loops to maintain a space requiring specific pressure, temperature, humidity, and lighting values. Individual control loops can be combined with other control loops

(B)

to form a **control system**. There are two basic configurations for control loops. They are the following:

- Open loop
- Closed loop

Open- and closed-loop configurations do not describe how a loop's control devices are connected, but how the loop is connected to the HVAC/R process. It is actually the sensor's location that determines whether the loop is open or closed.

In an **open-loop control configuration**, the sensor is upstream of the location where the **control agent** causes a change in the **controlled medium**, **Figure 16.25**. The control agent is the fluid that transfers energy or mass to the controlled medium. It is the control agent (such as hot or cold water) that will flow through a final control device (water valves). The controlled medium is what absorbs or releases the energy or mass transferred to or from the HVAC/R process. Controlled mediums can be air in a duct or water in a pipe. In **Figure 16.25**, the control agent is the hot water in the coil, the controlled medium is the air in the duct, the control point is the outdoor air temperature, and the final control device is the hot water valve. **Figures 16.26(A)–(C)** show three analog (modulating) final control devices. The flow of information in an open-loop configuration travels in only one direction. Because the sensor is located upstream of the control agent, it never senses the results of the action of the final control device (hot water valve). Open-loop control systems cannot maintain a balance between the energy transferred to or from the system and the process's heating or cooling loads. The sensor does

(C)

not monitor a control point like supply air temperature, but can monitor a variable like the outdoor air temperature in **Figure 16.25**. The sensor is simply making sure that if the outdoor air temperature is ever less than 40 degrees, the hot water valve will open. This opening or closing of the hot water valve would be considered a binary, or two-position, response; it is simply preventing the controlled variable (outdoor air temperature) from exceeding a predetermined design limit.

A **closed-loop control configuration** can maintain the controlled variable, like the air in the duct in **Figure 16.27**, at its set point because the sensor in now located in the air being heated or cooled (controlled medium). The sensor is located downstream of the water coils or point where energy or mass is being introduced. The sensor can now sense what the final control device (water valve) did and make adjustments. This is called a **feedback loop**. The feedback loop actually "closes" the information loop, causing the flow of information to be in a circle. This is where the term *closed loop* originated. This type of control loop can now maintain a controlled medium at a set point—whether the control is a modulating (analog) or digital (binary) type. With the modulating closed-loop control in **Figure 16.27**, there can now be a balance between the HVAC/R process load and the energy transferred from the controlled agent. Refer to Section 24.22, "Step-Motor Expansion Valves," and Section 24.23, "Algorithms and PID Controllers," in Unit 24, "Expansion Devices," for an example of a closed-loop control configuration in which you can apply the principles you have just learned about DDC. These sections discuss DDC applied to an expansion valve for a commercial refrigeration system used in today's supermarkets.

DDC control systems in large buildings or supermarkets can be responsible for the following:

- Total building energy management
- HVAC/R functions
- Building lighting
- Fire protection
- Temperature setback
- Refrigeration

DDCs use a typical personal computer or laptop to assimilate and distribute information to other, small computers in the system, such as control boards. The small computers that are part of the DDC system for each section of the building are tied to the main personal computer. There may be multiple sensors and controllers for each portion of the building feeding information to the individual control computers. An advantage is that the technician can control the system from wherever there is an Internet connection. Security codes prevent others from accessing the system. A technician who gets a call about a building temperature being out of control can get on the Internet or a wireless cable modem and view all the building conditions, what is running and what is not running, and what the conditions are in all parts of the system. The corrective action can often be entered from a remote location. This gives building maintenance personnel some extra freedom and eliminates some overtime calls for the owners. Reliable sensors and their control wiring are the greatest challenge in this type of system.

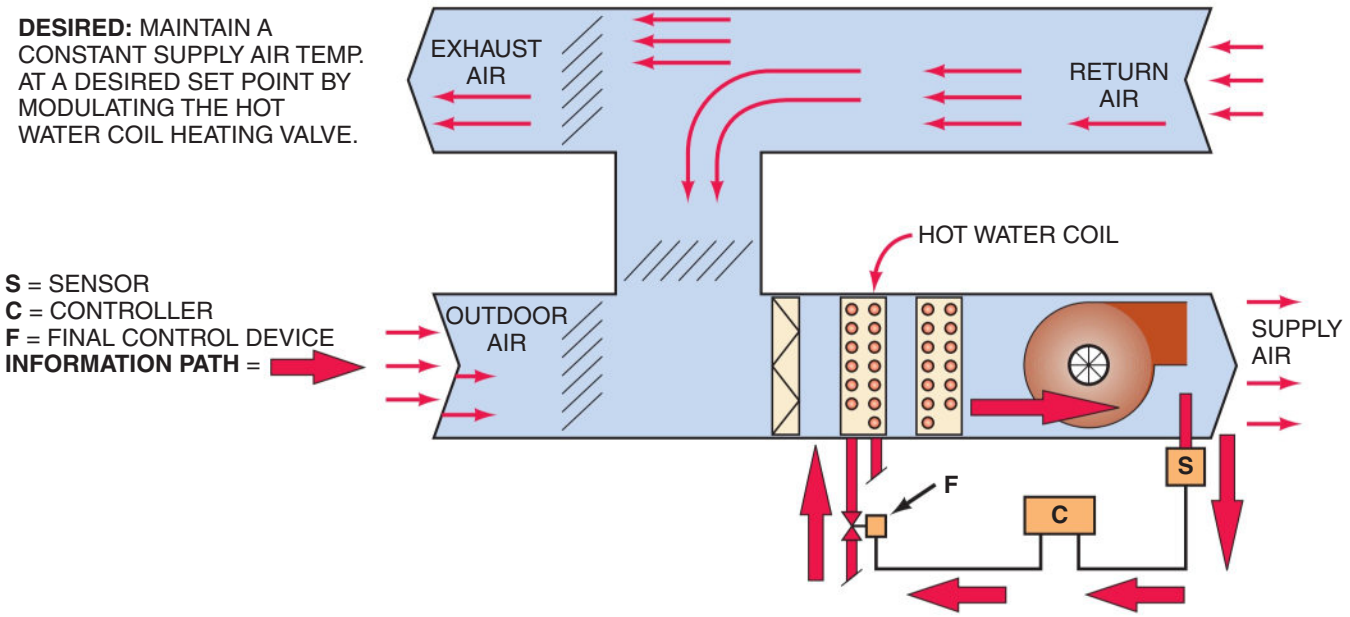
Figure 16.27 A closed-loop control configuration.



Building management may want to perform what is known as ***load shedding*** *or* ***duty cycling*** *to lower electrical power costs. Electrical load shedding uses management methods to reduce the power consumption.* For example, suppose the air conditioner is turned off at exactly 5:00 PM rather than 5:30 PM. The people exiting the building may notice that the space temperature is rising, but it does not matter because they are leaving. Duty cycling is shutting down nonessential equipment during high peak loads; for example, water coolers, decorative water fountains, ice makers, water heaters, and other nonessential devices can be shut down temporarily to reduce the electrical load. Remember, every Btu that is allowed into the building must be removed by the air-conditioning system in the summer. It pays to shut nonessential devices off when they are not needed.

Power companies use a system called **demand metering** to charge for electricity in commercial buildings. Demand metering bills the owner at the power rate for the month based on the highest usage for some time span, usually 15 or 30 min. Power companies try to collect in a way that charges for the demand on their systems. To understand how demand billing works, suppose a building's air-conditioning system had not been operated for a 30-day period, and on the next day, it becomes very hot toward the last part of the day. If the system operated at maximum capacity for the last 30 min of the last day of the month, the building owners would be billed for the entire month at that rate, even the previous 30 days. A sharp operator or a computer-analyzed control and power system would discover this and not allow the system to operate at full capacity or would shed some nonessential loads. The power bill for the month would then be greatly reduced. In fact, a well-designed system can monitor a building's power consumption by the minute for the entire year.

A system can be designed to stop at a certain time at night and start early in the morning. This allows the equipment to bring the building conditions to temperature at a lower power consumption as opposed to running at full load for a short period of time. The pull-down time in the summer and the heat-up time in the winter can also be lengthened to reduce energy consumption. The computer system can keep a record of the pull-down time for the building and allow for extra time or less time as needed during future events. It keeps a history of how the system responds to specific condition changes and works to make it more efficient. Weather patterns can be tracked to predict fast temperature changes that may be needed and phase them in at lower energy cost. Different solar zone requirements can also be predicted and adjusted. The energy requirements are different for the east side of a building than for the west side at different times of day because of the changing position of the sun. In actuality, there are so many variations that can be accomplished with DDC and a good computer system that they cannot all be mentioned here.

Figure 16.28 is a simple example of a closed-loop control system that controls a chilled water coil to a conditioned space using DDC. The thermostat in the return air from the conditioned space is checking the air temperature. Suppose we want to maintain the temperature at 75°F. The digital signal voltage range is from 0 to 10 V and we want to have a sensitivity (often called *gain* in electronics) of 1.7 V per degree of temperature change. The voltage should read

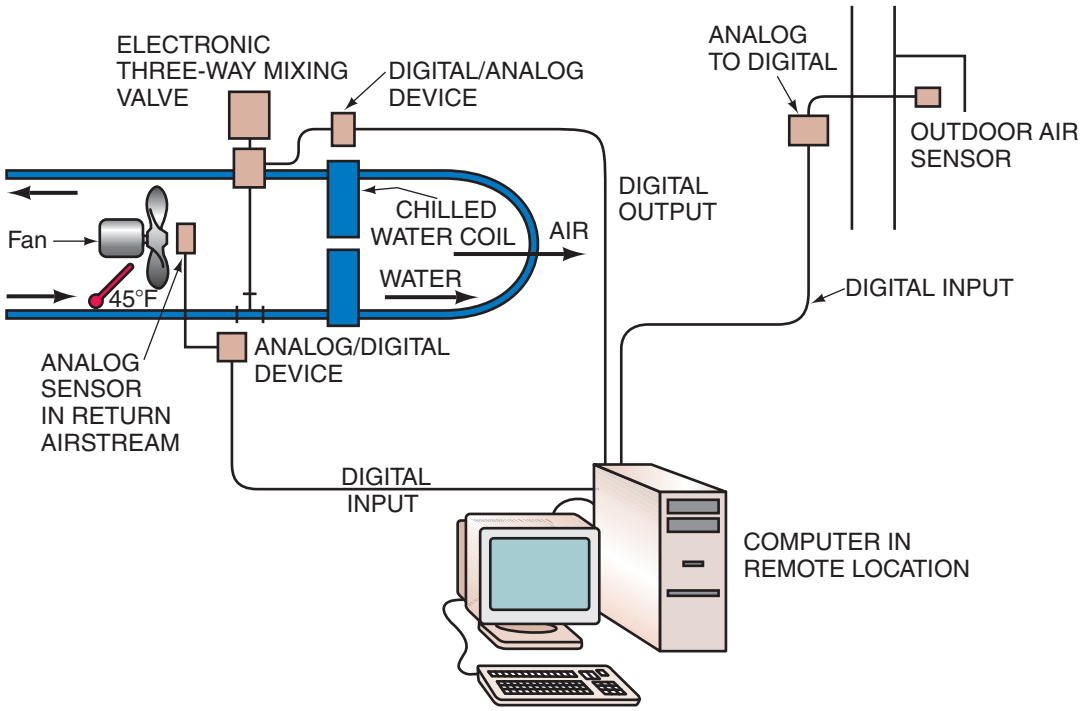
Figure 16.28 The analog signal from the return air sensor is changed to a digital signal and analyzed by the computer to allow more or less chilled water to flow through the chilled water coil to maintain space temperature.



5 V at 75°F. The three-way mixing valve should be bypassing about 50% of the water, and 50% should be passing through the coil to cool the air. This should result in about a 5°F rise in the water temperature if it has a 10°F rise at full load. The coil is operating at about 50% capacity. If the return air temperature goes up to 76°F, the voltage will rise to 6.7 V and the three-way mixing valve will begin to allow more chilled water through the coil, bypassing less water. When the load begins to reduce, the sensor will alert the computer to tell the valve to bypass more water. The technician can use the DC voltage feature of the voltmeter to monitor these voltages and make adjustments. After checking the voltage at various points to determine how the controller is supposed to react, the technician can make changes accordingly. The reason for using a three-way mixing valve for this system is that the central water chiller must have a constant flow through it. It is not like the boiler and hot water coil used in the pneumatic example. If too many chilled water coils were to shut down using straight-through valves instead of bypassing the water, the chiller would be in danger of approaching freezing conditions that could result in damage. It is customary to use mixing valves for chilled water circuits.

There is a lot of versatility in these control arrangements, particularly for large buildings, **Figure 16.29**. These control advantages are beginning to be incorporated into residential systems because the commercial systems have been proven to work. Electronic control components, like computers, are becoming more affordable for the average person.

Many old buildings are still outfitted with pneumatic controls, and it is not cost-effective to replace them. This is what makes the DDC system so versatile. DDC systems can be meshed in with the older systems for less cost than a complete building update. Both control systems are reliable and work well together when the system is designed correctly. Again, it is best to have the designer's prints to know what is really expected of a system.

16.7 RESIDENTIAL ELECTRONIC CONTROLS

Technicians have been dealing with electronic controls in residential systems for many years, often without knowing it. The residential oil burner control board is an example. Some technicians seem to be afraid of the word *electronics*, but it is not necessary to have the knowledge of a radio or TV technician to work with the electronic controls in the HVAC/R industry. We do not check out the individual components like the TV technician; we work with complete circuit boards. We use manufacturers' diagnostic systems or treat the circuit board as a switch in many cases. Many systems use error messages at the thermostat or blinking light-emitting diodes (LEDs) as codes for problems. Manufacturers' literature has become vital for troubleshooting. Attending manufacturers'

service classes will help you understand their goals for the equipment and controls.

Electronics are used in virtually every type of equipment today. The electronic thermostat often uses thermistors to control temperature. Recall the discussion about thermistors from Unit 12, "Basic Electricity and Magnetism". A thermistor changes resistance with a change in temperature. Thermistors are very small and respond quickly to a temperature change, and they can send a different signal for a different temperature. **Figure 16.30** shows a thermistor temperature and resistance graph. The thermistor can be tested with a quality ohmmeter. Just record the temperature of the actual element with an accurate thermometer and check out the plot on a graph for that thermistor. The change in temperature of the thermistor can be used in electronic circuits to monitor temperatures throughout the system and send

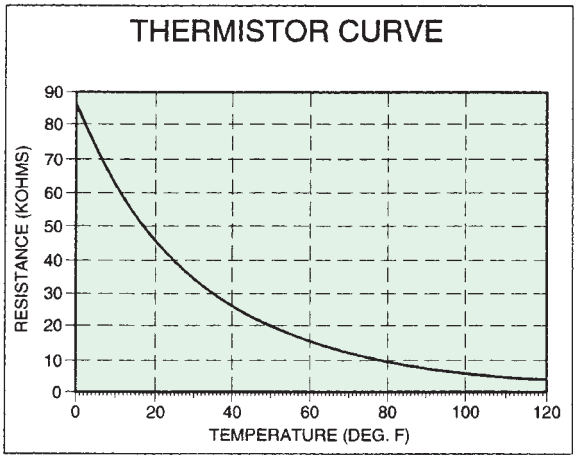
Figure 16.30 This is a temperature-resistance graph for a thermistor. The technician can use this graph, a thermometer, and an ohmmeter to test a thermistor for accuracy.

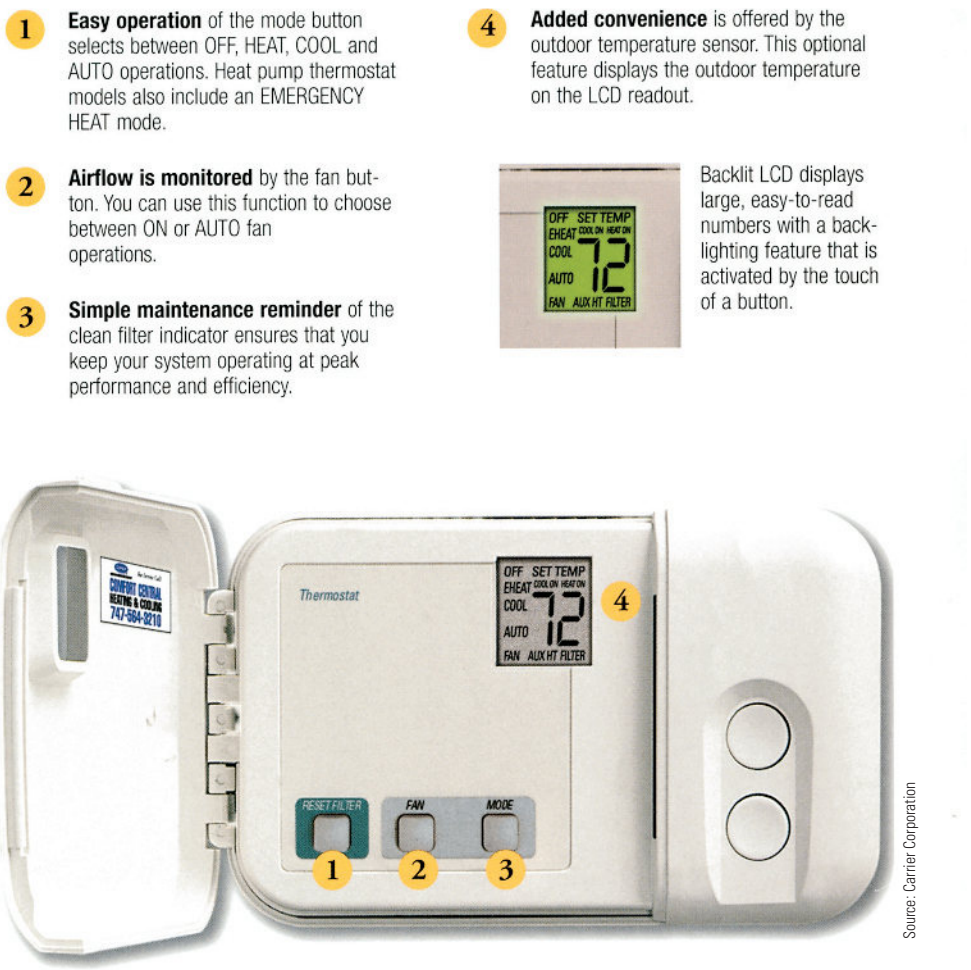


information to the circuit board that contains a computer chip, a small computer. It can, in turn, respond and cause a change in conditions. Space temperature is not the only temperature that is important in modern systems. Other temperatures that may be important are the following:

- Discharge-line temperature
- Motor-winding temperature
- Return air temperature
- Suction-line temperature
- Liquid-line temperature
- Flue-gas temperature
- Outdoor temperature
- Supply air temperature
- Indoor temperature

Figure 16.31 shows an electronic thermostat that performs many functions other than just turning the equipment on and off. This thermostat can be used with a two-stage

Figure 16.31 The electronic thermostat can perform many functions that could not be accomplished with earlier thermostats.



Source: Carrier Corporation

cooling or heating system and is fully programmable for different events 7 days per week. *It is suitable for a working family that wants to change the space temperature at night and during the day while at work and then have the space temperature brought back to the comfortable set point while at home. It can be programmed to stay at the comfortable set point for weekends and to go to setback functions for vacations. This is typical of many versatile thermostats on the market.*

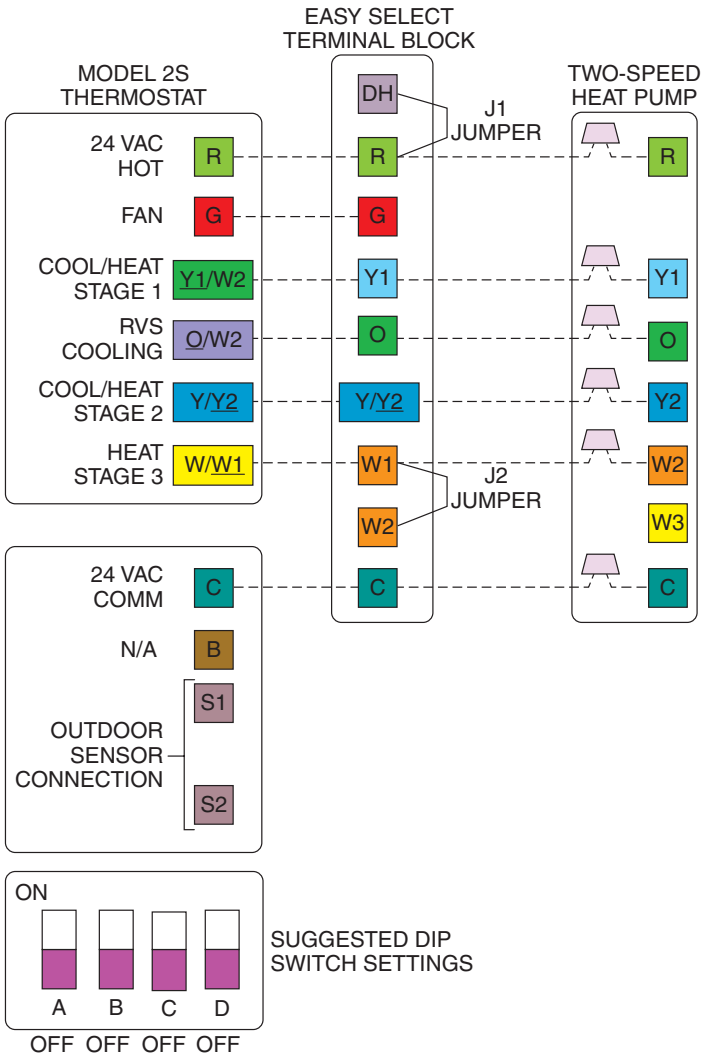
Some of the functions of this thermostat are

- 3-minute compressor off time to prevent compressor short cycling
- 15-minute cycle timer to prevent the heating system from short cycling
- 15-minute stage timer to prevent the second-stage heat from starting up too soon
- 3-minute minimum on timer for staged heat
- Heat/cool set points for desired temperature
- Auto changeover from heat to cool and back
- Emergency heat mode for heat pumps
- Power-on check
- Low-voltage check
- Error codes for thermostat operation, line-voltage drops, and outdoor temperature sensor problems
- Outdoor temperature smart recovery that tells the system when to restart the equipment after night or day setback.

The thermostat has some small switches in the back that are called dual in-line pair (DIP) switches. These allow the technician to set the thermostat up for the particular piece of equipment it is controlling. Using DIP switches and following the wiring diagram for the particular installation will give the customer the desired type of control over the equipment. **Figure 16.32** is the wiring diagram and DIP switch setup for a two-speed heat pump operated with a variable-speed fan coil. The two-speed heat pump (two speeds are achieved with a combination two- and four-pole compressor motor) allows the system to operate at 50% compressor capacity in cooling and heating, and the reduced fan speed is used to keep the air temperature up in winter and control humidity removal in the summer. This adds a lot of capabilities to the system, and it is all accomplished with electronics. Other versions of this thermostat have an actual humidity control that varies the fan speed to remove more or less moisture, which is a great advantage because the equipment is shipped all over the country, to desert low-humidity regions and to the southern coastal regions where humidity is very high.

The outdoor unit for a heat pump also has some electronics that the technician will be interested in. The circuit board in the outdoor unit receives a signal from the thermostat asking it to either heat or cool, at either high or low speed. When all is well, there is nothing to worry about. Suppose the technician arrives at the job because of a service complaint of no heat. What should be done first?

Figure 16.32 This diagram shows the field control wiring diagram and the DIP switches that must be set up for the various configurations that the thermostat can accomplish.



- Check the thermostat to see if the indoor fan will run. If not, check the power supply.
- Make sure there is power to the indoor unit, which may be under the house or in the attic.
- When power is established, make sure the indoor fan will run; then verify power to the outdoor unit. Make sure the thermostat is calling for it to operate.

When all signs seem to call for operation at the outdoor unit and it will not run, remove the cover and look at what the manufacturer recommends. **Figure 16.33** is a table called an LED control function light code that shows the status lights

for this particular manufacturer's equipment. This chart is typical of what the technician can expect. During the service call, the technician can look at the status lights and see what is supposed to be happening. If the equipment is supposed to be running and is not running, more investigation is in order.

The manufacturer will supply a trouble chart to take the technician to the next step. Manufacturers are working to design more efficient equipment with unique features. Installers and service technicians must keep up-to-date. Most contractors try to work with one or two brands of equipment so that their installers and service technicians can be efficient with those systems.

Figure 16.33 This chart shows the control function light codes for this particular system.

NOTE: A Signal (code) is not sent through the L lead to thermostat unless a failure has occurred.

LED Control Function Light Code		
CODE	**DEFINITION**	*
Constant flash No pause	No demand Stand by	9
1 flash w/pause	Low-speed operation	8
2 flashes w/pause	High-speed operation	7
3 flashes w/pause	Outdoor ambient thermistor failure	6
4 flashes w/pause	Outdoor coil thermistor failure	5
3 flashes pause 4 flashes	Thermistor out of range+	4
5 flashes w/pause	Pressure switch trip (LM1/LM2)	3
6 flashes w/pause	Compressor PTC's out of limit	2
Constant light No pause No flash	Board failure	1

Based on Carrier Corporation

* Function light signal order of importance in case of multiple signal request; 1 is most important.
+ Check both thermistors to determine which is faulty.

SUMMARY

- Modern control systems use modulating controls as well as on/off control systems.
- A basic control loop has a sensor, controller, and something to be controlled.
- In a home air-conditioning system the thermostat is the sensor, the contactor is the controller, and the compressor (with its associated fans) is the controlled device.
- Pneumatic controls are explosion-proof, simple, safe, and reliable.
- Since pneumatic controls use air, they can often be heard repositioning as the air bleeds from the control.
- Direct digital control (DDC) is a control process in which a microprocessor, acting as a digital controller, constantly updates a database of internal information. Through sensors, the microprocessor updates this information by watching and monitoring information from an external controlled environment or conditioned space. The microprocessor then continually produces corrections and outputs this corrected information to the controlled environment.
- Computers are used to create logic in control systems and make possible the coordination of many more features and control points.
- DDCs and pneumatic controls may be used together; therefore, older systems can be updated with DDC systems.
- Modern electronic controls have been developed, tried, and proven in commercial systems and are now being used in many residential applications.
- The residential technician does not have to be an electronic technician to troubleshoot electronic systems. Many of these systems have built-in diagnostics.
- The electronics control temperature, humidity, air, and refrigerant flow in residential systems.

REVIEW QUESTIONS

1. True or False: Pneumatic controls are explosion-proof.
2. Pneumatic controls are operated by
   A. water.
   B. electricity.
   C. electronics.
   D. air.
3. One advantage of a modern control system is
   A. simplicity.
   B. faster response.
   C. ability to modulate.
   D. that they are less expensive.

4. A control loop contains _____, _____, and _____.
5. Pneumatic air must
   A. be clean and dry.
   B. have very high pressure.
   C. encompass a large volume.
   D. be hot.
6. The air supplied to a diaphragm is 20 psig, and the diaphragm has a diameter of 6 in. How much pressure can this diaphragm apply to a plunger?
7. When a large volume of air is needed at a diaphragm, the thermostat may feed branch line pressure to the _____.
8. Which are the typical tools that a pneumatic control technician would use?
   A. Gauge manifold and nitrogen cylinder
   B. Flue-gas analyzer and thermometer
   C. Flaring tools, adjustable wrench, and screwdriver
   D. Pressure gauge, Allen wrench, and pocket thermometer
9. True or False: Electronic controls operate on either low voltages or milliamperes.
10. An analog control signal
    A. has an infinite number of control steps.
    B. is very limited in the number of control steps.
    C. makes a hissing noise when the position is changed.
    D. is not used in this industry.
11. Another term used to describe sensitivity in electronic controls is
    A. temperature.
    B. gain.
    C. rpm.
    D. pressure.
12. One of the advantages of DDCs is
    A. total building control management.
    B. that they are simple.
    C. that no air compressor is needed.
    D. that they operate on high voltage.
13. True or False: Electronic controls have been used in the residential industry for a long time.
14. One of the major components of a residential electronic control circuit that measures temperature is a
    A. thermometer.
    B. thermistor.
    C. capacitor.
    D. filter.
15. True or False: Diagnostic light-emitting diodes are often used to alert the technician to problems.
16. Describe a final control device, and give three examples of these devices used in a DDC system in today's HVAC/R industry.
17. Describe what a sensor does in a DDC system used in today's HVAC/R industry, and list five examples of sensors.
18. What is the difference between an active and a passive sensor used in DDC control systems?
19. A control system consists of what three basic components?
20. List six advantages that DDC control systems have over traditional control systems.
21. Describe the difference between the analog and digital signals in a DDC control system.
22. Describe the difference between an open-loop and a closed-loop control configuration in a DDC system.

ELECTRIC MOTORS

Units

Unit 17 Types of Electric Motors
Unit 18 Application of Motors
Unit 19 Motor Controls
Unit 20 Troubleshooting Electric Motors

UNIT 17

TYPES OF ELECTRIC MOTORS

OBJECTIVES

After studying this unit, you should be able to

- describe the different types of open single-phase motors used to drive fans, compressors, and pumps.
- describe various types of motor applications.
- state which motors have high starting torque.
- list the components that cause a motor to have a higher starting torque.
- describe a multispeed, permanent, split-capacitor motor and indicate how the different speeds are obtained.
- explain the operation of shaded pole motors.
- explain potential and current motor relays and positive temperature coefficient resistors (PTCRs).
- explain the operation of a three-phase motor.
- describe a motor used for a hermetic compressor.
- explain the motor terminal connections in various compressors.
- describe the different types of compressors that use hermetic motors.
- describe the use of variable-speed motors, inverters, variable frequency drives (VFDs) and electronically commutated motors (ECMs).

17.1 USES OF ELECTRIC MOTORS

Electric motors are used to turn the prime movers of air, water, and refrigerant, which are the fans, pumps, and compressors, **Figure 17.1**. Several types of motors, each with its particular use, are available. For example, some applications need motors that will start under heavy loads and develop their rated work horsepower under continuous running conditions. Some motors run for years in dirty operating conditions, and others operate in a refrigerant atmosphere. These are a few of the typical applications of motors in the HVAC/R industry. The technician must understand which motor is suitable for each job in order to troubleshoot effectively and, if necessary, to replace a motor with the proper type. But the basic operating principles of an electric motor must first be understood. Although there are many types of electric motors, most operate on similar principles.

17.2 PARTS OF AN ELECTRIC MOTOR

Electric motors have a **stator** with windings, a **rotor**, **bearings**, **end bells**, **housing**, and some means to hold these parts in the proper position, **Figure 17.2** and **Figure 17.3**. The stator is a winding that, when energized, will generate a magnetic field—because there will be current flowing through it. The rotor is the rotating portion of the motor and is made of iron or copper bars bound on the ends with aluminum. The rotor is not wired to the power source like the stator is. The motor shaft is connected to the rotor; therefore, when the rotor turns, so does the motor shaft. The motor's bearings allow for low-friction rotation of the rotor. Bearings help reduce the friction

Figure 17.1 (A) Fans move air. (B) Pumps move water.

Figure 17.2 A cutaway of an electric motor.

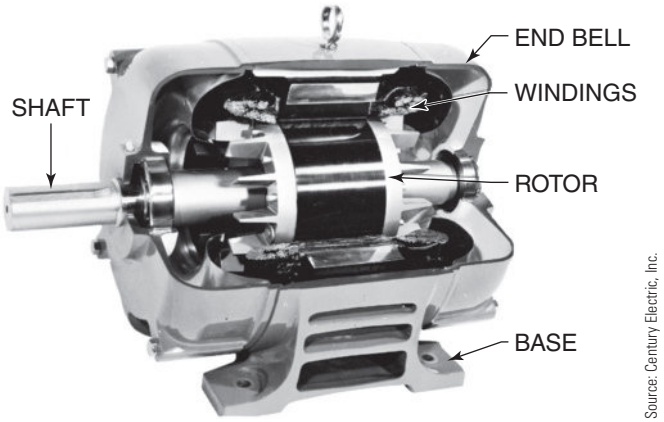

Figure 17.3 Individual electric motor parts.

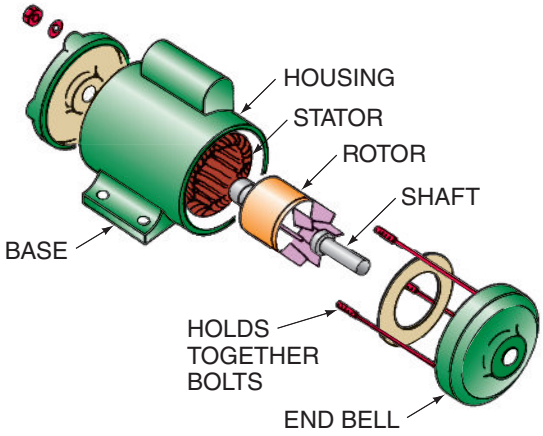
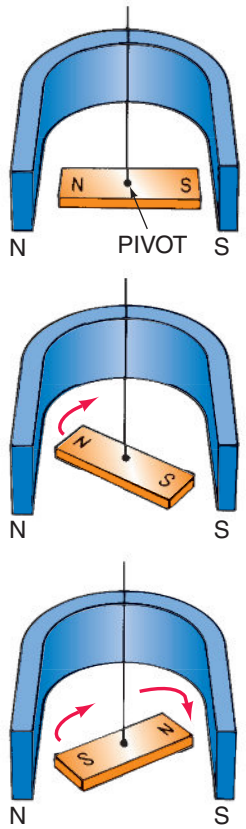


and the heat generated by the motor's moving and rubbing parts and surfaces. The motor housing, end bells, and base hold the motor components in place and provide a means for securely mounting the motor itself.

17.3 ELECTRIC MOTORS AND MAGNETISM

Electricity and magnetism are used to create the rotation in an electric motor to drive the fans, pumps, and compressors. Magnets have two different electrical poles, north and south. Unlike poles of a magnet attract each other, and like poles repel each other. If a stationary horseshoe magnet were placed with its two poles (north and south) at either end of a free-turning magnet as in **Figure 17.4**, one pole of the free-rotating magnet would line up with the opposite pole of the horseshoe magnet. If the horseshoe magnet were an electromagnet and the wires on the battery were reversed, the poles of this magnet would reverse, and the poles on the free magnet would be repelled, causing it to rotate until the unlike poles again were

Figure 17.4 Poles (north and south) on a rotating magnet will line up with the opposite poles on a stationary magnet.

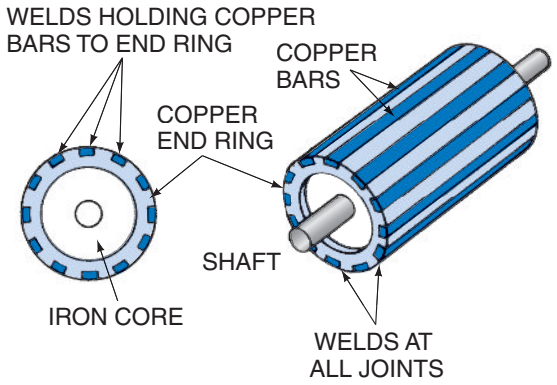


lined up. This is the basic principle of electric motor operation. In this example, the horseshoe magnet acts as the stator, and the free-rotating magnet acts as the rotor.

In a two-pole split-phase motor, the stator has two poles with insulated wire windings, called the **run windings**. When an electrical current is applied, these poles become an electromagnet with the polarity changing constantly. In normal 60-cycle operation, the polarity changes 120 times per second.

The rotor may be constructed of bars, **Figure 17.5**, a type called a **squirrel cage rotor**. The rotor is positioned

Figure 17.5 A simple sketch of a squirrel cage rotor.



between the run windings. When an alternating current (AC) is applied to these windings, a magnetic field is produced in the windings and is also induced in the rotor. The bars in the rotor actually form a coil. This is similar to the field induced in a transformer secondary by the magnetic field in the transformer primary. The field induced in the rotor has a polarity opposite to that in the run windings. The opposite poles of the run winding are wound in different directions. If one pole is wound clockwise, the opposite pole would be wound counterclockwise. This would set up opposite polarities for the attraction and repulsion forces that cause rotation.

The attracting and repelling action between the poles of the run windings and the rotor sets up a rotating magnetic field and causes the rotor to turn. Since this is AC reversing 60 times per second, the rotor turns, in effect "chasing" the changing polarity in the run windings. The motor will continue to rotate as long as power is supplied. The motor starting method determines the direction of motor rotation. The motor will run equally well in either direction.

17.4 DETERMINING A MOTOR'S SPEED

In the United States, AC power is supplied at a frequency of 60 hertz (Hz, or cycles per second). This means that in a 1-sec time interval, 60 complete sine waves are generated. From this, we can conclude that one cycle is completed in 1/60 (one-sixtieth) of a second. During this very brief instant, the direction of current flow changes twice, **Figure 17.6**. This means that every second, the current changes direction 120 times.

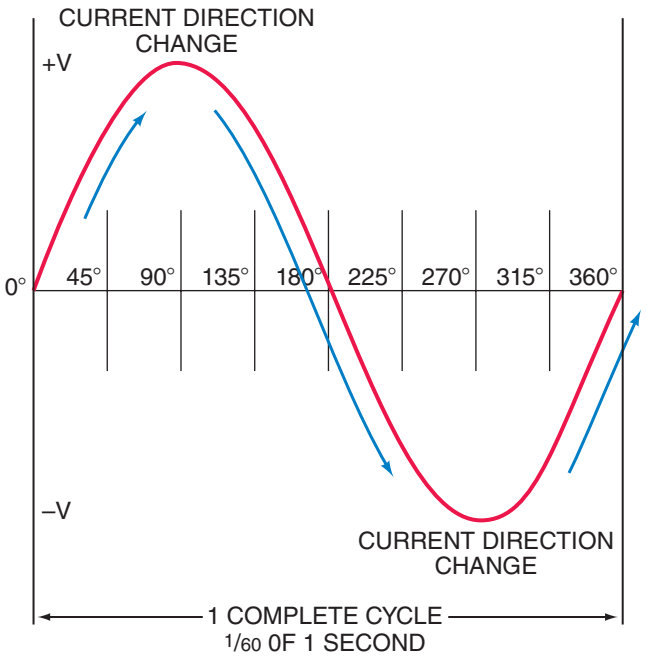
Referring back to our horseshoe magnet example, **Figure 17.4**, the rotating bar magnet will come to rest when the north pole of the bar magnet is aligned with the south pole of the horseshoe magnet and when the south pole of the bar magnet is aligned with the north pole of the horseshoe magnet. So, in order for the bar magnet to turn 360 degrees, or one full rotation, the horseshoe magnet must change the polarity of its poles twice. We are discussing AC power; therefore, during each sine wave, the current changes direction twice each cycle. So, the rotor of a motor with two poles, as in our bar magnet example, will turn 60 times every second, or 3600 times a minute. The more poles a motor has, the slower the motor will turn.

The following formula can be used to determine the synchronous speed (without load) of motors in rpm, or rotations per minute:

$$S\,(\text{rpm}) = \frac{\text{Frequency} \times 120}{\text{Number of poles}}$$

NOTE: *The magnetic field builds and collapses twice each cycle (each time it changes direction); the 120 is a time conversion that changes seconds into minutes. It is also a conversion from the motor's pole pairs (poles/2) to the actual number of poles.* •

Figure 17.6 The direction of current flow changes twice during each cycle.



$$\text{Speed of Two-Pole, Split-Phase Motors} = \frac{60 \times 120}{2}$$

$$= 3600 \text{ rpm}$$

$$\text{Speed of Four-Pole, Split-Phase Motors} = \frac{60 \times 120}{4}$$

$$= 1800 \text{ rpm}$$

The speeds indicated above are the calculated speeds and not the actual speeds at which the motor will turn. Internal motor component friction and the mechanisms or drives to which the motor is connected add a certain amount of resistance to rotation. This resistance, referred to as the motor **slip**, is often expressed as a percentage. Motor slip represents the difference between the motor's calculated and actual speeds. Our 3600 rpm motor actually turns at a speed of about 3450 rpm. We can calculate slip as follows:

$$\text{Motor Slip (\%)} = \frac{\text{Calculated Motor speed} - \text{Actual Motor Speed}}{\text{Calculated Motor Speed}} \times 100$$

In this example we have the following:

$$\text{Motor Slip (\%)} = \frac{3600 - 3450}{3600} \times 100$$

$$= \frac{150}{3600} \times 100$$

$$= 4.17\%$$

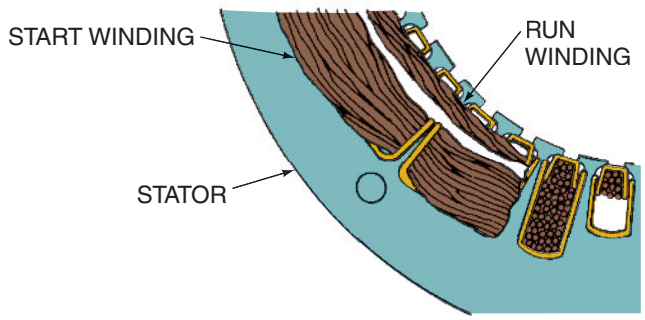
It is left as an exercise for the reader to verify that the motor slip for an 1800-rpm motor that is turning at 1725 rpm is also 4.17%. Excessive motor slip can be an indication of improper motor lubrication, defective motor bearings, poorly adjusted belts (too tight), or an improperly selected motor for the desired application (overloaded).

17.5 START WINDINGS

The preceding explanation does not include how the motor rotation is started. This is accomplished by using a separate motor winding called the start winding. The start winding is wound next to the run winding but is a few electrical degrees out of phase with the run winding. This design is much like the pedals on a bicycle—if both pedals were at the same angle, it would be very hard to get started. The start winding is in the circuit only for as long as it takes the rotor to get close to its rated speed, and it then is electrically disconnected, **Figure 17.7**. The start winding has more turns than the run winding and is wound with a smaller diameter wire. Opposite poles of the start winding are wound in different directions. If one pole is wound clockwise, then the opposite pole would be wound counterclockwise. This sets up opposite polarities for the attraction and repulsion forces that cause rotation and produces a larger magnetic field and greater resistance, which helps the rotor to start turning and determines the direction in which it will turn. Because this winding is located between the run winding, it changes the phase angle between the voltage and the current in the windings.

We have just described a two-pole split-phase **induction motor**, which is rated to run at 3600 revolutions per minute (rpm). It actually turns at a slightly slower speed when running under full load. When the motor approaches its normal speed, the start winding is often removed from the circuit, leaving only the run windings energized. Many split-phase motors have four poles and run at 1800 rpm.

Figure 17.7 The placement of the start and run windings inside the stator.



17.6 STARTING AND RUNNING CHARACTERISTICS

Two major considerations in electric motor applications are the starting and running characteristics. A motor that runs a refrigeration compressor must have a high starting **torque**—it must be able to start under heavy starting loads. Torque is the twisting power of the motor shaft. The starting torque is the power to turn the shaft from the stopped position. The motor must also have enough torque to operate under the load of the application. Some motors must have a great deal of starting torque to turn the motor from the stopped position but do not need a great deal of torque to maintain speed. For example, systems equipped with capillary tubes can typically use compressors with low starting torque, as the system pressures can equalize during the off cycle. Some systems with thermostatic expansion valves (TXV) require greater starting torque, as there may be a pressure differential across the compressor even when the compressor is not operating.

Motors have two different current ratings, full-load or rated-load amperes (FLA or RLA) and locked-rotor amperes (LRA). Locked-rotor amperage is often referred to as inrush current. When a motor is still, it takes a great deal of torque to get it turning, particularly if it has a load on start-up. Typically, the LRA for a motor is about five times the FLA/RLA. For example, suppose a compressor operates on 25 A when at full load. This same compressor will pull about 125 A for just a moment on start-up. As the motor gets up to speed, the amperage will reduce to FLA, 25 A. Since this inrush of current is of short duration, it does not figure in the wire sizing for the motor. A refrigeration compressor may have a head pressure of 155 psig and a suction pressure of 5 psig and be required to start in systems where the pressures do not equalize. The pressure difference of 150 psig is the same as saying that the compressor has a starting resistance of 150 psi of piston area. If this compressor has a 1-in.-diameter piston, the area of the piston is 0.78 in^2 ($A = \pi r^2$, or $3.14 \times 0.5 \times 0.5$). This area multiplied by the pressure difference of 150 psi is the starting resistance for the motor (117 lb), comparable to a 117-lb weight resting on top of the piston when it tries to start, **Figure 17.8**.

A motor does not need as much starting torque to start a small fan. The motor must simply overcome the friction needed to start the fan moving. There is no pressure difference because the pressures equalize when the fan is not running, **Figure 17.9**. A high starting load, called starting torque, puts more load on the compressor compared to the light load of the fan. These are two different motor applications and require two different types of motors. These applications will be discussed individually in this unit when we discuss the different types of motors.

Figure 17.8 A compressor with a high-side pressure of 155 psig and a low-side pressure of 5 psig.

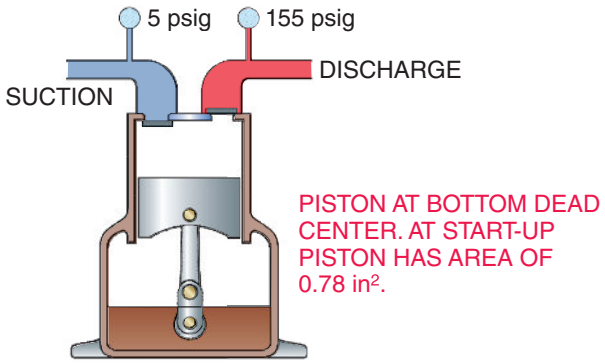


Figure 17.9 This fan has no pressure difference to overcome while starting. When the fan stops, the air pressure equalizes.

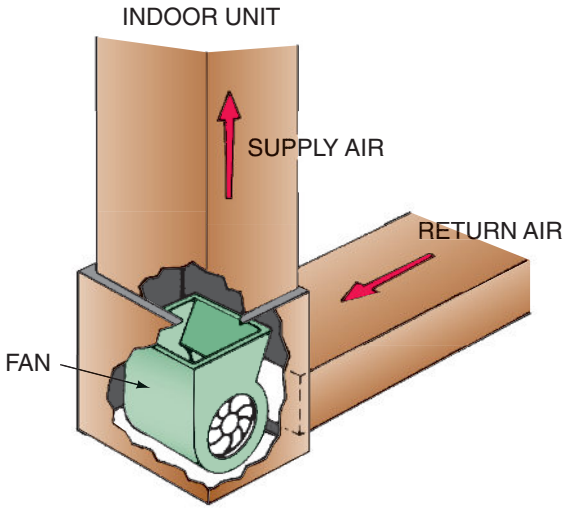

17.7 ELECTRICAL POWER SUPPLIES

The power company furnishes power to customers and determines the type of power supply. Power is moved across the country by means of high-voltage transmission lines to transformers that reduce the power to the voltage needed at the consumer level. Residences are typically furnished with a single-phase power supply (ϕ is the symbol often used for phase). The power pole to the house may look like the one in **Figure 17.10**. Several homes may be supplied by the same power-reducing transformer, which has three wires that pass through the meter base and on to the house electrical panel, where the power is distributed through the circuit protectors (circuit breakers or fuses) to the various circuits in the house and then to the power-consuming equipment, **Figure 17.11**. The power panel in the house would look like the illustration

Figure 17.10 A single-phase power supply.

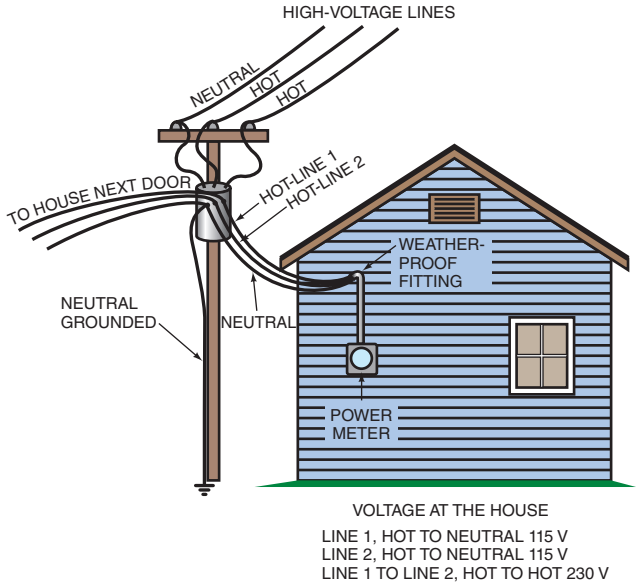

Figure 17.11 A wiring diagram of a main circuit breaker panel for a typical residence.

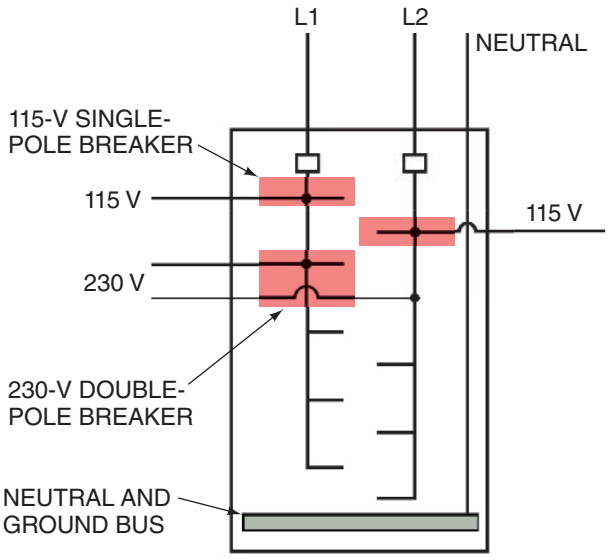

in **Figure 17.11**. Notice that it will furnish both 115-V and 230-V service. Typically, the 230-V service is used for the electric dryer, electric range, electric oven, many electric heat devices, and the air-conditioning. All other appliances are typically operated from the 115-V circuits.

Equipment in commercial buildings and factories is large enough to require three-phase power. A three-phase power supply may furnish several different voltage options:

A. 115-V single-phase for common appliances
B. 230-V single-phase for heavy-duty appliances

C. 230-V three-phase for large loads such as electric heat or motors
D. 460-V three-phase for large loads such as electric heat or motors
E. 277-V single-phase for lighting circuits (may be obtained between 460 V and neutral with certain systems)
F. 560-V three-phase for special industrial systems

The wiring for a typical three-phase system from the pole, which is furnished by the power company, may look like the illustration in **Figure 17.12**. The building could very well have made use of a 230-V three-phase power supply. One of the reasons for using 460-V three-phase is that it reduces the wire size to all components in the building, which reduces the materials and labor cost of the installation. The same load using 230 V would use twice the current flow, so the wire would have to be sized up to twice the current-carrying capacity. Many of the components in the building will need to operate from 115 V and maybe even 230 V, so a step-down transformer is used for equipment like small fans, computers, and office equipment. The step-down transformer enables the building to take advantage of the benefits of 460 V, 277 V, 230 V, and 115 V in the same system, **Figure 17.13**.

SAFETY PRECAUTION: *A technician must be very careful with any live power circuits. 460-V circuits are particularly dangerous, and the technician must take extra care while servicing them.* •

Figure 17.12 A 460-V, three-phase power supply to a commercial building.

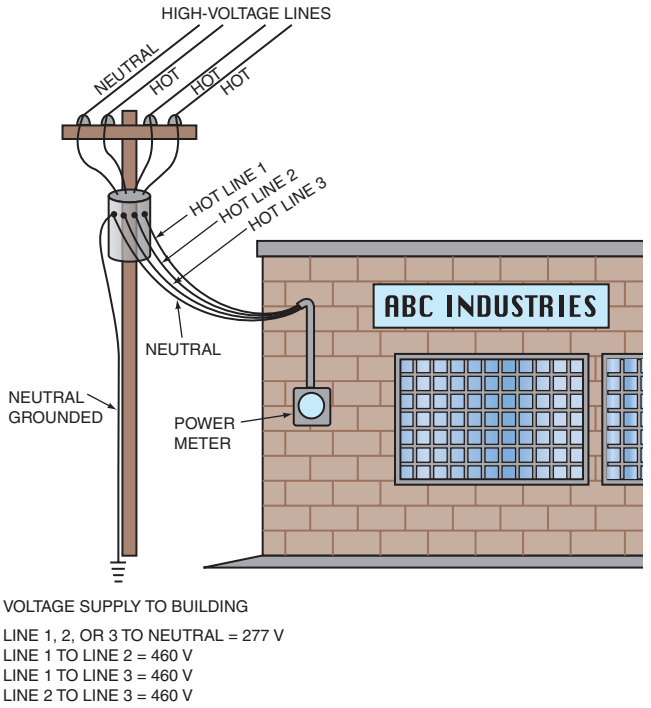

Figure 17.13 When a building has a 460-V power supply, it will have a step-down transformer to provide 115-V circuits to power office machines and small appliances.

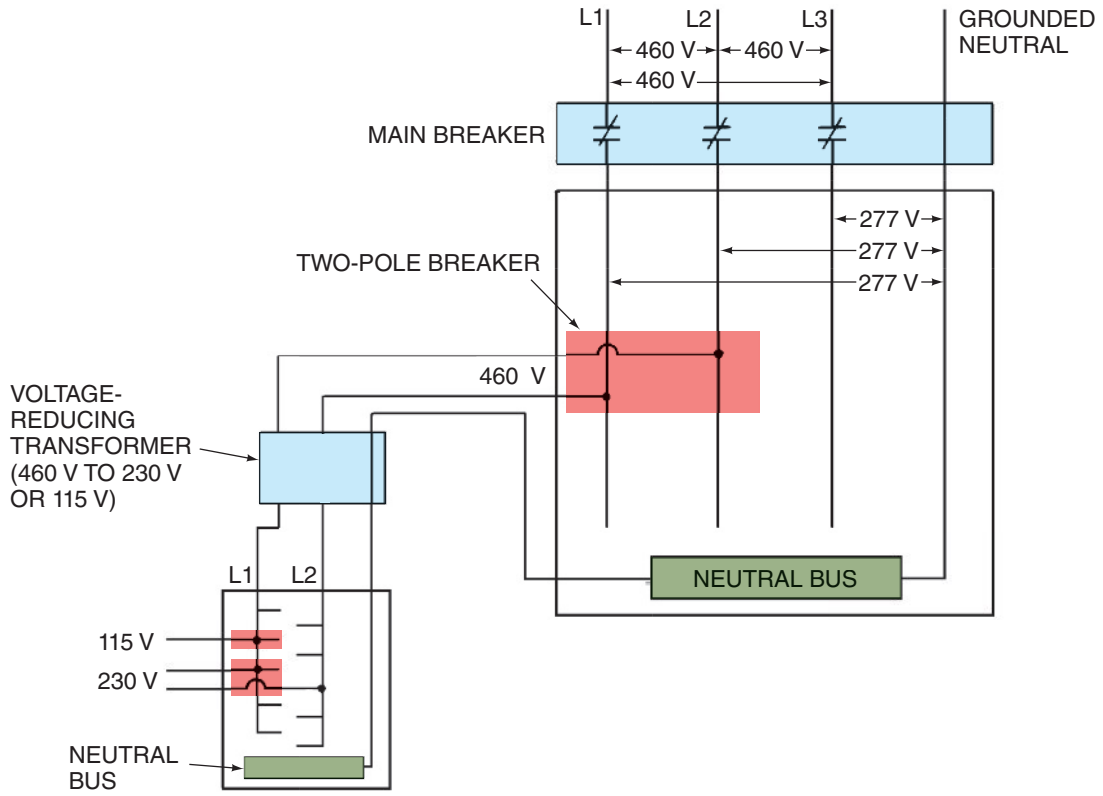

Following is a description of some motors currently used in the heating, air-conditioning, and refrigeration industry. We emphasize the electrical characteristics, not the working conditions. Some older motors are still in operation, but they are not discussed in this text.

17.8 SINGLE-PHASE OPEN MOTORS

The power supply for most **single-phase** motors is either 115 V or 208 V to 230 V. A home furnace uses a power supply of 115 V, whereas the air conditioner outside uses a power supply of 230 V. A commercial building may use either 208 V, 230 V, or 460 V, depending on the power company. Some single-phase motors can operate in dual voltage. They have two run windings and one start winding. The two run windings have the same resistance, and the start winding has a high resistance. The motor will operate with the two run windings in parallel in the low-voltage mode. When the high-voltage mode is required, the technician changes the numbered motor leads according to the manufacturer's instructions. This wires the run windings in series with each other and delivers an effective voltage of 115 V to each winding. The motor windings are actually only 115 V because they operate only on 115 V, no matter which mode they are in. The technician can change the wiring connections at the motor terminal box, **Figure 17.14**. Some commercial and industrial installations may use a 460-V power supply for large motors and reduce that to a lower voltage to operate smaller motors. The smaller motors may be single-phase and must operate from the same power supply, **Figure 17.13**.

Figure 17.14 The wiring diagram of a dual-voltage motor. This motor is designed to operate at either 115 V or 230 V, depending on how the motor is wired in the field. (A) A 230-V wiring diagram. (B) A 115-V wiring diagram.

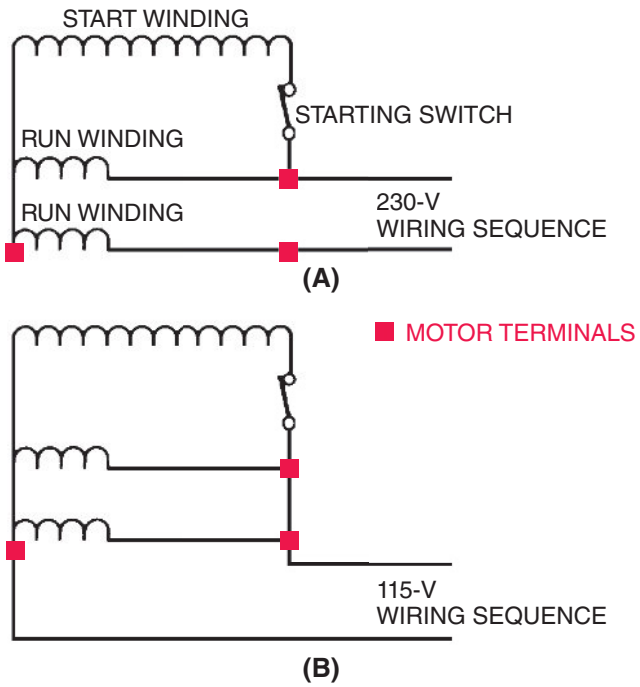

Figure 17.15 The direction of rotation of a single-phase motor can be reversed by changing the connections in the motor terminal box. This will change the direction of current flow through the start winding.

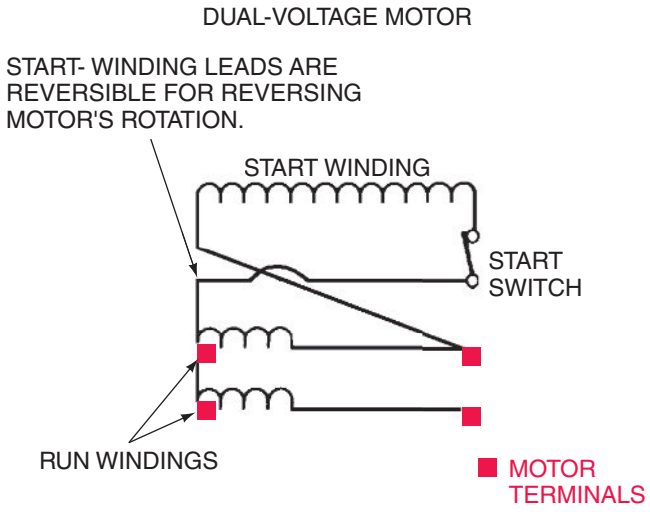

A single-phase motor can rotate clockwise or counterclockwise. Some are reversible from the motor terminal box, **Figure 17.15**. By reversing the start winding leads, the direction of current flow through the start winding is reversed, changing the charges of the poles. This will cause the motor to rotate in the opposite direction.

17.9 SPLIT-PHASE MOTORS

Split-phase motors have two distinctly different windings, **Figure 17.16**. They have a medium amount of starting torque and a good operating efficiency and are normally used for operating fans in the fractional horsepower range. The normal operating ranges are 1800 rpm and 3600 rpm. An 1800-rpm motor will operate at 1725 rpm to 1750 rpm under a load. If the motor is loaded to the point where the speed falls below 1725 rpm, the current draw will climb above the rated amperage. Motors rated at 3600 rpm will normally slip in speed to about 3450 rpm to 3500 rpm, **Figure 17.17**. Some of these motors are designed to operate at either speed, 1750 rpm or 3450 rpm. The speed of the motor is determined by the number of motor poles and by the method of wiring the motor poles. The technician can change the speed of a two-speed motor at the motor terminal box.

17.10 THE CENTRIFUGAL SWITCH

All split-phase motors have a start and run winding. The start windings must be disconnected from the circuit within a very short period of time or they will overheat. Several methods

Figure 17.16 Diagram of the split-phase motor start and run windings.

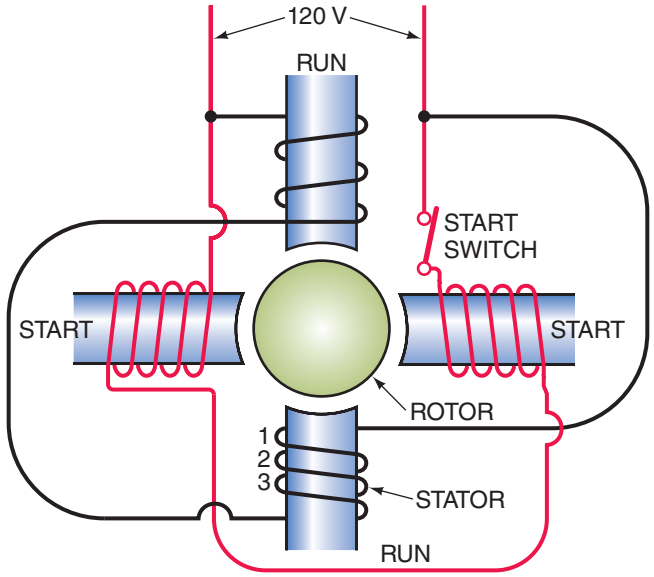

Figure 17.17 Motor speed changes depend on the load on the split-phase motor.

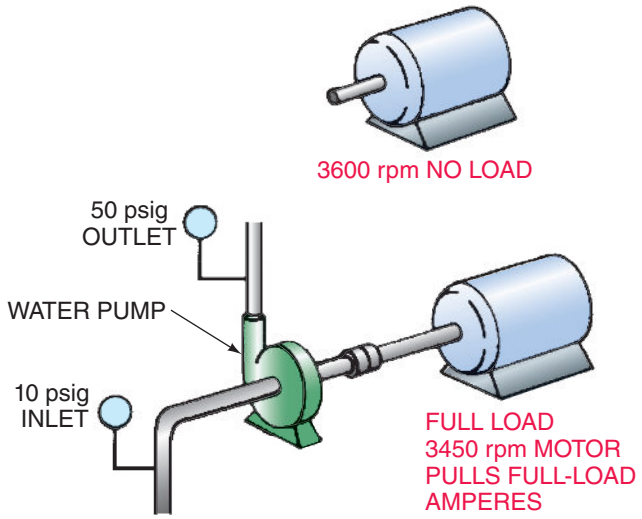
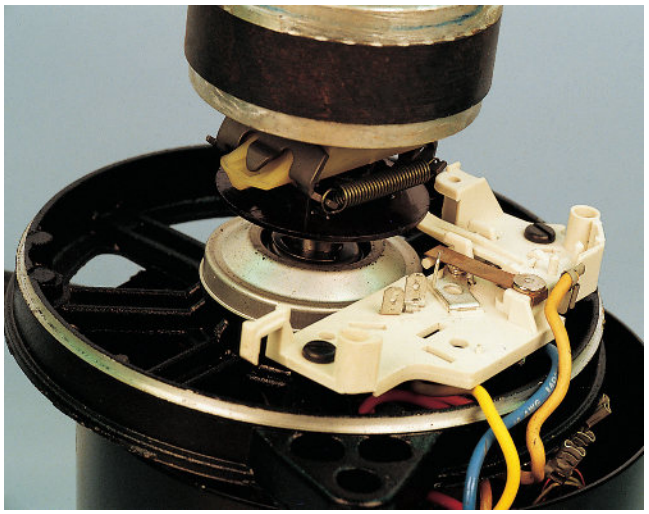


are used to disconnect the start windings. The centrifugal switch is the most common method in open motors; however, electronic start switches are sometimes used.

The **centrifugal switch** is used to disconnect the start winding from the circuit when the motor reaches approximately 75% of the rated speed. Motors described here are those that run in the atmosphere. (Hermetic motors that run in the refrigerant environment are discussed later in this unit.) When a motor is started in the air, the arc from the centrifugal switch will not harm the atmosphere. (It will harm the refrigerant, so there must be no arc in a refrigerant atmosphere.)

A centrifugal switch is a mechanical device attached to the end of the shaft with weights that will sling outward when the motor reaches approximately 75% speed. For example, if the motor has a rated speed of 1725 rpm, the centrifugal weights will change position at 1294 rpm (1725 × 0.75) and open a switch to remove the start winding from the circuit. This switch is under a fairly large current load, so a spark will occur. If the switch fails to open its contacts and remove the start winding, the motor will draw too much current, and the overload device will cause it to stop. When the motor is deenergized, it will slow down and the centrifugal switch will close its contacts in preparation for the next motor starting attempt. The more the switch is used, the more its contacts will burn from the arc. If this type of motor is started many times, the first thing that will likely fail is the centrifugal switch. This switch makes an audible sound when the motor starts and stops, **Figure 17.18.**

Figure 17.18 The centrifugal switch is located at the end of the motor.



17.11 THE ELECTRONIC RELAY

The **electronic relay** is used with some motors to open the start windings after the motor has started. This solid-state device is designed to open the start winding circuit when the design speed has been obtained. Other devices are also used to perform this function; they are described in the discussion of hermetic motors.

17.12 CAPACITOR-START MOTORS

The capacitor-start motor is basically the same motor as the split-phase motor, **Figure 17.19**. It has two distinctly different windings for starting and running. However, a start capacitor is wired in series with the start windings to give the motor more starting torque. **Figure 17.20** shows voltage and current cycles in an induction motor. In an inductive circuit the current *lags* the voltage. In a capacitive circuit, the current **leads** the voltage. The amount by which the current leads or lags the voltage is the *phase angle*. A capacitor is chosen to create a phase angle that it is the most efficient for starting the motor, **Figure 17.21**. The capacitor is not designed to be used while the motor is running, and it must be switched out of the circuit soon after the motor starts. This is done at the same time the windings are taken out of the circuit, and with the same switch.

Once the start winding and the start capacitor have been removed from the circuit, the motor will continue to operate with only the run winding energized. The rotating motor shaft and rotor will create, or induce, the needed imbalance in the magnetic field to keep the motor turning. For this reason, capacitor-start motors are often referred to as CSIR motors, which stands for capacitor-start-induction-run. A simplified wiring diagram for a CSIR motor is shown in **Figure 17.22**.

Figure 17.19 A capacitor-start motor.

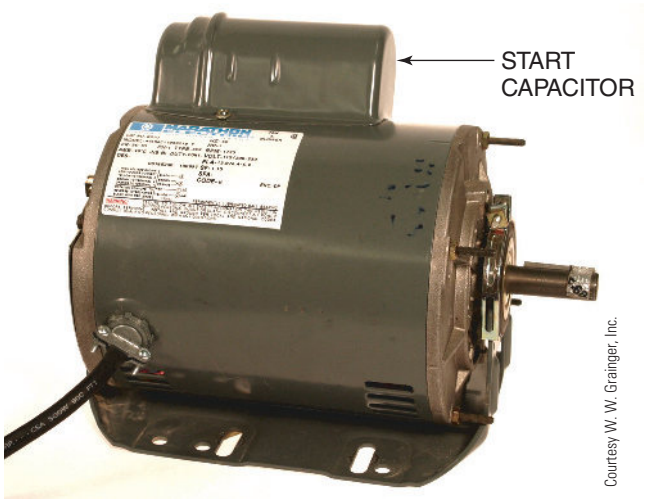


Figure 17.20 The current lags the voltage in an inductive circuit.

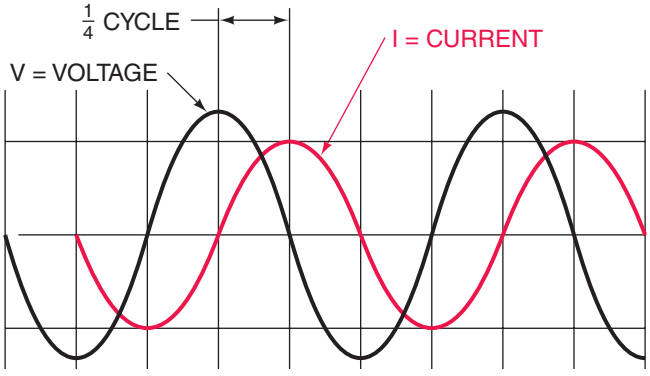

Figure 17.21 A start capacitor.

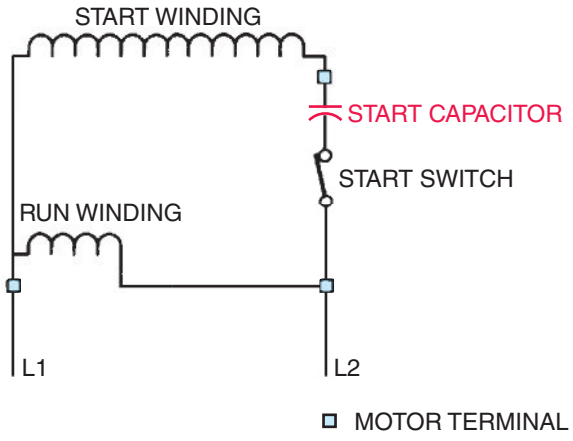
Figure 17.22 Wiring diagram of a capacitor-start motor.



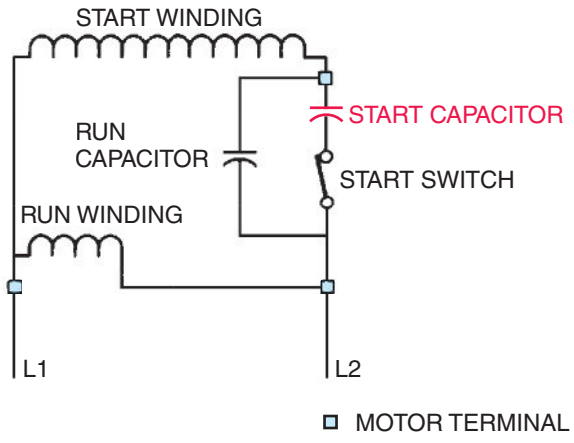
17.13 CAPACITOR-START, CAPACITOR-RUN MOTORS

Capacitor-start, capacitor-run motors are much the same as the split-phase motor. A run capacitor is wired into the circuit to provide the most efficient phase angle between the current and voltage when the motor is running and is in the circuit at any time the motor is running. Both the run and start capacitors are wired in series with the start winding but are in parallel to one another, **Figure 17.23**. The microfarad rating of the run capacitor is much lower than that of the start capacitor for any given motor application. The capacitances of two capacitors in parallel add their values the same as resistors do in series. If the run capacitor has a capacitance of 10 microfarads and the start capacitor has a capacitance of 110 microfarads, their total capacitance would add to be 120 microfarads. During start-up, this added capacitance in series with the start winding causes a greater phase angle between the run and start windings, which gives the motor more starting torque.

When the start switch opens, the start capacitor is taken out of the circuit. It is used for nothing but adding starting torque. However, the run capacitor and start winding stay in the circuit. The run capacitor stays in series with the start winding for extra running torque. The capacitor, being in series with the start winding during the running mode, also limits the current through the start winding so the winding will not get hot. If a run capacitor fails because of an open circuit within the capacitor, the motor may start, but the running amperage will be about 10% too high and the motor will get hot if operated at full load. The motor is actually a permanent split-capacitor (PSC) motor when running (PSC motors will be discussed in the next section). These motors are specially designed to have the start winding energized whenever the motor is energized, so be sure to use and wire the motor according to the manufacturer's recommendations and guidelines.

The capacitor-start, capacitor-run motor is one of the most efficient motors used in refrigeration and air-conditioning equipment. It is normally used with belt-drive fans and compressors. Belt-driven motor and blower assemblies offer a great deal of resistance to the motor when it initially starts because the motor must turn the pulley, which is connected to a belt, which is then connected to a pulley and blower assembly. The added starting torque is needed to help overcome this resistance. Once the motor starts, however, keeping it turning does not require the same amount of torque.

Figure 17.23 Wiring diagram of a capacitor-start, capacitor-run motor. The start capacitor is in the circuit only during motor start-up, whereas the run capacitor is in the circuit whenever the motor is energized.



17.14 PERMANENT SPLIT-CAPACITOR MOTORS

The PSC motor has windings very similar to those of the split-phase motor, **Figure 17.24**, but it does not have a start capacitor. Instead it uses one run capacitor wired into the circuit in a way similar to the run capacitor in the capacitor-start, capacitor-run motor. The run capacitor is connected to the L2 sides of the start and run windings. The PSC motor does not utilize a start switch as both the start and run windings, along with the run capacitor, are in the active electric circuit whenever the motor is energized. This is the simplest split-phase motor. It is very efficient and has no moving parts to start the motor; however, the starting torque is very low, so it can be used only in low-starting-torque applications, **Figure 17.25**.

A multispeed PSC motor can be identified by the many wires at the motor electrical connections, **Figure 17.26** and **Figure 17.27**. As the resistance of the motor winding decreases, the speed of the motor increases. When more resistance is wired into the circuit, the motor speed decreases. Most manufacturers use this motor in the fan section of air-conditioning and heating systems. Motor speed

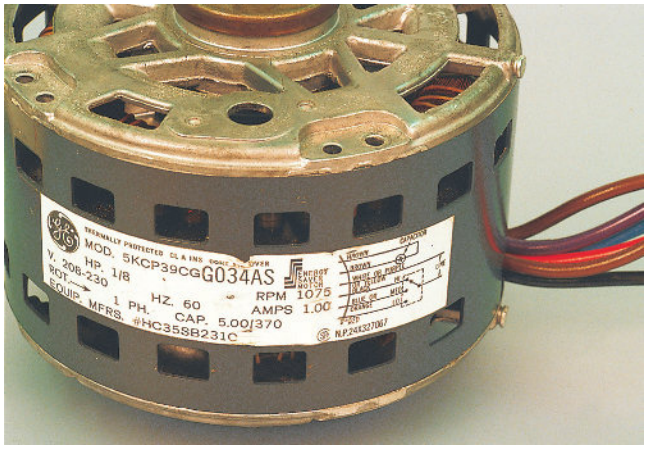

Figure 17.27 This diagram shows how the windings of a three-speed PSC motor are configured. As the winding resistance increases, the motor speed decreases.

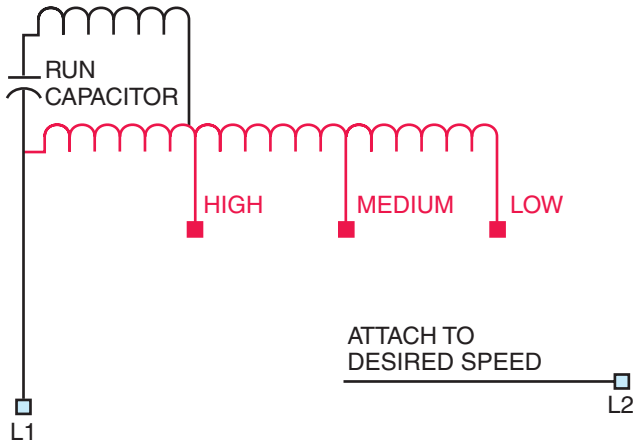
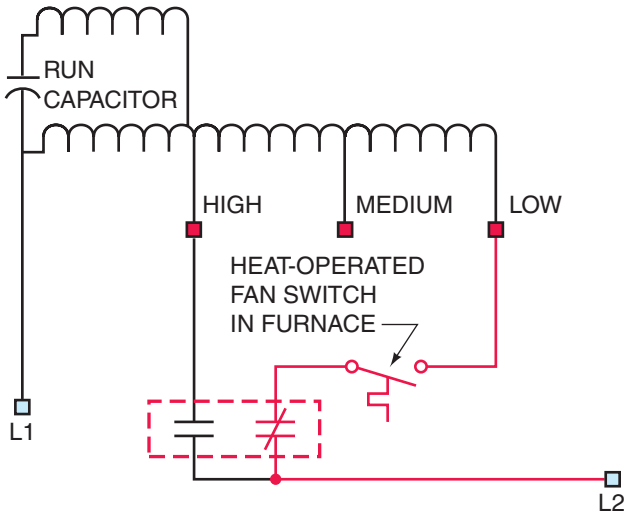


can be changed by switching the wires. Earlier systems used a capacitor-start, capacitor-run motor and a belt drive, and air volumes were adjusted by varying the drive pulley diameter. Many PSC motors are manufactured in 2-, 4-, 6-, and 8-pole designs. The speed in rpm of these motors depends on the frequency of the AC source and the number of poles wired in the motor. The higher the frequency, the faster the motor. The more poles there are, the slower the rpm of the motor. For 60-Hz operation, the rated or synchronous speeds would be 3600, 1800, 1200, and 900 rpm, respectively. However, due to motor slip, the actual speeds would be 3450, 1725, 1075, and 825 rpm.

The PSC motor may be used to obtain slow fan speeds during the winter heating season for higher leaving-air temperatures for gas, oil, and electric furnaces. The fan speed can be increased by switching to a different resistance in the winding using a relay. This will provide more airflow in summer to satisfy cooling requirements, **Figure 17.28**. The PSC fan motor also has another advantage over the split-phase motor in fan applications: It has a very soft start-up. When a split-phase motor is used for a belt-drive application, the motor, belt, and fan must get up to speed very quickly, which often creates a start-up noise. The PSC

Figure 17.28 Diagram showing how a multispeed PSC motor is wired to operate at low speed (lower air volume) in the winter and high speed (higher air volume) in the summer.



FAN RELAY: WHEN ENERGIZED, SUCH AS IN COOLING, THE FAN CANNOT RUN IN THE LOW-SPEED MODE. WHEN DEENERGIZED, THE FAN CAN START IN THE LOW-SPEED MODE THROUGH THE CONTACTS IN THE HEAT-OPERATED FAN SWITCH.

IF THE FAN SWITCH AT THE THERMOSTAT IS ENERGIZED WHILE THE FURNACE IS HEATING, THE FAN WILL MERELY SWITCH FROM LOW TO HIGH. THIS RELAY PROTECTS THE MOTOR FROM TRYING TO OPERATE AT 2 SPEEDS AT ONCE.

motor starts up very slowly, gradually getting up to speed, which is very desirable if the fan is close to the return air inlet to the duct system.

17.15 SHADED-POLE MOTORS

The shaded-pole motor has small starting windings or shading coils at the corner of each pole that help the motor start by providing an induced current and a rotating field, **Figure 17.29**. The location of the shading coil on the pole face determines the direction of rotation. For years the shaded-pole motor has been used in air-cooled condensers and evaporators to turn the fans, **Figures 17.30(A)** and **(B)**. On most shaded-pole motors, rotation can be reversed by disassembling the motor and turning the stator over, **Figure 17.30(C)**. This moves the shaded coil to the side opposite to the one the pole faces and reverses rotation. The motor has very little starting torque and is not as efficient as the PSC motor, so it is used only for light-duty applications. From the standpoint of initial cost, it is an economical motor and is normally manufactured in the fractional horsepower range.

17.16 THREE-PHASE MOTORS

Three-phase motors, which range from about 1 hp into the thousands of horsepower, have some characteristics that make them popular for many applications. The motors are very efficient and require no start assist for high-torque applications—they have no starting windings or capacitors. They are used mainly on commercial equipment, and the building power supply must have three-phase power available. (Three-phase power is seldom found in a home.)

Figure 17.31 Wiring diagram of a three-phase power supply.

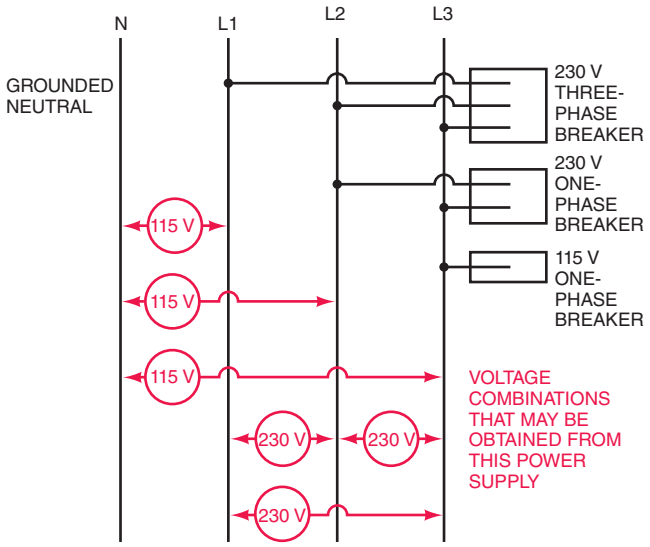

Figure 17.32 (A) Diagram of a three-phase power supply. (B) Diagram of a typical single-speed, three-phase motor.

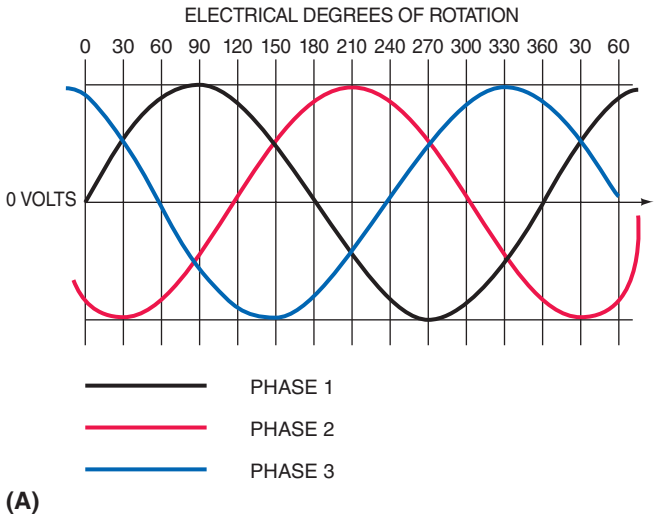
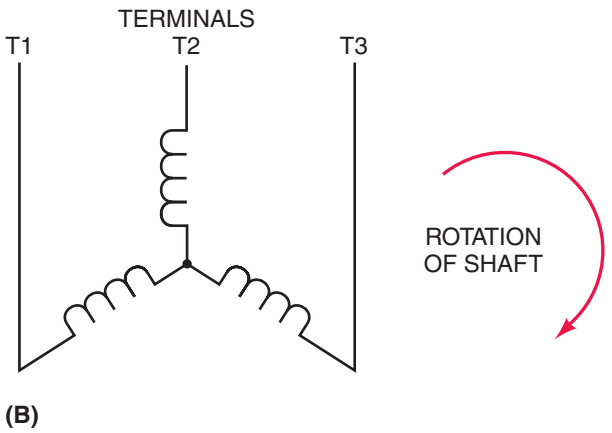


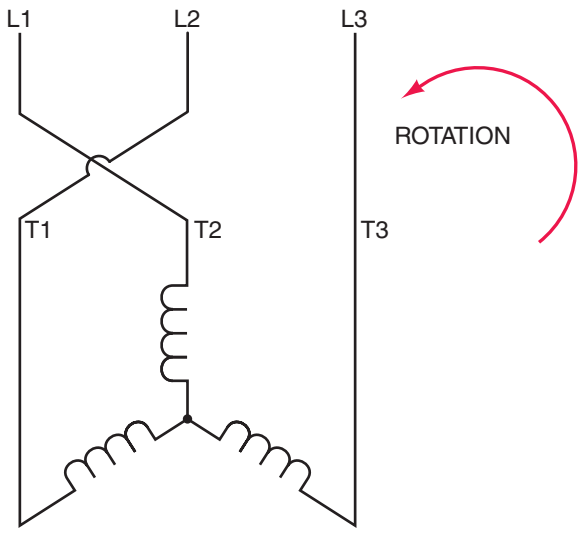


The motors can be thought of as having three single-phase power supplies, **Figure 17.31**, with each of the phases having either two or four poles. A 3600-rpm motor will have three sets, each with two poles (total of six), and an 1800-rpm motor will have three sets, each with four poles (total of 12). Each phase changes the direction of current flow at different times but always in the same order. A three-phase motor has high starting torque because of the three phases of current under which it operates. At any given part of the rotation of the motor, one of the windings is in position for high torque. This makes starting large fans and compressors very easy, **Figure 17.32**. The three-phase motor rpm slips to about 1750 rpm and 3450 rpm when under full load. The motor is not normally available with dual speed; it is either an 1800-rpm or a 3600-rpm motor.

Three-phase power supply consists of three single-phase power supplies that are generated 120 electrical degrees out of phase with each other. As can be seen in **Figure 17.32(A)**, phase number 1, indicated by the black sine wave, starts at "0" electrical degrees of rotation and has a potential of 0 volts. At 90 electrical degrees, phase number 1 has reached its maximum potential, and at 360 electrical degrees it has completed a full cycle. It can be seen that phases 2 and 3 start at 120 and 240 electrical degrees of rotation, respectively. All three of these phases are 120 degrees out of phase with each other. It should be noted that 120 degrees after the start of phase number 3 (which is at 360 electrical degrees), phase number 1 is ready to start another cycle.

The rotation of a three-phase motor may be changed by switching any two motor leads, **Figure 17.33**. The rotation must be carefully observed when it drives three-phase fans. If a fan rotates in the wrong direction, it will move only about half as much air. If this occurs, reverse the motor leads, and the fan will turn in the correct direction.

Figure 17.33 The direction of rotation of a three-phase motor can be reversed by switching any two power leads.

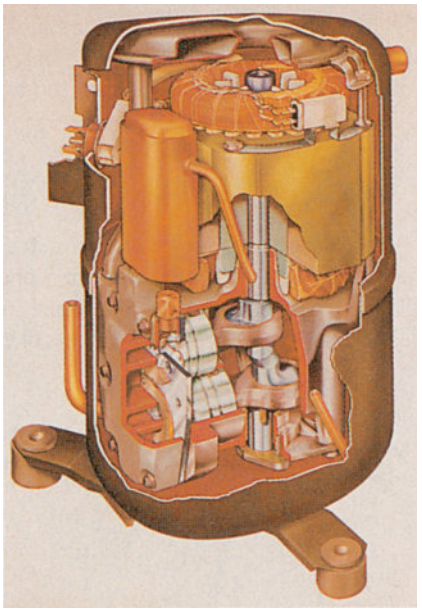


Motors have other characteristics that must be considered when selecting them for a particular application, for example, the motor mounting. Is the motor solidly mounted to a base, or is there a flexible mount to minimize noise? The sound level is another factor. Will the motor be used where ball bearings would make too much noise? If so, sleeve bearings should be used. Still another factor is the operating temperature of the motor surroundings. A condenser fan motor that pulls the air over the condenser coil and then over the motor requires a motor that will operate in a warmer atmosphere. The best advice is to replace any motor with exactly the same type whenever possible.

17.17 SINGLE-PHASE HERMETIC MOTORS

The wiring in a single-phase hermetic motor is similar to that in a split-phase motor. It has start and run windings, each with a different resistance. The motor runs with the run winding and may have a start assist to open the circuit to the start windings. A run capacitor is often used to improve running efficiency. A hermetic motor is designed to operate in a refrigerant, usually vapor, atmosphere. Materials that make up the hermetic compressor motor must be compatible with the refrigerant and oil circulating in the system. The coatings on the windings, ties for the motor windings, and the papers used as wedges must be of the correct material. The motor is assembled in a dry, clean atmosphere. It is undesirable for liquid refrigerant to enter the shell—for example, from an overcharge of refrigerant. Single-phase hermetic compressors usually are manufactured up to 5 hp, **Figure 17.34**. If more capacity is needed, multiple systems or larger three-phase units are used.

Figure 17.34 A typical motor for a hermetic compressor.



Source: Tecumseh Products Company.

Figure 17.35 The motor terminal box on the outside of the compressor shell.

Hermetic motors are started in much the same way as the other motors we have described. The start windings must be removed from the circuit when the motor nears normal operation, but not in the same way as for an open motor because the windings are in a refrigerant atmosphere. Open single-phase motors are operated in air, and a spark is allowed when the start winding is disconnected. This cannot be allowed in a hermetic motor because the spark will cause the refrigerant to deteriorate. Special devices determine when the compressor motor is drawing the desired current or running at the correct speed to disconnect the start winding from outside the compressor shell.

Because the hermetic motor is enclosed in refrigerant, the motor leads must pass through the compressor shell to the outside. A terminal box on the outside houses the three motor terminals, **Figure 17.35**, one for the run winding, one for the start winding, and one for the line common to the run and start windings. See **Figure 17.36** for a wiring diagram of a three-terminal compressor. The start winding has more

Figure 17.36 A wiring diagram of the terminal and internal wiring connections on a single-phase compressor.

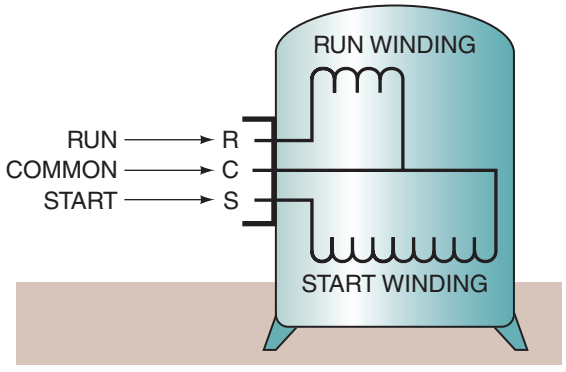


Figure 17.37 These motor terminals use neoprene O rings as insulators between the terminals and the compressor housing.

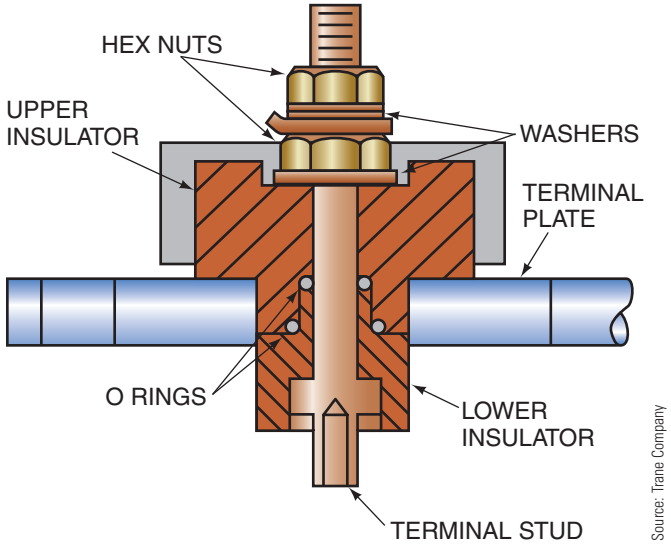

resistance than the run winding. The motor leads are insulated from the steel compressor shell. Neoprene was the most popular insulating material for years. However, if the motor terminal becomes too hot, due to a loose connection, the neoprene may eventually become brittle and possibly leak, **Figure 17.37**. So many compressors now use a ceramic material to insulate the motor leads.

17.18 THE POTENTIAL RELAY

Potential relays are used with single-phase capacitor-start, capacitor-run motors that need relatively high starting torque, **Figure 17.38(A-2)**. **Figure 17.38(A-1)** shows the specifications and type of a potential relay printed on its packaging box. Their main function is to assist in starting the motor. These relays are sometimes referred to as voltage relays or potential magnetic relays (PMRs). Potential relays consist of a high-resistance coil and a set of normally closed contacts, **Figure 17.38(B)**. The coil is wired between terminals 2 and 5, and the normally closed contacts are wired between terminals 1 and 2, **Figure 17.38(C)**. Other terminal designations on the relay, sometimes referred to as accommodation terminals, serve only as wire connections. These dummy terminals are often used for wiring such devices as condenser fans or capacitors.

When power is applied through the compressor's contactor contacts, both the run and start windings are energized and the motor's rotor starts to turn. The start winding is wired in series with both the start and run capacitors. The run and start capacitors are in parallel with one another, but both are in series with the start winding, **Figure 17.38(C)**. Parallel capacitors add like resistors in series, so their capacitances add, giving the motor high starting torque. The large metal mass of the motor's rotor turning at high speeds with motor windings in close proximity has a voltage-generating effect, more across the start winding because it is wound with a longer and thinner wire

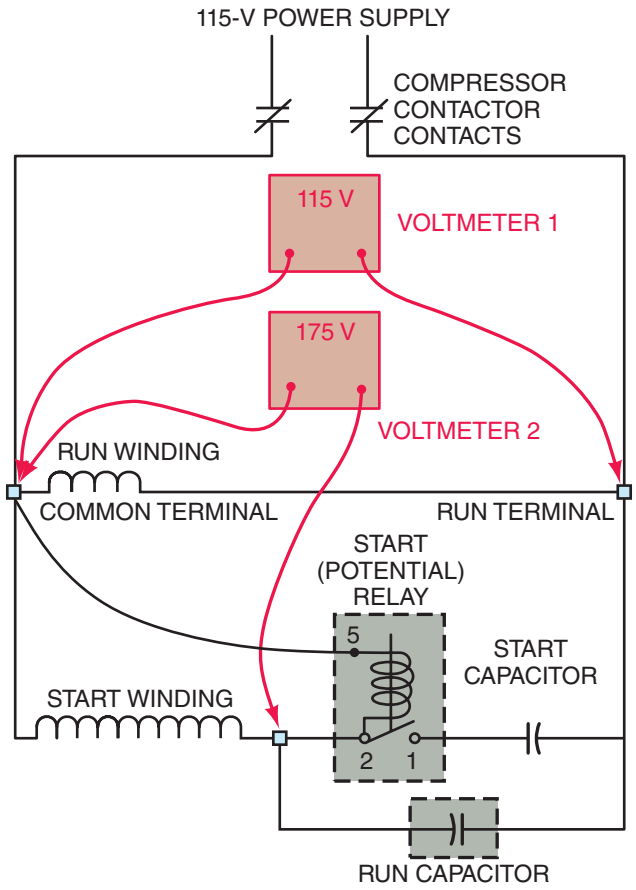
(B)

Figure 17.38 (*Continued*)(C) Diagram illustrating the higher induced voltage that is measured across the start winding in a typical motor.



(C)

than the run winding. This generated voltage is often referred to as induced voltage, or **back electromotive force (BEMF)**. This BEMF, measured with a voltmeter across the start winding, opposes line voltage. It is higher than line voltage and can range over 400 V AC in a 230-V circuit, **Figure 17.38(C).** All motors have different magnitudes of BEMF.

The BEMF generated across the start winding causes a small current to flow in the start winding and potential relay coil because they are in parallel with one another. When the BEMF has built up to a high enough value—referred to as "**pick-up voltage**"—the contacts between terminals 1 and 2 will be picked up or "opened." This will take the start capacitor out of the start winding circuit. The start winding is still in the BEMF circuit keeping the relay coil energized while the motor is running at full speed. Pickup voltage usually occurs at about 3/4 motor speed. The run capacitor causes a small phase shift between the run and start winding for better running torque. It also limits the current through the start winding so overheating does not occur during the running cycle.

When the compressor contactor contacts open, line voltage is taken away from the motor. The motor's rotor now decreases in speed; thus the BEMF generated across the start winding decreases in magnitude. The relay coil now sees a decreased BEMF and no longer can generate enough magnetism in its iron core to keep the contacts between terminals 1 and 2 open. The contacts thus return to their originally closed position by spring power as the motor coasts to a stop. The voltage at which the contacts return to their original closed position is called the "**drop-out voltage**." One benefit of using the PMR as a starting relay is that the start winding can be brought back into the active electric circuit if the motor should encounter a temporary load increase. If the motor slows down and the normally closed contacts between terminals 1 and 2 close, this will bring the start capacitor back into the circuit and provide additional torque to get the motor back up to speed. Once the induced voltage rises (indicating that the motor is operating at a satisfactory speed), the contacts will open to remove the start capacitor from the circuit.

Because these motors generate different BEMF values, potential relays must be sized to each individual compressor. The pick-up voltage needed to open the contacts is one of the considerations for sizing the relay. The actual current-carrying capacity of the relay contacts, the drop-out voltage, and the continuous coil voltage are other important considerations when sizing the relay. Consult a service manual, supply house, or the compressor manufacturer to select the correct potential relay for a specific compressor.

POTENTIAL RELAY SPECIFICATIONS

The pick-up voltage for a specific potential relay will be listed as a minimum and a maximum, **Figure 17.38(A)**. For proper operation, the pick-up voltage must stay within this range. (The pickup voltage is the BEMF voltage generated across the start winding by the motor's rotor when it is up to about 3/4 speed.) If the pick-up voltage generated by BEMF is under the minimum, the contacts between terminals 1 and 2 will never open. The start capacitor will then stay in the circuit, which will cause high amp draws and open the motor's protective devices. If the pick-up voltage generated by BEMF is above the maximum, the relay coil stands a good chance of overheating and opening the circuit. Again, the contacts between terminals 1 and 2 would stay closed, causing high amp draws if the relay coil opens the circuit. Potential relays also have a **continuous coil voltage** rating. This is the maximum EMF that the relay's coil can tolerate "continuously" without overheating and opening the circuit.

As mentioned, potential relays also have a drop-out voltage rating. The drop-out voltage is the BEMF voltage that must be generated across the relay coil to "hold" the contacts open once they have been picked up (opened). Note that it takes more BEMF (pick-up voltage) to pick up and open the contacts than it does to hold them open (drop-out voltage). Once the cycling control opens the circuit, the rotor will decrease in speed, thus generating less BEMF across the start winding and relay coil. As the BEMF drops below the drop-out voltage, the contacts between terminals 1 and 2 will return to their normally closed position and be ready for the next starting cycle.

Because of these three voltage rating specifications, potential relays must be sized to each individual compressor. Consult a service manual, the compressor manufacturer, or a supply house for information on selecting the correct potential relay. Replacement relays from different manufacturers can be cross-referenced in convenient tables. Whenever possible, the model number on the old relay should be used when ordering a new one. Adjustable and universal potential relays are also available that can serve as replacements for many potential relays presently being manufactured.

17.19 TROUBLESHOOTING

Please refer to **Figure 17.38(C)** for troubleshooting the potential relay. A simple ohmmeter is all that is needed to troubleshoot. After taking all connecting wires off the relay, measure the resistance across the 1 and 2 terminals. The resistance should read close to zero, since they are normally closed contacts. If the ohmmeter reads infinity, the contacts are stuck open and the relay should be discarded and replaced. Open contacts will prevent the start capacitor and start winding circuit from being energized, which will lock the rotor and cause locked-rotor amps (LRA), thus opening the compressor's protection device. In time, short cycling on the compressor's compression device can overheat and open a winding. Often the relay contacts could be stuck or arced in the closed position. In this case, the start capacitor would never be taken out of the circuit, and high amp draws would open motor protective devices. If the contacts are stuck in the closed position, the relay will have to be checked in the running mode, since the contacts between 1 and 2 are normally closed when not in operation.

Once the motor is up and running, use a voltmeter to measure the voltage across terminals 1 and 2 of the relay. A voltage reading of zero volts would prove that the contacts are not opening. Also, high amp draws from the start capacitor still being in series with the start winding circuit is a telltale sign that the contacts have not opened.

After disconnecting all wires from the relay, ohm the coil located between terminals 2 and 5. It is not uncommon to have the resistance read in the many thousands of ohms. If the ohmmeter reads infinity, the relay coil is open. The relay should be discarded and a new one installed. An open relay coil will prevent the contacts between 1 and 2 from opening due to no magnetism in the iron core. High amp draws will again be experienced. When replacing a potential relay, always use the model number on the old relay when ordering a new one, or cross-reference it to a different manufacturer's relay. This will ensure that all relay specifications are met.

17.20 THE CURRENT RELAY

Current relays are used on single-phase, fractional horsepower motors requiring low starting torque. Their main function is to assist in starting the motor. Current relays, also referred to as current magnetic relays, or CMRs, are often seen when capillary tubes or fixed orifices are used as metering devices, because systems employing capillary tubes or fixed-orifice metering devices equalize pressure during their off cycles. This causes a lower starting torque condition than in systems that do not equalize pressure during their off cycles, as with the conventional thermostatic-expansion or automatic-expansion metering devices. Some typical applications for current relays include domestic refrigeration compressors, drinking fountains, small window air conditioners, small ice makers, and small unitary supermarket display cases.

Current starting relays consist of a low-resistance coil (1 Ω or less) and a set of normally open contacts. The coil is short in length and large in diameter. In fact, the current relay may always be identified by the size of the wire in the relay coil. This wire is large because it must carry the full-load current of the motor. The coil is wired between terminals L and M, and the contacts usually are wired between terminals L and S, **Figure 17.39**. The standard designation is L for line, S for start winding, and M for main winding.

When power is applied, both the run (main) winding and relay coil are at LRA. This happens because the relay coil is in series with the run winding. For this reason, the relay coil is designed to be of very small resistance; otherwise, it would drop too much voltage and interfere with the run winding's power consumption needs. The start winding will not experience the LRA because the contacts between L and S are

Figure 17.39 Wiring diagram of a current magnetic relay. The "L" indicates line voltage, the "M" refers to the main, or run, winding, and the "S" refers to the start winding. The coil is connected between the L and M terminals; the relay contacts are connected between the L and S terminals.

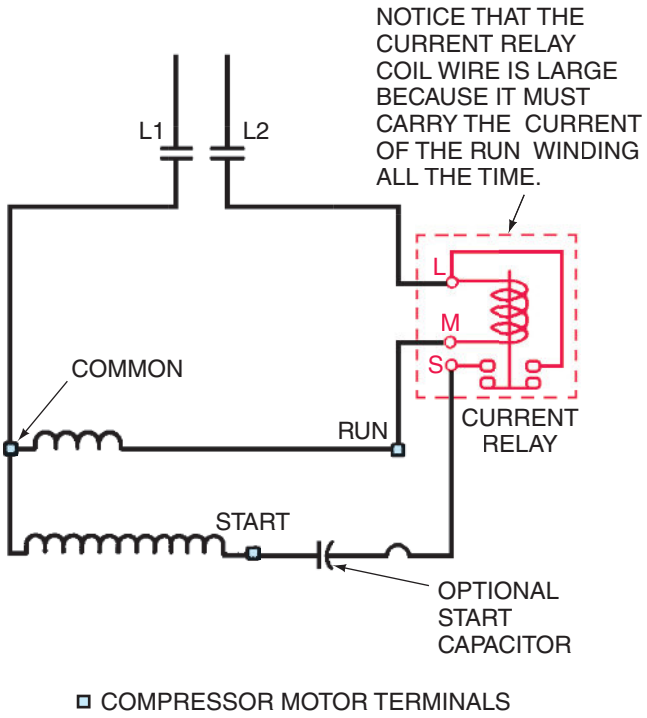


Figure 17.40 The current magnetic relay is easily identified by the large wire used to wind the holding coil.

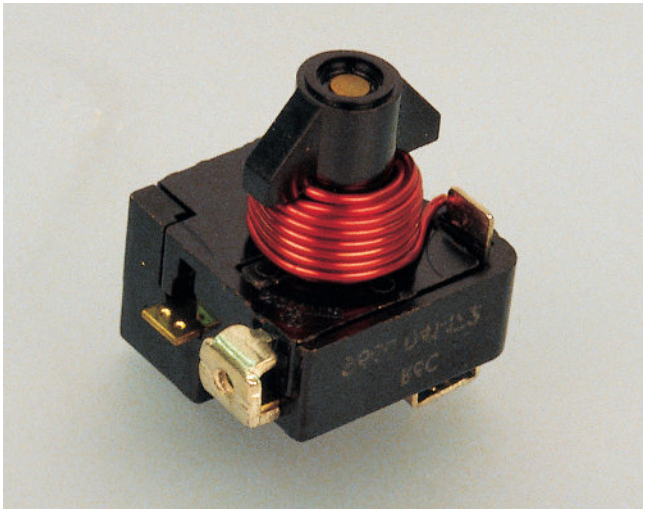

normally open. Once the relay coil experiences LRA, a strong electromagnetic field is generated around it. This will make an electromagnet out of the iron core that the coil surrounds. This magnetic force will close the contacts between L and S and energize the start winding. The motor's rotor then starts to turn, **Figure 17.40**.

Once the start winding circuit is closed, the motor will quickly accelerate in speed. After the motor starts, the current draw of the run winding will decrease because of a BEMF generated in its winding. It is this reduced current draw that will decrease the magnetism in the iron core of the relay. Now spring pressure or gravity forces the contacts between L and S back to their normally open position because the magnetic field generated by the lower FLA/RLA is not strong enough to keep the relay contacts closed. When power is taken away from the circuit, the motor will coast to a stop and the contacts will already be open and waiting for the next run cycle.

These starting methods are used on many compressors with split-phase motors that need high starting torque. If a system has a capillary tube metering device or a fixed-bore orifice metering device, the pressures will equalize during the off cycle and a high starting torque compressor may not be necessary.

17.21 POSITIVE TEMPERATURE COEFFICIENT RESISTOR (PTCR)

Positive temperature coefficient resistors (PTCRs) are compressor starting devices. They are variable resistors that vary their resistance when the surrounding temperature changes. Because they have a positive temperature coefficient, as their temperature increases so does their resistance. Also, as their temperature decreases, so does their resistance. PTCRs have a low resistance over a wide temperature range. However, when they reach a certain higher temperature, their resistance greatly increases. This very high resistance can act as an open circuit and stop all current flow through a circuit. When the heat source on the PTCR is removed, its resistance will return to its initial room temperature resistance. PTCRs are made from a very pure semiconducting ceramic material, **Figure 17.41(B)**.

This type of variable resistor is often used in the HVAC/R industry in place of current and potential relays. In fact, the ice-making industry is using PTCRs in place of potential relays in commercial ice machines. PTCRs are also used in air-conditioning and heat pump systems having either an orifice metering device or TXV with a bleed port to equalize pressure during the off cycle. PTCRs make wiring much easier and get rid of a lot of nonessential, high-maintenance moving parts like relay contacts, coils, and springs.

The PTCR is wired in parallel with the run capacitor and in series with the start winding in a permanent split capacitance (PSC) motor, **Figure 17.41(A)**. PTCRs can supply the extra starting torque needed with a single-phase, PSC compressor motor, usually on systems that can somewhat equalize system pressures before starting. When the cycling control brings power to the motor, both the run and start winding experience a heavy inrush of current. The run (main) winding sees heavy current flow because its low resistance winding is wired across Line 1 and Line 2 directly. The start (auxiliary) winding also sees heavy current flow because its low resistance winding also sees Line 1 and Line 2 directly for a split instant. By increasing the current flow in the start winding, additional starting torque is provided by the compressor motor because the PTCR is at room temperature and its resistance is very low. It actually shunts out the run capacitor because it acts like a straight wire with very low resistance when it is at room temperature. Since both the run and start winding see high current that is a bit out of phase from their different inductance values, the motor will have torque to start. The high current flow through the PTCR will now increase its temperature and it will produce a very high resistance in less than 1 sec. This will act as an open circuit in the PTCR circuit. The run capacitor will no longer be shunted out and the motor will now run as a permanent split capacitance (PSC) motor for the remainder of its running cycle. The PTCR will remain hot and at a high resistance value as long as voltage remains on the circuit.

To assist in PSC motor starting, some ice machine manufacturers that use PTCRs as starting relays incorporate a hot gas solenoid (harvest) valve to assist in compressor motor start-up. Energizing a hot gas solenoid valve located between the compressor's discharge line and the entrance to the evaporator prior to starting will somewhat equalize

Figure 17.41 (A) A PTCR in a motor starting circuit. (B) Two positive temperature coefficient resistors (PTCRs).

(B)

system pressures and lead to much easier starting. Many times manufacturers will allow the hot gas solenoid valve to remain energized for up to 45 sec to ensure system equalization before compressor starting. To ensure the compressor is started and will not stall, often the hot gas solenoid valve is energized for 5–10 sec after the compressor has started.

It is important that the PTCR be cooled down to near ambient temperature before attempting to restart the compressor. If the cool-down process is not completed, the high starting torque of the PSC compressor motor may not last long enough. Often, a good PTCR may be too hot to operate properly at start-up because the compressor motor has short cycled or the compressor overload has opened. A low voltage situation at the compressor on start-up may also cause the compressor to not have enough starting torque and it will stall.

17.22 TROUBLESHOOTING THE PTCR

In normal operation, a PTCR may reach over 200°F while the compressor is running. To check for a bad PTCR, visually inspect it for physical signs of damage. Next, wait for at least 10–15 min for the PTCR to cool down to room temperature with the unit off. Isolate the PTCR from the unit and use an ohmmeter to measure its resistance. The manufacturer of the refrigeration unit should provide resistance values for room-temperature PTCRs. If the resistance value falls outside the acceptable range specified by the manufacturer, simply replace the PTCR.

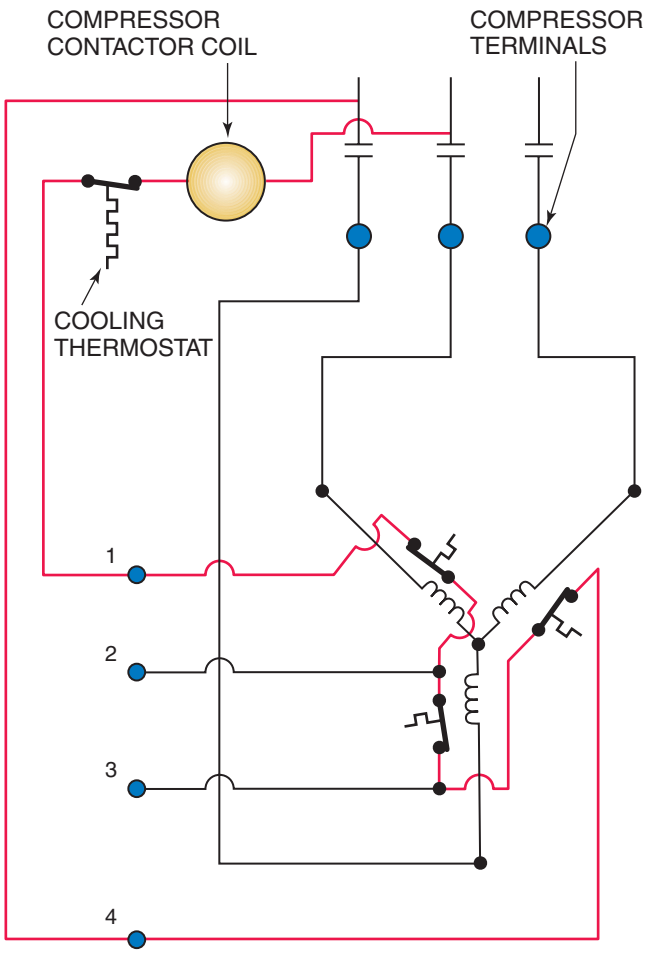
17.23 TWO-SPEED COMPRESSOR MOTORS

Two-speed compressor motors are used by some manufacturers to control the capacity of small compressors. For example, a residence or small office building may have a 5-ton air-conditioning load at the peak of the season and a 2 1/2-ton load as a minimum. Capacity control is desirable in this application, which may be accomplished with a two-speed compressor. Two-speed operation is obtained by wiring the compressor motor to operate as a two-pole motor or a four-pole motor. The automatic changeover is accomplished through the space temperature thermostat and the proper compressor contactor for the proper speed. For all practical purposes, these motors can be considered as two motors in one compressor housing. One motor turns at 1800 rpm, the other at 3600 rpm. The compressor uses either motor, based on capacity needs. The compressor has more than three motor terminals to operate its two motors.

17.24 SPECIAL APPLICATION MOTORS

Although some special application single-phase motors may have more than three motor terminals, they may not be two-speed motors. Some manufacturers design an auxiliary winding in the compressor to give the motor more efficiency. These motors are normally in the 5-hp and smaller range. Other special motors may have the winding thermostat wired through the shell with extra terminals. A large three-phase compressor motor may have a winding thermostat for each winding. This calls for three thermostats within the compressor housing. Using a combination of four small terminals, they can be wired in series so that any one of them will shut the compressor off. If one of them fails, the extra terminals would still allow the others to be used for some motor protection, **Figure 17.42.**

Figure 17.42 This compressor has extra winding thermostat terminals. In the event that one winding thermostat goes bad, the others can still be used.



17.25 THREE-PHASE COMPRESSOR MOTORS

Large commercial and industrial installations will have three-phase power for air-conditioning and refrigeration equipment. Three-phase compressor motors normally have three motor terminals, but the resistance across each winding is the same, **Figure 17.43.** As explained earlier, three-phase motors have a high starting torque and, consequently, should experience no starting problems.

For many years, welded hermetic compressors were limited to 7 1/2 tons but are now being manufactured in sizes up to about 50 tons. The larger welded hermetic compressors are traded back to the manufacturer when they fail and are then remanufactured. They must be cut open for service, **Figure 17.44.**

Figure 17.43 A three-phase compressor motor with three leads for the three windings. Unlike a single-phase motor, the resistance of all three windings is the same.

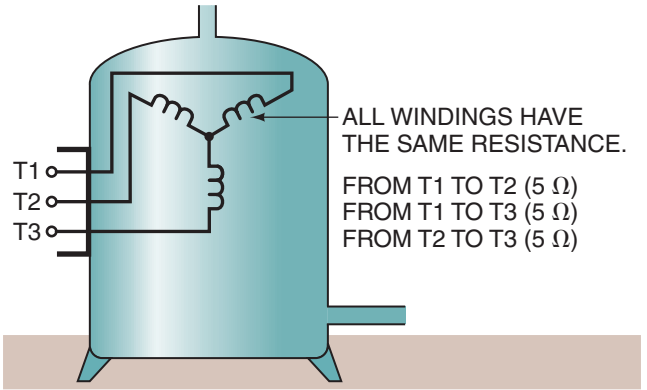


Figure 17.44 A large welded hermetic compressor.

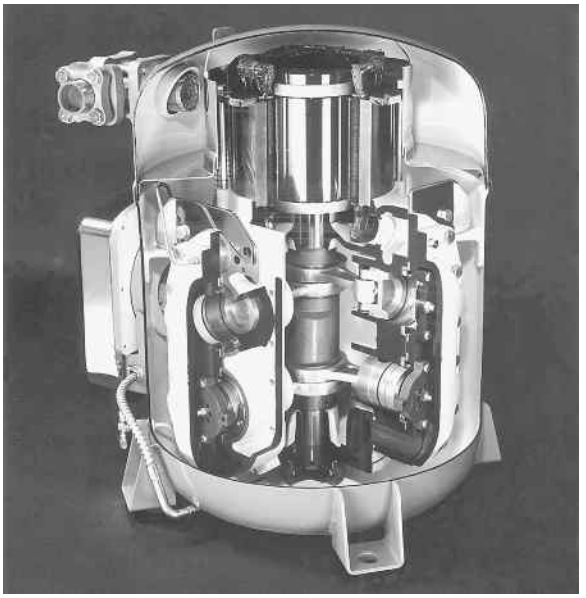
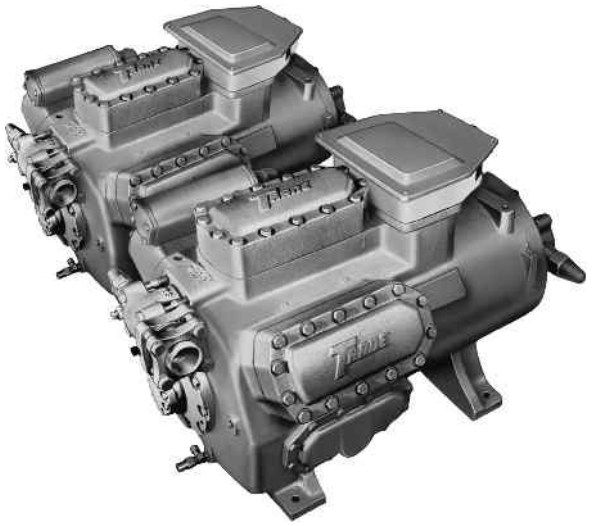


Source: Trane Company

Figure 17.45 Serviceable compressors.



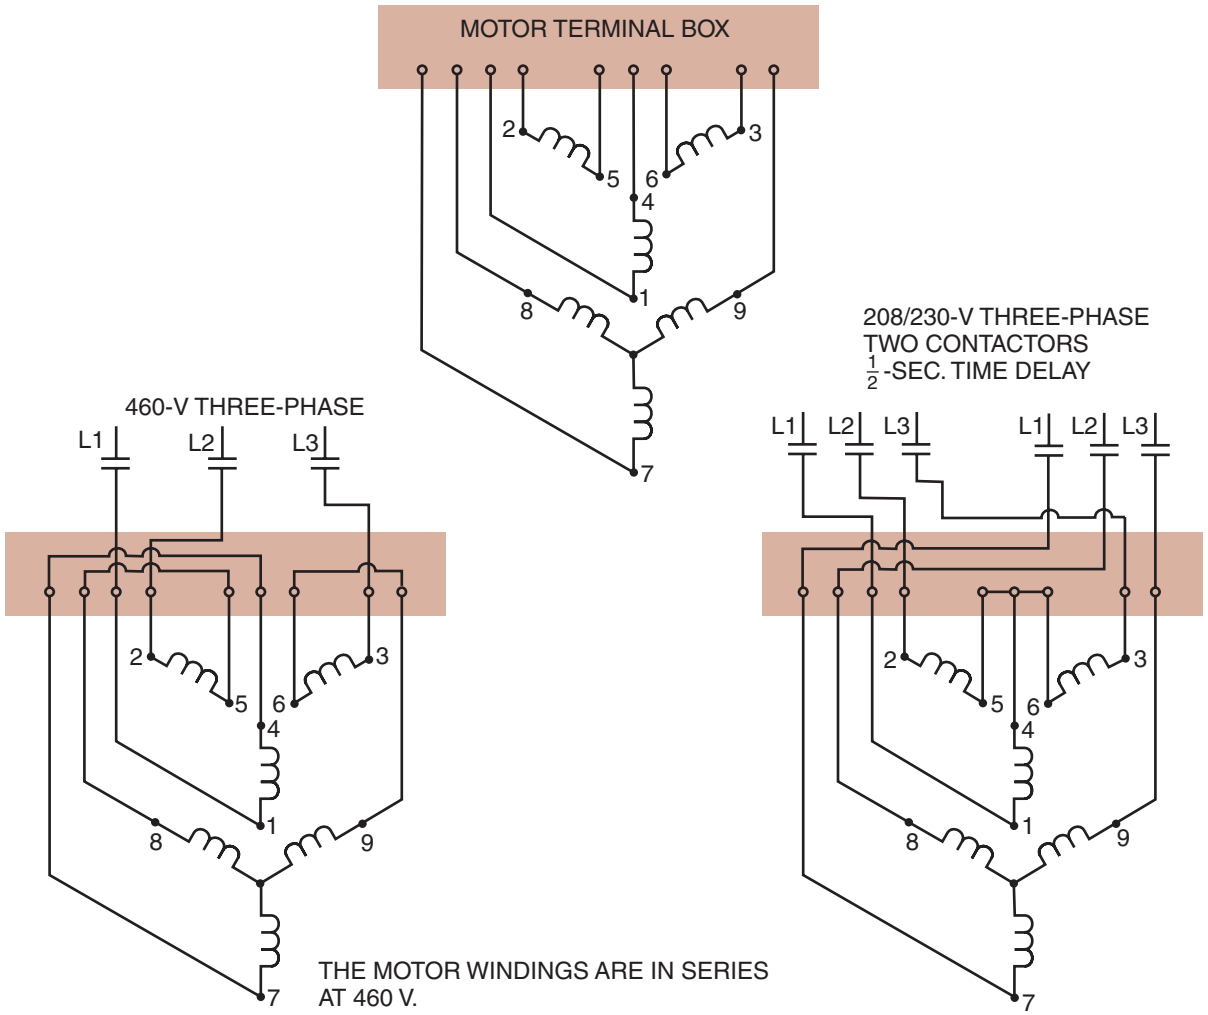
Source: Trane Company

Serviceable hermetic compressors of the reciprocating type are manufactured in sizes up to about 125 tons, **Figure 17.45**. These compressors may have dual-voltage motors for 208-V to 230-V or 460-V operation, **Figure 17.46**. When the motor fails, the compressors are normally rebuilt or remanufactured, so an overhaul is considered upon motor failure. The compressors may be rebuilt in the field or traded in for remanufactured ones. Companies that can rebuild the compressor to the proper specifications are located in most large metropolitan areas. (The difference between rebuilding and remanufacturing is that one is done by an independent rebuilder and the other by the original manufacturer or an authorized rebuilder.)

17.26 VARIABLE-SPEED MOTORS

The desire to provide more efficient fans, pumps, and compressors has led the industry to explore the development and use of variable-speed motors. Most motors do not need to operate at full

Figure 17.46 A dual-voltage compressor motor wiring diagram. This motor may be used for either 208 V/230 V or 460 V.



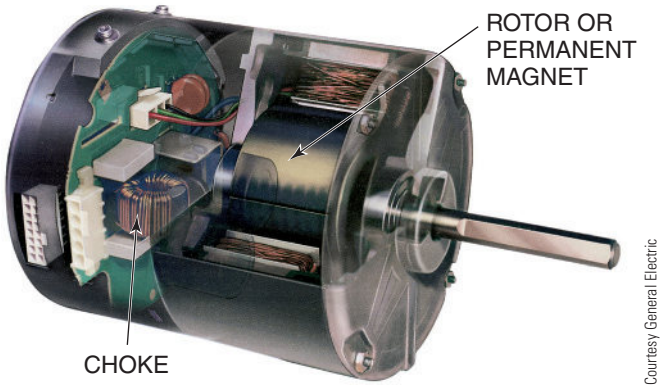
speed and load except during the peak temperature of the season and could easily satisfy the heating or air-conditioning load at other times by operating at a slower speed. When the motor speed is reduced, the power to operate the motor is reduced proportionately. For example, if a home or building needs only 50% of the capacity of the air-conditioning unit to satisfy the required space temperature, it would be advantageous to reduce the capacity of the unit rather than stop and restart it. When power consumption can be reduced in this manner, the unit becomes more efficient. As mentioned earlier, when motors are initially started, they draw locked-rotor amperage, which can be five to seven times greater than the full-load or rated-load amperage of the motor. By limiting the number of times the motor starts, the rate of power consumption is reduced. In addition, having (for example) a compressor motor operate at a lower speed for a longer period of time will result in more even cooling of an occupied space.

The frequency (cycles per second) of the power supply and the number of poles determine the speed of a conventional motor. Some new motors can operate at different speeds by using electronic circuits. There are several methods of varying the frequency of the power supply, depending on the type of motor. Depending on the needs of the system, compressor motors and the fan motors may be controlled by any number of speed combinations.

Unit 12, "Basic Electricity and Magnetism," covered some of the fundamentals of AC electricity. All of the electricity furnished in the United States is AC and the current frequency is 60 cycles per second, or 60 hertz (Hz). It is much more efficient to distribute AC than direct current (DC), moreover, AC can be converted to DC by means of rectifiers. Many applications for motors in the industry require variable-speed motors, which traditionally have been DC. These motors are typically much more complicated to work with because they have both a field (stator) and an armature (rotor) winding and use brushes to carry power to the rotor. Brushes are carbon connectors that rub on the armature and create an arc. The brushes on the armature cannot be used inside a refrigerant atmosphere; therefore, DC motors with brushes cannot be used for hermetic compressors.

In the past, variable-speed systems using DC have used open-drive DC motors, but the hermetic compressor is the most common variable-speed application. In addition, variable-speed motors can be used to drive many types of equipment, such as pumps and fans and fractional horsepower equipment. The two types of motors found in equipment today are the squirrel cage induction motor and the ECM (electronically commutated) DC motor. Instead of brushes rubbing on an armature, the motor is electronically commutated, **Figure 17.47**. This motor can run a fan as well as fractional horsepower equipment. Electronic components now make variable-speed AC motor operation possible. The electronic components can switch power on and off in microseconds without creating an arc; therefore, open-type contacts are not necessary for switching purposes. The no-arc

Figure 17.47 An electronically commutated motor (ECM).



components have virtually no wear, have a long life cycle, and are reliable. **Figure 17.48** shows a transistor that is essentially an electronic switch with no contacts to arc.

The air-conditioning load on a commercial or industrial building varies during the season and during each day. The central air-conditioning system in a house or other building would have many of the same operating characteristics. Let us use a house as an example. Starting at noon, the outside temperature may be 95°F and the system may be required to run at full load all the time to remove heat as fast as it is entering the house. As the house cools off in the evening, the unit may start to cycle off and then back on, based on the space temperature. Remember, every time the motor stops and restarts, there is wear at the contactor contacts and a burden is put on the motor in the form of starting up. Motor inrush current stresses the bearings and windings. Most motor bearing wear occurs in the first few seconds of start-up because the bearings are not lubricated until the motor is turning. It would be best not to ever turn the motor off and instead just keep it running at a reduced capacity.

When an air conditioner shuts off, there is normally a measurable temperature rise before it starts back up. This is very noticeable in systems that only stop and start. The humidity rises during this period. In the winter, the typical

Figure 17.48 This power transistor is basically an electronic switch that does not arc when it changes position and has the ability to turn on and off very quickly.

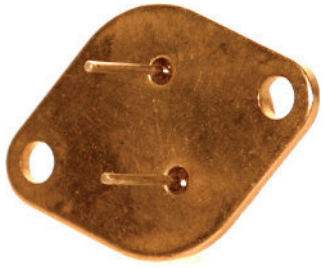


Figure 17.49 This typical ON/OFF furnace thermostat has a 3°F temperature swing during its cycle. This is enough temperature swing to be noticeable to the occupants of the space.

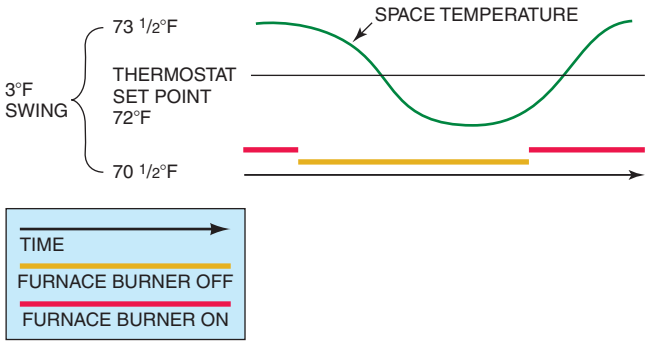

gas or oil furnace does the same thing. It starts up and runs until the thermostat is satisfied and then it shuts off. There is a measurable temperature rise before it shuts off and a measurable temperature drop before it starts back up. The actual space temperature at the thermostat may look like the graph in **Figure 17.49**. When variable-speed motor controls are used along with a variable firing rate for a furnace, the temperature graph may look more like the one in **Figure 17.50**. The same temperature curve profile would be true for the cooling season—a flatter profile with fewer temperature and humidity variations.

Variable-speed motors can smooth out air conditioner operation by running for longer periods of time. In any building you may notice when the system thermostat is satisfied and the unit shuts off. Suppose we could just keep the unit running at a reduced capacity that matched the building load. If we could gently ramp the motor speed down as the load reduces and then ramp it up as the load increases, the temperature and the humidity would be more constant in the summer. This can be accomplished with modern electronics and variable-speed motor drives.

For example, a light bulb turns on and off 120 times per second when used with a typical household 60-cycle current. **Figure 17.51** shows a sine wave of the current that is furnished to the home. The voltage goes from 0 V to 120 V

Figure 17.50 This furnace is controlled by a variable-speed fan motor and firing rate. It has only a 1°F temperature swing during its cycle. This will not be noticeable.

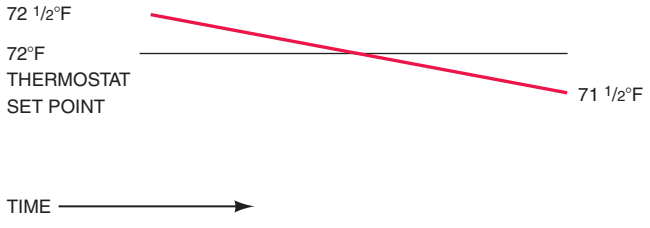

Figure 17.51 This sine wave is generated in one-sixtieth (1/60) of a second.

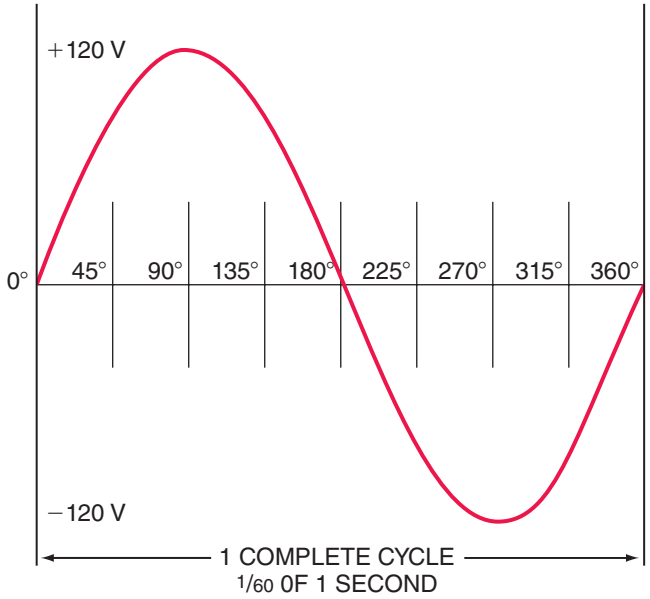
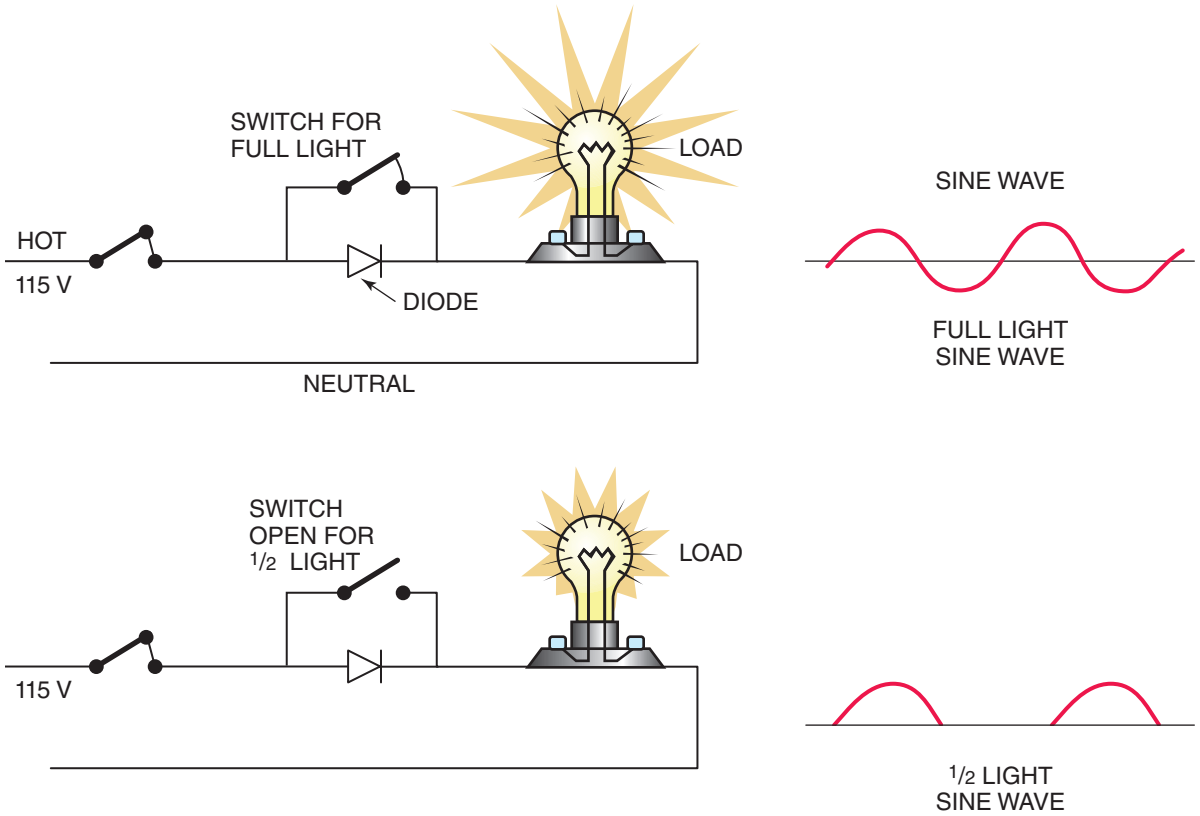


to 0 V and back to 120 V 60 times per second; thus it is a 60-cycle current. Current to the light bulb element is interrupted 120 times in that second. The light from the bulb comes from the glowing element. Because it does not cool off between the cycles, you do not notice the interruptions in the current. Electronic devices can detect any part of the sine wave and switch off the current at any place in time.

If a switch could be installed to make even more interruptions in the current to the light bulb, it would produce a lower light output. **Figure 17.52** shows a simple rectifier in the form of a diode installed in the line that will interrupt the current flow to the light bulb on half of the sine wave cycle. The light bulb will now glow at half of its light output. This diode does not draw any current or have any moving parts but interrupts half of the current flow to the light bulb. The light bulb not only uses half power, it also gives off half as much light. The diode is like a check valve in a water circuit; it allows current flow in only one direction. The term *alternating current* tells you that current flows in two directions, one direction in one part of the cycle and the other direction in the other part of the cycle. When the current tries to reverse for the other half of the cycle, the diode stops it from flowing. This saves power and gives the owner some control over the light output.

AC electric motors can be controlled in a similar manner with electronic circuits. AC motor speed is directly proportional to the cycles per second (hertz, Hz). If the cycles per second are varied, the motor speed will vary. The voltage must also be varied in proportion to the cycles per second for the motor to remain efficient at all speeds. Once the voltage is converted to DC and filtered, it then goes through

Figure 17.52 This light dimmer uses a diode to cut the voltage in half at low light.



an inverter to change it back to controllable AC. (Actually, this is still pulsating DC.) The reason for all of this is to change the frequency (cycles per second) and voltage at the same time. As the frequency is reduced, the voltage must also be reduced at the same rate. If only the voltage is reduced, the motor will overheat. For example, if you have a 3600-rpm, 230-V, 60-cycle-per-second motor and you want to reduce the speed to 1800 rpm, the voltage and the cycles must be reduced in proportion. By reducing the voltage to 115 V and the frequency to 30 cycles per second, the motor will have the correct power to operate at 1800 rpm. It will not lose its torque characteristics. The motor will also operate on about half the power requirement of the full-load operation.

AC supplied from the power company is very hard to regulate at the motor, so it must be altered to make the process easier and more stable. This involves changing the incoming AC voltage to DC with a device called a converter or rectifier, which is much like a battery charger that converts AC to 14-V DC to charge an automobile battery. This DC voltage is actually pulsating DC voltage, so it is then filtered using capacitors to create a more pure DC voltage. A simplified diagram of a circuit used to accomplish the voltage conversion is shown in **Figure 17.53**. There are many components in an actual system, but the technician should think about the system one component at a time for the purposes of understanding and troubleshooting it.

17.27 DC CONVERTERS (RECTIFIERS)

There are two basic types of converters, the *phase-controlled rectifier* and the *diode bridge rectifier*. The phase-controlled rectifier receives the AC supplied by the power company and converts it to variable voltage DC using silicon-controlled rectifiers (SCRs) and transistors that can be turned off and back on in microseconds. **Figure 17.54** shows the waveform of AC furnished by the power company that enters the phase-controlled rectifier and the DC current that leaves the device. Notice the connection for turning these diodes or transistors on and off. The DC voltage leaving this rectifier is varied within the rectifier to coincide with the motor speed. The frequency of the power will be adjusted to the required motor speed in the inverter, which is between the converter and the motor. Remember, both the voltage and the frequency must be changed to achieve an efficient motor speed adjustment.

Figure 17.53 A simple diagram of a variable-speed motor drive.

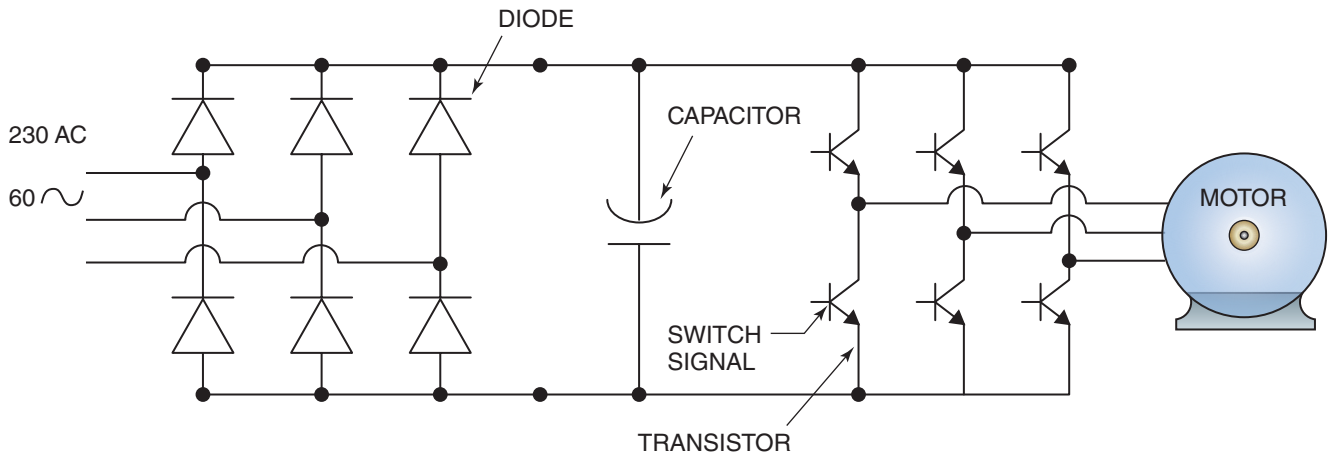


Figure 17.54 The full-wave rectifier moves the entire sine wave to the positive side of the graph.

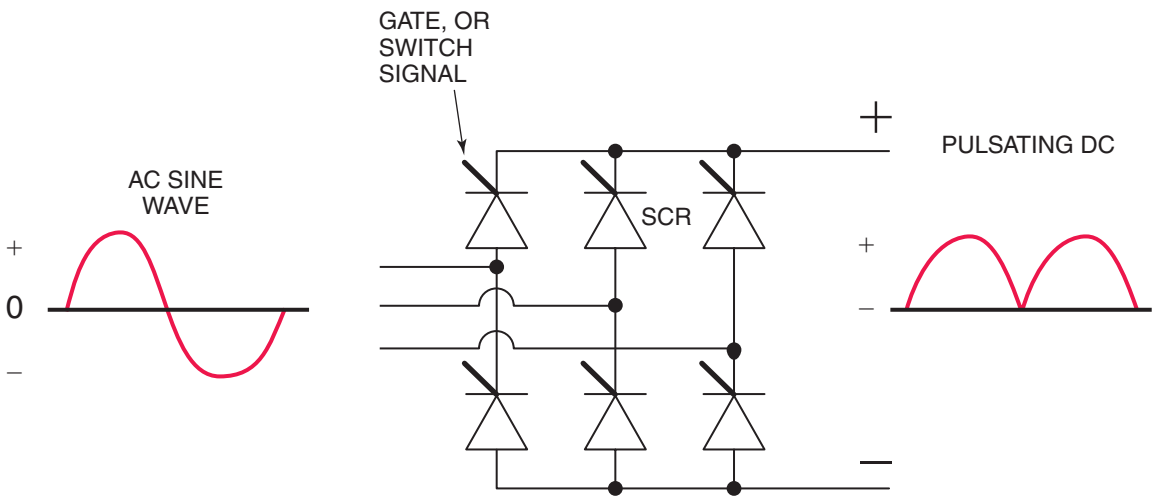
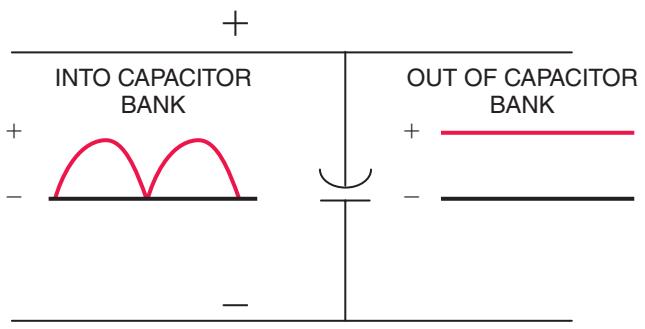


The other component in the system is a capacitor bank used to smooth out the DC voltage. The rectifier turns AC into a pulsating DC voltage that appears as though all of the AC voltage is on one side of the sine curve. When it leaves the capacitor bank, the voltage looks more like pure DC voltage, **Figure 17.55**. This type of capacitor bank is used with any rectifier to create a better DC profile.

The diode bridge rectifier is a little different in that it does not regulate the DC voltage. The diodes used in this rectifier are not controllable. The voltage and the frequency will be adjusted at the inverter of the system. Constant pure DC voltage is produced after it has been filtered through the capacitor bank. The diode bridge rectifier has no connection for switching the diodes on and off.

Figure 17.55 Pulsating DC enters the capacitor bank and straight-line DC leaves.



17.28 INVERTERS AND VARIABLE FREQUENCY DRIVES (VFDs)

Inverters produce the correct frequency for the motor speed desired. The speed of a conventional motor is controlled by the number of poles, and the frequency is a constant 60 Hz. In variable-speed motors, inverters can control motor speeds down to about 10% of the rated speed at 60 Hz and up to about 120% of the rated speed by adjusting the hertz to above the 60-Hz standard.

There are different types of inverters. A common one is a *six-step* inverter, and there are two variations. One controls voltage and the other controls current. The six-step inverter has six switching components, two for each phase of a three-phase motor. This inverter receives regulated voltage from the converter, such as the phase-controlled inverter, and the frequency is regulated in the inverter. The voltage-controlled six-step inverter has a large capacitor source at the output of the DC bus that maintains the output voltage, **Figure 17.56**. Notice that the controllers are transistors that can be switched on and off. The current-controlled six-step inverter also receives controlled voltage at the input. It uses a large coil, often called a choke, in the DC output bus, **Figure 17.57**. This helps stabilize the current flow in the system.

The **pulse-width modulator** (PWM) inverter receives a fixed DC voltage from the converter and then pulses the voltage to the motor. At low speeds, the pulses are short; at high speeds, the pulses are longer. The PWM pulses are sine-coded so that they are narrower at the part of the cycle close to the ends. This makes the pulsating signal look more like a sine wave to the motor. **Figure 17.58** shows the signal the motor receives. This motor speed can be controlled very closely.

Four variable frequency drives (VFDs) for motors are shown in **Figure 17.59**. The world's first mass-produced VFD was introduced in 1968. Computerization, the reduced cost of

Figure 17.56 When the control system (computer) sends a signal to the base connection on the transistor, the transistor turns on and allows current to flow through the device. When the signal is dropped, the transistor turns off.

electronics, and the interfacing with direct digital control (DDC) systems, along with their energy savings, have made VFDs even more popular today. In fact, VFDs for evaporator and condenser fans and compressor motors are often standard equipment in many newer, high-efficiency rooftop air-conditioning systems that incorporate greener, more efficient, HFC-based refrigerants like R-410A. The payback period for retrofitting HVAC systems with VFDs ranges from 1 to 2 years, depending on the type, size, and application of the system. This is a very short time and yields fast cost savings, considering that most commercial HVAC systems have life cycles of 15–20 years. It is estimated that motors incorporating VFDs, and linked to the building's DDC system, are 65% to 75% more efficient than motors operating at a constant speed at line voltage.

It is usually only on the hottest and coldest days of the year that HVAC systems must operate at 100% capacity with full fan, compressor, and/or centrifugal pump speeds. Most of the time, HVAC system motors can operate much more energy efficiently at reduced capacities and speeds. HVAC/R systems with variable-speed fan motors (VFDs) have the ability to deliver variable air volume (VAV) flows, which allows the airflows to exactly match the system's heating and cooling demands and provides an opportunity to save electrical energy and money. VFDs also contribute to the overall comfort level within the building by regulating air and water flows according to the instantaneous heating or cooling load. This allows closer control of system set points for temperatures and humidity, resulting in higher human comfort levels. Noise levels are also reduced when VFDs are used on HVAC system motors. A VFD can also eliminate motor line starting shock (in-rush current) by soft starting the motor and gradually ramping it up to the speed required for the heating or cooling load at that time, instead of starting the motor at full speed and drawing locked-rotor amperage (LRA). Soft starting can reduce maintenance costs and downtimes. VFDs also eliminate short cycling of motors, which will result in longer life for the motors and driven equipment.

Major compressor manufacturers are also incorporating VFDs to control the speed of compressor motors, which provides more accurate control of the capacity of the system. HVAC systems that incorporate VFD technology on a combination of motors, including evaporator and condenser fans, compressors, and centrifugal pumps for chilled water systems, optimize cost savings and energy efficiency. Other opportunities to save costs within HVAC systems include the following motors:

- Cooling tower fans
- Cooling tower water pumps
- Make-up air fans
- Exhaust fans
- Air handler fans
- Booster fans
- Centrifugal hot water pumps
- Centrifugal cool water pumps

The following formula can be used to determine the no-load (synchronous speed) of an AC motor in revolutions per minute (rpm):

$$\text{rpm} = \frac{(\text{Hz}) \times (60 \text{ sec/min})}{(\#\text{ of Pole Pairs})}$$

where:

- Hz = the frequency of the voltage in cycles/second
- rpm = revolutions/minute, or motor speed

Notice that units of revolutions/minute are on one side of the equation, but (Hz) is in units of cycles/seconds. Seconds are converted to minutes by multiplying by 60 seconds/minute. After this time conversion from minutes to seconds, it is apparent that rpm is governed by the frequency (Hz) and the number of poles. As one can see from the equation, the more poles the motor has, the slower it will turn. Also, as the motor's frequency decreases, the rpm, or speed, of the motor will decrease. Conversely, as frequency increases, the motor's speed will increase. Conventional motor speeds are controlled by the number of poles, and the frequency is constant at 60 Hz. It is much easier to change the frequency (Hz) of the voltage coming into the motor with electronics than it is to increase or decrease the number of poles in the motor. This is where VFDs come into play.

The equation can be rewritten in the simpler form that follows:

$$\text{rpm} = \frac{(Hz)\ (60 \text{ sec/min})}{(\#\ of\ Pole/2)}$$

By multiplying the numerator and denominator (top and bottom) of the equation by 2, the equation now becomes

$$\text{rpm} = \frac{(Hz)120(\text{sec/min})}{(\#\ of\ Poles)}$$

Rewriting the equation again without the units, it becomes

$$\text{rpm} = \frac{(Hz)120}{(\#\ of\ Poles)}$$

This is the form of the equation used in most books. However, do not get the 120 confused with voltage. It does not represent 120 volts!

OPERATION OF THE VFD

A VFD has three separate electronic sections. Their functions and accompanying electronics components are:

- Rectification (diodes) or converter section
- Filtering (capacitors and inductors) or DC bus section
- Switching (transistors) or inverter section

RECTIFICATION. **Figure 17.60** shows a circuit diagram of a three-phase VFD. Notice that all three lines of the three-phase power go through diodes in the form of a bridge rectifier. Diodes let current pass in only one direction. The bridge circuit of diodes rectifies (changes) the three-phase AC voltage to pulsating DC current. The diodes reconstruct the negative half of the waveform into the positive half. So the DC bus section sees a fixed DC voltage. The output of this section is actually 12 half-wave pulses, which are electronically 60 degrees apart.

FILTERING. The filtering section of the VFD makes the pulsating DC smoother or filters out its imperfections. This section can have more than two capacitors wired in parallel with one another, but in series with the bridge rectifier and an inductor. The capacitance of capacitors adds when they are in series. The charging and discharging of the capacitors is synchronous with the three-phase input voltage. This makes a pure DC signal from the half-wave signal of the bridge rectifier. The capacitors in parallel filter the voltage wave and the inductor filter the current wave. Both the inductor and capacitors work together to filter out any AC component of the DC waveform. The smoother the DC waveform, the cleaner the output waveform from the drive.

SWITCHING. The switching or transistor section of the VFD produces an AC voltage at just the right frequency for motor speed control. This section, also called the **inverter** section, converts the DC back to AC. Inverters consist of an array of transistors that can be switched on and off, with two transistors for each output phase that act as switches for current flow. When the control system sends a signal to the base connection of the transistor, the transistor turns on and allows current to flow through it. When the signal is dropped, the transistor turns off and no current will flow. The base or controlling part of the transistor is controlled by a preprogrammed microprocessor that fires the transistors in six steps at appropriate times. Each set of transistors is connected to a positive and negative side of the filtered DC line, **Figure 17.60**.

Almost all modern inverters use transistors to switch the DC bus on and off at specific intervals, a process also known as pulse-width modulation (PWM). Thus, inverters produce the correct frequency of voltage and current to the motor for the desired speed. This is the origin of the term *variable frequency drive* (VFD). In other words, the inverter creates a variable AC voltage and frequency output. Inverters can actually control motor speed down to about 50% of their rated speed and up to about 120% to their 60-Hertz rated speed. Always consult with the specific motor manufacturer before using a VFD controller on any motor.

MOTOR SPEED. The motor's speed is controlled by supplying the stator (stationary) coils with small voltage pulses. At low speeds, the voltage pulses are short; at high speed, the pulses are longer. The PWM pulses are sine-coded, meaning that they are narrower at the part of the cycle close to the ends. The output wave is not an exact replica of the AC input sine waveform, but the pulsating signal looks like a sine wave to the motor, **Figure 17.58**. The VFD's microprocessor or controller signals the power device to "turn on" the waveform's positive half or negative half. The longer the power device remains on, the higher the output voltage will be. The less time the power device is on, the lower the output, **Figure 17.61**. The speed at which power devices switch on and off is referred to as the **switch frequency** or **carrier frequency**. As the switch frequency increases, the resolution

Figure 17.60 Circuit diagram of a three-phase variable-frequency drive.

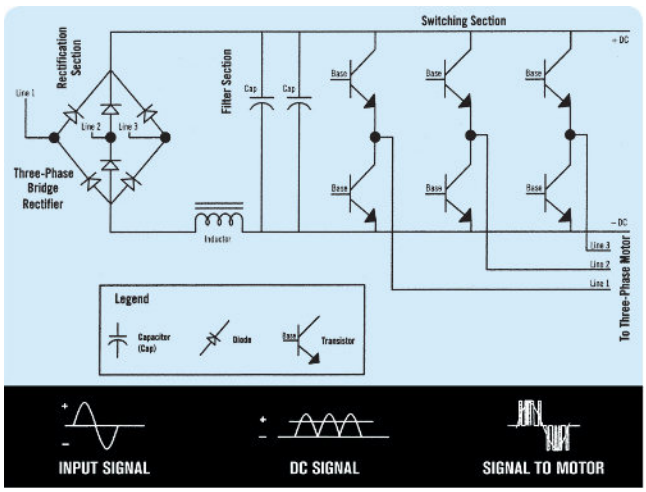

Figure 17.61 The microprocessor or controller signals the power device to "turn on" the waveform's positive half or negative half wave pulses.

and smoothness of the output waveform increases. However, as the switch frequency increases, the heat in the power device also increases.

17.29 ELECTRONICALLY COMMUTATED MOTORS (ECMs)

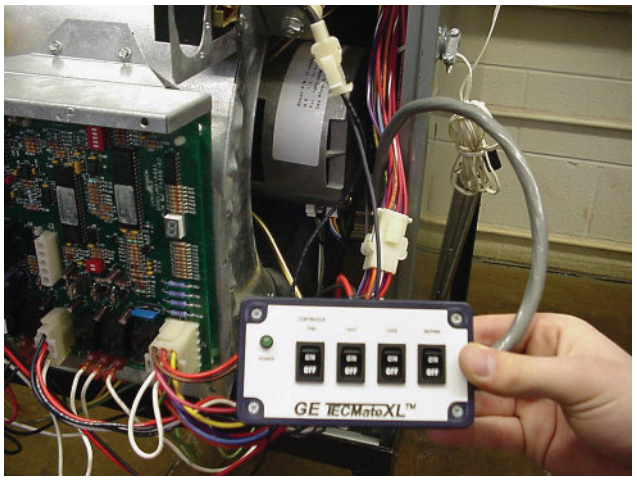
The ECM is used for applications involving open-drive fans that are 1 hp and smaller, **Figure 17.47**. The ECM is reliable and produces energy savings that are worth the difference in cost over time. The technology electronically commutates a DC motor, eliminating the need for brushes, as mentioned earlier. The DC motor has always been more efficient than the AC motor, but it required DC power to magnetize the armature with the brushes. Now, the armature can be commutated (magnetized) with permanent magnets that are attached to the armature with reliable high-tech adhesives.

The ECM motor is calibrated at the factory to suit the piece of equipment. Speed, torque, airflow, and external static pressure relationships are programmed into the motor for a particular application, which helps the air handler supply the correct airflow under different field conditions. For example, restricted system air filters or closed supply registers reduce airflow. With the ECM, the motor simply speeds up to accommodate the reduced airflow and stabilizes at the correct level. This is made possible by the relationships of airflow to torque, speed, and external static pressure already set up by the manufacturer. The ECM can also be applied to any system that can furnish the correct 24-V signal to the motor for load demand. The technology has been incorporated in variable-speed motors for gas furnaces, air-conditioning systems, oil burner systems, and heat pumps. It is also used in the refrigeration industry for variable loads in refrigerated cases, **Figure 17.62**.

Figure 17.62 This very small motor may be used for a refrigerated case.

Courtesy General Electric

Figure 17.63 This analyzer is connected to the motor and control board. The technician can diagnose whether the problem lies within the motor or the board itself.



Courtesy Ferris State University. Photo by John Tomczyk

The ECM is actually a two-piece motor: the controls and the motor section. If the technician suspects that the motor is defective, the controls can be removed and the motor may be checked using an ohmmeter in the conventional manner. If the motor turns out to be electrically sound, a test module (furnished by the manufacturer) can be fastened to the motor and operated manually at variable speeds, **Figure 17.63**. When the motor will operate correctly with the test module and not operate without it, the ECM electronic portion of the motor can be checked for correct input and tight connections. If the motor cannot be made to operate with the correct signal to the ECM control portion, the ECM controls can be changed and the same motor used.

NOTE: *Each motor has its own ECM control package, which is not interchangeable with any other ECM control package from the same manufacturer. Remember, the control package is programmed for the specific piece of equipment. If it is to be replaced, an exact replacement must be used.*

All variable-speed motors must have very close fault control. They all tend to give off a lot of electronic noise, peaks, and valleys to the input supply AC voltage because they are constantly stopping and starting the input current flow to the converter. If a large current flow is stopped in the middle of the entering sine wave cycle, the power furnished by the power company will have a tendency to fluctuate, which will create a spike in voltage. The same thing will happen if a large current load is started, like the inrush current on start-up of a motor. The fluctuations must be filtered to prevent causing problems with computers and other electronic equipment in the vicinity. The manufacturer of the equipment has taken special precautions to avoid this and all of the manufacturer's directions should be followed.

One of the advantages of variable-speed motors is that they can be started at a reduced speed, which will reduce inrush current. As discussed earlier, the inrush current is about five times the running current. When a large motor is started in an office building, the inrush current can cause the voltage in the entire building to drop to a lower value, causing lights to blink and computers to cycle off if the drop is extreme. There are methods of softening the start-up of large motors. Variable-speed motors have what is called a soft start-up, at a reduced speed. Then the motor speed is ramped up to full load and full current.

The compressor motor is the largest motor in the system. When the load is reduced, the indoor fan and the condenser fan speeds must be reduced in proportion to the load on them. By reducing the indoor fan speed, the humidity in the conditioned space can be controlled. If the indoor fan speed is not reduced when the compressor speed is reduced, the suction pressure will rise and proper humidity removal will not be accomplished. By reducing the indoor fan speed, the suction pressure will be reduced and humidity removal will continue. The same is true of the condenser fan motor. If the compressor load is reduced, the load on the condenser is reduced. If the condenser fan is still operating at full speed, the head pressure will become too low and operating problems may occur.

As electronic components become more cost-effective, they will be used in smaller equipment, which will create very efficient systems. Each manufacturer has established a troubleshooting procedure, which should be followed. Always check the incoming power supply to any device to make sure it is what it should be before you decide the electronics are the problem. It is possible to have one fuse blown on a three-phase circuit. A quick check with a voltmeter will verify whether the power supply is good.

Some benefits of variable-speed technology are

- Power savings
- Load reduction based on demand
- Soft starting of the motor (no LRA)
- Better space temperature and humidity control
- Solid-state motor starters without open contacts
- Oversized units for future expansion that can run at part load until the expansion
- Load and capacity matching.

17.30 COOLING ELECTRIC MOTORS

All motors must be cooled because part of the electrical energy input to the motor is given off as heat. Most open motors are air-cooled; hermetic motors may be cooled by air or refrigerant gas, **Figure 17.64**. Small and medium-sized motors are water-cooled. An air-cooled motor has fins on the surface to help give the surface more area for dissipating heat. These motors must be located in a moving airstream. To cool properly, refrigerant gas-cooled motors must have an adequate refrigerant charge.

Figure 17.64 All motors must be cooled or they will overheat. (A) This compressor is cooled by the refrigerant gas that passes over the motor windings. (B) This compressor is cooled by air from the fan. The air-cooled motor has fins on the compressor to help dissipate heat.

SUMMARY

- Compressors used in refrigeration applications normally require motors with high starting torque.
- Small fans normally need motors that have low starting torque.
- The voltage supplied to a particular installation will determine the motor's voltage. The common voltage for furnace fans is 115 V; 230 V is the common voltage for home air-conditioning systems.
- Common single-phase motors are split-phase, PSC, shaded-pole, and electronically commutated (ECM).
- When more starting torque is needed, a start capacitor is added to the motor.
- A run capacitor improves the running efficiency of the split-phase motor.
- A centrifugal switch breaks the circuit to the start winding when the motor is up to running speed. The switch changes position with the speed of the motor.
- The common rated speed of a single-phase motor is determined by the number of poles or windings in the motor. The common speeds are 1800 rpm, which will slip in speed to about 1725 rpm, and 3600 rpm, which will slip to about 3450 rpm.
- The difference between 1800/3600 and the running speeds of 1750/3450 is known as slip. Slip is due to the load imposed on the motor while operating.
- Three-phase motors are used for all large applications. They have a high starting torque and a high running efficiency. Three-phase power is not available to most residences, so these motors are limited to commercial and industrial installations.
- Since the winding of a hermetic compressor is in the refrigerant atmosphere, a centrifugal switch may not be used to interrupt the power to the start winding.
- A potential relay takes the start winding out of the circuit using BEMF.
- A current relay breaks the circuit to the start winding using the motor's run current.
- The PSC motor is used when high starting torque is not required. It needs no starting device other than the run capacitor.
- The PTC device is used with some PSC motors to give small amounts of starting torque. It has no moving parts.
- Dual-voltage three-phase compressors are built with two motors wired into the housing.
- Variable-speed motors operate at higher efficiencies with varying loads.
- The electronically commutated motor (ECM) is a DC motor that does not have brushes.
- Variable-speed motors can even out the load on the heating and air-conditioning systems by adjusting the equipment speed to the actual load.
- Motor speed can be varied from about 10% of rated speed to about 120% using electronics.
- Electronic switches, silicon-controlled rectifiers (SCRs), and transistors can be turned on and off without creating an arc. They are reliable and do not use much power.
- DC converters convert AC power to DC power.
- Capacitors even out the pulsating DC power.
- Inverters create an alternating frequency that can be varied.
- The frequency and the voltage must be changed together for the motor to perform efficiently.

REVIEW QUESTIONS

1. The two popular operating voltages for residences are _____ V and _____ V.
2. When an open motor gets up to speed, the _____ switch takes the start winding out of the circuit.
3. Is the resistance in the start winding **greater** or **less** than the resistance in the run winding?
4. Which of the following devices may be wired into the starting circuit of a motor to improve the starting torque?
   A. Another winding
   B. A start capacitor
   C. A thermostat
   D. A winding thermostat
5. Which of the following devices may be wired into the running circuit of a motor to improve the running efficiency?
   A. A start capacitor
   B. A run capacitor
   C. Both a start and a run capacitor
   D. None of the above
6. Define BEMF.
7. Why is the hermetic compressor motor manufactured from special materials?
8. The two types of motors used for hermetic compressors are _____ and _____.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

9. How does power pass through the compressor shell to the motor inside?
10. The two types of relays used to start hermetic compressors are the _____ relay and the _____.
11. A PTC device is used
    A. to start a hermetic compressor.
    B. as a motor protector.
    C. to protect against low oil pressure.
    D. to protect against high oil temperature.
12. True or False: Three-phase motors have low starting torque.
13. True or False: All large motors are three-phase.
14. Why is it desirable to have a two-speed compressor?
15. True or False: All electric motors must be cooled or they will overheat.
16. True or False: An SCR is an electronic switch.
17. When a transistor is used as a switch
    A. a great deal of power is consumed.
    B. it makes a lot of noise.
    C. it is subject to quick failure.
    D. it does not create an arc.
18. Capacitors are used after the converter to
    A. smooth out the DC current.
    B. suppress the noise.
    C. change the voltage frequency.
    D. reduce the voltage.
19. The converter
    A. changes the frequency of the power.
    B. changes AC to DC.
    C. is a switch.
    D. is used only with DC motors.
20. The inverter
    A. adjusts the frequency.
    B. adjusts the DC voltage.
    C. smooths out the AC power.
    D. makes a lot of noise.
21. Briefly describe the operation of the three electronic sections of a variable frequency drive (VFD) using **Figure 17.60** for assistance.

UNIT 18

APPLICATION OF MOTORS

OBJECTIVES

After studying this unit, you should be able to

- explain service factor amperage (SFA).
- explain full-load amperage (FLA) and rated-load amperage (RLA).
- explain compressor amperage performance data.
- identify the proper power supply for a motor.
- describe the application of three-phase versus single-phase motors.
- describe other motor applications.
- explain how the noise level in a motor can be isolated from the conditioned space.
- describe the different types of motor mounts.
- identify the various types of motor drive mechanisms.

SAFETYCHECKLIST

- ✔ Ensure that electric motor ground straps are connected properly when appropriate so that the motor will be grounded.
- ✔ Never touch a motor drive belt when it is moving. Be sure that your fingers do not get between the belt and the pulley.

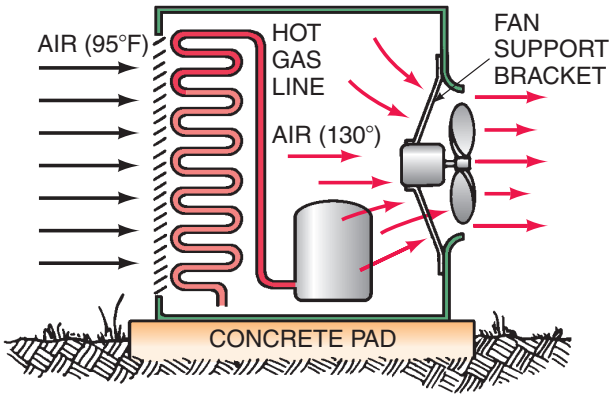
18.1 MOTOR APPLICATIONS

Because electric motors perform so many different functions, choosing the proper motor is necessary for safe and effective performance. Usually, the manufacturer or design engineer for a particular job chooses the motor for each piece of equipment. However, as a technician you often will need to substitute a motor when an exact replacement is not available, so you should understand the reasons for choosing a particular motor for a job. For example, when a fan motor burns out in the air-conditioning condensing unit, the correct motor must be obtained or another failure may occur. **NOTE:** *In an air-cooled condenser, the air is normally pulled through the hot condenser coil and passed over the fan motor. This hot air is used to cool the motor. You must be aware of this, or you may install the wrong motor.* • The motor must be able to withstand the operating temperatures of the condenser air, which may be as high as 130°F, **Figure 18.1**.

Open motors are discussed in this unit because they are the only ones from which a technician has a choice of selection. Some design differences that influence the application are as follows:

- Power supply
- Work requirements
- Motor insulation type or class
- Bearing types
- Mounting characteristics
- Cooling requirements

Figure 18.1 This motor is operating in the hot airstream after the air has been pulled through the condenser.



18.2 THE POWER SUPPLY

The power supply must provide the correct voltage and sufficient current. For example, the power supply in a small shop building may be capable of operating a 5-hp air compressor. But suppose air-conditioning is desired. If the air-conditioning contractor prices the job expecting the electrician to use the existing power supply, the electrical service for the whole building may have to be changed. The motor equipment nameplate and the manufacturer's catalogs provide the information needed for the additional service, but someone must put the whole project together. The installing air-conditioning contractor may have that responsibility. See **Figure 18.2** for a typical motor nameplate and **Figure 18.3** for a part of a page from a manufacturer's catalog that includes the electrical data. **Figure 18.4** is an example of a typical electrical panel rating.

The power supply data contain the following:

1. The voltage (115 V, 208 V, 230 V, 460 V)
2. The current capacity in amperes

Figure 18.4 A nameplate on an electrical panel used for a power supply.

Photo by Bill Johnson

3. The frequency in hertz or cycles per second (60 cps in the United States and 50 cps in many foreign countries)
4. The phase (single or three phase)

Motors and electrical equipment must fit within the system's total electrical capacity, or failures may occur. Inadequate voltage and current are most often encountered. The technician can check them, but it is usually preferable to have a licensed electrician make the final calculations.

VOLTAGE

The voltage of an installation is important because every motor operates within a specified voltage range, usually within ±10%. **Figure 18.5** gives the upper and lower limits of common voltages. If the voltage is too low, the motor will draw a high current. For example, if a motor is designed to operate on 230 V but the supply voltage is really 200 V, the motor's current draw will go up. The motor is trying to do its job, but it lacks the power and it will overheat, **Figure 18.6**.

If the applied voltage is too high, the motor may develop local hot spots within its windings, but it will not always experience high amperage. The high voltage will actually give the motor more power than it can use. A 1-hp motor with a voltage rating of 230 V that is operating at 260 V is running above its 10% maximum. This motor may be able to develop 1 1/4 hp at this higher-than-rated voltage, but the windings are not

Figure 18.5 This table shows the maximum and minimum operating voltages of typical motors.

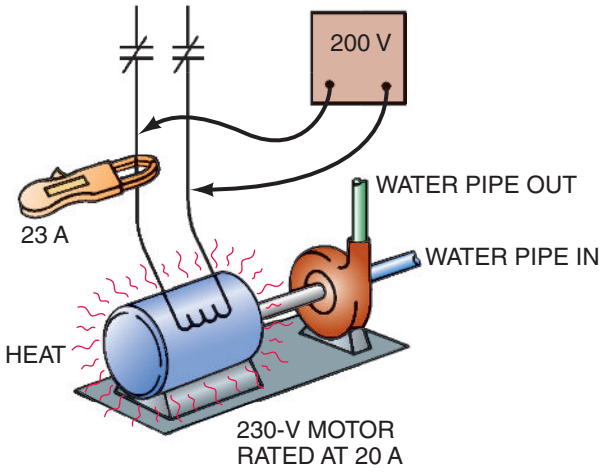
Figure 18.6 A motor operating under a low-voltage condition.



designed to operate at that level. The motor can overheat and eventually burn out if it continually runs overloaded. This can happen *without* drawing excessive current, **Figure 18.7**.

CURRENT CAPACITY

There are two current ratings for a motor. The full-load amperage (FLA) is the current the motor draws while operating at a full-load condition at the rated voltage. When the full-load torque and horsepower of a motor is reached, the amperage the motor is drawing is referred to as the full-load amperage (FLA). FLA is determined under laboratory conditions and is printed on the motor's nameplate. For example, a 1-hp motor will draw approximately 16 A at 115 V or 8 A at 230 V in a single-phase circuit. **Figure 18.8** shows approximate amperages for some typical motors.

Figure 18.7 A motor rated at 230 V and operating at 260 V.

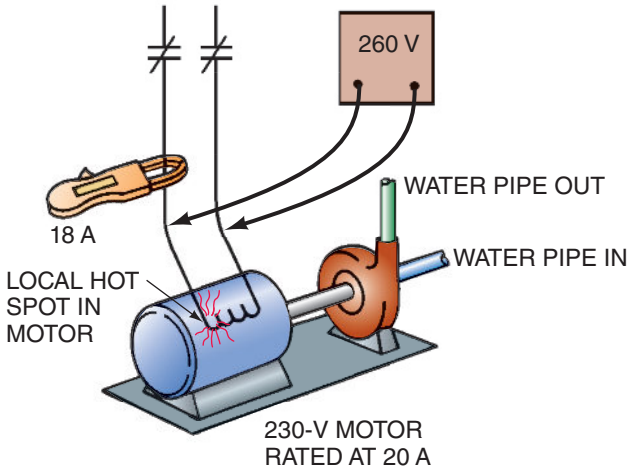


Figure 18.8 This chart shows approximate full-load amperage values.

Another amperage rating that may be given for a motor is the locked-rotor amperage (LRA). The LRA is the amperage the motor draws at start-up before the rotor has started to turn. The two current ratings are available for every motor and are stamped, for an open motor, on the motor nameplate. By taking amperage readings at start-up and while the motor is operating under load and comparing these readings with those on the motor nameplate, the technician can determine whether the motor is operating within its design parameters. Both ratings may not be printed on the nameplate of some motors. Normally, the LRA is about five times the FLA. For example, a motor that has a FLA of 5 A will normally have a LRA of about 25 A. If the LRA is given on the nameplate and the FLA is not, divide the LRA by 5 to get an approximate FLA or RLA. For example, if a compressor nameplate shows a LRA of 80 A, the approximate FLA is 80/5 = 16 A.

Rated-load amps (RLA) is a mathematical calculation used to get Underwriters Laboratories (UL) approval for a compressor motor. It should not be confused with full-load amps (FLA). Full-load amps (FLA) have not been used by compressor manufacturers since 1972, when UL changed the rating to rated-load amps (RLA).

Refrigeration and air-conditioning service technicians deal with compressor motors whose loads and amp draws vary and are dependent on:

- Surrounding ambient temperature
- Condensing and evaporating temperatures

- Compressor return gas temperatures
- Liquid temperatures entering the metering device
- Voltage at the compressor

In these cases, the service technician must obtain compressor performance data from the compressor manufacturer. Many times, this data can be found on the Internet at the manufacturer's website. **Figure 18.9(A)** illustrates compressor data in table form. Notice in **Figure 18.9(A)** that the amperage drawn by the compressor depends on both the condensing and evaporating temperatures. This type of data also comes in curve form, often referred to as a rating chart or performance data for a particular compressor. Compressor manufacturers publish a rating or performance chart for each compressor they manufacture. Let's use **Figure 18.9(A)** to help solve a compressor field problem.

Problem: Let's assume the R-22 compressor in **Figure 18.9(A)** is operating at 230 V and has an evaporator temperature of −15°F and a condensing temperature of 100°F. Determine the correct current (amp) draw for this compressor using the table.

Solution: Using the current (amperage) table in **Figure 18.9(A)**, the intersection of the 100°F condensing temperature with a −15°F evaporating temperature results in an amp draw of 29.4 A. This data tells us that this compressor operating under these pressures should draw close to 29.4 A at 230 V. The allowable tolerance is ±10%. If the compressor was operating at 460 V, the amperage values in the table would have to be multiplied by 1/2. Remember, the compressor must be operating at the proper voltage for the table to be meaningful.

If the service technician now actually measures the compressor amps with an ammeter at the compressor and finds the amps to be very close to 29.4 A, he has a pretty good idea that the compressor is up to specifications. If, however, the technician measures the current draw of the compressor and finds that it is pulling only 13 A under these same conditions, there is a problem somewhere. Following is a list of reasons why a compressor may draw low amperage:

- Bad suction and/or discharge valve
- Starved evaporator
- Worn rings
- Leaking head gasket or valve plate gasket
- Restricted liquid line or filter drier
- Undercharged system
- Weak motor
- Metering device starving evaporator

The service technician must now systematically check each of these causes to find the one that is the reason for the low amp draw. Amperage tables like the one used in this example are invaluable tools in systematically troubleshooting and diagnosing compressor problems.

Notice in **Figure 18.9(A)** that as the condensing temperature decreases, so do the amps, assuming a constant evaporating temperature. Also, as the evaporating temperature decreases, so do the amps, assuming a constant condensing pressure. Decreased condensing temperatures mean lower condensing pressures and a lower compression ratio. The compressor's piston now operates with less pressure against it as it compresses the suction gases. This, in turn, places less stress on the motor and draws less amperage. As the evaporating temperature decreases, so do the evaporating pressures. These lower pressures entering the compressor's cylinders mean the vapors filling the cylinders are less dense, and the compressor pumps less mass flow rate of refrigerant vapor. This causes a decreased amp draw.

NOTE: *Operating conditions other than just evaporating and condensing temperatures (pressures) are used in these tables. The conditions in the upper left-hand corner of* **Figure 18.9(A)** *must be met for the values to be 100% accurate. The conditions are:*

- *65°F return gas temperature*
- *0°F liquid subcooling*
- *95°F ambient air over the condenser*
- *60-Hz operation*

If these conditions are not met, the table will not be 100% accurate. However, for purposes of systematic field troubleshooting, these inaccuracies are not large enough to have any major effect on a good service technician's judgment. •

The point is, when troubleshooting a refrigeration or air-conditioning compressor's motor, the RLA or FLA value should not be used to determine if the compressor is good or bad or if it is drawing the correct amps. Compressor performance data like those in **Figure 18.9(A)** must be used for a specific compressor. The value of RLA or FLA to a refrigeration or air-conditioning service technician is simply to size wires, fuses, overloads, and contactors for the compressor. The nameplate RLA does not change as the compressor motor load changes with temperatures and pressures. And the RLA should not be used by the service technician to determine the proper refrigerant charge or to determine if the compressor is running properly. In summary, always refer to performance or rating data from the manufacturer for that compressor. More detailed coverage of compressor performance data in table and curve form will be provided in Unit 23, "Compressors."

Every motor has a service factor, which may be listed in the manufacturer's literature. This service factor is actually reserve horsepower. A service factor of 1.15 means that the motor can periodically operate at 15% over the nameplate horsepower before it is out of its design parameters. A motor operating with a variable load and above normal conditions for short periods of time should have a larger service factor. If at a particular installation the voltage varies, a motor with a high service factor may be chosen. The service factor is standardized by the National Electrical Manufacturer's Association (NEMA).

Figure 18.9(B) Service factors for different horsepower motors at different synchronous speeds.

Horsepower (hp)	SERVICE FACTOR (SF) Synchronous Speed (RPM)			
	3600	800	1200	900
1/6, 1/4, 1/3	1.35	1.35	1.35	1.35
1/6	1.25	1.25	1.25	1.25
3/4	1.25	1.25	1.15	1.15
1.0	1.25	1.15	1.15	1.15
1.5 and up	1.15	1.15	1.15	1.15

The chart in **Figure 18.9(B)** shows different service factors for drip-proof motors at synchronous speed (rpm). These service factors are actually "periodic" overload capacities at which the motor can operate without damage, overheating, or overloading. The service factor is not intended to be a general increase in the motor's horsepower rating. A motor that operates "continuously" at a service factor greater than 1 will have a reduced life expectancy compared to when operating at its rated nameplate horsepower. Also, the bearing and insulation life will be reduced if the motor operates at its service factor load. Never rely on a motor to perform continuous duty if it is running on its service factor loading. The appropriate use of the service factor rating is to handle short-term or occasional overloads.

Any motor that has a service factor greater than 1 must have the service factor indicated on its nameplate. In some instances, the current the motor is drawing at its service factor loading is also indicated on the nameplate. This is usually expressed as **service factor amperes (SFA)**.

FREQUENCY

The frequency in cycles per second (cps) is the frequency of the electrical current that the power company supplies. The technician has no control over this. Most motors are 60 cps in the United States but could be 50 cps in another country. Most 60-cps motors will run on 50 cps, but they will develop only five-sixths of their rated speed (50/60). If you believe that the supply voltage is not 60 cps, contact the local power company. When motors are operated with local generators as the power supply, the generator's speed will determine the frequency. A cps meter is normally mounted on the generator and can be checked to determine the frequency.

PHASE

The number of phases of power to be supplied by the power company is determined by the type of equipment to be used at a particular installation. For equipment using three-phase motors, three-phase power must be supplied. Normally, single-phase power is supplied to residences and three-phase power is supplied to commercial and industrial installations when needed. Single-phase motors will operate on two phases of three-phase power, **Figure 18.10**. Three-phase motors will not operate on single-phase power, **Figure 18.11**.

The power company furnishes the power to the respective services to meet the specifications of the particular job. For example, if the job or system calls for a large electrical

Figure 18.10 This wiring diagram shows how single-phase motors are wired into a three-phase circuit.

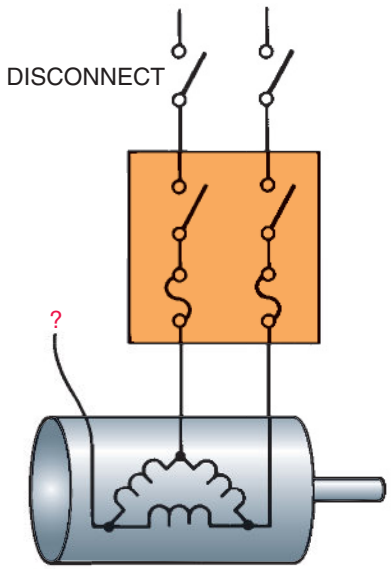
Figure 18.11 A three-phase motor with three power leads cannot be connected to a single-phase power supply.



load, such as a manufacturing plant or high-rise building, it will consult with the engineers about what they recommend. Power companies rate the voltage furnished according to the nominal voltage furnished, which is typically 480 V, 240 V, 208 V, and 120 V. Motors and appliances are typically rated at 460 V, 230 V, 208 V, and 115 V. The technician must work with the rated motor and appliance voltages. Usually, the power supply will be close to the power company rating and still be within the motor's rating.

The technician needs to know the characteristics of the voltage supplied. The supplied voltage depends on the power company's transformer and the way it is connected. The two transformer types commonly used for commercial and industrial applications are the wye, or star, transformer and the delta transformer, **Figure 18.12**.

The wye transformer is configured in a Y-shaped connection with three windings going to a center tap. The center tap is considered the neutral or grounded neutral leg. The consumer typically will have a power supply of 208 V at the secondary terminals from phase to phase and 115 V (120 V) from any phase to the grounded neutral.

Figure 18.12 Two different transformers for commercial and industrial applications.

Another option for the wye transformer is to furnish 460 V (480 V) phase to phase and 277 V phase to the grounded neutral. The 277 V to the neutral is often used for the building's lighting service. Smaller wire sizes can be used in the lighting circuits. When 460-V (480 V) and 277-V grounded neutral are used, there must be a further reduction of voltage for any 115-V (120-V) circuits in the building. This is accomplished with step-down transformers at locations near the point of consumption. The wye transformer connection service is popular because it is easier to balance the load of each phase-to-phase transformer connection. This is necessary to keep the load on the power supply balanced.

The delta transformer service has been popular in some localities in the past. This service furnishes 230 V and can have a "center-tapped" leg to furnish 115 V. Notice that this service furnishes 230 V phase to phase, 115 V from phase 1 to neutral, and 115 V from phase 2 to neutral. It is hard to balance the loads on this system because of the two phases that have a relationship to neutral. **NOTE:** *The relationship from the third phase to neutral is not usable. This is often called a "wild leg" or a "high leg" and is identified with orange along its length to prevent confusion. This leg often has 185 V or more to neutral or ground. If a 115-V appliance is connected to this leg, it will be burned out in short order.* •

The technician is advised to carry and use a quality voltmeter and to always check the power supply voltages to know exactly what is available at the job site.

18.3 ELECTRIC-MOTOR WORKING CONDITIONS

The motor's working conditions determine which motor is the most economical for a particular installation. An open motor with a centrifugal starting switch (single-phase) for an air-conditioning fan may not be used in a room containing explosive gases. When the motor's centrifugal switch opens to interrupt the power to the start winding, the gas may ignite. Instead, an explosion-proof motor enclosed in a housing must be used, **Figure 18.13**. Local codes should be checked and adhered to. Because the explosion-proof motor is too expensive to be installed in a standard office building, another type of motor should be chosen. A motor operated in a very dirty area may need to be enclosed, which would give no ventilation for the motor windings. This motor must have some method of dissipating the heat from the windings, **Figure 18.14**. A drip-proof motor should be used where water may fall on the motor; it is designed to shed water, **Figure 18.15**.

18.4 INSULATION TYPE OR CLASS

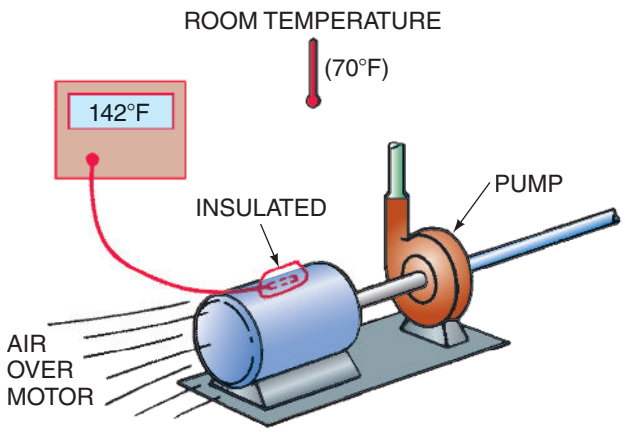
The insulation type or class of a motor describes how hot the motor can safely operate in a particular ambient temperature condition. The earlier example of the motor used in an air-conditioning condensing unit is typical. This motor must be designed to operate in a high ambient temperature. Motors are classified by the maximum allowable operating temperatures of the motor windings, **Figure 18.16**.

For many years, motors were rated by allowable temperature rise of the motor above the ambient temperature. Many motors still in service are rated this way. A typical motor has a temperature rise of 40°C. If the maximum ambient temperature is 40°C (104°F), the motor should have a winding temperature of 40°C + 40°C = 80°C (176°F). When troubleshooting these motors, the technician may have to convert from Celsius to Fahrenheit or may need a conversion table if the temperature rating is given only in Celsius. If the temperature of the motor winding can be determined, the technician can tell if a motor is running too hot for the conditions. For example, a motor in a 70°F room is allowed a 40°C rise on the motor. The maximum winding temperature is 142°F (70°F = 21°C; 21°C + 40°C rise = 61°C, which is 142°F), **Figure 18.17**.

Figure 18.16 Temperature classifications for typical motors.

Class A	221°F	(105°C)
Class B	266°F	(130°C)
Class F	311°F	(155°C)
Class H	356°F	(180°C)

Figure 18.17 This motor is being operated in an ambient temperature that is equal to the maximum allowable for its insulation with a 40°C rise.



NOTE: CARE MUST BE TAKEN THAT TEMPERATURE TESTER LEAD IS TIGHT ON MOTOR AND NEXT TO MOTOR WINDINGS. THE LEAD MUST BE INSULATED FROM SURROUNDINGS. THE TEMPERATURE CHECK POINT MUST BE AS CLOSE TO THE WINDING AS POSSIBLE.

18.5 TYPES OF BEARINGS

Load characteristics and noise level determine the type of bearings that should be selected for the motor. Two common types are the *sleeve* bearing and the *ball* bearing, **Figure 18.18**. Large motors use a type of ball bearing called a *roller bearing*, which has cylindrically shaped rollers instead of balls.

The sleeve bearing is used where the load is light and the noise must be low (e.g., a fan motor on a residential furnace). A ball-bearing motor would probably make excessive noise in the conditioned space. Metal ductwork is an excellent sound carrier, and any noise in the system is carried throughout the entire system. For this reason, sleeve bearings are normally used in smaller applications, such as in residential and light commercial air-conditioning systems. They are quiet and dependable, but they cannot stand great pressures (e.g., if fan belts are too tight). Motors that use sleeve bearings can have either vertical or horizontal shafts. The typical air-cooled condenser has a vertical motor shaft and pushes the air out the top of the unit. This results in a downward thrust on the motor bearings, **Figure 18.19**. A furnace fan has a horizontal motor shaft, **Figure 18.20**. These two types may not look very different, but they are. The vertical condenser fan is trying to fly downward into the unit to push air out the top. This puts a real load on the end of the bearing (called the **thrust surface**), **Figure 18.21**.

Figure 18.19 This motor is working against two conditions: the normal motor load and the fact that the fan is trying to fly downward while pushing air upward.

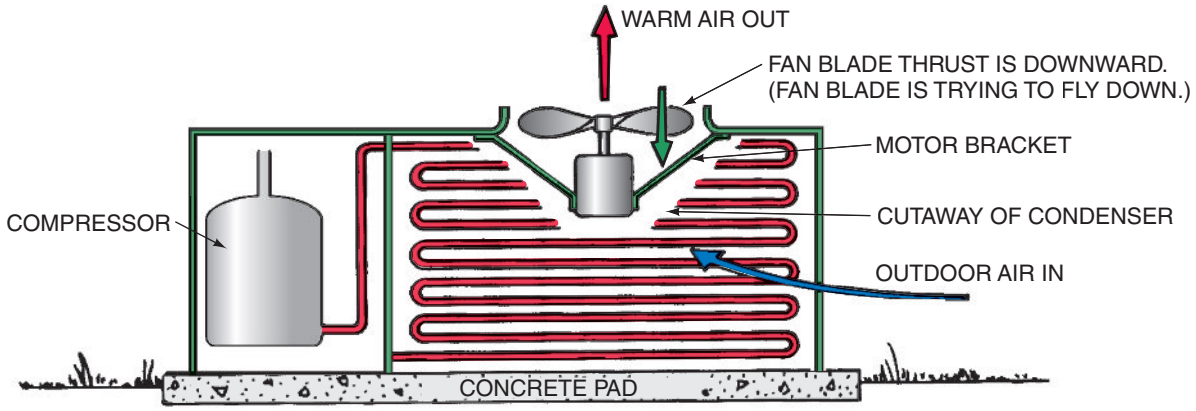

Figure 18.20 A furnace fan motor mounted in a horizontal position.

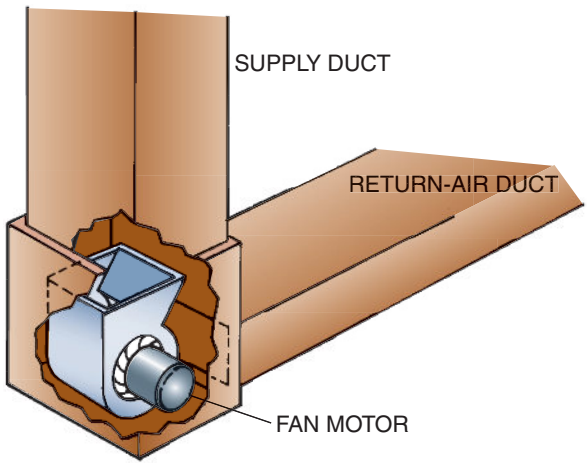

Figure 18.21 The thrust surface on a fan motor bearing.

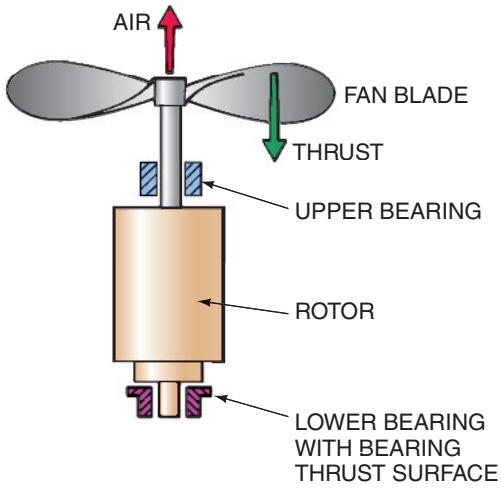

Sleeve bearings are made from material that is softer than the motor shaft. The bearing must have lubrication—an oil film between the shaft and the bearing surface. The shaft actually floats on this oil film and should never touch the bearing surface. The oil film is supplied by the lubrication system. Two types of lubrication systems for sleeve bearings are the *oil port* and the *permanently lubricated* bearing.

The oil port bearing has an oil reservoir that is filled from the outside by means of an access port. This bearing must be lubricated at regular intervals with the correct type of oil, which is usually 20-weight nondetergent motor oil or an oil specially formulated for electric motors. If the oil is too thin, it will allow the shaft to run against the bearing surface. If the oil is too thick, it will not run into the clearance between the shaft and the bearing surface. The correct interval for lubricating a sleeve bearing depends on the design and use of the motor. The manufacturer's instructions will indicate the recommended interval. Some motors have large reservoirs and do not need lubricating for years. This is good if there is limited access to the motor.

The permanently lubricated sleeve bearing is constructed with a large reservoir and a wick to gradually feed oil to the bearing. This bearing truly does not need lubrication until the oil deteriorates, which will happen if the motor has been running hot for many hours. Shaded-pole motors operating in the heat and weather have these bearing systems, and many have operated without failure for years.

Ball-bearing motors are not as quiet as sleeve-bearing motors and are used in locations where their noise levels will not be a problem. Large fan motors and pump motors are normally located far enough from the conditioned space that the bearing noises will not be noticed. These bearings are made of very hard material and usually lubricated with grease rather than oil. Motors with ball bearings generally have permanently lubricated bearings or grease fittings. Permanently lubricated ball bearings are similar to permanently lubricated sleeve bearings, except that they have reservoirs

Figure 18.22 A fitting through which the bearing is greased.

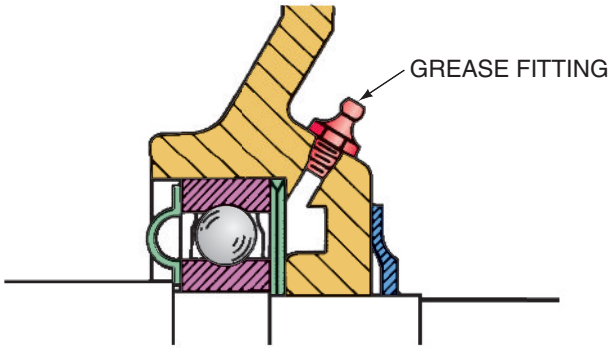

Figure 18.23 A motor bearing using grease for lubrication. Notice the relief screw.

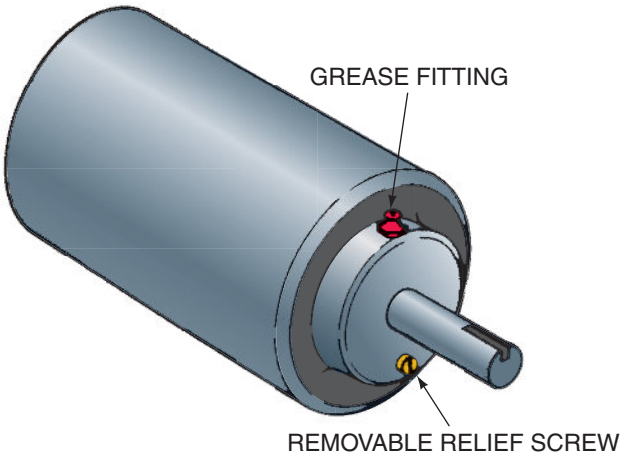

of grease sealed in the bearing. They are designed to last for years with the lubrication furnished by the manufacturer, unless the conditions in which they operate are worse than those for which the motor was designed.

Bearings needing lubrication have grease fittings so a grease gun can force grease into the bearing. This is often done by hand, **Figure 18.22**. Only an approved grease should be used. In **Figure 18.23**, the slotted screw at the bottom of the bearing housing is a *relief screw*. When grease is pumped into the bearing, this screw must be removed or the pressure of the grease may push the grease seal out, and grease will leak down the motor shaft.

18.6 MOTOR MOUNTING CHARACTERISTICS

The mounting characteristics of a motor determine how it will be secured during its operation. When mounting a motor, the technician must consider noise level. The two primary mountings are the rigid mount and the resilient, or rubber, mount.

Figure 18.24 The grounding strap to carry current from the frame if the motor has a grounded winding.

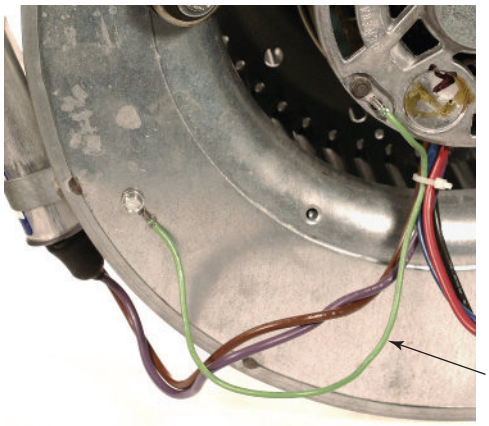

Photo by Bill Johnson

Rigid-mount motors are bolted, metal to metal, to the frame of the fan or pump and will transmit any motor noise into the piping or ductwork. Motor hum is an electrical noise, which is different from bearing noise, and must also be isolated in some installations. **Resilient-mount motors** use different methods of isolating the motor and bearing noise from the metal framework of the system. Notice the ground strap on the resilient-mount motor, **Figure 18.24**. This motor is electrically and mechanically isolated from the metal frame. If the motor were to have a ground (circuit from the hot line to the frame of the motor), the motor frame would be electrically hot without the ground strap. **SAFETY PRECAUTION:** *When replacing a motor, always connect the ground strap properly or the motor could become dangerous,* **Figure 18.25**. •

The four basic mounting styles are **cradle mount**, **rigid-base mount**, **end mount** (with tabs or studs or flange mount), and **belly-band mount**, all of which fit standard dimensions established by NEMA and which are distinguished from each other by *frame numbers*. **Figure 18.26** shows some typical examples.

Figure 18.25 This illustration shows how the grounding strap works.

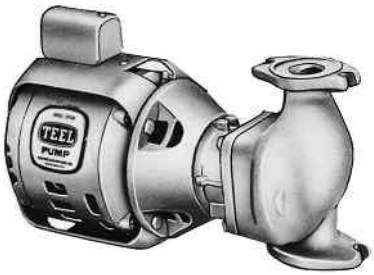
CRADLE-MOUNT MOTORS

Cradle-mount motors are used in either direct-drive or belt-drive applications. A cradle fits the motor end housing at each end, and the end housing is held down with a bracket, **Figure 18.27**. The cradle is fastened to the equipment or pump base with machine screws, **Figure 18.28**. Cradle-mount motors are available only in the small horsepower range. A handy service feature is that the motor can be removed easily.

Figure 18.28 A cradle fastened to the base of a pump.



Courtesy W. W. Grainger, Inc.

RIGID-BASE-MOUNT MOTORS

Rigid-base-mount motors are similar to cradle-mount motors except that the base is fastened to the motor body, **Figure 18.29**. It is the belt, if one is used, which drives the prime mover that provides the sound isolation for this motor. The belt is flexible and dampens motor noise. This motor is

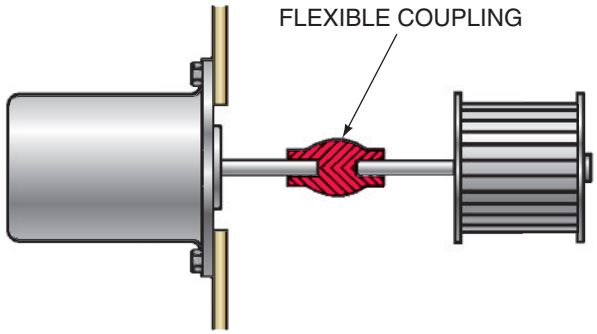
Figure 18.30 A direct-drive motor with flexible coupling.



often used as a direct drive to turn a compressor or pump. A flexible coupling is used between the motor and prime mover in a direct-drive installation, **Figure 18.30.**

END-MOUNT MOTORS

End-mount motors are very small motors mounted to the prime mover with tabs or studs fastened to the motor housing, **Figure 18.31**. Flange-mounted motors have a flange as a part of the motor housing, for example, an oil burner motor, **Figure 18.32.**

BELLY-BAND-MOUNT MOTORS

Motors with belly-band mounts have a strap that wraps around the motor to secure it with brackets mounted to the strap. These motors are often used in air-conditioning air handlers. Several universal types of motor kits are belly-band-mounted and will fit many different applications. These motors are all direct drive, **Figure 18.33.**

18.7 MOTOR DRIVES

Motor drives are devices or systems that connect a motor, the driving device, to the driven load, a fan for instance. Motors drive their loads by belts or direct drives through couplings, or the driven component may be mounted on the motor shaft. Gear drives, a form of direct drive, will not be covered in this text because they are used mainly in large industrial applications.

The drive mechanism is intended to transfer the motor's rotating power or energy to the driven device. For example, a compressor motor is designed to transfer the motor's power to the compressor, which compresses the refrigerant vapor and pumps refrigerant from the low side to the high side of the system. Efficiency, speed of the driven device, and noise level are some factors involved in this transfer. It takes energy to turn the belts and pulleys on a belt-drive system in addition to the compressor load. Therefore, a direct-drive motor may be better suited for

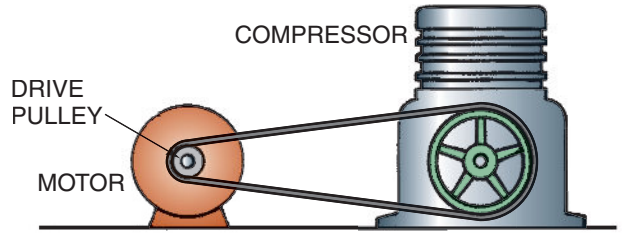
this application. **Figure 18.34** shows an example of both direct and belt drives.

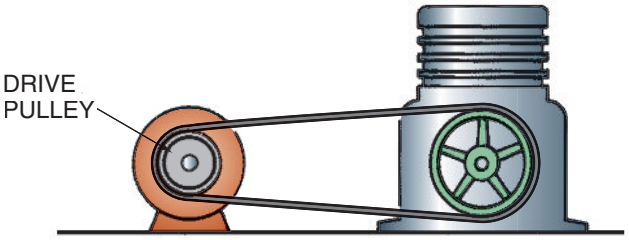
Belt-driven systems have been used for years to drive both fans and compressors. A feature of the belt-drive system is its versatility: both pulley sizes and the speed of the driven device may be changed, **Figure 18.35**. This can be a great advantage if the capacity of a compressor or a fan speed needs to be altered. However, the changes must be made according to the capacity of the drive motor.

There is a definite relationship between the speed of the motor and the speed of a blower, which involves the diameters of the drive and of the driven pulleys. The drive pulley is the pulley connected to the motor shaft; the driven pulley

Figure 18.35 A belt drive.



(A)



SAME MOTOR. LARGER DRIVE PULLEY WILL CAUSE THE COMPRESSOR TO TURN FASTER.

(B)

is the pulley connected to the blower shaft. The relationship is as follows:

Motor Speed × Drive Pulley Diameter
= Blower Speed × Driven Pulley Diameter

This formula assumes that the belts are positioned at the outermost edge of the pulleys, **Figure 18.36**. If the belts are resting in the pulley grooves with the outermost edge of the belt well within the pulley itself, use this formula: diameter of the

Figure 18.36 A belt riding at the outer edge of the pulley.

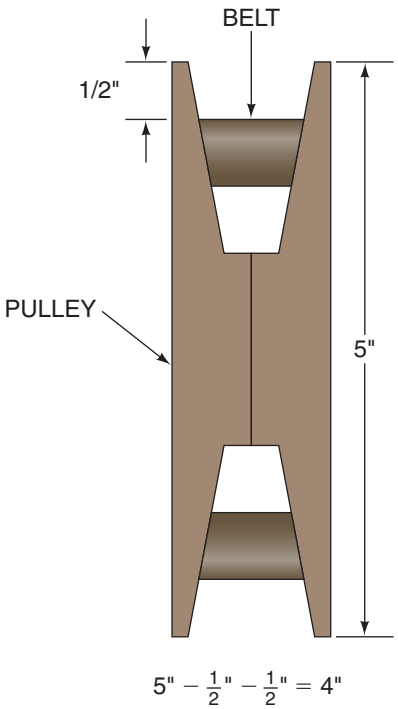
Figure 18.37 The belt is riding inside the pulley, so adjustments need to be made to the calculations.



pulley minus twice the distance between the top of the belt and the edge of the pulley, **Figure 18.37**.

Consider the pulley arrangement in **Figure 18.38**. The motor is turning at an actual speed of 3000 rpm and has a 4-inch pulley connected to its shaft. The blower shaft has a 6-inch pulley attached to it. How fast is the blower turning? From the formula, we get:

Motor Speed × Drive Pulley Diameter
= Blower Speed × Driven Pulley Diameter
3000 rpm × 4 in. = Blower Speed × 6 in.
Blower Speed = [(3000 rpm)(4 in.)] ÷ 6 in.
Blower Speed = 2000 rpm

Figure 18.38 A blower-speed example.

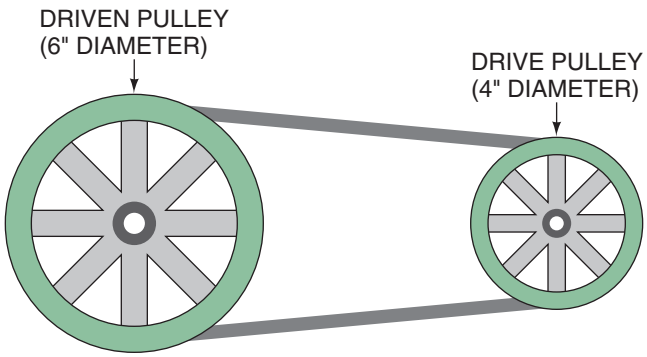


Figure 18.39 The correct method for installing belts over a pulley. The adjustment is loosened to the point that the belts may be passed over the pulley.

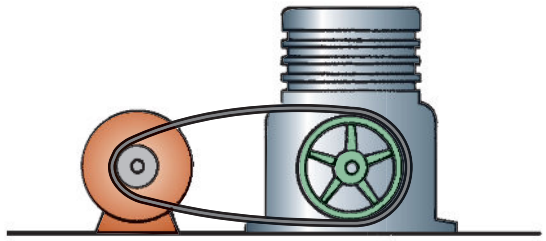

As long as three of the four values are known, the fourth can be computed using this very useful formula.

Belts are manufactured in different types and sizes. Some are made with different fibers to prevent stretching. **SAFETY PRECAUTION:** *Handle belts carefully during installation. A belt designed for minimum stretch must not be installed by forcing it over the side of the pulley because it may not stretch enough. Fibers will break and the belt will be weakened,* **Figure 18.39**. *Do not get your fingers between the belt and the pulley. Never touch the belt when it is moving.*•

Belt widths are denoted "A" and "B." An A-width belt must not be used with a B-width pulley nor vice versa, **Figure 18.40**. Belts can also have different grips, **Figure 18.41**. When a drive has more than one belt, the belts must be matched. Two belts marked with the same length are not necessarily matched. They may not be exactly the same length. A *matched* set of belts means the belts are *exactly* the same length. A set of 42-in. belts *marked* as a matched set means each belt is exactly 42 in. If the belts are not marked as a matched set, one may be 42 1/2 in. and the other may be 41 3/4 in. Thus the belts will not pull evenly—one belt will take most of the load and will wear out first.

Figure 18.40 A- and B-width belts.

Figure 18.41 This belt with grooves has a tractor-type grip.

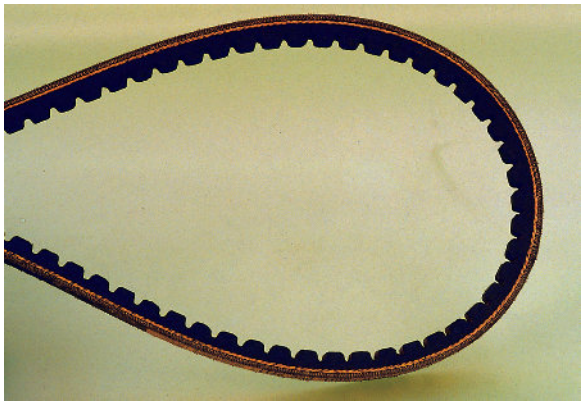

Photo by Bill Johnson

Belts and pulleys wear like any moving or sliding surface. When a pulley begins to wear, the surface roughens and wears out the belts. Normal pulley wear is caused by use or running time. Belt slippage will cause premature wear. Pulleys must be inspected occasionally, **Figure 18.42**.

Belts must have the correct tension, or they will cause the motor to operate in an overloaded condition. A belt tension gauge should be used to correctly adjust belts to the proper tension. This gauge is used in conjunction with a chart that gives the correct tension for different types of belts of various lengths, **Figure 18.43**.

Direct-drive motors are normally used with fans, pumps, and compressors. Small fans and hermetic compressors are direct drive, but the motor shaft is actually an extended shaft with the fan or compressor on the end, **Figure 18.44**. The technician can do nothing to alter these. When used in an open-drive application, some sort of coupling must be installed between the motor and the driven device, **Figure 18.45**. Some couplings are connected with springs to absorb small amounts of vibration from the motor or pump.

A more complicated coupling is used between the motor and a larger pump or a compressor, **Figure 18.46**.

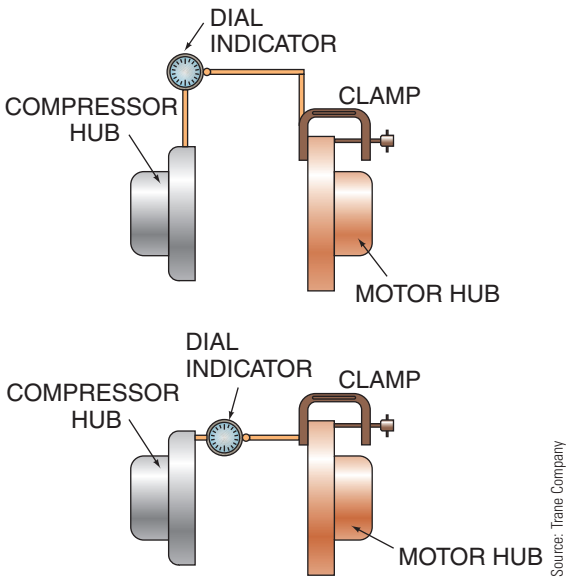
Figure 18.47 The alignment of the two shafts must be very close for the system to operate correctly.



Source: Trane Company

This coupling and shaft must be in very close alignment or vibration will occur. The motor shaft must be parallel to the compressor or pump shaft. Alignment is a very precise operation and is done by experienced technicians. If two shafts are aligned to within tolerance while the motor and driven mechanism are at room temperature, the alignment must be checked again after the system is run long enough to get it up to operating temperature. The motor may not expand and move the same distance as the driven mechanism, and the alignment may need to be adjusted to the warm value, **Figure 18.47**.

When an old motor must be replaced, try to use an exact replacement. An exact replacement may be found at a motor supply house or it may have to be obtained from the original equipment manufacturer. If the motor is not normally in stock, much time can be saved by taking the old motor to the distributor or supply house so that the motor's specifications can be matched.

SUMMARY

- In many installations only one type of motor can be used.
- The power supply determines the applied voltage, the current capacity, the frequency, and the number of phases.
- The working conditions (duty) for a motor specify the atmosphere in which the motor must operate (e.g., wet, explosive, or dirty).
- Motors are also classified according to the insulation of the motor windings and the motor temperature under which they operate.
- Each motor has sleeve, ball, or roller bearings. Sleeve bearings are the quietest but will not stand heavy loads.
- **SAFETY PRECAUTION:** *Motors must be mounted according to how they were designed to be installed.* •
- **SAFETY PRECAUTION:** *An exact motor replacement should be obtained whenever possible.* •
- The drive mechanism transfers the motor's energy to the driven device (the fan, pump, or compressor).

REVIEW QUESTIONS

1. List four characteristics of an application that would influence the selection of an electric motor.
2. Power supply data should include the following information:
   A. _____
   B. _____
   C. _____
   D. _____
3. The voltage range for an electric motor is usually within + or − _____%.
4. If an electric motor is rated for 208 V, the maximum allowable voltage would be _____, and the minimum allowable voltage would be _____.
5. Briefly explain how a service technician can tell if a compressor motor is drawing the proper amperage when it is running.
6. In the United States, the frequency in cycles per second (cps) at which an AC electric motor operates under normal conditions is
   A. 50.
   B. 60.
   C. 120.
   D. 208.
7. True or False: Three-phase motors are often used in air-conditioning systems in residences.
8. Two types of bearings commonly used on small motors are _____ and _____.
9. An open single-phase motor with a centrifugal starting switch may not be used in
   A. an air-conditioning condenser fan motor.
   B. an air-conditioning indoor air handler.
   C. an area where explosive gases exist.
   D. a ventilating fan motor.
10. What is meant by the service factor of an electric motor?
11. How does the insulation factor of a motor affect its use?
12. A(n) _____ bearing surface must be used in a vertical shaft motor application.
13. Two primary electric-motor mount characteristics are _____ and _____.
14. NEMA has established standardized motor dimensions. NEMA stands for _____ _____ _____ _____.
15. Two types of motor drives are _____ and _____ drives.
16. What is a matched set of belts?
17. Name the different types of belts.
18. Why must direct-drive couplings be aligned?
19. An instrument often used to check the alignment of two shafts is the
   A. micrometer.
   B. dial indicator.
   C. manometer.
   D. sling psychrometer.
20. Why must resilient-mount motors have a ground strap?
21. A belt-driven blower assembly is equipped with a motor that turns a 5-in. drive pulley at a speed of 3450 rpm. The blower is turning at a speed of 1725 rpm. Determine the size of the driven pulley.
22. Briefly describe what is meant by the term *service factor* as it applies to a motor.
23. Briefly explain what is meant by the term *full-load amperage* (FLA) as it applies to an electric motor.
24. Briefly explain what is meant by the term *rated-load amperage* (RLA) as it applies to compressor motors.

UNIT 19

MOTOR CONTROLS

OBJECTIVES

After studying this unit, you should be able to

- describe the differences between a relay, a contactor, and a starter.
- state how the locked-rotor current of a motor affects the choice of a motor starter.
- list the basic components of a contactor and starter.
- compare two types of external motor overload protection.
- describe conditions that must be considered when resetting safety devices to restart electric motors.

SAFETYCHECKLIST

- ✔ When a motor is stopped for safety reasons, do not restart it immediately. If possible, determine the reason for the overload condition before restarting.
- ✔ Conductor wiring should not be allowed to pass too much current or it will overheat and cause conductor failure or fire.
- ✔ When replacing or servicing line voltage components, ensure that the power is off, that the panel is locked and tagged, and that you have the only key.

19.1 INTRODUCTION TO MOTOR CONTROL DEVICES

This unit concerns those automatic components used to close and open the power supply circuit to the motor. These devices are called relays, contactors, and starters.

For example, a compressor in a residential central air conditioner is controlled in the following manner. With a temperature rise in the space to be conditioned, the thermostat contacts close and pass low voltage to energize the coil on the compressor contactor. This closes the contacts in the compressor contactor, allowing the applied or line voltage to pass to the compressor motor windings. Relays, contactors, and starters are the different names given to these motor controls, even though they perform the same function (but with some simple differences). Relays are designed to control loads that draw less than 20 A of electric current; contactors are designed to control loads that draw more than 20 A of current. Motor starters are, simply put, three-pole contactors with motor overload protection built into the device. More details will be presented as we discuss each of these system components.

Figure 19.1 is a diagram of a typical motor circuit. In this circuit there is a contactor as well as a potential magnetic relay (PMR) that is acting as a motor-starting relay. The contactor passes power to the motor on an external call for motor operation, and the starting relay helps the motor start on a call for operation. Notice the contactor is a major part of the motor circuit even though it is external to the motor windings. Power is fed to the motor windings and starting relay from the contactor.

The size of the motor and the application usually determine the type of switching device used (relay, contactor, or starter). For example, a small manual switch can start and stop a handheld hair drier, and a person operates the switch. A large 100-hp motor that drives an air-conditioning compressor must start, run, and stop unattended. It will also consume much more current than the hair drier. The components that start and stop large motors must be more elaborate than those that start and stop small motors.

Figure 19.1 Typical motor wiring diagram utilizing a contactor and a potential magnetic relay (PMR) as a motor-starting relay.

19.2 FULL-LOAD AND LOCKED-ROTOR AMPERAGE

Electric motors have two current (amperage) ratings: the **full-load amperage (FLA)**, and the **locked-rotor amperage (LRA)**. As the load or torque on a motor increases, the amperage draw required to power the motor will also increase. When the full-load torque and horsepower on the motor is reached, the corresponding amperage the motor is drawing is referred to as the full-load amperage (FLA). This value is determined in a test laboratory and recorded on the nameplate of the motor. It is used to select the correct wire size, overload, and motor starter devices to serve and protect the motor. The LRA is the current drawn by the motor just as it begins to start but before the rotor begins to rotate. The LRA of a motor is typically five times higher than the FLA of the motor and can be as high as seven times the FLA. Both currents must be considered when choosing the component (relay, contactor, starter) that passes the line voltage to the motor. Refer to Unit 18, "Application of Motors," Section 18.2 "The Power Supply" for a more detailed explanation of RLA, FLA, and LRA.

19.3 THE RELAY

The **relay** has a magnetic coil that opens or closes one or more sets of contacts, **Figure 19.2**. It is considered a throwaway device because parts are not available for rebuilding it when it no longer functions properly.

Relays are designed for light-duty applications. *Pilot-duty* relays can switch (on and off) larger contactors or starters. These relays are not designed to directly start motors. Relays designed for starting motors are not really suitable as switching relays because they have more resistance in the contacts. The pilot-duty relay contacts are often made of a fine silver alloy and designed for low-level current switching. Use on a higher load would melt the contacts. Heavier-duty motor switching relays are often made of silver cadmium oxide with a higher surface resistance and are physically larger than pilot-duty relays.

If a relay starts the indoor fan in the cooling mode of a central air-conditioning system, it must be able to withstand the inrush current of the fan motor on start-up, **Figure 19.3**. (A motor normally has a starting current of five times the running current, but only for a very short time.) Relays are often rated in horsepower: If a relay is rated for a 3-hp motor, it will be able to stand the inrush or locked-rotor current of a 3-hp motor as well as the run current.

A relay may have more than one type of contact configuration. It could have two sets of contacts that close when the magnetic coil is energized, **Figure 19.4**, or it may have two sets of contacts that close and one set that opens when the coil is energized, **Figure 19.5**. A relay with a single set

Figure 19.2 General-purpose relay typically used for starting a motor that has a relatively low amperage draw. This relay has a holding coil, one normally open set of contacts, and one normally closed set of contacts. Both sets of contacts change position when the holding coil is energized.

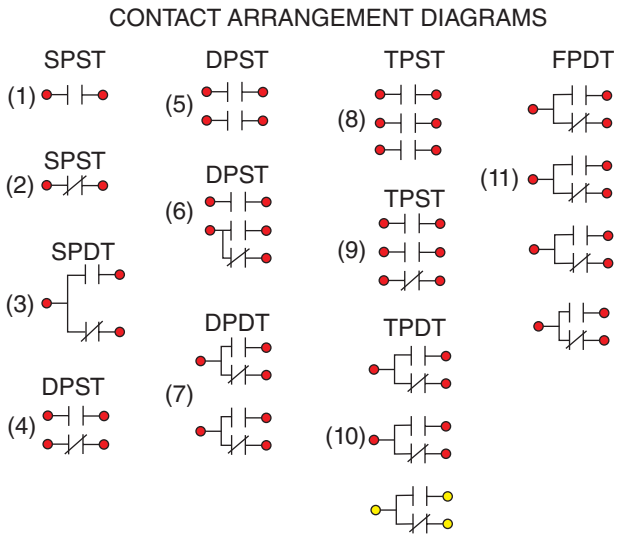
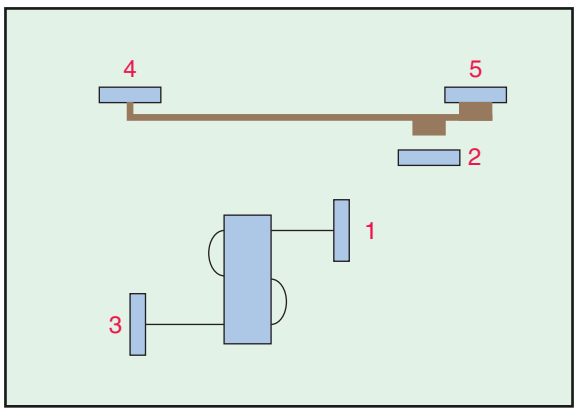
Figure 19.6 Some of the more common configurations of contacts found on relays.



of contacts that close when the coil is energized is called a *single-pole–single-throw, normally open relay* (spst, NO). A relay with two contacts that close and one that opens is called a *triple-pole–single-throw,* with two *normally open* contacts and one *normally closed contact* (tpst). **Figure 19.6** shows some different relay contact arrangements.

Most relays have wiring diagrams printed on the side of the device. These diagrams identify the coil terminals as well as the normally open and normally closed contacts. **Figure 19.7** shows the wiring diagram of the relay shown in **Figure 19.2**. By referring to the diagram and identifying these marked terminals on the relay itself, replacing one relay with another in the event of component failure is not a complicated process. Many relays use terminals 1 and 3 for the coil, terminals 2 and 4 for a normally open set of contacts, and terminals 2 and 5 for a normally closed set of contacts.

Figure 19.7 Wiring diagram of the relay shown in **Figure 19.2**. The coil is connected between terminals 1 and 3. Terminals 2 and 4 are connected to the NO contacts and terminals 4 and 5 are connected to the NC contacts.



19.4 THE CONTACTOR

The **contactor** is a larger version of a relay, **Figure 19.8.** It can be rebuilt if it fails, **Figure 19.9.** A contactor has movable and stationary contacts. The holding coil can be designed for various operating voltages: 24-V, 115-V, 208-V to 230-V, or 460-V operation.

Figure 19.8 (A) A common contactor. (B) Modern-day contactors for larger motors. There are circuit breakers and current sensing coils before each contactor. The current sensors monitor current flow through the motors for feedback to a microprocessor providing running status, overload protection, and remote monitoring.

Figure 19.9 The parts of a contactor that can be replaced: the contacts (both moving and stationary), the holding coil, and the contact holding springs.

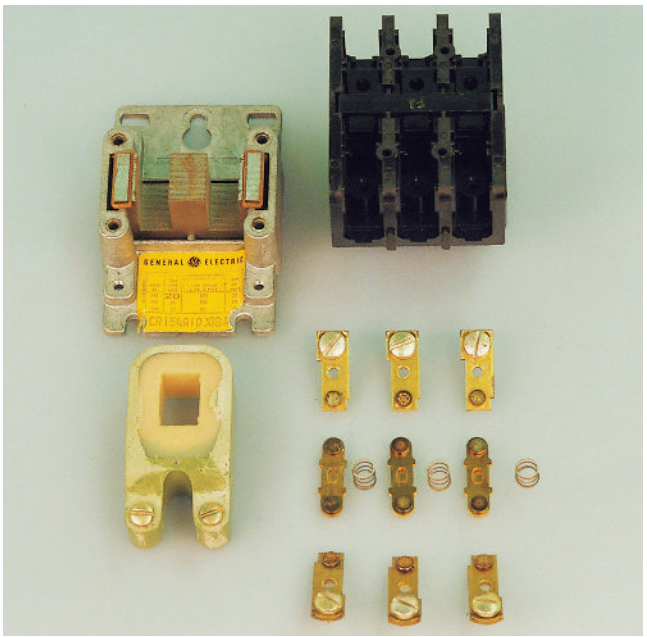

Photo by Bill Johnson

Contactors can be very small or very large, but all have similar parts. A contactor may have many configurations of contacts, from the most basic, which has just one contact, to more elaborate types with several. The single-contact contactor is used on many residential air-conditioning units. **Figure 19.8(B)** shows a larger compressor motor contactor that incorporates a current induction coil. This coil monitors current flow through the motor for feedback to a microprocessor for overload protection and remote monitoring of the compressor motor. It interrupts power to one leg of the compressor, which is all that is necessary to stop a single-phase compressor. Sometimes a single-contact contactor is needed to provide crankcase heat to the compressor. A trickle charge of electricity passes through line 2 to the motor windings and crankcase heater when the contacts are open, during the off cycle, **Figure 19.10**. If you use a contactor with two contacts for a replacement, the compressor would not have crankcase heat. Once again, an exact replacement is the best choice. **Figure 19.11** shows another method of supplying crankcase (oil sump) heat only during the off cycle.

Some contactors have as many as five or six sets of contacts. Generally, for large motors there will be three heavy-duty sets to start and stop the motor; the rest (*auxiliary contacts*) can be used to switch auxiliary circuits.

Auxiliary contacts are rated at lower amperages than the main contacts. The auxiliary contacts are typically used to open and close control circuits and to energize and deenergize other, smaller system loads that have low current requirements. Auxiliary contacts can be normally open or normally closed

Figure 19.10 This contactor (a single-pole contactor) has only one set of contacts. Only one line of power needs to be broken to stop a motor like the one in the diagram. This is a method commonly used to supply crankcase heat to the compressor during the off cycle. When the contacts close, current will bypass the heater.

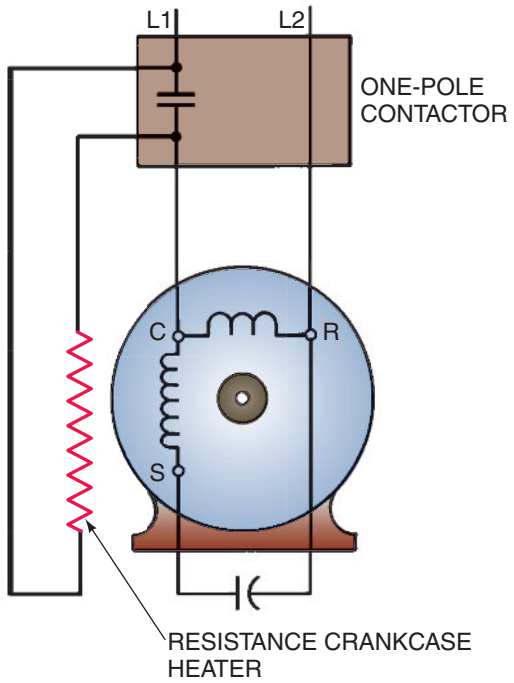

Figure 19.11 A contactor with auxiliary contacts for switching other circuits.

and are often mounted to the side of the contactor, where its moving armature can change the position of the auxiliary contacts at the same moment the main contacts change position.

19.5 MOTOR STARTERS

The *starter,* or motor starter as it is sometimes called, is similar to the contactor. In some cases, a contactor may be converted to a motor starter. The motor starter differs from a contactor because it has motor overload protection built into its framework, **Figure 19.12** and **Figure 19.13**. A motor starter may be rebuilt and is available in a wide range of sizes.

Motor protection is discussed more fully later in this unit, but you should know that overload protection protects a particular motor. **Figure 19.14** shows a melting alloy-type overload heater. The fuse or circuit breaker cannot be wholly relied on for motor protection because it protects the entire circuit, not the circuit's individual components. In some cases, the motor-starter protection can indicate a motor problem better than can the motor-winding thermostat protection.

The contact surfaces become dirtier and more pitted with each motor starting sequence, **Figure 19.15**. Some technicians believe that these contacts may be buffed or cleaned with a file or sandpaper. **NOTE:** *Contacts may be cleaned, but this should be done as a temporary measure only. Filing or sanding exposes base metal under the silver plating and speeds deterioration. Replacing the contacts is the only recommended repair.* • If the device is a relay, the complete relay must be replaced. If the device is a contactor or a starter, the contacts may be

Figure 19.12 A motor starter equipped with motor overload heaters that are interchangeable and can be sized to fit motors of different horsepower. The overload contact can be manually reset. The manual reset feature prevents excessive wear and tear on the motor by preventing short cycling.

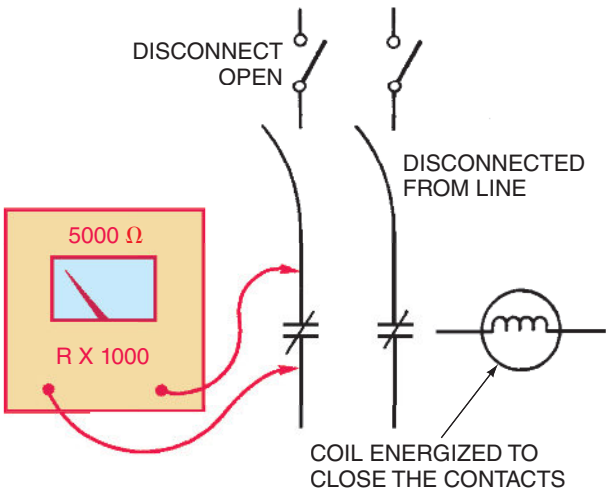
replaced with new ones, **Figure 19.15**. Both movable and stationary contacts and springs hold tension on the contacts.

You can use a voltmeter to check resistance across a set of contacts under full load. When the meter leads are placed on each side of a set of contacts and measure a voltage, there is resistance in the contacts. When the contacts are new and have no resistance, the meter should read no voltage. An old set of contacts will have some slight voltage drop and will produce heat, due to resistance in the contact's surface, where the voltage drop occurs. **Figure 19.16** shows an example of how contacts may be checked with an ohmmeter.

Figure 19.16 Checking contacts with an ohmmeter shows resistance in the contacts caused by dirty surfaces. Make certain that there is no current flowing through the contacts when checking resistance.



Each time a motor starts, the contacts will be exposed to the inrush current (the same as LRA). The contacts are under a tremendous load for this moment. When the contacts open, the breaking of the electrical circuit causes an arc. The contacts must make and break as fast as possible. A magnet pulls the contacts together with a mechanism to take up any slack. For example, three large movable contacts in a row may all need to be held equally tight against the stationary contacts. The springs behind the movable contacts keep this pressure even, **Figure 19.17**. If there is a resistance in the contact surface, the contacts may get hot enough to take the tension out of the springs, which will make the contact-to-contact pressure even less and the heat greater. The tension in these springs must be maintained.

19.6 MOTOR PROTECTION

The electric motors used in air-conditioning, heating, and refrigeration equipment are the most expensive single components in the system. These motors consume large amounts of electrical energy, and the motor windings undergo considerable stress. Therefore, they deserve the best protection possible within the economic boundaries of a well-designed system. The more expensive the motor, the more expensive and elaborate the protection should be.

Fuses are used as circuit (not motor) protectors. **SAFETY PRECAUTION:** *The conductor wiring in the circuit must not be allowed to pass too much current or it will overheat and cause conductor failures or fires.* • A motor may be operating in an overloaded condition that would not cause the conductor to be overloaded; hence, the fuse will not open the circuit. Let

Figure 19.17 When energized, springs will hold the three movable contacts tightly against the stationary contacts.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

us use a central air-conditioning system as an example. There are two motors in the condensing unit: the compressor (the largest) and the condenser fan motor (the smallest). In a typical unit, the compressor may have a current draw of 23 A and the fan motor may use 3 A. The fuse protects the total circuit. The circuit will be fused to protect the circuit wiring. If one motor is overloaded, the fuse may not open the circuit, **Figure 19.18**. Each motor needs to be protected within its own operating range. The condenser fan motor and the compressor will have an inherent (internal) motor protector that protects the fan motor at 3 A and the compressor at 23 A.

Motors can operate without harm for short periods under a slight overcurrent condition. The overload protection is designed to disconnect the motor at some current draw value that is slightly more than the FLA value so that the motor can be operated at its full-load design capacity. Time is involved in this value in such a manner that the higher the current value above FLA, the more quickly the overload should react. In other words, the amount of the overload and the time are both figured into the design of the particular overload device.

Overload current protection is applied to motors in different ways. Overload protection, for example, is not needed for some small motors that will not cause circuit overheating or will not damage themselves. Some small motors do not have overload protection because they will not consume enough power to damage the motor unless shorted from winding to winding or from the winding to the frame (to ground).

Figure 19.18 Two motors in the same circuit are served by the same conductors and have different overload requirements. The main circuit fuses protect the entire circuit and not the individual circuit components.

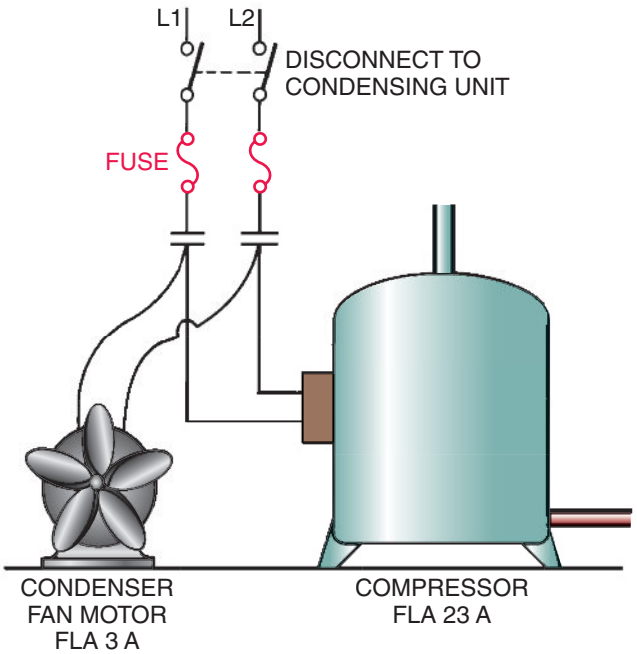

Figure 19.19 A small condenser fan motor that does not pull enough amperage at locked-rotor amperage (LRA) to create enough heat to be a problem. This is known as impedance motor protection.

Courtesy Ferris State University. Photo by John Tomczyk

See **Figure 19.19** for an example of a small condenser fan motor that does not draw enough amperage at the LRA condition to overheat. It is not an expensive motor, and it does not have overload protection; it is described as "impedance protected." It may only generate 10 W of power, the same as a 10-W light bulb. If the motor fails because of a burnout, the current draw will be interrupted by the circuit protector.

Overload protection is divided into inherent (internal) protection and external protection.

19.7 INHERENT MOTOR PROTECTION

Inherent (internal) overload protection is provided by internal thermal overloads either embedded in, or located near, the motor's windings, **Figures 19.20(A)** and **(C)**. External overload motor protection is provided by thermally activated snap-discs (bimetals) located on the compressor's exterior shell, **Figures 19.20(B)**, **(D)**, and **(E)**.

19.8 EXTERNAL MOTOR PROTECTION

External protection is often applied to the device passing power to the motor contactor or starter. These devices normally are actuated by current overload and break the circuit to the contactor coil. The contactor stops the motor. When

(E)

started with a relay, the motor is normally small and has only internal protection, **Figure 19.21**. Contactors are used to start larger motors, and either inherent protection or external protection is used. Large motors (above 5 hp in air-conditioning, heating, and refrigeration systems) use starters and overload protection built into either the starter or the contactor's circuit.

The value (trip point) and type of the overload protection are normally chosen by the system design engineer or by the manufacturer. The technician checks the overload devices when there is a problem, such as random shutdowns because of an overload tripping. The technician must be able to understand the designer's intent with

regard to the motor's operation and the operation of the overload device because they are closely related in a working system.

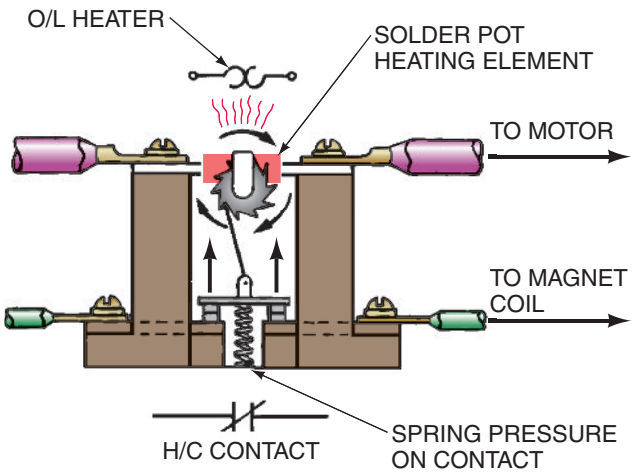
Many motors have a *service factor*; this is the reserve capacity of the motor and is expressed as a percentage above the full-load amperage (FLA) of the motor. The motor can operate above the FLA and within the service factor without harm. Typical service factors are 1.15 to 1.40. A service factor of 1.15 indicates that the motor can operate at an amperage that is 15% higher than the nameplate operating current, whereas a motor with a service factor of 1.40 can operate at amperages that are 40% higher than nameplate. The smaller the motor, the larger the service factor. For example, a motor with a FLA of 10 A and a service factor of 1.25 can operate at 12.5 A (10 A × 1.25 = 12.5 A) without damaging the motor. The overload protection for a particular motor takes the service factor into account.

19.9 NATIONAL ELECTRICAL CODE® STANDARDS

The *National Electrical Code*® (NEC) sets the standard for all electrical installations, including motor overload protection. The code book published by the National Electrical Manufacturer's Association (NEMA) should be consulted for any overload problems or misunderstandings that may occur regarding correct selection of the overload device.

The purpose of the overload protection device is to disconnect the motor from the circuit when an overload condition occurs. Detecting the overload condition and opening the circuit to the motor can be done by an overload device mounted on the motor starter or by a separate overload relay applied to a system with a contactor. **Figure 19.22** shows an example of a thermal overload relay.

Figure 19.22 An overload using a resistor-type heater that heats a low-temperature solder.



19.10 TEMPERATURE-SENSING DEVICES

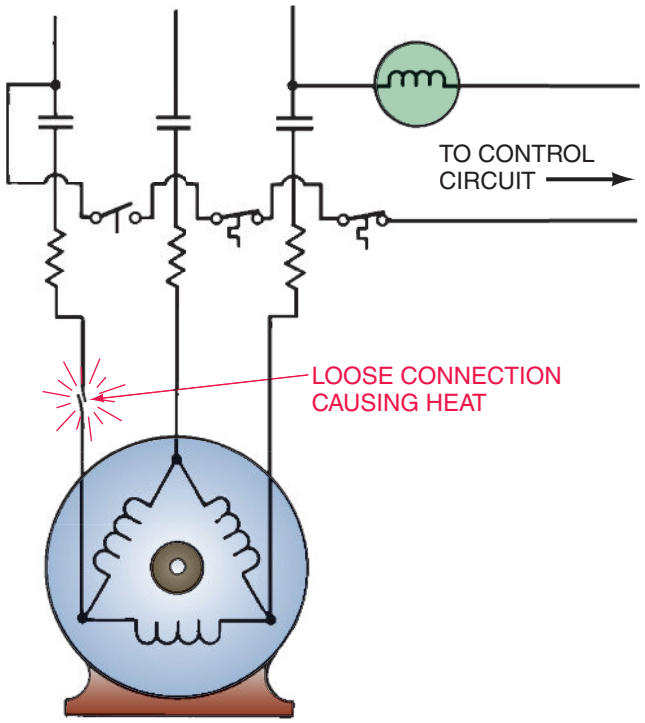
Various sensing devices are used to detect overcurrent situations. The most popular ones are those sensitive to temperature changes.

The bimetal element is an example of such sensing devices. The line current of the motor passes through a heater (which can be changed to suit a particular motor amperage) that heats a bimetal strip. When the current is excessive, the heater warps the bimetal, opening a set of contacts that interrupt power to the contactor's coil circuit. All bimetal overload devices are designed with snap action to avoid excessive arcing. These thermal-type overloads are sensitive to any temperature and conditions around them, such as high ambient temperature and loose connections. **Figure 19.23** shows an example of a thermal overload with a loose connection.

Figure 19.23 The overload is tripping because of a loose connection.

Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 19.24 Local heat, such as from a loose connection, will influence the thermal-type overload.



A low-melting solder, called a **solder pot**, may be used in place of the bimetal. Heat caused by an overcurrent condition will melt the solder. The overload heater is sized for the particular amperage draw of the motor it is protecting. The overload control circuit will interrupt the power to the motor contactor coil and stop the motor in case of overload. The solder melts, and the overload mechanism turns because it is spring-loaded. It can be reset when it cools, **Figure 19.22**.

Both of these overload protection devices are sensitive to temperature. The temperature of the heater causes them to function. Heat from any source, even if it has nothing to do with motor overload, makes the protection devices more sensitive. For example, if the overload device is located in a metal control panel in the sun, the heat from the sun may affect the performance of the overload protection device. A loose connection on one of the overload device leads will cause local heat and may cause it to open the circuit to the motor even though there is actually no overload, **Figure 19.24**.

19.11 MAGNETIC OVERLOAD DEVICES

Magnetic overload devices are separate components and are not attached to the motor starter. This type of component is very accurate and not affected by ambient temperature,

Figure 19.25 A magnetic overload device.

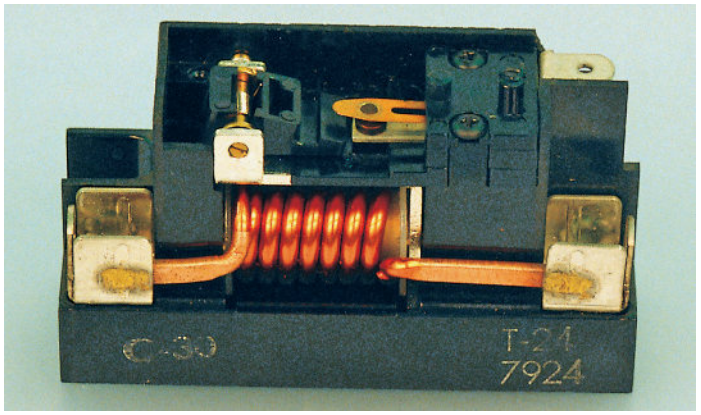


Photo by Bill Johnson

Figure 19.25, so a magnetic overload device can be located in, say, a hot cabinet on the roof and will not be affected the temperature. It will shut the motor off at an accurate ampere rating regardless of the temperature.

19.12 RESTARTING THE MOTOR

SAFETY PRECAUTION: *When a motor has been stopped for safety reasons, such as an overload, do not restart it immediately. Look around for the possible problem before a restart.* • When a motor stops because it is overloaded, the overload condition at the instant the motor is stopped is reduced to 0 A. This does *not* mean that the motor should be restarted immediately. The cause of the overload may still exist, and the motor could be too hot and may need to cool.

There are various ways of restarting a motor after an overload condition has occurred. Some manufacturers design their control circuits with a manual reset to keep the motor from restarting, and some use a time delay to keep the motor off for a predetermined time. Others use a relay that will keep the motor off until the thermostat is reset. The units that have a manual reset at the overload device may require someone to go to the roof to reset the overload if that is where the unit is located. See **Figure 19.12** for an example of a manual reset. When the reset is in the thermostat circuit, the protection devices may be reset from the room thermostat. This is convenient, but several controls may be reset at the same time, and the technician may not know which control is being reset. When the manual reset button is pushed and a restart occurs, there is no doubt which control has been reset to start the motor. Time-delay reset devices keep the unit from short cycling but may reset themselves even though a problem condition still exists.

SUMMARY

- The relay, the contactor, and the motor starter are three types of motor starting and stopping devices.
- The relay is used for switching circuits and motor starting.
- Motor starting relays are used for heavier-duty jobs than are switching relays.
- Contactors are large relays that may be rebuilt.
- Starters are contactors with motor overload protection built into the framework of the contactor.
- The contacts on relays, contactors, and starters should not be filed or sanded.
- Large motors should be protected from overload conditions through the use of devices other than normal circuit overload protection devices.
- Inherent motor overload protection is provided by sensing devices within the motor.
- External motor overload protection is applied to the current-passing device: the relay, the contactor, or the starter.
- The service factor is the reserve capacity of the motor.
- Bimetal and solder-pot devices are thermally operated.
- Magnetic overload devices are very accurate and not affected by ambient temperature.
- **SAFETY PRECAUTION:** *Most motors should not be restarted immediately after shutdown from an overload condition because they may need time to cool. When possible, determine the reason for the overload condition before restarting the motor.*

REVIEW QUESTIONS

1. The recommended repair for a defective relay is to
   A. replace it.
   B. send it to a repair shop.
   C. fix it yourself.
   D. none of the above.
2. What components can be changed on a contactor and a starter for rebuilding purposes?
3. The two types of relays are _____ and _____.
4. The two amperages that influence the choice for replacing a motor starter are _____ and _____.
5. What is the difference between a contactor and a starter?
6. True or False: A contactor can always be converted to a starter.
7. What are the contact surfaces of relays, contactors, and starters made of?
8. What causes an overload protection device to function?
9. Which is not a typical operating voltage used for relays, contactors, and motor starters?
   A. 12 V
   B. 24 V
   C. 115 V
   D. 230 V
10. Why is it not a good idea to file or sand the contactor contacts?
11. Why is it not a good idea to use circuit protection devices to protect large motors from overload conditions?
12. Under what conditions are motors allowed to operate with slightly higher-than-design loads?
13. Describe the difference between inherent and external overload protection.
14. What is the purpose of overload protection at the motor?
15. True or False: It is OK to restart a motor immediately after it has stopped or been overloaded.

UNIT 20

TROUBLESHOOTING ELECTRIC MOTORS

OBJECTIVES

After studying this unit, you should be able to

- describe different types of electric motor problems.
- list common electrical problems in electric motors.
- identify various mechanical problems in electric motors.
- describe a capacitor checkout procedure.
- explain the difference between troubleshooting a hermetic motor problem and troubleshooting an open motor problem.

SAFETYCHECKLIST

- ☑ If it is suspected that a motor has electrical problems, pull the motor disconnect to prevent further damage or an unsafe condition, lock and tag the panel, and keep the only key on your person.
- ☑ Before checking a motor capacitor, short from one terminal to the other with a 20,000-Ω, 5-W resistor to discharge the capacitor. This practice is recommended even if the capacitor has its own bleed resistor. Use insulated pliers.
- ☑ When wiring a motor-run capacitor be sure to connect the lead that feeds power to the capacitor to the terminal identified for this purpose.
- ☑ Turn the power off before trying to turn the open drive compressor over using a wrench.

20.1 MOTOR TROUBLESHOOTING

Electric motor problems are either mechanical or electrical. Mechanical problems may appear to be electrical. For example, a bearing dragging in a small, permanent split-capacitor (PSC) fan motor may not make any noise. The motor may not start, and it appears to be an electrical problem. The technician must know how to diagnose the problem correctly. This is particularly true with open motors because if the driven component is stuck, a motor may be changed unnecessarily. If the stuck component is a hermetic compressor, the whole compressor must be changed; if it is a serviceable hermetic compressor, the motor can be replaced or the compressor running gear can be rebuilt.

20.2 MECHANICAL MOTOR PROBLEMS

Mechanical motor problems normally occur in the bearings or the shaft where the drive is attached. The bearings may be tight or worn due to lack of lubrication. Grit can easily get into the bearings of some open motors and cause them to wear. Overtightened belts can also put excessive stress on the motor's bearings, causing them to wear and fail prematurely.

Problems with large motors are not usually repaired by heating, air-conditioning, and refrigeration technicians. They are handled by technicians trained in rebuilding motors and rotating equipment. A motor vibration may require you to seek help from a qualified balancing technician. Explore every possibility to ensure that the vibration is not caused by a field problem, such as a fan loaded with dirt or liquid flooding into a compressor.

Motor bearing failure with roller and ball bearings can often be identified by the bearing noise. When sleeve bearings fail, they normally lock up (will not turn) or sag to the point that the motor is out of its magnetic center. At this point the motor will not start. When motor bearings fail, they can be replaced. If the motor is small, the motor is normally replaced because it would cost more to change the bearings than to purchase and install a new motor. The labor involved in obtaining bearings and disassembling the motor can take too much time to be profitable. This is particularly true for fractional horsepower fan motors. These small motors almost always have sleeve bearings pressed into the end bells of the motor, and special tools may be needed to remove and install new bearings, **Figure 20.1**.

When deciding whether to repair or replace a motor, a number of factors should be considered. These factors include the availability of a new motor versus the availability of the parts needed to repair the motor, the cost of repairing the motor, the cost of the new motor, the labor involved in repairing as opposed to replacing the motor, and the warranty/guaranty on the new and repaired motors. If the cost of repairing the motor is close to the cost of replacing the motor, for example, it would definitely pay to replace the motor if the new component carries a one-year warranty and the repaired motor carries only a 90-day guaranty.

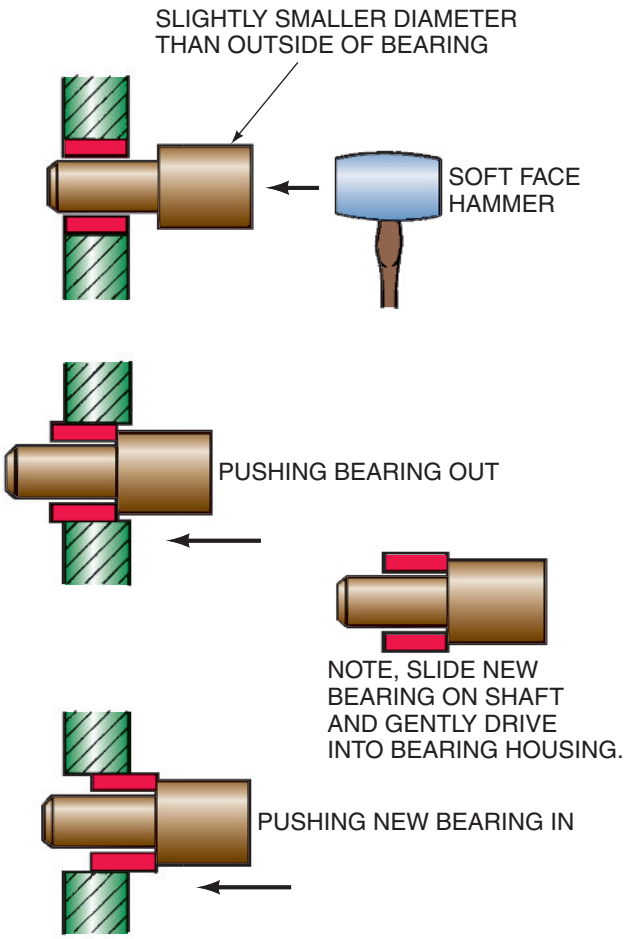
Figure 20.1 A special tool for removing bearings.



20.3 REMOVING DRIVE ASSEMBLIES

To remove the motor, you need to remove the pulley, coupling, or fan wheel from the motor shaft. The fit between the shaft and whatever assembly it is fastened to may be very tight. **SAFETY PRECAUTION:** *Removing the assembly from the motor shaft must be done with care.*• The assembly may have been running on this shaft for years, and there may be rust between the shaft and the assembly. You must remove the assembly without damaging it. Special pulley pullers, **Figure 20.2**, will help, but other tools or procedures may be required.

Most assemblies are held to the motor shaft with setscrews threaded through the assembly and tightened against the shaft. A flat spot is usually provided on the shaft for the seating of the setscrew and to keep it from damaging the shaft surface, **Figure 20.3**. The setscrew is made of very hard steel, much harder than the motor shaft. Larger motors with more torque normally have a matching keyway machined into the shaft and assembly. This keyway with a key provides a better bond between the motor and assembly, **Figure 20.4**.

Figure 20.2 A pulley puller.

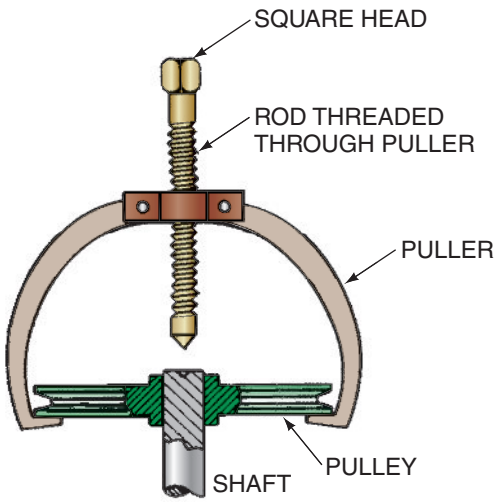


Figure 20.3 A flat spot on the motor shaft where the pulley setscrew is tightened.

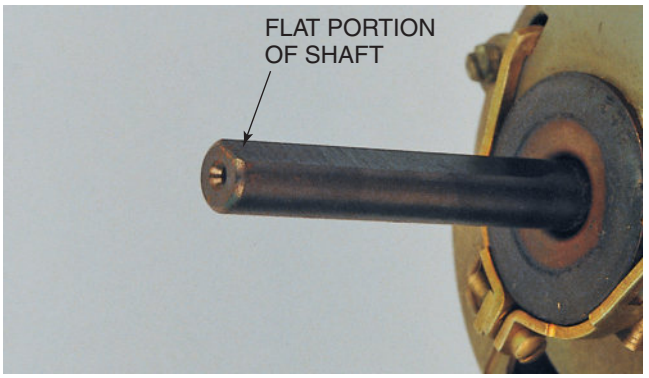

Photo by Bill Johnson

Figure 20.4 A pulley with a groove cut in it that matches a groove in the shaft. A key is placed in these grooves and the setscrew is often tightened down on top of the key.

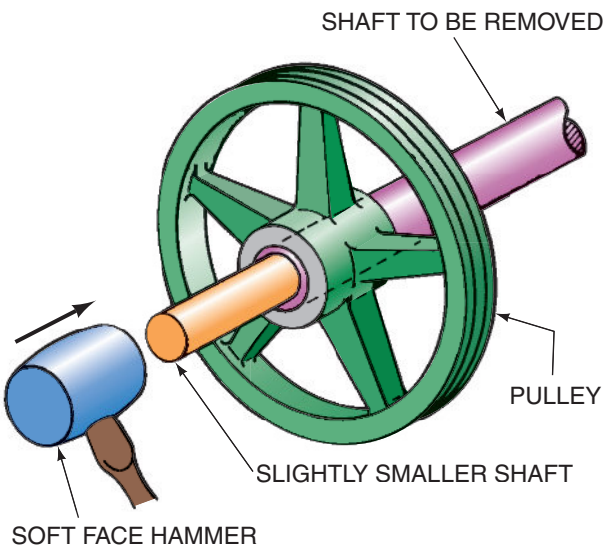
Figure 20.5 A motor shaft damaged from trying to drive it through the pulley.

Photo by Bill Johnson

Figure 20.6 A shaft driven through the pulley with another shaft as the contact surface. The shaft that is used as the contact surface has a smaller diameter than the original shaft.



A setscrew is then often tightened down on the top of the key to secure the assembly to the motor shaft.

Many technicians make the mistake of trying to drive a motor shaft out of the assembly fastened to the shaft. In doing so, they blunt or distort the end of the shaft. When it is distorted, the motor shaft will never go through the assembly without damaging it, **Figure 20.5**. The shaft is made from mild steel and can be damaged easily. If the shaft must be driven, you may need to use as the driving tool a similar shaft with a slightly smaller diameter, **Figure 20.6**. Before attempting to remove a belt from a motor shaft, it is a good idea to clean, sand, and remove all debris from the shaft. In addition, spraying the shaft with a rust-dissolving solution or penetrating oil will help make the removal process much easier.

20.4 BELT TENSION

Many motors fail because of overtightened belts and incorrect alignment. The technician should be aware of the specifications for the motor belt tension on belt-drive systems. A belt tension gauge will ensure properly adjusted belts when

Figure 20.7 A belt that is too tight.

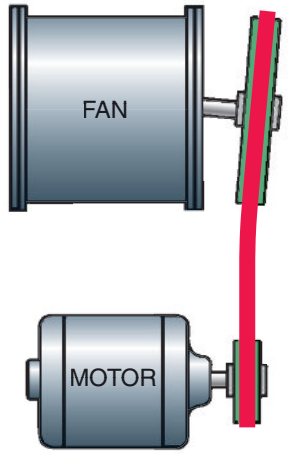


Figure 20.8 A belt tension gauge.

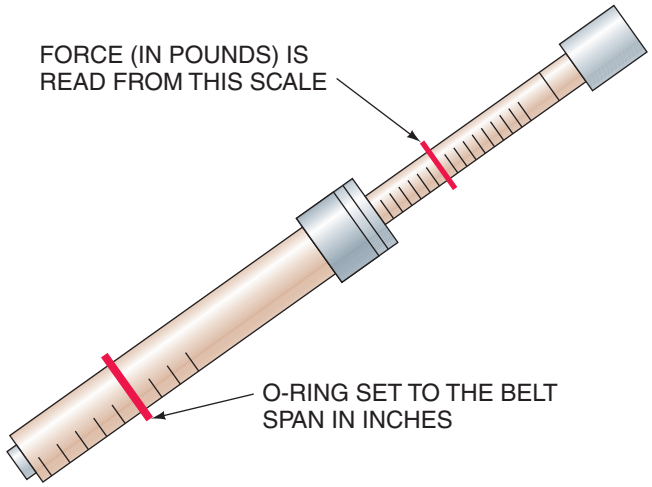

the gauge manufacturer's directions are followed. Belts that are too tight strain the bearings so that they wear out prematurely, **Figure 20.7**. **Figure 20.8** shows one type of belt tension gauge.

The belt tension gauge uses two O-rings. When using the gauge, the center-to-center measurement must be taken between the two shafts, **Figure 20.9**. The larger O-ring is positioned on the gauge so that it is lined up with the corresponding distance, in inches, between the two shafts. A straightedge is then rested across the two pulleys. The gauge is then positioned at the center of the belt span between the two pulleys and pushed toward the other end of the pulley until the large O-ring is even with the straightedge, **Figure 20.10**. The smaller O-ring will register a force, in pounds, on the top portion of the gauge. By comparing this value with the chart that accompanies the gauge, the technician can determine if the belt is too tight or too loose. A low force reading indicates that the belt is too loose, whereas a force reading that is too high indicates that the belt is too tight.

Figure 20.9 The measurement between the centers of the drive and driven shafts.

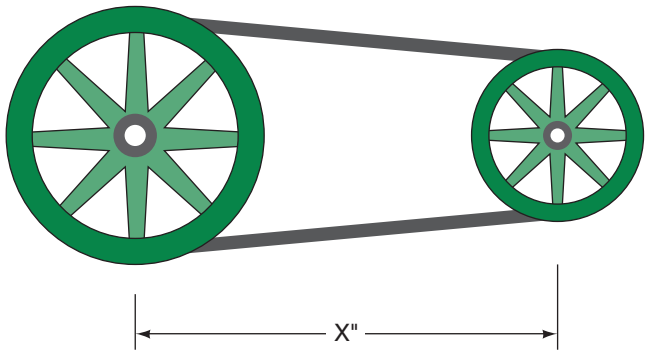

Figure 20.10 Using the belt tension gauge.

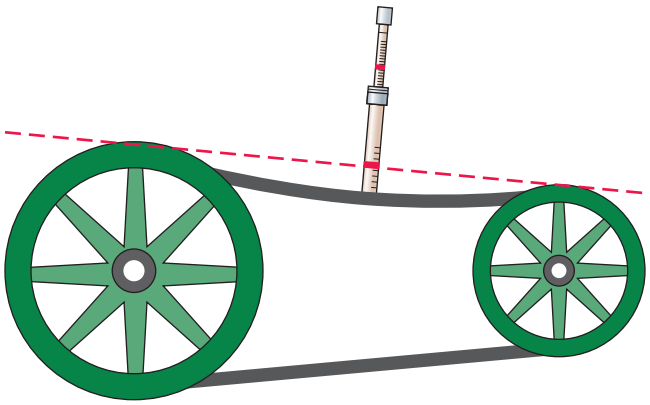


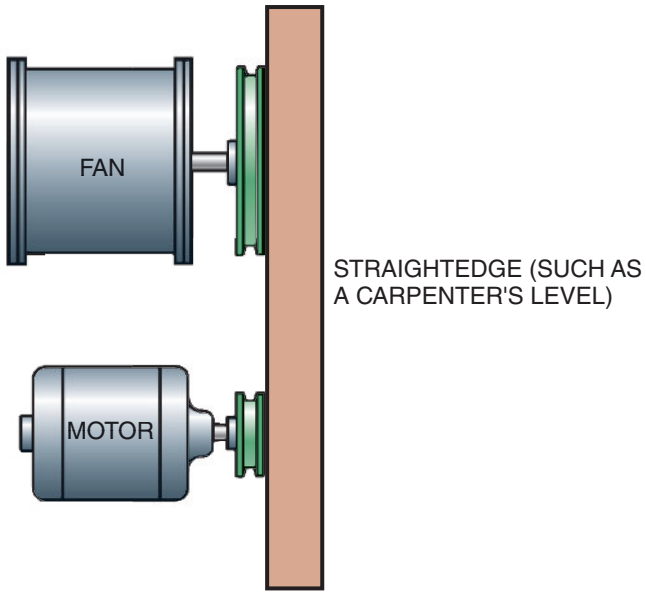
Belts that are too loose can cause problems—as can those that are too tight. Loose belts have a tendency to slip, and slipping belts are a cause of reduced airflow through the air distribution system. Since motors often rely on the air moving over them to cool the windings, a reduction in airflow can cause motors to overheat. As a result, the internal thermal overload on a motor may open and give the technician reason to believe that there is an electrical problem with the motor.

20.5 PULLEY ALIGNMENT

Pulley alignment is very important. If the drive pulley and driven pulley are not in line, a strain is imposed on the drive mechanisms of the shafts. The pulleys may be aligned with the help of a straightedge, **Figure 20.11**. On small motors, a certain amount of adjustment tolerance is built into the motor base, and this may be enough to allow the motor to be out of alignment if the belt becomes loose. Aligning shafts on some pieces of equipment may not be easy to do, but it must be done or the motor or drive mechanism will not last.

When mechanical problems occur with a motor, the motor is normally either replaced or taken to a motor repair shop. Bearings can sometimes be replaced in the field by a competent technician, but it is generally better to leave this type of repair to motor experts. When the problem is the pulley or drive mechanism, the air-conditioning, heating, and refrigeration technician may be responsible for the repair.

Figure 20.11 Pulleys must be in proper alignment or excessive belt and bearing wear will occur. The pulleys can be aligned using a straightedge.



NOTE: *Proper tools must be used for motor repair, or shaft and motor damage may occur.* •

20.6 ELECTRICAL PROBLEMS

Electrical motor problems are the same for hermetic and open motors. Open motor problems are a little easier to understand or diagnose because they can often be seen. When an open motor burns up, this can often be easily diagnosed because the winding may be seen through the end bells. It may also smell burned. With a hermetic motor, instruments must be used because they are the only means of diagnosing problems inside the compressor, which are not visible. There are three common electrical motor problems: (1) an open winding, (2) a short circuit from winding to winding, and (3) a short circuit from the winding to ground.

20.7 OPEN WINDINGS

Open windings in a motor can be found with an ohmmeter. On every motor there should be a known, measurable resistance from terminal to terminal for it to run when power is applied to the windings. Single-phase motors must have the applied system voltage at the run winding to run and at the

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

start winding during starting, **Figure 20.12**. **Figure 20.13** is an illustration of a motor with an open start winding.

A single-phase motor that is in good working order may have the following resistance readings between the motor terminals:

Common to start: 3 Ω
Common to run: 2 Ω
Run to start: 5 Ω

This situation is shown in **Figure 20.14**.

The resistance reading from the common terminal to the run terminal provides the technician only with the resistance reading of the run winding. The resistance reading from the common terminal to the start terminal provides the technician only with the resistance reading of the start winding.

Figure 20.12 A wiring diagram with run and start windings.

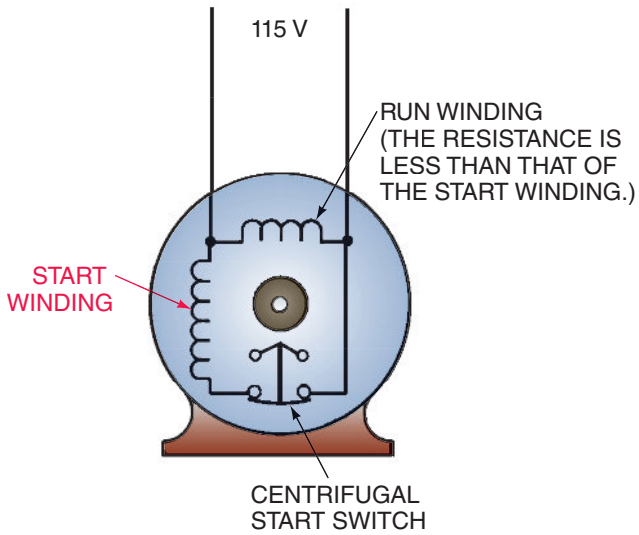


Figure 20.13 A motor with an open winding.

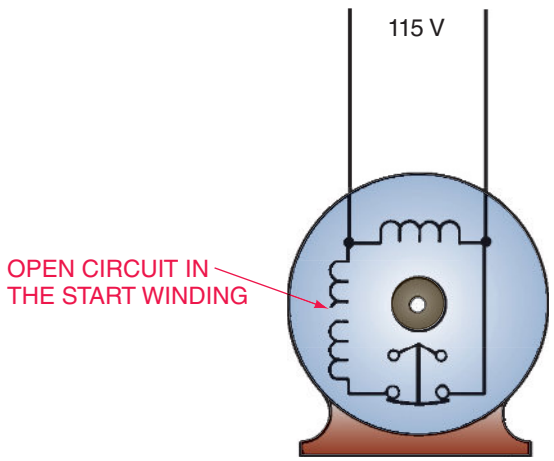

Figure 20.14 Resistance readings between the terminal pairs on a hermetic motor.

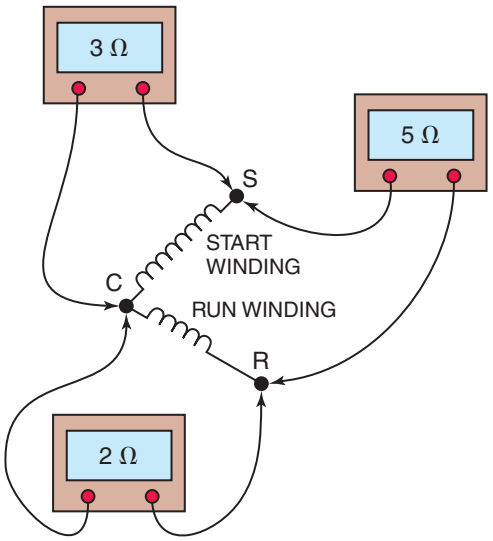

The resistance between the start and run terminals gives the sum of the resistances of both the start and run windings. If the start winding in this example were to open, the resistance readings for the same motor would be as follows:

Common to start: (∞) (infinite resistance)
Common to run: 2 Ω
Run to start: (∞) (infinite resistance)

The open winding would affect the resistance reading of the start winding as well as the resistance reading between the run and start terminals, **Figure 20.15**.

Figure 20.15 Resistance readings between terminal pairs on a hermetic motor with an open start winding.

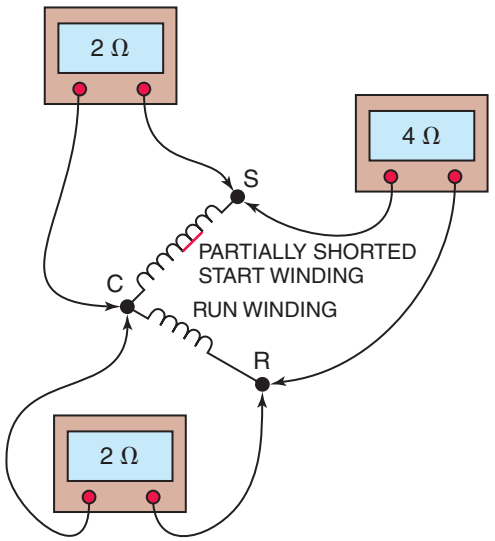
20.8 SHORTED MOTOR WINDINGS

Short circuits in windings occur when the conductors in the winding touch each other where the insulation is worn or in some way defective. This creates a short path through which the electrical energy flows. This path has a lower resistance and increases the current flow in the winding. Although motor windings appear to be made from bare copper wire, they are coated with an insulator to keep the copper wires from touching each other. The measurable resistance mentioned in the previous paragraph is known for all motors. Some resistances for motor windings have been published. The best way to check a motor for electrical soundness is to *know what the measurable resistance should be for a particular winding and verify it with a good ohmmeter,* **Figure 20.16**. This measurable resistance will be less than the rated value when a motor has short-circuit problems. The decrease in resistance causes the current to rise, which causes motor overload devices to open the circuit and possibly even trips the circuit overload protection. If the resistance does not read within these tolerances, there is a problem with the winding. A table is helpful when you troubleshoot a hermetic compressor. Tables may not be easy to obtain for open motors, and the windings are not as easy to check because the individual windings do not all come out to terminals as they do on a hermetic compressor.

If the decrease in resistance in the windings is in the start winding, the motor may not start. The reason for this is that, in order to start, the motor relies on an imbalance in the magnetic field. If the start winding is partially shorted, the resistance in that winding will be closer to the resistance of the run winding. This will reduce, or possibly even eliminate, the magnetic field imbalance that is needed to start the motor, **Figure 20.17**. If the decrease in resistance is in the run winding, the motor may start and draw too much current while running. If the resistance of the run winding is lowered, the imbalance in magnetic fields between the start and the run winding will be increased, and the starting torque of the motor will actually increase, **Figure 20.18**, but the motor may very well overheat. If the motor winding resistance cannot be determined, then it is hard to know whether a motor is overloaded or whether it has a defective winding when only a few of its coils are shorted.

Figure 20.17 Resistance readings between terminal pairs on a hermetic motor with a partially shorted start winding.



When stretched out, the windings of a motor may be many feet long. This insulated winding wire is wound into coils. The shorting of a winding wire may make it a shorter winding; thus a higher amperage reading and a localized "hot spot" will occur where the windings are shorted together. For example, suppose the total winding length is 50 ft and the factory ohm reading is supposed to be 30 Ω. When it is shorted to 45 ft where two turns are touching due to insulation failure, the ohm reading may be reduced to 27 Ω. There would be a hot spot where they touch and the amperage would go up slightly.

When the motor is an open motor, the load can be removed. For example, the belts can be removed, or the coupling can be taken apart, and the motor can be started without the load, **Figure 20.19**. If the motor starts and runs correctly without the load, the load may be too great.

Figure 20.16 Resistances for some typical hermetic compressors.

Compressor Model	Voltage	MOTOR AMPS				FUSE SIZE		Winding Resistance in Ohms

Figure 20.18 Resistance readings between terminal pairs on a hermetic motor with a partially shorted run winding.

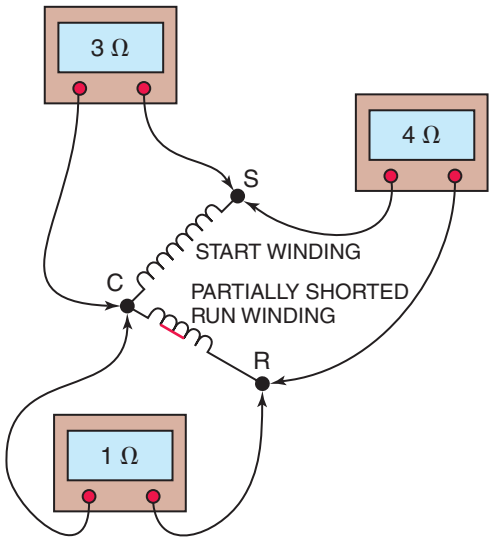

Figure 20.19 The coupling was disconnected between this motor and the pump because it was suspected that the motor or pump was locked up and would not turn.

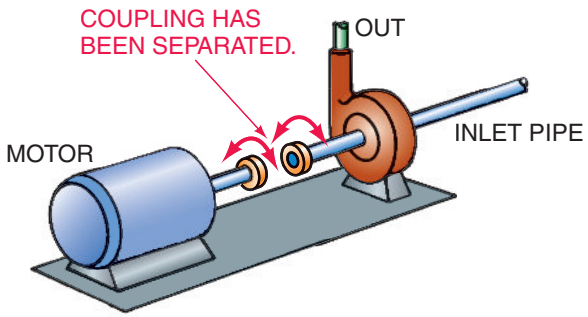


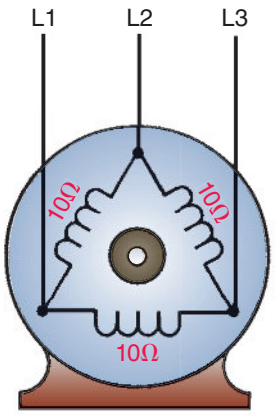
Three-phase motors must have the same resistance for each winding. (There are three identical windings.) Otherwise, there is a problem. An ohmmeter check will quickly reveal an incorrect winding resistance, **Figure 20.20.**

20.9 SHORT CIRCUIT TO GROUND (FRAME)

A short circuit from winding to ground or to the frame of the motor may be detected with a good ohmmeter. No circuit should be detectable from the winding to ground. The copper suction line on a compressor is a good source for checking to the ground. **NOTE:** *"Ground" or "frame" are interchangeable terms because the frame should be grounded to the earth ground through the building electrical system,* **Figure 20.21.** •

To check a motor for a ground, use a good ohmmeter with an R × 10,000-Ω scale. Special instruments for finding very high resistances to ground are used for larger, more sophisticated motors. Most technicians use ohmmeters. Top-quality

Figure 20.20 A wiring diagram of a three-phase motor. The resistance is the same across all three windings.



instruments can detect a ground in the 10,000,000-Ω and higher range, for which a megohmmeter may be used. This instrument has an internal high-voltage, direct-current (DC) supply to help create conditions for detecting the ground, **Figure 20.22.**

Megohmmeters (meggers) are electrical meters used to check the resistance and condition of the motor windings and the condition of the refrigeration and oil environment around motor windings. A megger is nothing but a giant ohmmeter that creates a very large DC voltage (usually 500 V DC) from its internal battery. The meter will read out in megohms (millions of ohms). Any motor winding or electrical coil can be checked with a megger. A megohmmeter's main function is to detect weak motor winding insulation and moisture accumulation and acid formations from the motor windings to ground before they can cause more damage to the winding insulation. With HVAC/R hermetic and semihermetic compressor motors, as contaminants in the refrigerant and oil mixture increase, the electrical resistance from the motor windings to ground will decrease. Regular preventive maintenance checks can be made with a megohmmeter, which can signal early motor winding breakdown from a contaminated system when accurate records are kept.

One probe of the megger is connected to one of the motor winding terminals, and the other probe to the shell of the compressor (ground). **NOTE:** *Make sure metal is exposed at the shell of the compressor where the probe is attached so that the compressor's shell paint is not acting as an insulator to ground.* • When a button is pushed and held on the megger, it will apply a high DC voltage between its probes and measure all electrical paths to ground. It is important to disconnect all wires from the compressor motor terminals when megging a compressor motor. Also, read the instructions that come with the meter to determine how long to energize the megger when checking winding or coils. If possible, it is a good idea to run the motor for at least one hour, disconnect power, disconnect all electrical leads, and then quickly connect the megger to the motor. This will give a more meaningful comparison between readings for the same compressor on different days because of the approximately similar winding temperatures.

(B)

Good motor winding readings should have a resistance value of a minimum of 100 megohms relative to ground. In fact, good motor winding resistance should be between 100 megohms and infinity. **Figure 20.22**(C) lists megohm readings with varying degrees of contamination and motor winding breakdown. Because of the very high resistance of

Figure 20.22(C) Megohmmeter readings with varying degrees of deterioration and motor winding breakdown.

Resistance Reading (megohms)	Condition Indicated	Required Preventive Maintenance	Percent of Winding in Field
Over 100	Excellent	None	30%
100–50	Some moisture present	Change filter drier	35%
50–20	Severe moisture and/or contamination	Several filter drier changes; change oil if acid is present	20%
20–0	Severe contamination	Check entire system and make corrections. Consider an oversized filter drier, refrigerant and oil change, and reevacuation. System burnout and clean-up procedures required.	15%

the motor winding insulation, a regular ohmmeter cannot be used in place of the megger. A regular ohmmeter does not generate enough voltage from its internal battery to detect high resistance problems like deteriorated winding insulation, moisture, or other system contamination.

Following are some other important tips service technicians should know about the use of a megohmmeter:

- Never use a megger if the motor windings are under a vacuum.
- Meggers can be used for electrical devices other than electric motors. Always consult with the meter manufacturer or user's manual for detailed instructions on megging other electrical devices such as coils.
- Meggers are often used in preventive maintenance programs, especially before a contractor signs a preventive maintenance contract, to determine the condition of the electrical devices.
- Any megger with a higher voltage output than 500 V DC should be used only by an experienced technician. A high voltage for too long a time may further weaken or fail motor windings and the winding insulation could be damaged by the testing procedure.

A typical ohmmeter will detect a ground of about 1,000,000 Ω or less. The rule of thumb is that if an ohmmeter set to the R × 10,000 scale will even move the needle with one lead touching the motor terminal and the other touching a ground (such as a copper suction line), the motor should be started with care. **SAFETY PRECAUTION:** *If the meter needle moves to the midscale area, do not start the motor,* **Figure 20.23.** When a meter reads a very slight resistance to ground, the windings may be dirty and damp if it is an open motor. Clean the motor, and the ground will probably be eliminated. Some open motors operating in a dirty, damp atmosphere may indicate a slight circuit to ground in damp weather. Air-cooled condenser fan motors are an example. When the motor is started and allowed to run long enough to get warm and dry, the ground circuit may disappear.

Hermetic compressors may occasionally have a slight ground due to the oil and liquid refrigerant in the motor splashing on the windings. The oil may have dirt suspended in it and show a slight ground. Liquid refrigerant makes this condition worse. If the ohmmeter shows a slight ground but the motor starts, run the motor for a little while and check again. If the ground persists, the motor is probably going to fail soon if the system is not cleaned. A suction-line filter drier may help remove particles that are circulating in the system and causing the slight ground.

The main instruments for troubleshooting electric motors are the ammeter and the voltmeter. If the resistance is correct, the motor is electrically sound. Other problems may be found using the ammeter.

20.10 SINGLE-PHASE MOTOR STARTING PROBLEMS

Single-phase open electric motors are fairly easy to troubleshoot for starting problems because they can be seen and heard. It is very frustrating when turning the power on to any motor if it fails to start. First, make sure that you really have full power to the motor leads. This entails fastening voltmeter leads to the motor terminals and reading the meter when the power is applied. Low voltage can occur at any place in the electrical system, such as at loose connections, loose fuse holders, undersized wire, or low voltage from the main electrical panel. The only way to be sure is to measure it at the motor terminals. Even at start-up when the motor is pulling LRAs, the voltage should be ±10% of the rated voltage. For example, if the motor is a combination 208/230-V fan motor, the minimum voltage should be 187 V (208 × 0.90 = 187.2) and the maximum should be 253 V (230 × 1.10 = 253). The motor's voltage must be within these limits during starting or running.

To start, the start winding and the run winding of open motors must receive power at the same time. The start winding is then disconnected from the circuit as the motor reaches about three-fourths of its rated speed. On some motors, such as capacitor-start, capacitor-run (CSCR) motors, the start winding remains in the circuit through the run capacitor. The run capacitor thus limits the current through the start winding to prevent it from getting too hot and burning up. The run capacitor is a low-microfarad capacitor. Disconnecting the start winding can be just as much a part of troubleshooting as operating the motor itself. When the open motor with a centrifugal switch is started and starts to turn, you should hear the audible disconnect of the start winding by the switch. When the motor is stopped, the switch makes an audible sound when the contacts close. If you hear the centrifugal switch function and the motor still will not start, you must apply meter leads to the start winding in the end bell (start to common terminals) of the motor to make sure full voltage is reaching the start winding during start-up. If the motor still will not start, perform the same test on the run windings (run to common terminals). The electronic start switch must be checked with a voltmeter applied to the start winding circuit in the end bell of the motor. This is a little more involved than just listening to the centrifugal switch.

The following are symptoms of electric-motor starting problems:

- The motor hums and then shuts off.
- The motor runs for short periods and shuts off.
- The motor will not try to start at all.

The technician must decide whether there is a motor mechanical problem, a motor electrical problem, a circuit problem, or a load problem. **SAFETY PRECAUTION:** *If the motor is an open motor, turn the power off. Lock and tag the panel. Try to rotate the motor by hand. If it is a fan or a pump, it should be easy to turn,* **Figure 20.24.** *If it is a compressor, the shaft may be hard to turn. Use a wrench to grip the coupling when trying to turn a compressor. Be sure the power is off.*

Figure 20.24 An example of how a pump or compressor coupling can be disconnected and the component's shaft turned by hand to check for a hard-to-turn shaft or a stuck component. **SAFETY PRECAUTION:** *Turn off the power to the motor and lock the panel out before servicing the motor.*

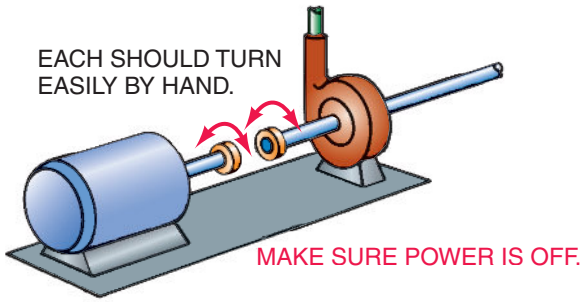

Figure 20.25 The end bell of this motor has been removed to examine the start switch and the windings.

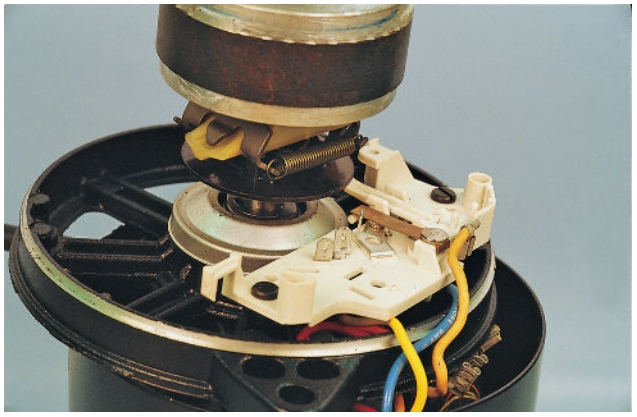

Photo by Bill Johnson

If the motor and the load turn freely, examine the motor windings and components. If the motor is humming and not starting, the starting switch may need replacing, or the windings may be burned. If the motor is open, you may be able to visually check them; if you cannot, remove the motor end bell, **Figure 20.25**.

20.11 CHECKING CAPACITORS

To some extent, motor capacitors may be checked with an ohmmeter in the following manner. Turn off the power to the motor and remove one lead of the capacitor. **SAFETY PRECAUTION:** *Short from one terminal to the other with a 20,000-Ω, 5-W resistor to discharge the capacitor in case the capacitor has a charge stored in it. Some start capacitors have a resistor across these terminals to bleed off the charge during the off cycle,* **Figure 20.26.** *Short across the capacitor anyway by using the*

Figure 20.26 A start capacitor with a bleed resistor across the terminals to bleed off the charge during the off cycle. **SAFETY PRECAUTION:** *Make certain that capacitors are completely discharged before you come into contact with the terminals.*•

Photo by Bill Johnson

above resistor. Use insulated pliers. The resistor may be open and will not bleed the charge from the capacitor. If you place ohmmeter leads across a charged capacitor, the meter movement may be damaged.• Set the ohmmeter scale on an analog meter to the R × 10 scale and touch the leads to the capacitor terminals, **Figure 20.27**. If the capacitor is good, the meter needle will go toward 0 and begin to fall back toward infinite resistance. If the leads are left on the capacitor for a long time, the needle will fall back to infinite resistance. If the needle falls part of the way back and will drop no more, the capacitor has an internal short. One internal plate is touching the other internal plate. If the needle will not rise at all, try the R × 100 scale. Try reversing the leads. The ohmmeter is charging the capacitor with its internal battery. This is DC voltage. When the capacitor is charged in one direction, the meter leads must be reversed for the next check. If the capacitor has

a bleed resistor, the capacitor will charge toward 0 Ω, then drop back to the value of the resistor.

This simple check with an ohmmeter will not give the capacitance of a capacitor. You need a capacitor tester to find the actual capacitance, **Figure 20.28**. Many modern digital multimeters also have the ability to check actual capacitance. These meters will automatically range to the proper resistance scale when checking resistances without the technician having to manually switch scales. It is not often that a capacitor will change in value, so this capacitor analyzer is used primarily by technicians who need to perform many capacitor checks.

20.12 IDENTIFICATION OF CAPACITORS

A run capacitor is contained in a metal can that is oil filled. If this capacitor gets hot due to overcurrent, it will often swell, **Figure 20.29**. The capacitor should then be changed. **SAFETY PRECAUTION:** *Run capacitors have an identified terminal to which the lead that feeds power to the capacitor should be connected. When the capacitor is wired in this manner, a fuse will blow if the capacitor is shorted to the container. If the capacitor is not wired in this manner and a short occurs, current can flow through the motor winding to ground during the off cycle and overheat the motor,* **Figure 20.30.**•

There are devices on the market that can act as universal replacement motor run capacitors, **Figure 20.29(C)**. The one shown in **Figure 20.29(C)** has six built-in capacitance values in one housing with a common center tap. It can replace

Figure 20.29 (A) A capacitor swollen due to internal pressure. (B) Various run capacitors.

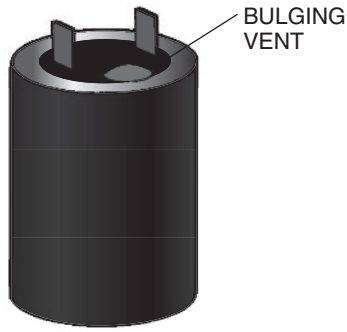
over 200 single- and dual-value capacitors with a rating of 370 VAC or 440 VAC by using the five supplied jumper wires. Larger kits offering more variations are also available. This simplifies the service technician's task of carrying a diverse supply of individual capacitors.

Figure 20.31 When the start capacitor has overheated, the small rubber diaphragm in the top of the component will bulge.



The start capacitor is a dry type and may be contained in a shell of paper or plastic. Paper containers are no longer used, but you may find one in an older motor. If this capacitor has been exposed to overcurrent, it may have a bulge in the vent at the top of the container, **Figure 20.31**. The capacitor should then be changed.

20.13 WIRING AND CONNECTORS

The wiring and connectors that carry the power to a motor must be in good condition. When a connection becomes loose, oxidation of the copper wire occurs. The oxidation acts as an electrical resistance and causes the connection to heat up more, which in turn causes more oxidation. This condition will only get worse. Loose connections will result in low voltages at the motor and in overcurrent conditions. Loose connections will appear the same as a set of dirty or burnt contacts and may be located with a voltmeter, **Figure 20.32**. If a connection is loose enough to create an overcurrent condition, it can often be located by a temperature rise at the connection.

Figure 20.32 When voltmeter leads are applied to both sides of a set of dirty or burnt contacts, it will read a voltage drop of 10 V or more.

20.14 TROUBLESHOOTING HERMETIC MOTORS

Diagnosing hermetic compressor motor problems differs from diagnosing open motor problems because the motor is enclosed in a shell and cannot be seen, and the motor sound level may be dampened by the compressor shell. Motor noises that are obvious in an open motor may become hard to hear in a hermetic compressor.

The motor inside a hermetic compressor can be checked electrically only from the outside. It will have the same problems as an open motor, that is, open circuit, short circuit, or grounded circuit. The technician must give the motor a complete electrical checkout from the outside of the shell; if it cannot be made to operate, the compressor must be changed. A motor checkout includes the starting and running components for a single-phase compressor, such as the run and start capacitors and the start relay.

As mentioned earlier, compressors operate in remote locations and are not normally attended. A compressor can throw a rod, tearing it up, and the motor may keep running until damaged. The compressor parts damage the motor, which may then burn out. The compressor damage is not detected because the damage cannot be seen. When a compressor is changed because of a bad motor, you should suspect mechanical damage as well.

20.15 SERVICE TECHNICIAN CALLS

SERVICE CALL 1

The manager of a retail store calls. *They have no air-conditioning and the piping going into the unit is frozen solid. The air handler is in the stockroom. The evaporator fan motor winding is open, and the outdoor unit has continued to run without air passing over the evaporator, freezing it solid.*

Upon arriving at the store, the service technician takes a minute to make sure his uniform is clean and tucked in and checks his face for dirt and grease smudges and his hair for neatness in the van's mirror. The technician politely introduces himself and his company to the store owner while handing the customer a business card. The technician writes the customer's name down so he can remember it later, especially when the job is complete and he has to bill the customer. After shaking hands, the technician asks the store owner for his account of the problem. After patiently listening, the technician politely asks the store owner some pertinent questions without being too technical. The technician remembers to never interrupt when the customer is answering his questions or simply talking to him. On arriving at the air handler in the stockroom and noticing that the fan is not running, the technician turns the cooling thermostat to OFF to stop the condensing unit, then turns the fan switch to ON.

SAFETY PRECAUTION: *The technician then turns off the power, locks and tags the panel, and removes the fan compartment cover.*• The fan motor body is cool to the touch, indicating the motor has been off for some time. The technician then turns on the power and checks power at the motor terminal block; the motor has power. The power is turned off and locked out. The technician checks the motor winding with an ohmmeter; the motor windings are open. The technician now provides the store owner with written work orders and an estimate.

The fan motor is changed. The unit cannot be started until the coil is allowed to thaw. The technician instructs the store manager to allow the fan to run until air is felt at the outlet in the men's room. This ensures the airflow has started. Then the technician waits 15 min and sets the thermostat to COOL and the fan switch to AUTO. The technician cleans up the work site, double-checks his work, politely tells the store owner of the service problem, and then informs the store owner of the detailed work description and gives him the billing information with costs. The technician informs the store owner that he will call him later in the day for feedback on the air-conditioning call. A call back later in the day indicates that the system is now cooling correctly.

SERVICE CALL 2

A residential customer calls. *There is no heat. The fan motor on the gas furnace has a defective run capacitor. The furnace burner is cycling on and off with the high-limit control. The fan will run for a few minutes each cycle before shutting off from overtemperature. The defective capacitor causes the fan motor current to run about 15% too high.*

After making sure the service van is not blocking the customer's driveway, the technician makes sure his uniform, shoes, and overall appearance looks good. He then rings the doorbell, remembering to keep a comfortable distance between himself, the door, and the customer. After he politely introduces himself and his company and handing the customer a business card, the homeowner invites the technician into the home. The technician patiently listens as the customer describes the problem, and, once the customer is done talking, he politely asks a few questions, being careful to talk clear and concisely and not too technically. The technician must use everyday language that the customer can understand to make him feel like he is helping with the solution to the problem. The technician asks permission to go under the house where the horizontal furnace is located, to which the customer agrees, and the technician leaves for under the house.

The furnace is hot. The technician hears the burner ignite and watches it for a few minutes. The burner shuts off, and about that time the fan comes on. The technician removes the fan compartment door and sees the fan turning very slowly. **SAFETY PRECAUTION:** *The power is shut off. The panel is locked and tagged.*• The motor is very hot. It seems to turn freely, so the bearings must be normal. The technician removes the run capacitor and uses an ohmmeter for a capacitor check, **Figure 20.27**. The capacitor is open—no circuit or

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

continuity. The capacitor is replaced. After shutting the fan compartment door, power is restored. It is evident from the sound of the motor that it is turning faster than before the capacitor was changed. The service technician now double-checks his work, turns off the power, oils the motor, replaces the air filter, and cleans the work site. Remembering the customer's name, the technician politely provides a written and verbal explanation of the problem solved, the work completed, billing information, and costs. The technician and customer shake hands and the technician leaves the house for his service van.

SERVICE CALL 3

A retail store customer calls. *There is no air-conditioning. The compressor, located outside, starts up, then shuts off. The fan motor is not running. The dispatcher tells the customer to shut the unit off until the technician arrives. The PSC fan motor for the condenser has bad bearings. The motor feels free to turn the shaft, but if power is applied to the motor when it is turning, the motor will stop.*

The technician arrives and talks to the store manager. The technician goes to the outdoor unit and disconnects the power so that the system can be controlled from outside. The room thermostat is set to call for cooling.

The technician goes back outside and turns the disconnect on and observes. The compressor starts, but the fan motor does not. **SAFETY PRECAUTION:** *The power is turned off. The panel is locked and tagged. The compressor leads are disconnected at the load side of the contactor so that the compressor will not be in a strain.* The technician makes the disconnect switch again and, using the clamp-on ammeter, checks the current going to the fan motor. It is drawing current and trying to turn. The technician does not know at this point if the motor or the capacitor is defective. The power is shut off. The technician spins the motor and turns the power on while the motor is turning. The motor acts like it has brakes and stops. This indicates bad bearings or an internal electrical motor problem.

The motor is changed, and the new motor performs normally even with the old capacitor. The compressor is reconnected and power is resumed. The system now cools normally. The technician changes the air filter and oils the indoor fan motor before leaving.

The following service calls do not describe the solution. Please discuss the solutions with your instructor.

SERVICE CALL 4

An insurance office customer calls. *There is no air-conditioning. This system has an electric furnace with the air handler (fan section) mounted above the suspended ceiling in the stockroom. The condensing unit is on the roof. The low-voltage power supply is at the air handler.*

After politely introducing himself, the service technician puts on shoe covers to protect the customer's floors. After carefully listening to the customer's account of the problem and answering any questions, the technician goes to the room thermostat. It is set on cooling, and the indoor fan is running. Before going out of the building and onto the roof, the service technician informs the customer why he is leaving. The technician goes to the roof and discovers the breaker is tripped. Before resetting the breaker, the technician decides to find out why the breaker tripped. The cover to the electrical panel to the unit is removed. A voltage check shows that all the voltage to the breaker is off. The contactor's 24-V coil is the only thing energized because its power comes from downstairs at the air handler.

The technician checks the motors for a ground circuit by placing one lead on the load side of the contactor and the other on the ground with the meter set on R × 10,000. The meter shows a short circuit to ground (no resistance to ground). See **Figure 20.23** for an example of a motor ground check. From this test, the technician does not know if the problem is the compressor or the fan motor. The wires are disconnected from the line side of the contactor to isolate the two motors. The compressor shows normal, no reading. The fan motor shows 0 Ω resistance to ground.

What is the problem and the recommended solution?

SERVICE CALL 5

A commercial customer calls. *There is no air-conditioning in the upstairs office. This is a three-story building with an air handler on each floor and a chiller in the basement.*

The service technician arrives and politely introduces himself to the customer. After handing the customer a business card and describing the service he can provide, the technician asks some pertinent questions using everyday language the customer can understand. The technician then carefully listens and makes the customer feel like part of the solution to the service call problem. Once the technician has permission to enter the building, he goes to the fan room where the complaint is. There is no need to go to the chiller or the other floors because there would be complaints if the chiller was not furnishing cooling to them.

The chilled water coil piping feels cold; the chiller is definitely running and furnishing cold water to the coil. The fan motor is not running. **SAFETY PRECAUTION:** *Because the motor may have electrical problems, the technician proceeds with caution by opening, locking, and tagging the electrical disconnect.* The technician pushes the reset button on the fan motor starter and hears the ratchet mechanism reset. The motor will not try to start while the technician is pushing the reset button because the disconnect switch is open. The unit must have been pulling too much current for the overload to trip.

Using an ohmmeter, the technician checks for a ground by touching one lead to a ground terminal and the other to one of the motor leads on the load side of the starter. The meter

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

is set on R × 10,000 and will detect a fairly high resistance to ground. See **Figure 20.23** for an example of a motor ground check. **SAFETY PRECAUTION:** *Any movement of the meter needle when the ohmmeter's leads are connected between ground and the motor lead would indicate a ground—so caution is necessary. If the meter needle movesas much as one-fourth of its scale, the circuit should not be energized until the ground is cleared up or physical damage may occur.* The motor is not grounded. The resistance between each winding is the same, so the motor appears to be normal. The technician then turns the motor over by hand to see whether the bearings are too tight; the motor turns normally.

The technician shuts the fan compartment door and then fastens the clamp-on ammeter to one of the motor leads at the load side of the starter. The electrical disconnect is then closed to start the motor. When it is closed, the motor tries, but will not start and pulls a high amperage. The motor seems to be normal from an electrical standpoint and turns freely, so the power supply is now suspected.

SAFETY PRECAUTION: *The technician quickly pulls the disconnect to the off position and gets an ohmmeter.* Each fuse is checked with the ohmmeter. The fuse in L2 is open. The fuse is replaced and the motor is started again. The motor starts and runs normally with normal amperage on all three phases. The question is, why did the fuse blow?

What is the problem and the recommended solution?

SERVICE CALL 6

A customer who owns a truck stop calls. *There is no cooling in the main dining room. The customer does some of the maintenance, so the technician can expect some problem related to this maintenance program.*

The technician arrives and can hear the condensing unit on the roof running; it shuts off about the time the technician gets out of the truck. The customer had just serviced the system by changing the filters, oiling the motors, and checking the belts. Since then, the fan motor has been shutting off. It can be reset by pressing the reset button at the fan contactor, but it will not run long.

Once arriving on the job on time and making sure the service van is not blocking any restaurant customer parking, the service technician makes sure his face, hair, and uniform are looking neat. He now enters the restaurant, explains to a waitress why he is there, and asks to talk to the owner. Once out of the way of the restaurant customers, the technician politely introduces himself to the owner while handing him a business card, always making eye contact. The fan is not running, and the condensing unit is shut down from low pressure. The technician fastens the clamp-on ammeter on one of the motor leads and restarts the motor. The motor is pulling too much current on all three phases, and the motor seems to be making too much noise.

What is the problem and the recommended solution?

SUMMARY

- Bearing problems are often caused by belt tension.
- Shaft problems may be caused by the technician while he or she is removing pulleys or couplings.
- Motor balancing problems are normally not handled by the heating, air-conditioning, and refrigeration technician.
- Make sure that the system is not causing vibration.
- Most electrical problems are caused by open windings, short-circuited windings, or grounded windings.
- The laws of electrical current flow must be used when troubleshooting motors.
- If the motor is receiving the correct voltage and is electrically sound, check the motor components.
- Troubleshooting hermetic compressor motors is different from troubleshooting open motors because hermetic motors are enclosed.

REVIEW QUESTIONS

1. True or False: If a sleeve bearing fails in a small, fractional horsepower motor, the motor is generally replaced.
2. An open winding in an electric motor means that
   A. the winding is making contact with the motor frame.
   B. one winding is making contact with another winding.
   C. a wire in one winding is broken.
   D. the centrifugal switch to the start winding is open.
3. There is a short circuit in an electric motor winding when
   A. there is an adverse weather condition.
   B. a winding conductor is worn bare and touches another part of the conductor that is also bare.
   C. there is a defect in the centrifugal start switch.
   D. the motor will not start.

4. An open winding or a shorted winding can be determined with which of the following instruments?
   A. Voltmeter
   B. Ammeter
   C. Ohmmeter
5. A decrease in resistance will cause the amperage to
   A. decrease.
   B. increase.
   C. decrease or increase.
   D. none of the above.
6. A(n) _____ may be used to detect resistances in the millions of ohms.
   A. megohmmeter
   B. voltmeter
   C. clamp-on ammeter
   D. psychrometer
7. What size of resistor is recommended for shorting across an electrical motor capacitor before checking with an ohmmeter?
8. To determine the capacitance of a capacitor, a(n) _____ should be used.
9. State the physical differences between a run and a start capacitor.
10. In a three-phase motor in good operating condition, the resistance
    A. should be the same across all three windings.
    B. should vary from a lower resistance in the first winding to a higher resistance in the third winding.
    C. across each winding is not important.
11. Describe what may happen to an electric motor if the drive belt is too tight.
12. How are the electrical components checked on a hermetic compressor?
13. A loose connection may result in _____ voltage and _____ current at the motor.
14. The amperage can be checked with a(n) _____ ammeter.
15. Electric motor roller and ball bearing failure often can be determined by the _____.

UNIT 21

EVAPORATORS AND THE REFRIGERATION SYSTEM

OBJECTIVES

After studying this unit, you should be able to

- define high-, medium-, and low-temperature refrigeration.
- determine the boiling temperature in an evaporator.
- identify different types of evaporators.
- describe a parallel-flow, plate-and-fin evaporator.
- describe multiple- and single-circuit evaporators.

SAFETYCHECKLIST

- ✔ Wear goggles and gloves when attaching or removing gauges to transfer refrigerant or to check pressures.
- ✔ Wear warm clothing when working in a walk-in cooler or freezer.

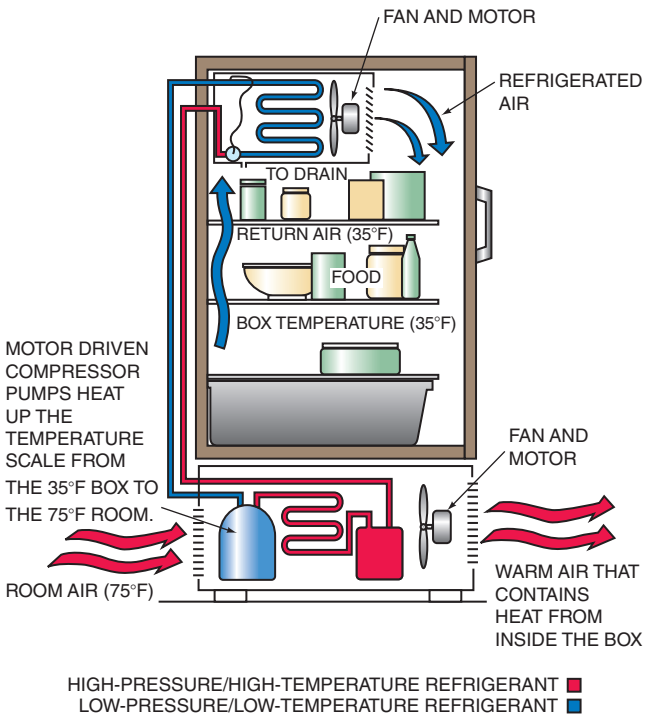
21.1 REFRIGERATION

Refrigeration is the process of removing heat from a place where it is not wanted and transferring that heat to a place where it makes little or no difference. Commercial refrigeration is similar to the refrigeration that occurs in your household refrigerator. The food that you keep in the refrigerator is stored at a temperature lower than the room temperature. Typically, the fresh-food compartment temperature is about 35°F. Heat from the room (typically 75°F) moves through the walls of the refrigerator to the cooler temperature in the refrigerator. Heat travels normally and naturally from a warm to a cool medium.

If the heat that is transferred into the refrigerator remains in the refrigerator, it will warm the food products and spoilage will occur. This heat may be removed from the refrigerator by mechanical means using the refrigerator's refrigeration equipment, which requires energy, or work. **Figure 21.1** shows how heat is removed with the compression cycle. Because it is 35°F in the box and 75°F in the room, the mechanical energy in the compression cycle actually pumps the heat to a warmer environment from the box to the room.

The heat is transferred into a cold refrigerant coil and pumped by the system compressor to the condenser,

Figure 21.1 Heat normally flows from a warm place to a colder place. When it is desirable for heat to be removed from a colder to a warmer place, the heat must be moved by force. The compressor in the refrigeration system is the pump that forces the heat up the temperature scale. These compressors are normally driven by electric motors.



where it is released into the room. This is much like using a sponge to move water from one place to another. When a dry sponge is allowed to absorb water in a puddle and you take the wet sponge to a container and squeeze it, you exert energy, much like a compressor in the refrigeration system, **Figure 21.2**.

Another example of refrigeration is a central air-conditioning system in a residence. It absorbs heat from the home by passing indoor air at about 75°F over a coil that is cooled to about 40°F. Heat will transfer from the room air to the coil cooling the air. This cooled air may be mixed

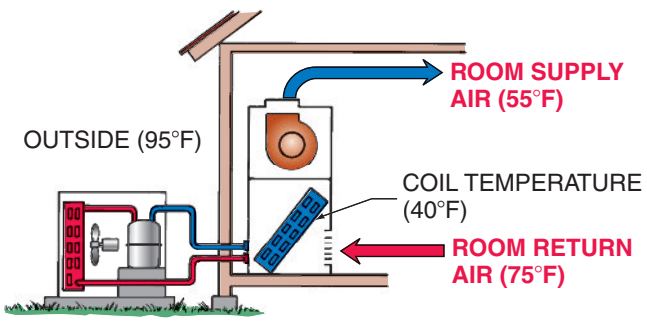
Figure 21.2 A sponge absorbs water. The water can then be carried in the sponge to another place. When the sponge is squeezed, the water is rejected to another place. The squeezing of the sponge may be considered the energy that it takes to pump the water.

with the room air, lowering its temperature, **Figure 21.3**. This process is called air-conditioning, but it is also refrigeration at a higher temperature level than that of the household refrigerator, so it is frequently called high-temperature refrigeration.

Commercial refrigeration is used in commercial business locations. The food store, fast-food restaurant, drug store, flower shop, and food processing plant are only a few of the applications. Some of the commercial systems are plug-in appliances, such as a small, reach-in ice storage bin at the local convenience store. The system is entirely located within the one unit. Some systems consist of individual boxes with single remote condensing units, and some are complex systems with several compressors in a rack serving several reach-in display cases, as in a supermarket. Most commercial refrigeration is installed and serviced by a special group of technicians who work only with commercial refrigeration and the food-service business.

Figure 21.3 An air-conditioning example of refrigeration.



21.2 TEMPERATURE RANGES OF REFRIGERATION

The temperature ranges for commercial refrigeration may refer to the temperature of the refrigerated box or the boiling temperature of the refrigerant in the coil. The following temperatures illustrate some of the guidelines used in the industry when discussing box temperatures.

HIGH-TEMPERATURE APPLICATIONS

High-temperature refrigeration applications will normally involve box temperatures of 47°F to 60°F. Storing such products as flowers and candy may require these temperatures.

MEDIUM-TEMPERATURE APPLICATIONS

The household refrigerator fresh-food compartment is a good example of medium-temperature refrigeration, which typically ranges from 28°F to 40°F. Many different products are stored at the medium-temperature range. For most products, the medium-temperature refrigeration range is above freezing; few products are stored below 32°F. Items such as eggs, lettuce, and tomatoes lose their appeal if they freeze in a refrigerator.

LOW-TEMPERATURE APPLICATIONS

Low-temperature refrigeration produces temperatures below the freezing point of water, 32°F. One of the higher low-temperature applications is the making of ice.

Low-temperature food storage applications generally start at 0°F and go as low as −20°F. At this temperature ice cream would be frozen hard. Frozen meats, vegetables, and dairy products are only a few of the foods preserved by freezing. Some foods may be kept for long periods of time and are appetizing when thawed for cooking, provided they are frozen correctly and kept frozen.

21.3 THE EVAPORATOR

The evaporator in a refrigeration system is responsible for absorbing heat into the system from whatever medium is to be cooled. This heat-absorbing process is accomplished by maintaining the evaporator coil at a lower temperature than the medium to be cooled. For example, if a walk-in cooler is to be maintained at 35°F to preserve food products, the coil in the cooler must be maintained at a lower temperature than the 35°F air that will be passing over it. **Figure 21.4** shows the refrigerant in the evaporator boiling at 20°F, which is 15°F lower than the entering air. The evaporator operating at these low temperatures removes latent and sensible heat from the cooler. Operating at 20°F, as in the preceding example, the evaporator will collect moisture from the air in the cooler, latent heat. The removal of sensible heat reduces the food temperature.

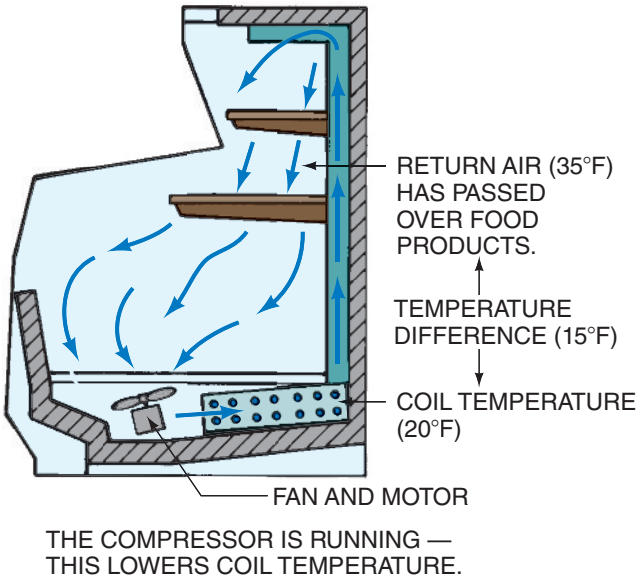
Figure 21.4 The relationship of the coil's boiling temperature to the air passing over the coil while it is operating in the design range.



21.4 BOILING AND CONDENSING

Two important factors in understanding refrigeration are the (1) boiling temperature and (2) condensing temperature. The boiling temperature and its relationship to the system involve the evaporator. The condensing temperature involves the condenser and will be discussed in the next unit. These temperatures can be followed by using the temperature/pressure chart in conjunction with a set of refrigeration pressure gauges, **Figure 21.5** and **Figure 21.6**.

21.5 THE EVAPORATOR AND BOILING TEMPERATURE

The **boiling temperature** of the liquid refrigerant determines the coil operating temperature. In an air-conditioning system a 40°F evaporator coil with 75°F air passing over it produces conditions used for air-conditioning or high-temperature refrigeration. Boiling is normally associated with high temperatures and water. Unit 3, "Refrigeration and Refrigerants," discussed the fact that water boils at 212°F at atmospheric pressure. It also discussed the fact that water boils at other temperatures, depending on the pressure. When the pressure is reduced, water will boil at 40°F. This is still boiling—changing a liquid to a vapor. In a refrigeration system, the refrigerant may boil at 20°F by absorbing heat from the 35°F food.

The service technician must be able to determine what operating pressures and temperatures are correct for the various systems being serviced under different load conditions. Much of this knowledge comes from experience. When taking readings from thermometers and gauges, the readings must be evaluated. There can be as many different readings as there are changing conditions. Guidelines can help the technician know the pressure and temperature ranges at which the equipment should operate. There are relationships between the entering air temperature and the evaporator for each system. These relationships are similar from installation to installation.

21.6 REMOVING MOISTURE

Dehumidifying the air means to remove the moisture, and this is frequently desirable in refrigeration systems. Moisture removal is similar from one refrigeration system to another. Knowing what the coil-to-air relationship is can help the technician know what conditions to look for. The load on the coil would rise or fall accordingly as the return-air temperature rises or falls. Warmer return air in the box will also have more moisture content, which imposes further load on the coil. If the cooler is warm due to food added to it, the coil would have more heat to remove because it has more load on it. It would be much like boiling water in an open pan on the stove. The water boils at one rate with the burner on medium and at an increased rate with the burner on high. The boiling pressure stays the same in the boiling water in a pan because the pan is open to the atmosphere. When this same boiling process occurs in an enclosed coil, the pressures will rise when the boiling occurs at a faster rate. This causes the operating pressure of the whole system to rise, **Figure 21.7**.

When the evaporator removes heat from air and lowers the temperature of the air, sensible heat is removed. When moisture is removed from the air, latent heat is removed. The moisture is piped to a drain, **Figure 21.8**. Latent heat is called hidden heat because it does not register on a thermometer, but it is heat, like sensible heat, and it must be removed, which takes energy.

The refrigeration evaporator is a component that absorbs heat from the conditioned space into the refrigeration system. The evaporator can be thought of as the *sponge* of the system. It is responsible for a heat exchange between the conditioned space or product and the refrigerant inside the system. Some evaporators absorb heat more efficiently than others. **Figure 21.9** illustrates the heat exchange between air and refrigerant.

21.7 HEAT EXCHANGE CHARACTERISTICS OF THE EVAPORATOR

The following are conditions that govern the rate of heat exchange:

1. The evaporator *material* through which the heat has to be exchanged. Evaporators may be manufactured from copper, steel, brass, stainless steel, or aluminum. Corrosion is one factor that determines what material is used.

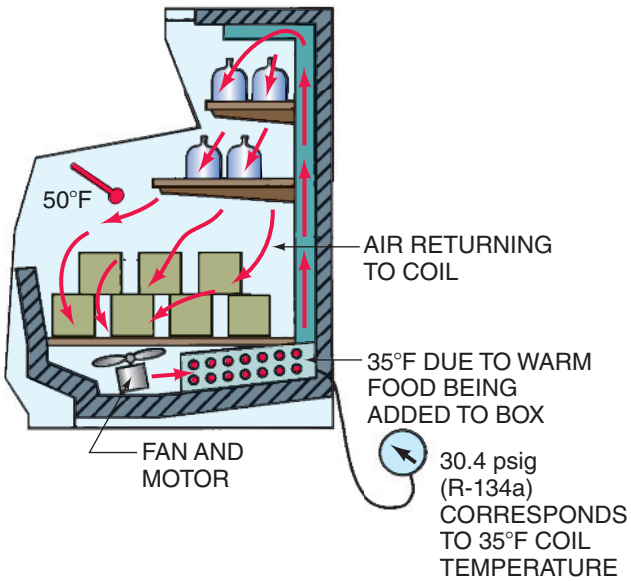
Figure 21.7 The coil-to-air temperature relationship under increased coil load.



For instance, when acidic materials need to be cooled, copper or aluminum coils would be eaten away. Stainless steel may be used instead, but stainless steel does not conduct heat as well as copper. Some evaporators are even coated with a plastic-like substance to protect the metal underneath from rust or oxidation. This application is often seen in restaurants with smaller commercial, medium-temperature coolers that store salad preparation materials, which are acidic because they often have a vinegar base for added flavor and for extended shelf life.

Figure 21.8 The cooling coil condenses moisture from the air.

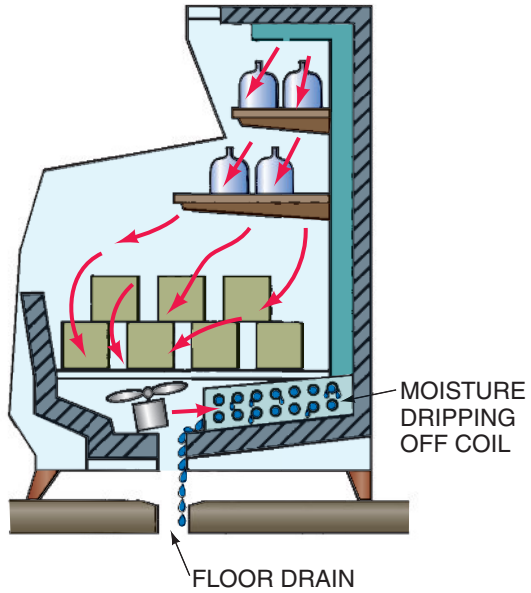


Figure 21.9 The heat exchange relationship between air and refrigerant.

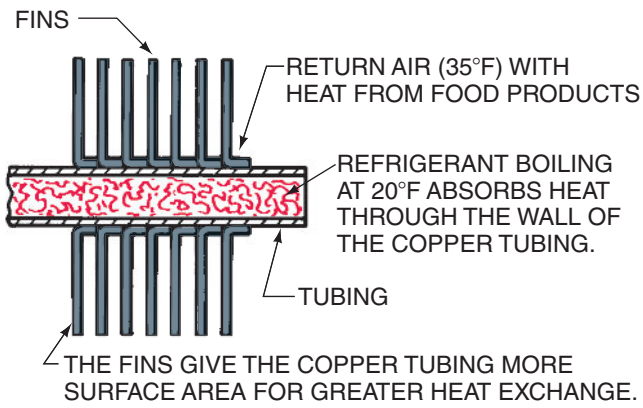

2. The *medium* to which the heat is exchanged. Giving heat up from air to refrigerant is an example. The best heat exchange occurs between two liquids, such as water to liquid refrigerant. This is because liquids are more dense than vapors and usually have a higher specific heat. However, this is not always practical because heat frequently has to be exchanged between air and vapor refrigerant. The vapor-to-vapor exchange is slower than the liquid-to-liquid exchange, **Figure 21.10**.
3. The **film factor**. This is a relationship between the medium giving up heat and the heat exchange surface. The film factor relates to the velocity of the medium passing over the exchange surface. When the velocity is too slow, the film between the medium and the surface becomes an insulator and slows the heat exchange. The velocity keeps the film to a minimum, **Figure 21.11**. The correct velocity is chosen by the manufacturer.

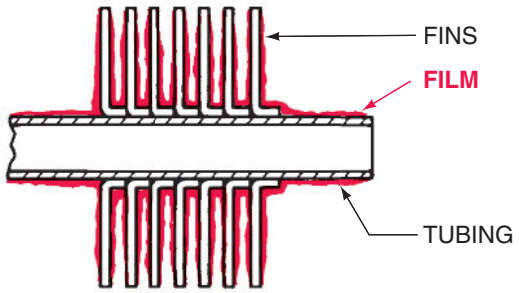

Figure 21.12 A bare-pipe evaporator.

4. The *temperature difference* between the two mediums in which the heat exchange is taking place. The greater the temperature difference between the evaporator coil and the medium giving up the heat, the faster the heat exchange will occur.

21.8 TYPES OF EVAPORATORS

Numerous types of evaporators are available, and each has its purpose. The first evaporators for cooling air were of the natural-convection type. They were actually bare-pipe evaporators with refrigerant circulating through them, **Figure 21.12.** This evaporator was used in early walk-in coolers and was mounted high in the ceiling. It relied on the air being cooled, falling to the floor, and setting up a natural air current. The evaporator had to be quite large for the particular application because the velocity of the air passing over the coil was so slow. Natural-convection evaporators are still occasionally used today. The use of a blower to force or induce air over the coil improved the efficiency of the heat exchange. This meant that smaller evaporators could be used to do the same job. Design trends in the industry have always been toward smaller, more efficient equipment, **Figure 21.13.**

The expansion of the evaporator surface to a surface larger than the pipe itself produces a more efficient heat exchange. The *stamped evaporator* was one of the first designs to create a large pipe surface. It consisted of two pieces of metal stamped with the impression of a pipe passage through it, **Figure 21.14.**

A pipe with fins attached, called a *finned-tube evaporator*, is today used more than any other type of heat exchanger between air and refrigerant. This heat exchanger is efficient because the fins are in good contact with the pipe carrying the refrigerant. **Figure 21.15(A)** shows an example of a finned-tube evaporator. **Figure 21.15(B)** shows a finned-tube evaporator used in

a low-temperature, commercial, well-type freezer. The leading fins come in contact with the air first and must have wider spacing between the fins. It is these leading fins that are more prone to frost accumulation. The wider fin spacing can accumulate more frost before becoming plugged and impeding the airflow. The fins toward the back of the evaporator then encounter drier air with less frost and so are more closely spaced.

Multiple circuits improve evaporator performance and efficiency by reducing pressure drop inside the evaporator. Even though the pipes inside the evaporator might be polished smooth, they still offer resistance to the flow of both liquid and vapor refrigerants. The shorter the evaporator is, the less resistance there is to this flow. The "U" bends at the ends of the evaporator also offer a great deal of resistance to the flow of refrigerant. As evaporators become longer, they have more and more pressure drop associated with refrigerant flowing through them. The manufacturer will design the evaporator so that the tubing bundles are in parallel to one another, **Figure 21.16**.

(B)

The evaporator for cooling liquids or making ice operates under the same principles as one for cooling air but is designed differently. It may be strapped on the side of a cylinder with liquid inside, submerged inside the liquid container, or be a double-pipe system with the refrigerant inside one pipe and the liquid to be cooled circulated inside an outer pipe, **Figure 21.17**.

Every central split-cooling system manufactured in the United States today must have a Seasonal Energy Efficiency Ratio (SEER) of at least 13. This energy requirement was mandated by federal law as of January 23, 2006. Also, with the phaseout of R-22 just around the corner, manufacturers of HVAC/R equipment have been looking for energy-efficient methods to apply to their equipment to meet these new energy requirements. The timeline for R-22 is as follows:

- 2010—R-22 use is banned at the original equipment manufacturer (OEM) level with a 75% reduction of HCFC production.
- 2015—90% reduction of HCFC production.
- 2020—Total ban of R-22 production.

The equipment covered by this federal mandate includes

- unitary equipment from 1.5 to 5 tons,
- split/packaged air conditioners and heat pumps.

Equipment not covered includes

- commercial equipment greater than 6 tons,
- space-constrained units smaller than 3 tons (room air conditioners),
- water-source units.

SEER is calculated on the basis of the total amount of cooling (in Btu) the system will provide over the entire season, divided by the total number of watt-hours it will consume. Higher SEERs reflect a more efficient cooling system. The federal mandate impacts 95% of the unitary market in the United States, which is about 8 million units manufactured at the time of this writing. Because of the new federal mandate of 13 SEER, most air-conditioning and heat pump manufacturers are looking for more efficient evaporator and condenser designs, more efficient compressors and fan motors, and more sophisticated control systems in order to meet the new energy-efficiency requirement.

One such evaporator design incorporates an aluminum parallel-flow, flat-plate-and-fin configuration with small parallel channels inside the flat plate. The plates are flattened, streamlined tubes each one of which is split into smaller, parallel ports, **Figure 21.18**. *Refrigerant will phase change or evaporate from a liquid to a vapor inside the channels in the plate, while strategically shaped fins (extended surfaces) will enhance heat transfer from the air into the evaporator. The plates and fins are bonded or soldered to increase heat transfer and to eliminate any contact resistance (air gaps) that will reduce heat transfer.* Headers at the inlet and outlet of the heat exchanger are also bonded to the plates through soldering.

Heat is transferred from the air to the evaporating refrigerant in three steps, as follows:

1. Air side—between the fins and the air to be cooled
2. Heat conduction—between the fins and the tubes
3. Refrigerant side—between the tubes and the evaporating refrigerant

The air side of the heat exchange can be enhanced through fin geometry. Louvres, lances, and rippled edges all increase heat transfer, **Figure 21.19**. *The conduction between the fins and the tubes is enhanced through the application of a metallic bond (soldering) that eliminates any air gaps.* The refrigerant side of the heat transfer deals with how much surface area of the inside of the tubes will come into contact with the phase-changing refrigerant. This internal surface area is often referred to as a *wetted perimeter*. As the internal surface area of the tubes increases, the heat transfer increases. Internal surface area can be increased by

- increasing the number of parallel channels inside the flat plates, and/or
- increasing the number of flat plates (decreasing the spacing between them).

The capacity (tonnage) of the heat exchanger can vary with its height and length. The plates can be oriented vertically for an evaporator application or horizontally for condenser applications. The vertical orientation of the flat plates allows condensate removal to occur naturally, alleviating any water drainage issues from the evaporator, **Figure 21.20**. This technology is being used with condensers as well as evaporators,

(A)

(B)

Figure 21.21. Applications in the HVAC/R field include residential air-conditioning, rooftop air-conditioning, chillers, geothermal heat pumps, electronic cooling, packaged terminal air conditioners (PTACs), ice machines, beverage dispensers, refrigerated display cases, and food-service refrigeration. Some of the benefits of this parallel-flow, plate-and-fin heat exchanger technology are as follows:

- Reduces static pressure through the coil—which means fewer fan watts and less horsepower
- Reduces coil depth for the evaporator and condenser, which leads to easier cleaning and less air-side static pressure
- Reduced internal volume reduces refrigerant charge
- Reduced face area of condenser and evaporator
- Smaller footprint for the condensing unit
- A 30% reduction in coil weight and size
- A reduction in packing costs, sizes, and weights
- The all-aluminum coil, header, and fins enhance corrosion resistance
- Lower system costs
- Higher system efficiencies than a round, copper-tube heat exchanger with aluminum fins, **Figure 21.16**(C)
- Lower operating costs
- Quieter operations

Field repair of leaking heat exchangers, **Figure 21.22**, can be accomplished by

- recovering the refrigerant,
- cleaning the leaking area with a solution,
- brushing the area with a wire brush,
- using a utility knife blade to remove any fins that may be in the local area,

- pulling a vacuum with a vacuum pump,
- applying a two-part epoxy that will be sucked into the flat plate where the leak exists,
- applying heat with an electric blow drier until the epoxy is cured,
- evacuating to a 500-micron vacuum,
- charging with the appropriate refrigerant.

Field cleaning heat exchangers can be accomplished using the same methods as for a standard round copper-tube heat exchanger with aluminum fins:

- Elevate the temperature of the mixed cleaner to 120°F.
- Use a power washer with a broad spray pattern.
- Use nonacidic cleaners (pH < 10.5).
- When the heat exchanger is clean, rinse the coil with clean water.

21.9 EVAPORATOR EVALUATION

Knowing the design considerations helps in *evaporator evaluation*. When the service technician arrives at the job, it may be necessary to evaluate whether a particular evaporator is performing properly. This can be considered one of the starting points in organized troubleshooting. The evaporator absorbs heat, the compressor pumps it, and the condenser rejects it. The following example pertains to a medium-temperature walk-in box. However, the procedure would be about the same for any typical application.

Evaporator Specifications

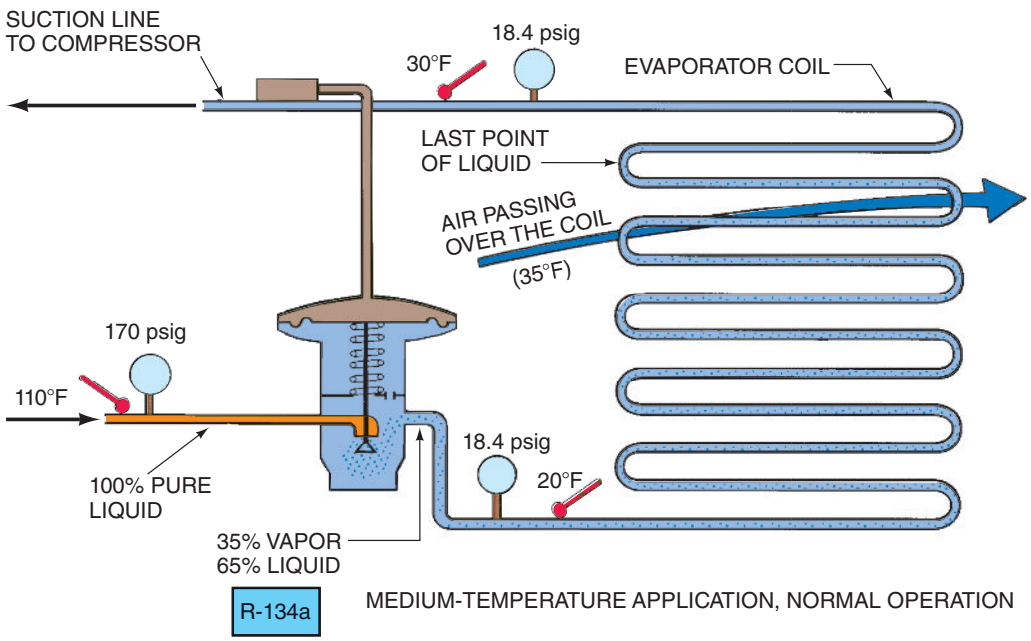
1. Copper-pipe coil
2. Aluminum fins attached to the copper-pipe coil
3. Forced draft with a prop-type fan
4. One continual refrigerant circuit
5. R-134a
6. Evaporator to maintain space temperature at 35°F
7. Evaporator clean and in good working condition

First we describe how the evaporator functions when it is working correctly.

As seen in **Figure 21.23**, warm liquid passes through the small opening in the expansion device into the low pressure (18.4 psig) of the evaporator side. Due to the pressure drop across the expansion device, approximately 35% of the liquid entering the expansion device at the evaporator is changed to a vapor and cools the remainder of the liquid to the evaporator's boiling temperature (20°F). So, entering the evaporator is a partial liquid-partial vapor mixture at 20°F and 18.4 psig; it is approximately 65% liquid and 35% vapor.

As the partial liquid–partial vapor mixture moves through the evaporator, more of the liquid changes to a vapor. This is called *boiling* and is a result of heat absorbed into the coil from whatever medium the evaporator is cooling. Finally, near the end of the evaporator the liquid is all boiled away to a vapor. At this point the refrigerant is known as **saturated vapor**. This means that the refrigerant vapor is saturated with heat. If any more heat is added to it, it will rise in temperature. If any heat is taken away from

Figure 21.23 When the 110°F liquid passes through the expansion valve orifice, some of the liquid flashes to a vapor and cools the remaining liquid to the evaporator temperature of 20°F.



Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

it, it will start changing back to a liquid. This vapor is saturated with heat, but it is still at the evaporating temperature corresponding to the boiling point, 20°F. *This is a most important point in the function of an evaporator because all of the liquid must be boiled away as close to the end of the coil as possible. This is necessary to (1) keep the coil efficiency up and (2) ensure that liquid refrigerant does not leave the evaporator and move into the compressor.* For efficient operation, the evaporator must be as full of liquid as possible without allowing liquid to reach the outlet of the coil, because the best heat exchange is between the liquid refrigerant and the air passing over the coil.

The pressure/enthalpy chart in **Figure 21.24** shows graphically what happens inside the evaporator of the preceding walk-in cooler example. The refrigerant enters the evaporator at point A (after leaving the expansion valve). The liquid pressure is 18.4 psig and contains 48.7 Btu/lb of heat at this point. Approximately 35% of the liquid flashed to a vapor when passing through the expansion valve. As the liquid proceeds through the evaporator, it is changing to a vapor. All of it has changed to a vapor at point B, but the vapor temperature is still 20°F and capable of absorbing heat, in the form of superheat. The vapor temperature starts to rise while it is still in the evaporator until the temperature is 30°F (containing 10°F of superheat). The vapor leaves the evaporator at point C with a heat content of 108.1 Btu/lb. The usable refrigeration in the evaporator is from points A to C, where the refrigerant absorbed 59.4 Btu/lb (108.1 Btu/lb − 48.7 Btu/lb). You only need to know how many Btu/h capacity is needed to determine the amount of refrigerant that needs to be circulated. For example, if the evaporator needs to have a capacity of 35,000 Btu/h, it must have 589.2 lb of refrigerant circulate through it per hour (35,000 Btu/h ÷ 59.4 Btu/lb = 589.2 lb/h). This sounds like a lot of refrigerant, but it is only 9.82 lb/min (589.2 lb/h ÷ 60 min/h = 9.82 lb/min). The size of the compressor and the system operating conditions determine how much refrigerant can be pumped.

Figure 21.24 The refrigeration effect in the evaporator.

21.10 LATENT HEAT IN THE EVAPORATOR

The latent heat absorbed during the change of state is much more concentrated than the sensible heat that would be added to the vapor leaving the coil. Refer to the example in Unit 1, "Heat, Temperature, and Pressure," Section 1.3, "Introduction to Heat," that showed how it takes 1 Btu to change the temperature of 1 lb of 68°F water to 69°F water. Section 1.8 also showed that it takes 970 Btu to change 1 lb of 212°F water to 212°F steam. The change of state is where the greatest amount of heat is absorbed into the system. The preceding example showed that 59.4 Btu of heat were absorbed for every 1 lb of refrigerant that was circulated (59.4 Btu/lb). This happened at a boiling temperature of 20°F, without a change in pressure.

21.11 THE FLOODED EVAPORATOR

To get the maximum efficiency from the evaporator heat exchange, some evaporators are operated full of liquid, or flooded, and are equipped with a device to keep the liquid refrigerant from passing to the compressor. These **flooded evaporators** are specially made and normally use a float metering device to keep the liquid level as high as possible in the evaporator. This text will not go into detail about this system because it is not a device often encountered. The manufacturer's literature should be consulted for any special application.

When an evaporator is flooded, it would operate much like water boiling in a pot with a compressor taking the vapor off the top of the liquid. There would always be a liquid level. If the evaporator is not flooded, that is, when the refrigerant starts out as a partial liquid and boils away to a vapor in the heat exchange pipes, it is known as a *dry-type,* or direct-expansion, evaporator.

21.12 DRY-TYPE EVAPORATOR PERFORMANCE

To check the performance of a dry-type evaporator, the service technician would first make sure that the refrigerant coil is operating with enough liquid inside the coil. To determine this, the technician must calculate the evaporator superheat. This is generally done by comparing the boiling temperature of the refrigerant inside the coil with the line temperature leaving the coil. The difference in temperatures is usually 8°F to 12°F. For example, in the coil pictured in **Figure 21.25**, the superheat in the coil was arrived at by converting the coil pressure (suction pressure) to temperature. In this example, the pressure is 18.4 psig, which corresponds to 20°F. The suction pressure reading is important to the technician because the boiling temperature must be known to arrive at the superheat reading for the coil. In the following example, the evaporator superheat reading is 10°F (30°F − 20°F).

Figure 21.25 The evaporator operating under normal load.

21.13 EVAPORATOR SUPERHEAT

The difference in temperature between the boiling refrigerant temperature and the evaporator outlet temperature is known as evaporator superheat. Superheat is the sensible heat added to the vapor refrigerant after the change of state has occurred. Superheat is the best method of checking to see when a refrigerant coil has a proper level of refrigerant. When a metering device is not feeding enough refrigerant to the coil, the coil is said to be a **starved coil**, and the superheat is greater, **Figure 21.26**. It can be seen from the example that all of the refrigeration takes place at the beginning of the coil. The suction pressure is very low, below freezing, but only a portion of the coil is being used effectively. This coil would freeze solid and no air would pass through it. The freeze line would creep upward until the whole coil was a block of ice, and the refrigeration would do no good. The refrigerated box temperature would rise because ice is a good insulator.

21.14 HOT PULLDOWN (EXCESSIVELY LOADED EVAPORATOR)

When the refrigerated space has been allowed to warm up considerably, the system must go through a hot pulldown. On a hot pulldown the evaporator and metering device are not expected to act exactly as they would in a typical design condition. For instance, if a walk-in cooler supposed to maintain 35°F were allowed to warm up to 60°F and had some food or beverages inside, it would take an extended time to pull the air and product temperature down. The coil may be boiling the refrigerant so fast that the superheat may not come down to 8°F to 12°F until the box has cooled down closer to the design temperature.

A superheat reading on a hot pulldown should be interpreted with caution, **Figure 21.27**. The reading will be correct only when the coil is at or near design conditions. However, many modern thermostatic expansion valves (TXVs) have wide temperature control ranges. Some can control evaporator superheat from +20°F to −20°F, and they are advertised to do this effectively even when under heavy or light heat loadings of the evaporator. TXVs should control superheat under most normal conditions. However, when a system is under a hot pulldown, the technician should let the system get past this heavy load period and reach a somewhat stabilized condition before trying to calculate an evaporator superheat reading. Hot pulldowns are not considered normal conditions, and the technician must be patient when calculating evaporator superheat. It takes time for a TXV to fill out the evaporator with refrigerant even when it is wide open during a hot pulldown.

When a dry-type coil is fed too much refrigerant, not all the refrigerant changes to a vapor. This coil is thought of as a *flooded* coil—flooded with liquid refrigerants, **Figure 21.28. Do not confuse this with a coil flooded by design**. This is a symptom that can cause real trouble because unless the liquid in the suction line boils to a vapor before it reaches the compressor, compressor damage may occur. **Remember,**

Figure 21.26 A starved evaporator coil showing 38°F (40°F − 2°F) of evaporator superheat.

Figure 21.27 Hot pulldown with a coil. This is a medium-temperature evaporator that should be operating at 18.4 psig (R-134a, 20°F). The return air is 55°F instead of 35°F. This causes the pressure in the coil to rise. The warm box boils the refrigerant at a faster rate. The thermostatic expansion valve is not able to feed the evaporator quickly enough to keep the superheat at 10°F. The evaporator has 15°F of superheat.

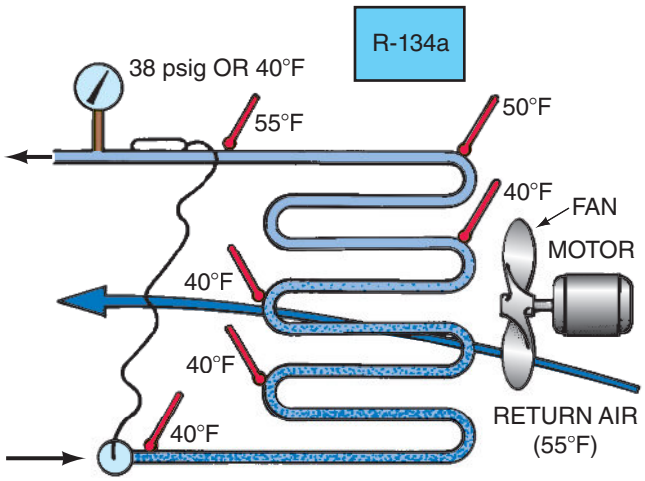

Figure 21.28 The evaporator is flooding because the thermostatic expansion device is not controlling refrigerant flow properly.

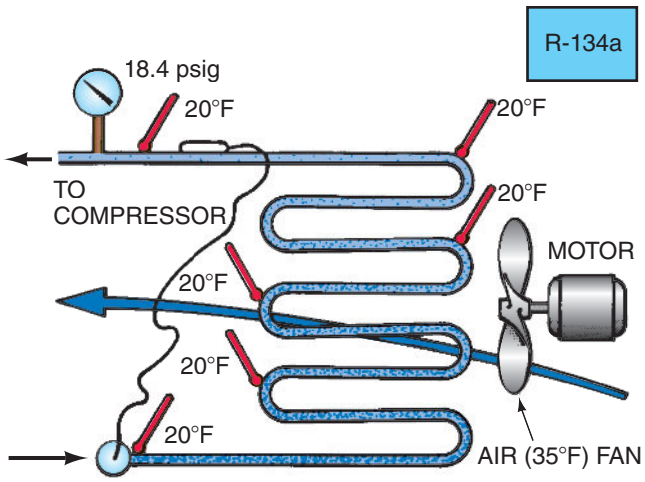
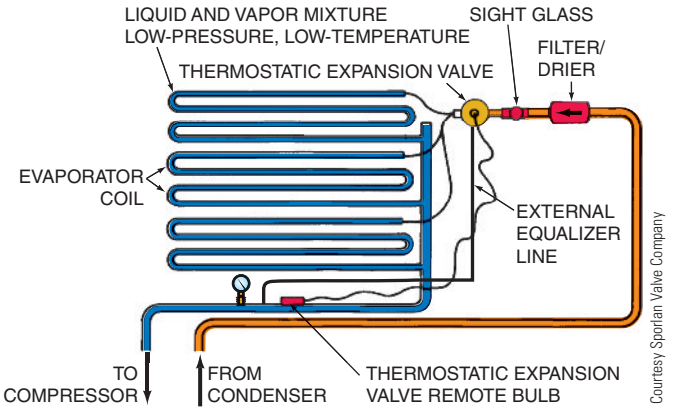


the evaporator is supposed to boil all of the liquid to a vapor. Therefore, a thermostatic expansion device that is not operating correctly can cause compressor failure.

21.15 PRESSURE DROP IN EVAPORATORS

Multicircuit evaporators are used when the coil would become too long for a single circuit, **Figure 21.29**. The same evaluating procedures hold true for a multicircuit evaporator as for a single-circuit evaporator.

Figure 21.29 A multicircuit evaporator.



A dry-type evaporator has to be as full as possible with refrigerant to be efficient. Each circuit should be feeding the same amount of refrigerant. If this needs to be checked, the service technician can check the common pressure tap for the boiling pressure, which can be converted to temperature. Then the temperature will have to be checked at the outlet of each circuit to see whether any circuit is overfeeding or starving, **Figure 21.30** and **Figure 21.31**.

Some reasons for uneven feeding of a multicircuit evaporator are the following:

- Blocked distribution system
- Dirty coil
- Uneven air distribution
- Coil circuits of different lengths

In larger commercial and industrial-type evaporators, an associated pressure drop usually is caused from friction as the refrigerant travels the length of the evaporator and down a long suction line to the compressor. This causes the pressure at the compressor to be a bit lower than the pressure at the evaporator outlet. With larger evaporators and longer suction lines, it is important to measure the refrigerant's pressure at the evaporator outlet—not at the compressor service valves—when measuring evaporator superheat, **Figure 21.29** and **Figure 21.30**. It is best to measure the refrigerant pressure at the same location that the evaporator outlet temperature is taken when measuring evaporator superheat. This will give the service technician a more accurate evaporator superheat reading and, therefore, better evaporator efficiencies. Schrader taps are often provided at the outlet of larger evaporators for this reason. Line taps also can be used to gain access to evaporator outlet pressure. This method also will protect the compressor from flooding or slugging problems caused by inaccurate evaporator superheat readings.

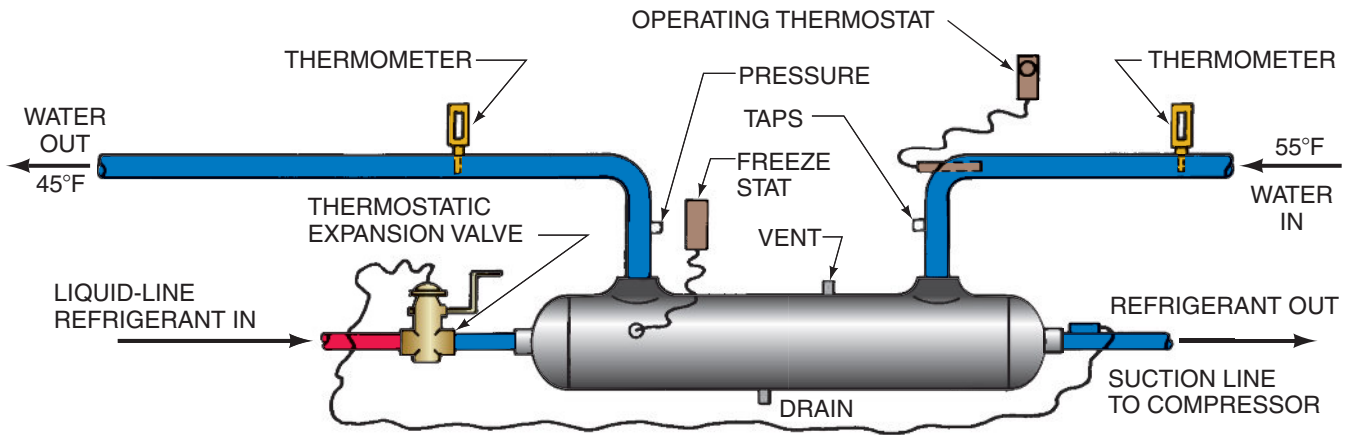
21.16 LIQUID COOLING EVAPORATORS (CHILLERS)

A different type of evaporator is required for liquid cooling. It functions much like the one for cooling air and is normally a dry-type expansion evaporator in smaller systems, **Figure 21.32(A)**. Evaporators for larger-tonnage chillers are usually the flooded type. They have saturated liquid/vapor refrigerant in the shell and the water to be chilled flows in the tube bundles, **Figure 21.32(B)**. They use a low side float to meter the refrigerant into the shell of the evaporator to maintain the proper refrigerant level.

Liquid cooling evaporators have more than one refrigerant circuit to prevent pressure drop. These evaporators sometimes have to be checked to see whether they are absorbing heat as they should. Using refrigeration gauges and some accurate method for checking the temperature of the suction line are very important. These evaporators have a normal superheat range similar to air-type evaporators (8°F to 12°F). When the superheat is within this range and all circuits in a multicircuit evaporator are performing alike, the evaporator is doing its job on the refrigerant side. However, this does not mean that it will cool properly. The liquid side of the evaporator must be clean so that the liquid will come in proper contact with the evaporator.

Figure 21.32 (A) A direct-expansion evaporator used for cooling liquids.



(A)

Figure 21.32 (B) A 100-ton (R-134a) flooded-type evaporator used to chill water for cooling a large building.

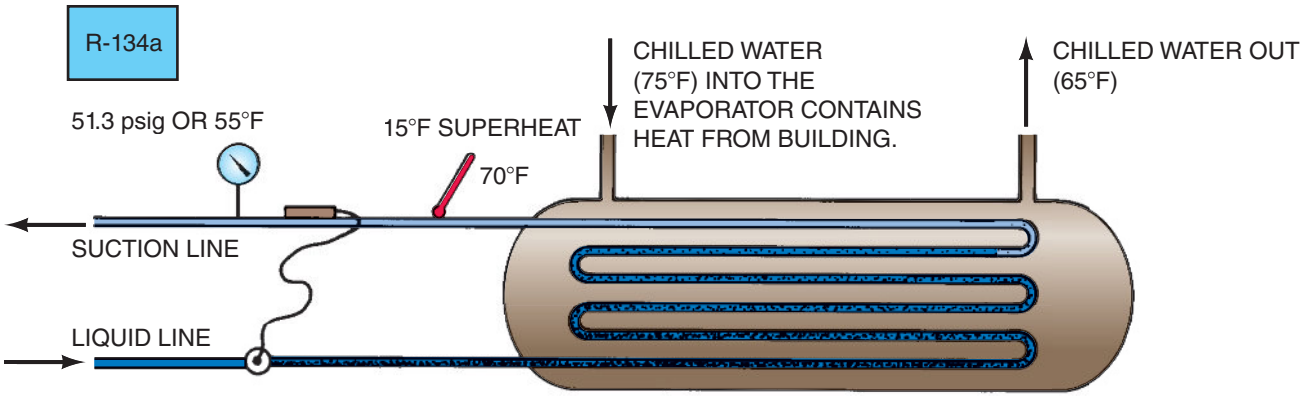
Figure 21.33 A hot pulldown on a liquid evaporator giving up its heat to refrigerant. This evaporator normally has 55°F water in and 45°F water out. The hot pulldown with 75°F water instead of 55°F water boils the refrigerant at a faster rate. The expansion valve may not be able to feed the evaporator quickly enough to maintain 10°F superheat. No conclusions should be made until the system approaches design conditions.



The following problems are typical on the liquid side of the evaporator:

1. Mineral deposits built up on the liquid side, acting like an insulator and causing a poor heat exchange
2. Poor circulation of the liquid to be cooled where a circulating pump is involved

When the superheat is correct and the coil is feeding correctly in a multicircuit system, the technician should consider the temperature of the liquid. The superheat may not be within the prescribed limits if the liquid to be cooled is not close to the design temperature. On a hot pulldown of a liquid product, the heat exchange can be such that the coil appears to be starved for refrigerant because it is so loaded up that it is boiling the refrigerant faster than normal. The technician must be patient because a pulldown cannot be rushed, **Figure 21.33**. Air-to-refrigerant evaporators do not have quite the pronounced difference in pulldown that liquid heat exchange evaporators do because of the excellent heat exchange properties of the liquid to the refrigerant.

21.17 EVAPORATORS FOR LOW-TEMPERATURE APPLICATIONS

Low-temperature evaporators used for cooling space or product to below freezing are designed differently because they require the coil to operate below freezing.

In an airflow application, the water that accumulates on the coil will freeze and will have to be removed. The design of the fin spacing must be carefully chosen, because a very small amount of ice accumulated on the fins will restrict the airflow. Low-temperature coils have fin spacings that are wider than medium-temperature coils, **Figure 21.34**.

Figure 21.34 Fin spacing. (A) Low-temperature evaporator. (B) Medium-temperature evaporator.

Other than the airflow blockage due to ice buildup, these lowd-temperature evaporators perform much the same as medium-temperature evaporators. They are normally dry-type evaporators and have one or more fans to circulate the air across the coil. The defrosting of the coil has to be done by raising the coil temperature above freezing to melt the ice. Then the condensate water has to be drained off and kept from freezing. Defrost is sometimes accomplished with heat from outside the system. Electric heat can be added to the evaporator to melt the ice, but this heat adds to the load of the system and needs to be pumped out after defrost.

21.18 DEFROST OF ACCUMULATED MOISTURE

Defrost can be accomplished with heat from inside the system using the hot gas from the discharge line of the compressor by routing a hot gas line from the compressor discharge line to the outlet of the expansion valve and installing a solenoid valve to control the flow. When defrost is needed, hot gas is released inside the evaporator, which will quickly melt any ice, **Figure 21.35**.

When the hot gas enters the evaporator, it is likely that liquid refrigerant will be pushed out of the suction line toward the compressor. In fact, when hot gas enters an evaporator and starts to cool as it melts ice or frost, it will soon lose all of its superheat and turn to liquid or condense. This liquid will go to the accumulator and fall to its bottom. Dense saturated vapors will be drawn into the compressor's suction stroke. The compressor will see an increased load from these dense vapors and may draw a higher amp than during the normal running cycle. If the system does not have an accumulator, this condensed liquid may flood the compressor's crankcase and foaming of the oil in the crankcase may occur, **Figure 21.36**. This can lower the oil level in the crankcase and cause scoring of bearing surfaces in the compressor. This condition is often referred to as **bearing washout**.

Flooding the compressor's crankcase with liquid refrigerant can also cause the foaming refrigerant and oil mixture to pressurize the crankcase, which causes the mixture of liquid and vapor refrigerant and oil foam to be forced through any crevice available, including the compressor's piston rings. The mixture is often pumped into the high side of the system by the compressor. The compressor's discharge temperature will

Figure 21.36 (A) A compressor's clear oil sight glass. (B) A sight glass from a flooding crankcase foams with liquid refrigerant.

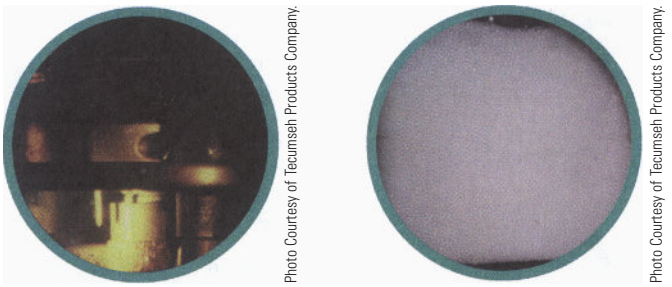

Figure 21.35 Using hot gas to defrost an evaporator.

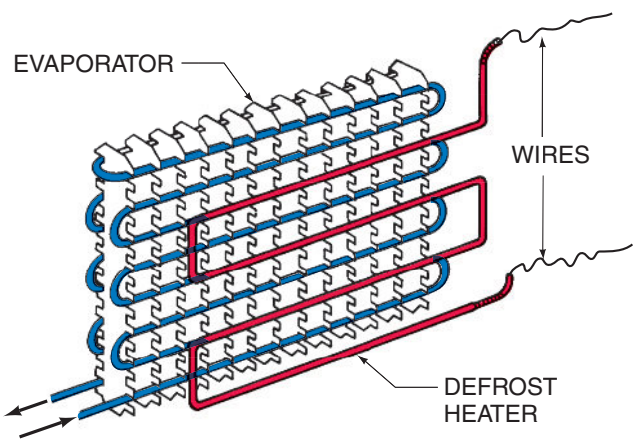
decrease from the **wet compression** of the rich mixture of refrigerant and oil foam. As soon as this mixture is compressed, it will vaporize and absorb heat away from the cylinder walls. This is what causes a lower-than-normal discharge temperature on the compressor's discharge line. Some manufacturers of systems incorporating hot gas defrost place a thermistor on the discharge line of the compressor to sense this cooler-than-normal discharge temperature while in the defrost mode. The thermistor relays a message to a control circuit to deenergize the hot gas solenoid; closing the hot gas solenoid temporarily prevents any more hot gas from entering the evaporator and thus turning to liquid. As the compressor's discharge temperature rises again, the thermistor senses the rise in temperature and relays a message to the control circuit to continue with hot gas defrost by energizing the hot gas solenoid again.

This sequence of events may continue until defrost is complete. The sequence simply protects the compressor from bearing washout and wet compression while in defrost. It may also protect the compressor during the refrigeration cycle by shutting down the compressor if the discharge temperature gets too low, indicating wet compression. To prevent this liquid from entering the compressor, often a suction line accumulator will be added to the suction piping, **Figure 21.35**.

The hot gas defrost system is economical because power does not have to be purchased for defrost using external heat, such as electric heaters that will heat the evaporator.The heat is already in the system.

Electric defrost is accomplished using electric heating elements located at the evaporator. The compressor is stopped and the heaters are energized on a call for defrost and allowed to operate until the frost is melted from the coil, **Figure 21.37**. These heaters are often embedded in the actual evaporator fins and cannot be removed if they burn out. Frequently, in the event that the heaters do burn out, hot gas defrost can be added to the system and the electric heat defrost procedures discontinued.

Figure 21.37 A heater used for electric defrost of low-temperature evaporators.



When either system is used for defrost, the evaporator fan is often turned off during defrost; if it is not, two things will happen:

1. The heat from defrost will be transferred directly to the conditioned space.
2. The cold, conditioned air will slow down the defrost process.

However, some manufacturers design their open frozen-food cases so that the evaporator fans are left on during defrost. This allows the supply-air and return-air ducts to be defrosted along with the coil. The warm defrost air is discharged from the supply duct and rises out of the case, having little effect on the product temperature. Fans are always shut off on closed, glass-door cases because of the problem of fogging on glass or mirrored surfaces.

Evaporators in some ice-making processes have similar defrost methods. They must have some method of applying heat to the evaporator to free the ice. Sometimes the heat is electric or hot gas. When the evaporator is being used to make ice, the makeup water for the ice maker is sometimes used for defrost. Evaporator defrosting is covered in more detail in Section 25.22, "The Defrost Cycle," of Unit 25, "Special Refrigeration System Components."

21.19 EVAPORATOR AND DEFROST EFFICIENCY CONTROLLER

As mentioned earlier in this unit, the evaporator is where heat is absorbed into the refrigeration system. An evaporator is basically a heat exchanger with refrigerant tubes and extended surfaces. The extended surfaces are often referred to as fins. The evaporator's function is to efficiently transfer heat from the surrounding area to the phase-changing refrigerant flowing through the evaporator. The refrigerant will be changing phase from a liquid to a vapor as it travels through the evaporator absorbing heat. As the evaporator's heat load changes, an expansion type metering device at the entrance of the evaporator will control the flow of refrigerant through the evaporator. The metering device will also ensure that all of the liquid in the evaporator has fully vaporized prior to exiting the evaporator.

THE EVAPORATOR AND ENERGY SAVINGS

The evaporator is a major component in the refrigeration system, and an efficient evaporator plays a key role in saving energy. Many commercial and industrial evaporator assemblies consist of:

- The evaporator coil
- Fans

Figure 21.38 Evaporator efficiency controller.

- An expansion device
- Defrost heaters
- A liquid line solenoid valve

By carefully timing, managing, and controlling each one of these components with an evaporator efficiency controller, **Figure 21.38**, the evaporator is able to provide the maximum output with the minimum amount of energy input.

FROST

Although frost is unavoidable on an evaporator, it is the most common cause of inefficiency in evaporator coils. When the evaporator's coil temperature drops below the dew point temperature, dew will begin to collect on the evaporator's cool surface. The dew point temperature is the temperature where dew starts to form. If the temperature of the evaporator coil continues to drop below the freezing point of water, the moisture on the evaporator's coil will begin to solidify, forming a thin layer of ice. The first thin layer of ice on the evaporator coil will actually enhance the evaporator's efficiency. This layer is very hard, with the consistency of an ice cube. It is a good conductor of heat, and it will also increase the surface area of the evaporator tubes. Thus, heat transfer into the evaporator's coil will, at first, be increased.

However, since the evaporator tubes now have an increased surface area, the area for airflow around the tubes will be reduced. This will cause a slight increase in the air's velocity through the coil, which will also increase heat transfer to the evaporator. Depending on humidity, evaporator temperature, and air flow, the subsequent layers of frost that accumulate on the evaporator may be more crystalline or snow-like. These layers of frost will hold more entrained air and will be very porous. This type of frost, often referred to as radiant frost or hoar frost, will insulate the evaporator and severely reduce its heat-absorbing ability. **Figure 21.39** illustrates how the performance of an evaporator is enhanced initially, but declines over time as hoar frost accumulates on the coil, insulating it. As the hoar frost accumulates, the evaporator will see less heat from the refrigerated space. This will cause the evaporator or suction pressure to drop and the evaporator coil will become colder. Higher compression ratios cause lower compressor volumetric efficiencies, less dense refrigerant return gasses entering the compressor, reduced mass flow rates of refrigerant, and loss of system capacity. A result of this insulating effect is the temperature of the evaporator coil must be reduced to maintain the same desired refrigerated space temperature. Now, the temperature difference (TD) between the evaporator coil and the refrigerated space will be greater.

Figure 21.39 Evaporator performance as the evaporator coil builds frost.

PUMP-DOWN CYCLE

The control system is based around a refrigerant pump-down cycle. Once the refrigerated space temperature is satisfied, the controller de-energizes (closes) the liquid line solenoid valve and turns the evaporator fans off. The compressor continues to run until any liquid refrigerant in the evaporator and suction line is fully vaporized and pumped to the high side of the refrigeration system. Automatic pump-down systems are covered in detail in Unit 25, "Special Refrigeration System Components." During this refrigerant pump down, the temperature of the evaporator coil will continue to drop because of the low pressure created in the coil from the pump-down process, and from the refrigeration effect of the vaporizing refrigerant remaining in the evaporator coil during pump down. This residual refrigeration effect, or flywheel effect, will drop the coil temperature below the refrigerated space temperature. The evaporator's controller is able to capture this energy and give it back to the refrigeration system by controlling the evaporator fans. The controller will now cycle the evaporator fans back on without starting the compressor. The refrigerated space temperature is now maintained by only the fans blowing air over a very cold evaporator coil. This greatly reduces the amount of energy used to maintain the refrigerated space temperature. Only when this stored "flywheel effect" energy is depleted out of the evaporator coil, will the compressor be cycled back on. By cycling the fans, the evaporator controller extends the time between compressor run times, thus saving energy.

FROST REMOVAL BY SUBLIMATION

During pump down, the evaporator fans are blowing air through a very cold evaporator coil with frost accumulated on its surfaces. The frost will change phase to a vapor through the process of sublimation. Sublimation is a process where a solid changes directly to a vapor, skipping the liquid phase. This sublimation process reduces the frost on the coil naturally. As the frost changes to vapor, it also returns valuable moisture to the refrigerated space. Higher humidity levels maintained in the refrigerated space reduce product shrinkage. Most defrost systems run the melted frost and residual energy down a drain and out of the refrigerated case. Also, many traditional defrost systems use three or four defrosts per day, each lasting perhaps for 45 to 60 minutes. When melting frost comes in contact with a 300°F defrost heater, it can flash into steam creating a fogging effect throughout the refrigerated case. This fog will re-condense on other cold surfaces in the refrigerated room, causing unwanted ice. **Figure 21.40** and **Figure 21.41** show a walk-in refrigerated space before and after an evaporator efficiency controller with an advanced defrost control algorithm was installed.

EVAPORATOR EFFICIENCY CONTROLLER AND EVAPORATOR TEMPERATURE DIFFERENCE (TD)

The evaporator efficiency controller uses a proprietary defrost control algorithm that eliminates the dependency on "time" for defrost initiation. Instead, the controller monitors

evaporator coil efficiency to initiate defrost and also minimizes the effects of defrost on space temperature. Maintaining a lower TD between the evaporator coil and the refrigerated case throughout the run time will reduce the rate of frost formation on the coil. This will lead to extended time between defrosts and save energy. Below are some important functions of the evaporator efficiency controller:

- Monitors evaporator efficiency and performance
- Creates an initial evaporator profile from a series of measurements
- Identifies the temperature relationship between the evaporator coil and refrigerated space temperature through two sensor locations, **Figure 21.42**
- Initiates a defrost once the evaporator coil efficiency is less than 90%
- Monitors coil temperature once in defrost. Once a predetermined temperature is reached, the heaters are turned off allowing the heat in the heater elements to be transferred to the evaporator coil. Once the heat is dissipated, the heaters are again energized to continue defrost. This saves energy, quickens defrost time, and eliminates fogging.
- Contain Ethernet network devices supporting industry standard protocols

In summary, when checking an evaporator remember that its job is to absorb heat into the refrigeration system.

Figure 21.42 Sensor locations to identify the temperature relationship between the evaporator coil and the refrigerated space.

SUMMARY

- Heat travels normally from a warm substance to a cool substance.
- For heat to travel from a cool substance to a warm substance, work must be performed. The motor that drives the compressor in the refrigeration cycle does this work.
- The evaporator is the component that absorbs the heat into the refrigeration system.
- The evaporator must be cooler than the medium to be cooled to have a heat exchange.
- The refrigerant boils to a vapor in the evaporator and absorbs heat because it is boiling at a low pressure and low temperature.
- The boiling temperature of the refrigerant in the evaporator determines the evaporator (low-side) pressure.
- Medium-temperature systems can use off-cycle defrost. The product is above freezing, and the heat from it can be used to initiate the defrost.
- Low-temperature refrigeration must have heat added to the evaporator to melt the ice.
- For the same types of installations, evaporators have the same characteristics regardless of location.
- Most refrigeration coils are copper with aluminum fins.
- The starting point in organized troubleshooting is to determine whether the evaporator is operating efficiently.
- Checking the superheat is the best method the service technician has for evaluating evaporator performance.
- Some evaporators are called dry-type because they use a minimum of refrigerant.
- Dry-type evaporators are also called direct-expansion evaporators.
- Some evaporators are flooded and use a float to meter the refrigerant. Superheat checks on these evaporators should be interpreted with caution.
- Some evaporators have a single circuit, and some have multiple circuits.
- Multicircuit evaporators keep excessive pressure drop from occurring in the evaporator.
- There is a relationship between the boiling temperature of the refrigerant in the evaporator and the temperature of the medium being cooled.
- The coil normally operates at temperatures from 10°F to 20°F colder than the temperature of the air passing over it.

REVIEW QUESTIONS

1. What is the function of the evaporator in the refrigeration system?
2. Refrigerant in the evaporator
   A. changes from vapor to liquid.
   B. changes from liquid to vapor.
   C. stays in the vapor state.
   D. stays in the liquid state.
3. The sensible heat that is added to a saturated vapor after all of the liquid has boiled away is referred to as _____.
4. What determines the pressure on the low-pressure side of the system?
5. A refrigerant system's evaporator typically runs about _____ degrees of superheat.
6. What does a high evaporator superheat indicate?
7. A low evaporator superheat indicates
   A. undercharge.
   B. system restriction.
   C. overcharge.
   D. dirt buildup.
8. Why is a multicircuit evaporator used?
9. Flooded evaporators use a(n) _____ type of expansion device.
10. An evaporator that is not flooded is thought of as what type of evaporator?
11. When an evaporator experiences a heat-load increase, the suction pressure
    A. remains constant.
    B. decreases.
    C. varies up and down.
    D. increases.
12. What is commonly used to defrost the ice from a low-temperature evaporator?
13. A medium-temperature refrigeration box operates within what temperature range?
    A. 28°F to 40°F
    B. 40°F to 60°F
    C. 0°F to −20°F
    D. 0°F to 50°F
14. List seven advantages that an aluminum parallel-flow, plate/fin evaporator has over a standard round, copper-tube plate/fin evaporator.

UNIT 22

CONDENSERS

OBJECTIVES

After studying this unit, you should be able to

- explain the purpose of the condenser in a refrigeration system.
- describe differences between the operating characteristics of water-cooled and air-cooled systems.
- describe the heat exchange in a condenser.
- explain the difference between a tube-within-a-tube coil-type condenser and a tube-within-a-tube serviceable condenser.
- describe the difference between a shell-and-coil condenser and a shell-and-tube condenser.
- describe a wastewater system.
- describe a recirculated water system.
- describe a cooling tower.
- explain the relationship between the condensing refrigerant and the condensing medium for cooling tower systems.
- compare an air-cooled, high-efficiency condenser with a standard condenser.
- describe the operation of head pressure control values, fan cycling controls, VFD condenser fan motors, dampers, condenser flooding, and condenser splitting.

SAFETYCHECKLIST

- ☑ Wear goggles and gloves when attaching or removing gauges to transfer refrigerant or to check pressures.
- ☑ Wear warm clothing when working in a walk-in cooler or freezer. A technician does not think properly when chilled.
- ☑ Keep hands well away from moving fans. Do not try to stop a fan blade as it slows after the power has been turned off.
- ☑ Do not touch the hot gas line.

22.1 THE CONDENSER

The condenser is a heat exchange device similar to the evaporator; it rejects from the system the heat absorbed by the evaporator. In the first passes of the condenser the heat is rejected from a hot, superheated vapor. The middle of the condenser rejects latent heat from saturated vapor and liquid, which is in the process of changing phase to a 100% saturated liquid. The last passes of the condenser reject heat from subcooled liquid. This further subcools the liquid to below its condensing temperature. In fact, the condenser performs three main functions on the refrigerant flowing through it. They are in order of occurrence:

1. Desuperheating the vapors
2. Condensing vapors to liquid
3. Subcooling the liquid

The greatest amount of heat is absorbed in the system when the refrigerant is at the point of changing state (liquid to a vapor). The same thing happens, in reverse, in the condenser. The point where the change of state (vapor to a liquid) occurs is where the greatest amount of heat is rejected.

The condenser operates at higher pressures and temperatures than the evaporator and is often located outside. The same principles apply to heat exchange in the condenser as in the evaporator. The materials a condenser is made of and the medium used to transfer heat make a difference in the efficiency of the heat exchanger.

22.2 WATER-COOLED CONDENSERS

The first commercial refrigeration condensers were water-cooled. Compared with modern water-cooled devices, these condensers were crude, **Figure 22.1.** Water-cooled condensers can operate at much lower condensing temperatures. Because water has a higher specific heat and density than air,

water-cooled condensers are more efficient than air-cooled condensers. Water-cooled equipment comes in several styles. Three of the most common are the tube within a tube (double tube), shell and coil, and shell and tube.

22.3 TUBE-WITHIN-A-TUBE CONDENSERS

The **tube-within-a-tube** condenser comes in two styles: the coil type and the cleanable type with flanged ends, **Figure 22.2.** The HVAC/R industry refers to these condensers as tube within a tube, double tube, and co-axial.

The tube within a tube that is fabricated into a coil is manufactured by slipping one pipe inside another and sealing the ends in such a manner that the outer tube becomes one container and the inner tube becomes another container,

Figure 22.2 Two types of tube-within-a-tube condensers. (A) A pipe within a pipe. (B) A flanged condenser. The flanged condenser can be cleaned by removing the flanges. Removal of the flanges opens only the water circuit, not the refrigerant circuit.

(B)

Figure 22.3. The two pipes are then formed into a coil to save space. The heat exchange occurs between the fluid inside the outer pipe and the fluid inside the inner pipe, **Figure 22.4.** *Some manufacturers will put extended surfaces or fins around the inner water tube to enhance heat transfer between the water and refrigerant. The fins add extra surface area to the inner tube, which enhances heat transfer. The fins also cause the refrigerant in the outer tube to have a more turbulent flow, which also enhances heat transfer,* **Figure 22.3(C).** Because water flows in the inner tube and hot refrigerant flows in the outer tube, the hot refrigerant also can reject some of its heat to the surrounding air. However, most of the heat goes from the refrigerant to the water because of the higher density, flow rate, and specific heat of the water.

The refrigerant in the outer tube and the water in the inner tube flow in opposite directions. This is referred to as a counter-flow arrangement. Counter-flowing the refrigerant with the water keeps a more evenly distributed, or consistent, temperature difference between the two fluids throughout the length of the heat exchange, as compared to fluids flowing in the same direction. At the beginning of the condenser heat exchanger, the superheated compressor discharge gas, which is the warmest refrigerant, experiences the warmest water. At the end of the condenser heat exchange, the coolest water experiences the coolest refrigerant, or subcooled, liquid. Because of their small internal volume, tube-in-tube condensers require a separate receiver.

22.4 MINERAL DEPOSITS

Even the cleanest water will leave mineral deposits and scale in a tube due to the heat in the vicinity of the discharge gas, which causes any minerals in the water to deposit onto the tube surface. This is a slow process, but it will happen in time to any water-cooled condenser. The mineral deposits act as an insulator between the tube and the water and must be kept to a minimum, **Figure 22.3(D).**

The water can be treated to help prevent this buildup of mineral scale. The treatment is normally added at the tower or injected into the water by chemical feed pumps. **Figure 22.5** shows treatment being added to a tower. **Figure 22.6** is an example of treatment being pumped into the water piping.

In some mild cases of scale buildup, putting more water into circulation will improve the heat exchange. Variable water-flow controls, introduced later in this unit, step up the water flow through the condenser on an increase in head pressure caused by a poor heat exchange due to mineral deposits. High head pressure in a dirty water-cooled condenser requires more energy to run. If the water is wasted, instead of being cooled and used again, the water bill would go up before the operator notices there is a condenser problem.

The tube-within-a-tube condenser that is made into a coil cannot be cleaned mechanically with brushes. These condensers must be cleaned with chemicals that are designed not to harm the metal, which is normally copper or steel and sometimes stainless steel or copper and nickel. Getting professional help from a company that specializes in water treatment is recommended when a condenser must be cleaned with chemicals.

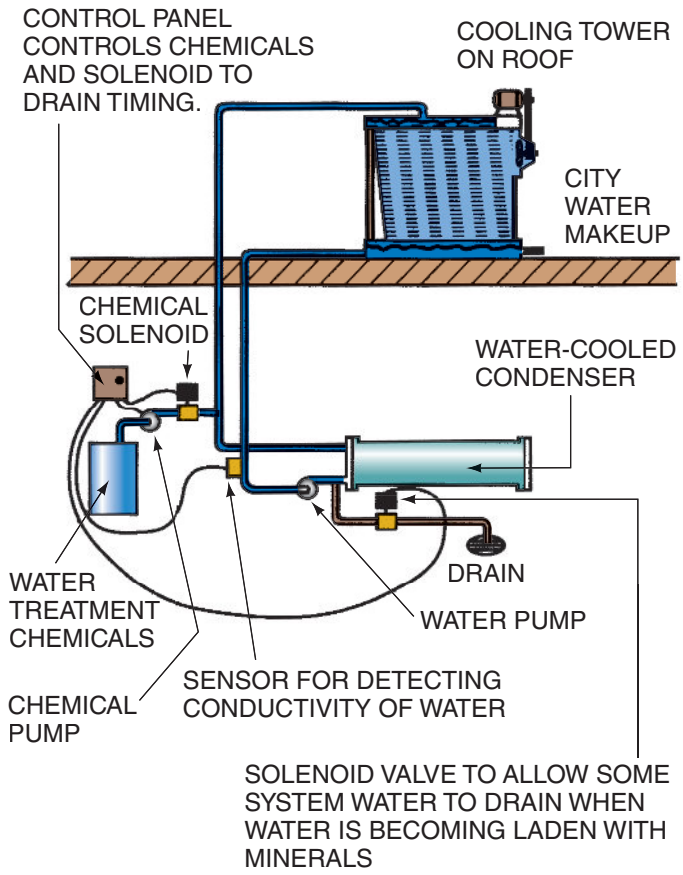
Figure 22.6 A system for automatically feeding treatment chemicals to the water. It includes a monitor that determines when chemicals need to be added. This system is normally used on larger installations because of its cost-effectiveness.



22.5 CLEANABLE TUBE-WITHIN-A-TUBE CONDENSERS

The tube-within-a-tube condenser that is fabricated with flanges on the end can be mechanically cleaned. The flanges can be removed, and the tubes can be examined and brushed with an approved brush, **Figure 22.7**. Consult the manufacturer for the correct brush; fiber or nylon is usually preferable. The flanges and gaskets on this type of condenser are in the water circuit; the refrigerant flows around the water tubes in a circuit that is not opened when the water tubes are cleaned. **Figure 22.8** shows how straight water tubes are cleaned. Cleanable water-cooled condensers with straight tubes are more expensive, but they are more easily serviced. **Figures 22.7(B)** and **(C)** show how a coiled tube-within-a-tube condenser is cleaned using a circulator pump and chemicals to descale the condenser's water tube circuit. A circulator pump circulates a chemical bath from a holding tank through the water tubes of the condenser and then back to the holding tank. The condenser's water circuit has a special bypass

(B)

circuit that parallels the normal flow of water and contains manual shutoff valves for use in cleaning. Always consult with the manufacturer of the condenser or water treatment company to make sure the circulated chemicals are safe to use with the materials used to construct the water-cooled condenser.

22.6 SHELL-AND-COIL CONDENSERS

The shell-and-coil condenser is similar to the tube-within-a-tube coil condenser. A coil of tubing (usually copper) is packed into a shell (usually steel) and then closed and welded. Normally, the refrigerant gas is discharged into the

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Figure 22.9 The shell-and-coil condenser. The hot refrigerant gas is piped into the shell, and the water is contained inside the tubes.

top of the steel shell and condenses as it comes in contact with the water coil. Subcooled liquid refrigerant is then picked up from the bottom with a standpipe or bottom drain. Water is circulated in the copper coil located within the shell. The shell of the condenser serves as a receiver storage tank for the extra refrigerant in the system, so the refrigeration system does not require a separate receiver. This condenser is not mechanically cleanable because the coil is not straight, **Figure 22.9**; it must be cleaned chemically.

22.7 SHELL-AND-TUBE CONDENSERS

Shell-and-tube condensers are the most expensive condenser and are normally used in larger installations, but they can be cleaned mechanically with brushes. Straight copper tubes are fastened into an end sheet within the steel shell. The number of water passes will vary with the end plate design. The shell acts as a receiver storage tank for extra refrigerant. The refrigerant is discharged into the shell, and water is circulated through the tubes. The ends of the shell are like end caps (known as **water boxes**) and have water circulating in them, **Figure 22.10**. The end caps can be removed so the tubes can be inspected and brushed out if needed.

The water-cooled condenser is used to remove heat from the refrigerant; after removal, it remains in the water, which gets warmer. Two things can be done at this point: (1) waste the water or (2) pump the water to a remote place, remove the heat, and reuse the water.

22.8 WASTEWATER SYSTEMS

Wastewater systems are just what the name implies. The water is used once and then thrown away—wasted down the drain, **Figure 22.11.** This is acceptable if the water is free or if only a small amount is used. Where large amounts of water are involved, it is probably more economical to save the water, cool it in an outside water tower, and reuse it.

The water supplied to systems that use the water only once and waste it has a broad temperature range. For instance, the water in summer may be 75°F out of the city mains and as low as 40°F in the winter, **Figure 22.12.**

Figure 22.10 (A) Water can be circulated back and forth through the condenser by using the end caps to give the water the proper direction. This is a four-pass shell-and-tube condenser. The number of water passes will vary with the end plate design. (B) Disassembled shell-and-tube condenser showing the water tubes.

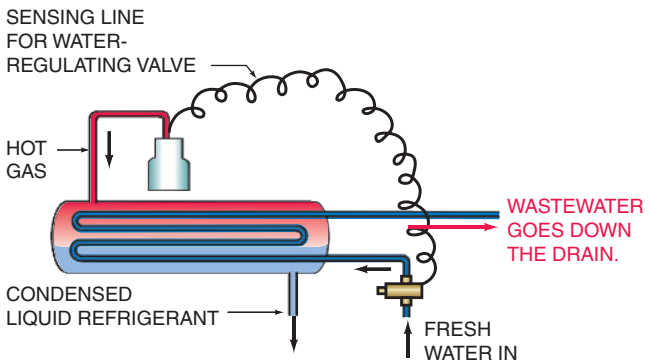
Figure 22.11 Wastewater systems are used when water is plentiful and at a low cost, such as from a well or lake.



Water piped through a building with long pipe runs may be warm in the beginning from standing in the pipes even though the water temperature in the main may be quite low. This change in water temperature has an effect on the refrigerant head pressure (condensing temperature). A typical wastewater system with 75°F entering water uses 1.5 gal/min per ton of refrigeration. In the winter, when the water temperature is lower, the water flow required will be lower.

For a designer's purpose, the amount of water needed to flow through a water-cooled condenser in gallons per minute per ton of refrigeration depends on the temperature difference between the water in and out of the condenser. If a cooling tower is being used, a 20-degree temperature difference is often used for design purposes. However, if city water

Figure 22.12 A wastewater condenser system under two sets of conditions. (A) Summer with warm water entering the system. (B) Winter with cooler water entering the system.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

is being used through the condenser and the water is then discharged down a drain back into the earth, a 10-degree temperature difference is often used for design purposes. The formula below governs how many gallons of water per minute per ton of refrigeration (GPM/ton) is required for a water-cooled condenser. A standard cooling tower can only cool water to within 7–8 degrees of the surrounding wet bulb temperature (WBT). For this reason, water from the cooling tower to the water-cooled condenser is usually warmer than if it were from a city water source. This is why there is a designed 20-degree temperature difference for a cooling tower compared to a 10-degree temperature difference using a city water or well water source.

Formula:

$$\text{GPM/Ton} = \frac{15{,}000 \text{ Btuh/Ton}}{(\text{Specific heat of water})(\text{Temperature difference}) \times (8.33 \text{ lbs/gallon})(60 \text{ min/hr})}$$

Where:

- 15,000 Btuh/ton is a standard condenser ton.
- Specific heat of water is 1 btu/lb per degree Fahrenheit temperature difference.
- 8.33 lbs/gallon is the density of water.
- Temperature difference is the temperature difference between water in and out of the water-cooled condenser.

Using the above formula for a cooling tower:

$$\text{GPM/Ton} = \frac{15{,}000 \text{ Btuh/Ton}}{(1\text{btu/lb./F})(20 \text{ degrees F})(8.33 \text{ lbs/gallon})(60 \text{ min/hr})}$$

$$\text{GPM/Ton} = 3.0$$

Using the above formula for a city or well water wastewater system:

$$\text{GPM/Ton} = \frac{15{,}000 \text{ Btuh/Ton}}{(1\text{btu/lb./F})(10 \text{ degrees F})(8.33 \text{ lbs/gallon})(60 \text{ min/hr})}$$

$$\text{GPM/Ton} = 1.5$$

Example:
How much water per day will a water-cooled condenser use if it is using city or well water and the system's capacity is 5 tons? The system is a wastewater system where the discharge water from the condenser goes down a drain and back to the earth.

Answer:
(1.5 GPM/Ton)(5 ton)(16 hrs/day)(60 min/hr) = 7,200 gallons of water per day. If the condenser was using cooling tower water with a 20-degree temperature difference, the water usage would be half of 7,200, or 3,600 gallons per day. However, this water would be re-circulated water to and from the cooling tower and water-cooled condenser.

22.9 REFRIGERANT-TO-WATER TEMPERATURE RELATIONSHIP FOR WASTEWATER SYSTEMS

In a wastewater system, the water flow can be varied to suit the need by means of a water-regulating valve. This valve has a pressure tap that fastens the bellows in the control to the high-pressure side of the system. When the head pressure goes up, the valve opens and allows more water to flow through the condenser to keep the head pressure correct, **Figure 22.13(A)**. Constant head pressure is maintained by letting more or less water into the water-cooled condenser as the head pressure changes. **Figures 22.13(A)** and **(B)** show a

direction arrow stamped on the body of the valve to let the service technician know that the valve must be installed so that the direction of the valve is in the direction of the water flow. **Figure 22.13(B)** shows how an increase in head pressure puts more pressure on the flexible bellows to push up on the moveable rod and open the valve to let more water through the condenser. This in turn keeps the head pressure constant at the spring's set point.

The spring pressure in the valve can be adjusted by turning the tension adjustment located on top of the valve with a refrigeration service wrench, standard slot screwdriver, or adjustable crescent wrench. A spring retainer plate with female threads rides up and down on a threaded stationary stud when the spring tension is adjusted, **Figure 22.13(C)**. An arrow on the top of the valve indicates that a counterclockwise turn will increase the head pressure setting by letting in less water. A pressure gauge connected to the high side of the refrigeration system while the spring tension of the water-regulating valve is being changed will show the head pressure change almost instantaneously. **Figure 22.13(D)** shows the valve specification plate and the refrigerants the valve is designed to be used with. A maximum water pressure and refrigerant pressure range is stamped on the specification plate for safety and operational reasons. Notice that the valve in the illustration can handle a water pressure of 150 psig maximum and that its adjustment, or refrigerant pressure, range is 70 to 260 psig. **Figure 22.13(E)** shows a water-regulating valve operating with a tube-within-a-tube water-cooled condenser. The water-regulating valve can be flushed by prying up on the bottom of the spring with two standard slot screwdrivers. This will rid the valve body of any loose scale deposits, dirt, or sand.

As mentioned, water inlet temperatures in wastewater systems often vary with the season. **Figure 22.12** illustrates a water-regulating valve maintaining a constant head pressure of 124 psig in an R-134a refrigeration system. When the water temperature entering the condenser is 75°F, the flow of water through the condenser is much greater and faster because the water-regulating valve is opened more to maintain a constant condensing temperature of 100°F (124 psig) for the R-134a system. Notice that the water exiting the condenser is 110°F, which is 10°F hotter than the condensing temperature of 100°F. This happens because the water exiting the condenser comes in contact with hot, superheated discharge gases from the compressor before it exits down the drain. In the winter months, when the entering water temperature is 40°F, the water regulating valve will reduce the water flow rate to maintain the same 100°F (124 psig) condensing temperature for the system. Because of the reduced flow rate, the water stays in contact longer with the condenser's internal tubing. Notice that this causes the water exiting temperature to be 120°F.

Because of the variable flow and variable temperature of water flowing through a wastewater system during different seasons of the year, there is no refrigerant-to-water temperature relationship or rule of thumb for the technician to go by.

The service technician must simply rely on the water-regulating valve to throttle more or less water through the condenser at different temperatures to maintain a constant head pressure of 124 psig.

22.10 RECIRCULATING WATER SYSTEMS

When a system is large enough to make saving water a concern, then a system that recirculates the water is considered. A recirculating water system will circulate approximately 3 gal of water per min per ton of refrigeration. Just as in the wastewater system, recirculating systems use the condenser to reject heat to water. The water is then pumped to an area away from the condenser where the heat is removed, **Figure 22.14**. The temperature relationship between the water and the refrigerant is known: The refrigerant will normally condense at a temperature about 10°F higher than the leaving-water temperature, **Figure 22.15**. The typical design temperature for the entering water is 85°F, and most systems have a 10°F rise across the condenser. Therefore, you could look for 85°F entering and 95°F leaving water temperature when the system is under full load. Since the R-134a refrigerant condenses at a temperature about 10°F higher than the leaving-water temperature, the approximate condensing temperature would be 105°F (95°F + 10°F). The head pressure for R-134a corresponding to this 105°F condensing temperature is 135 psig.

Figure 22.14 This water-cooled condenser absorbs heat from the refrigerant and pumps the water to a cooling tower at a remote location. The condenser is located close to the compressor, and the tower is on the roof outside the structure.

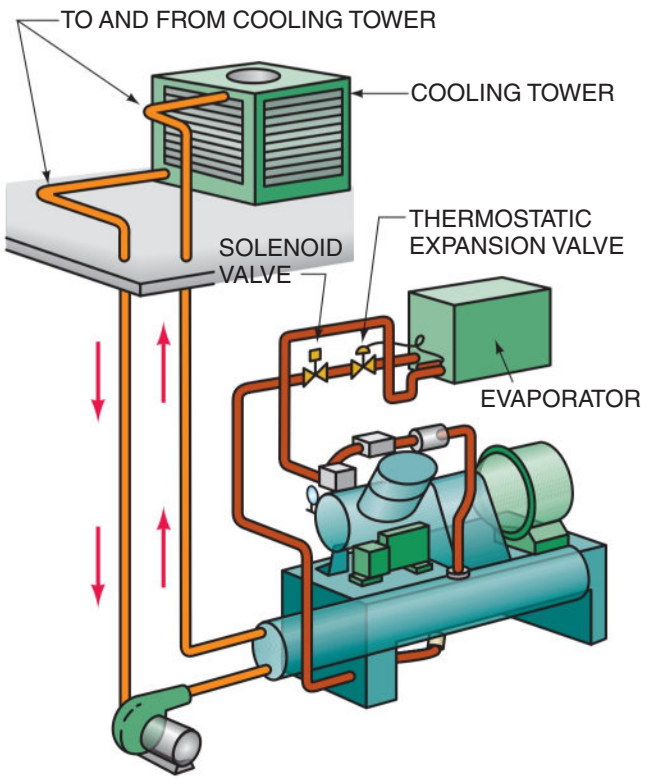

Figure 22.15 The relationship of the condensing refrigerant to the leaving-water temperature.

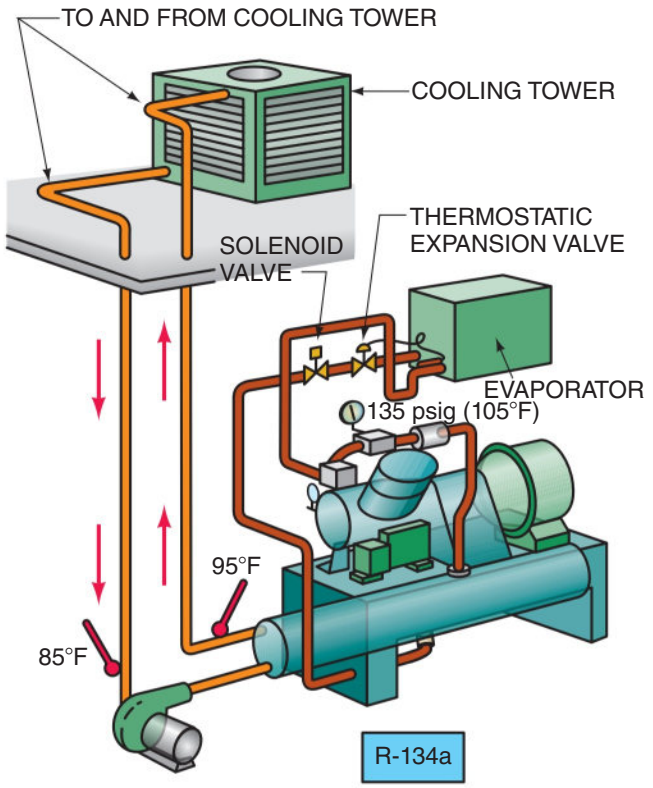

22.11 COOLING TOWERS

The **cooling tower** is a device that passes outside air over water to remove the system heat. Its capacity is limited by the amount of evaporation that occurs at any given time. The evaporation rate is linked to the wet-bulb temperature of the outside air (humidity). Usually, a cooling tower can cool the water that returns to the condenser to within 7°F of the wet-bulb temperature of the outside air, **Figure 22.16**. With 78°F wet-bulb temperature air entering the cooling tower, the water in the tower can be cooled to 85°F. Towers come in sizes that can handle about 2 tons of refrigeration and up and can be either (1) natural draft, (2) forced draft, or (3) evaporative.

22.12 NATURAL-DRAFT TOWERS

The **natural-draft tower** is customarily made of some material that the weather will not deteriorate, such as redwood, fiberglass, or galvanized sheet metal. It does not have a blower to move air through it but relies on the natural prevailing breezes and so must be located in the prevailing wind.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

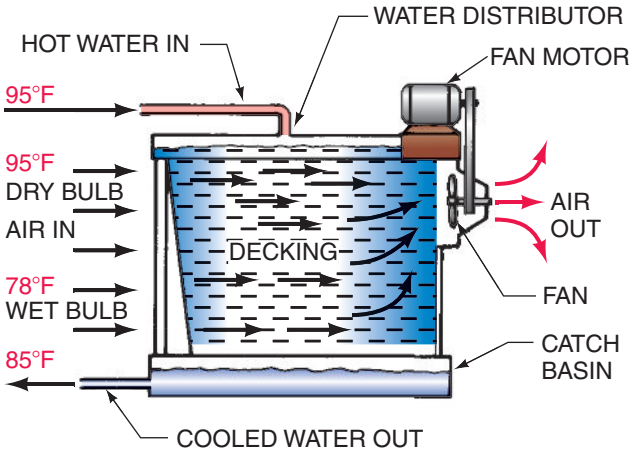
Figure 22.16 The relationship of a forced-draft cooling tower to the ambient air. Cooling tower performance depends on the wet-bulb temperature of the air. This relates to the humidity and the ability of the air to absorb moisture.



Water from the condenser is sprayed into the top of the tower through spray heads; some of the water evaporates as it falls to the bottom of the tower where the rest of the water is collected in a basin. The evaporation removes heat from the water remaining and adds to the capacity of the tower. To make up for the evaporated water, a makeup system with a float assembly is connected to the water supply and automatically adds fresh water, **Figures 22.17(A)** and **(B)**.

The tower location must be carefully chosen. If a tower is placed in a corner between two buildings where the breeze cannot blow through it, higher-than-normal water temperatures will occur, which will cause higher-than-normal head pressures, **Figure 22.18**. Towers also have two weather-related limitations that must be considered:

1. The tower must operate in the winter, and the water can freeze in some climates if freeze protection is not provided. Heat can be added to the water in the basin of the tower; antifreeze will also prevent a freeze-up, **Figure 22.19**.
2. The water can get cold enough to cause a drop in head pressure. A water-regulating valve can be installed to prevent this. Also, it is possible that winds can be strong enough to blow water out of the tower. Natural-draft towers on top of buildings sometimes look like they are made of slats. These slats help keep the water from blowing out of the tower, **Figure 22.20**.

22.13 FORCED- OR INDUCED-DRAFT TOWERS

Forced-draft or induced-draft cooling towers differ from natural-draft towers because they have a fan to move air over a wetted surface, **Figure 22.21**. They are customarily designed so that the warm water from the condenser is pumped into a flat basin at the top of the tower. Calibrated holes are drilled into the basin to allow a certain amount of water to pass downward through the fill material, **Figure 22.22(A)**. The holes in the basin often become plugged with scale from minerals in the water, **Figure 22.22(B)**, which can cause an erratic water flow through the fill material and make the tower less efficient. The fill material is usually redwood or manmade fiber and is used to enlarge the wetted surface area over which the fan blows air to evaporate and cool the water, **Figure 22.23**. Modern fill materials used in cooling towers are usually made of plastic formed into a honeycomb pattern for higher efficiencies and ease of cleaning, **Figure 22.17(B)**. As the water is evaporated, it is replaced by a water makeup system using a float, similar to the system used with the natural-draft tower.

Figure 22.17 (A) A makeup water system in a cooling tower. Because the cooling tower performance depends partly on evaporation of water from the tower, the makeup system is necessary. (B) Makeup water with a ball-and-water valve assembly. Plastic honeycomb fill material is shown in the background.

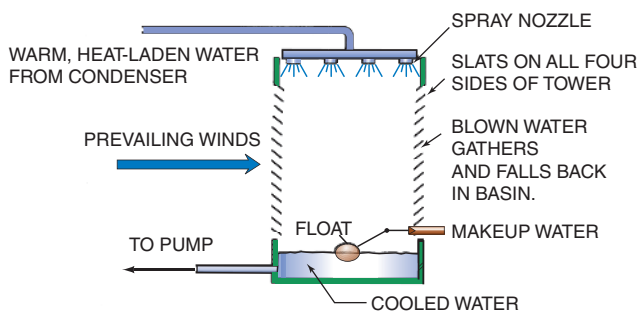

Figure 22.21 (A) A forced-draft tower. (B) An induced-draft tower.

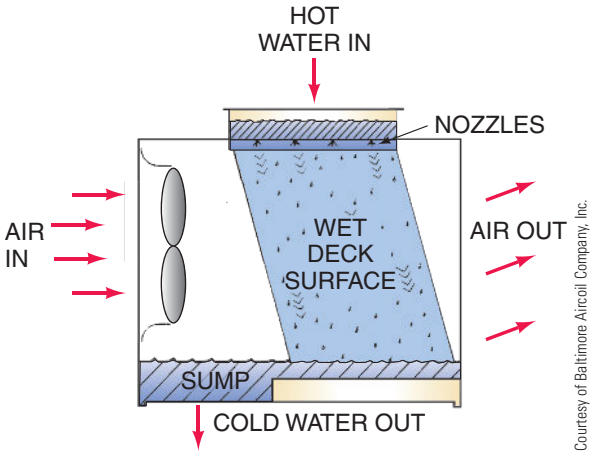
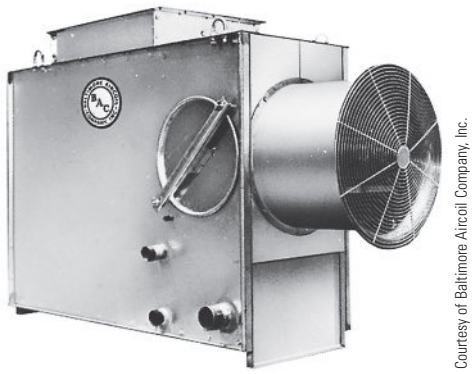


(A)



(B)

Forced- or induced-draft towers can be located almost anywhere because the fan can move the air. They can even be located inside buildings, where the air is brought in and out through ducts, **Figure 22.24**. The tower is fairly enclosed to the prevailing winds, so no water-regulating valve is normally necessary. The fan can be cycled off and on to control the water temperature and thus control the head pressure. The mass of the water in the tower provides a long cycle between the time the fan starts and stops. Forced-draft towers are small compared with natural-draft towers. They are versatile because of the forced movement of air. **NOTE:** *An induced-draft tower is similar to a forced-draft tower, but the air is pulled, not pushed, across the wetted surface.* •

22.14 EVAPORATIVE CONDENSERS

Although often confused with cooling towers, **Figure 22.25**, **evaporative condensers** are a different type altogether from other condensers because they are actually located inside a cooling tower. In the cooling towers just discussed,

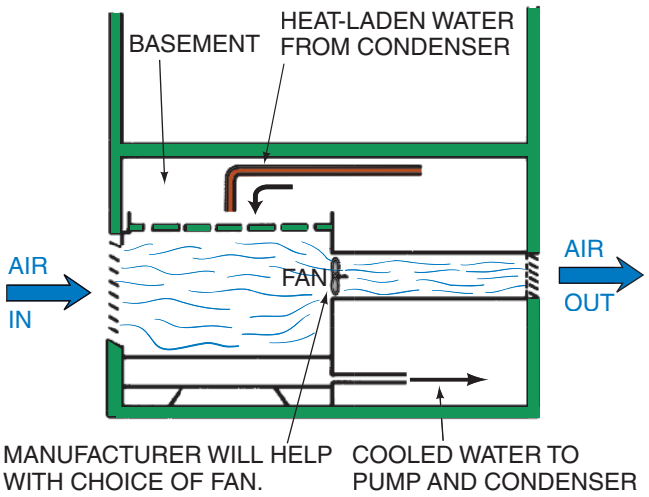
Figure 22.24 An induced-draft tower located inside a building with air ducted to the outside.



the condenser containing the refrigerant was remote from the tower and the water was piped through the condenser to the tower. The evaporative condenser uses the same water over and over by means of a pump located at the tower. As the water is evaporated, it is replaced by a makeup system using a float, as with the other towers. In cold climates, freeze protection must be provided in winter. In an evaporative condenser, both air and water are used to desuperheat, condense, and subcool the refrigerant. The water is sprayed over the condenser and absorbs heat from the warmer refrigerant. The air is pulled in from the side, passes over the condenser, and absorbs heat from the condensing refrigerant. The process is based on the principle of evaporative cooling, because as the water spray evaporates, much more heat can be absorbed from the refrigerant.

As water is evaporated from any cooling tower system, minerals will become more concentrated in the remaining water. If these minerals are allowed to become overconcentrated, they will begin to deposit on the condenser surface and cause head pressure problems. To prevent this from happening, water must be allowed to escape the system on a continuous basis. Water that is allowed to escape down the drain,

Figure 22.25 Water recirculates in the evaporative condenser. The condenser tubes are in the tower, rather than in a condenser shell located in a building.

called **blowdown**, is made up with fresh water from the float system. It is not unusual for people who do not know the purpose of blowdown to shut off the drain line for what appears to be clean water being wasted down the drain. Problems will result. Technicians must establish a regular procedure for checking the rate of blowdown. Cooling towers and blowdown are discussed in more detail in Unit 48, "Cooling Towers and Pumps."

22.15 AIR-COOLED CONDENSERS

Air-cooled condensers use air as the medium into which the heat is rejected. This can be advantageous where it is difficult to use water. The first air-cooled condensers were bare pipe over which air from the compressor flywheel was blown. At this time the compressors were open drive. To improve the efficiency of the condenser and to make it smaller, the surface area was then extended with fins, normally steel as was the condenser, **Figure 22.26**. These condensers resembled radiators and were sometimes referred to as radiators.

Steel air-cooled condensers are still used in refrigeration installations. **Figure 22.27(A)** is a photo of a condenser for a large refrigeration system. **Figures 22.27(B)** and **(C)** illustrate some newer technology in condenser and evaporator coil design to improve system efficiency. One such condenser design incorporates an aluminum, parallel-flow, flat-plate-and-fin configuration that has small parallel channels inside the flat plate. These plates are flattened, streamlined tubes split into smaller, parallel ports. Refrigerant will change phase or condense from a vapor to a liquid inside the channels in the plate, while strategically shaped fins (extended surfaces) will enhance heat transfer from the condenser coil to the air. The plates and fins are bonded or soldered to increase heat transfer and to eliminate any contact resistance (air gaps) that will reduce heat transfer. Headers at the inlet and outlet

Figure 22.26 Fins designed to give the coil more surface area.

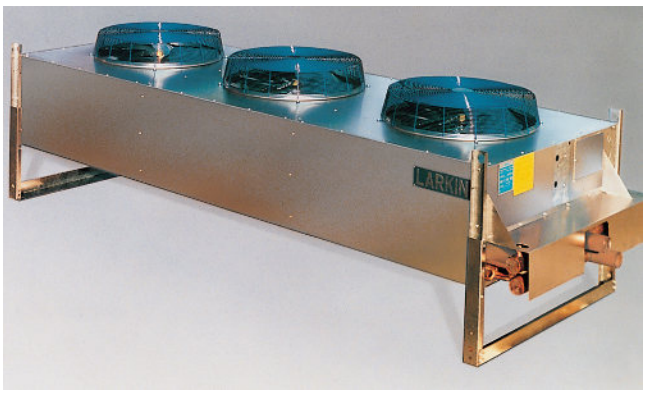
of the heat exchanger are also bonded to the plates through soldering. (Refer to Unit 21, "Evaporators and the Refrigeration System," for a more detailed explanation about using the parallel-flow, flat-plate-and-fin condenser and evaporator configuration to increase the efficiency of a refrigeration or air-conditioning system.)

Air-cooled condensers come in a variety of styles. In some, the air blows horizontally through, subject to prevailing winds, **Figure 22.28**. In other air-cooled condensers, the airflow pattern is vertical. They take air into the bottom and discharge it out the top. The prevailing winds do not affect these condensers to any extent, **Figure 22.29**. Another style of air-cooled condenser takes the air in at the sides and discharges it out the top. This condenser can be affected by prevailing winds, **Figure 22.30**.

Smaller refrigeration systems are often located in a conditioned space, such as a restaurant or store. Their air-cooled condensers normally have widely spaced steel fins on a steel coil, which allows more time before the coil will stop up with dust and other airborne material. The hot gas normally enters the air-cooled condenser at the top, so the beginning tubes of the condenser receive the hot gas, which is highly superheated, straight from the compressor. (Remember that superheat is heat that is added to the refrigerant after the change of state in the evaporator.) When the superheated refrigerant from the evaporator reaches the compressor and is compressed, more superheat is added to the gas. Part of the energy applied to the compressor transfers into the refrigerant in the form of heat energy. This additional heat added by the compressor causes the refrigerant leaving the compressor to be heavily laden with heat. On a hot day (95°F) the hot gas leaving the compressor could easily reach 250°F. **SAFETY PRECAUTION:** *DO NOT TOUCH the hot gas discharge line from the compressor. It will burn your fingers.* • The condenser must remove heat from the refrigerant until it reaches the condensing temperature before any condensation can occur.

Figure 22.29 A condenser with a vertical airflow pattern. Air enters the bottom and is blown out the top. It is unaffected by prevailing winds.

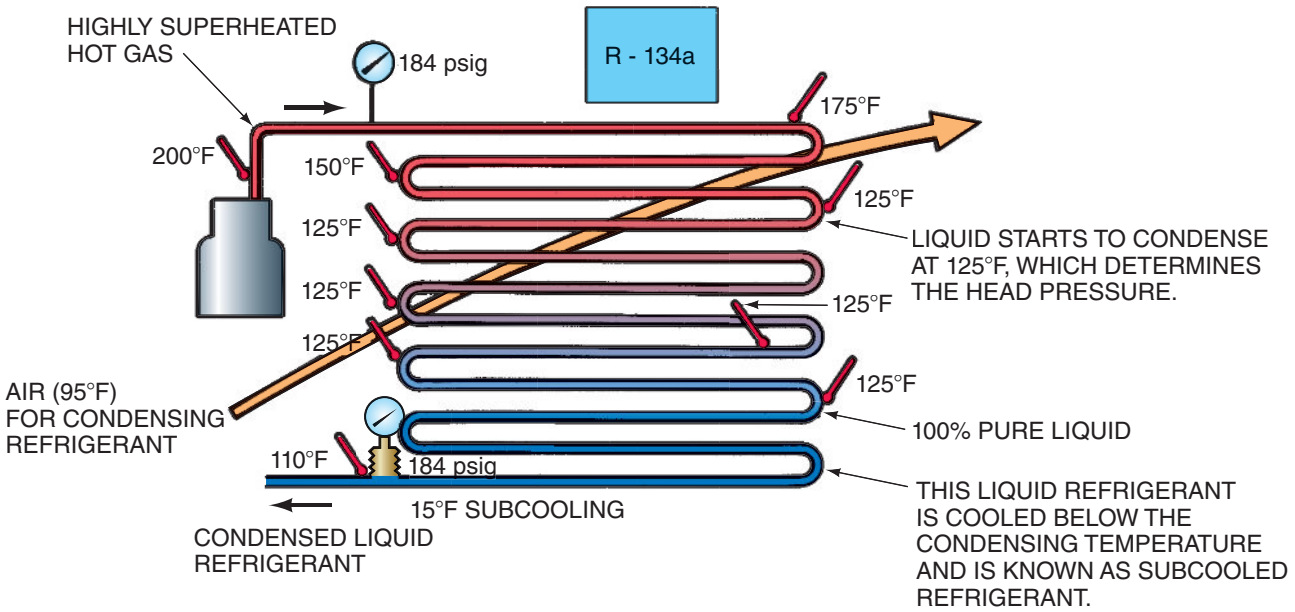


Source: Heatcraft, Inc., Refrigeration Products Division

Air-cooled condensers have a relationship to the temperature of the air passing over them (much like the evaporator in the previous unit). For instance, the refrigerant inside the coil will normally condense at a 30°F higher temperature than the air passing over it (also known as the ambient air). This is true for most standard-efficiency condensers that have been in service long enough to have a typical dirt deposit on the fins and tubing. Efficiency can be improved by adding condenser surface area. With an outside air temperature of 95°F, the condensing temperature will be about 125°F. With the refrigerant R-134a condensing at 125°F, the head pressure or high-pressure gauge should read 184 psig. (See the temperature/pressure chart for R-134a, **Figure 21.5.**) This is important because it helps the service technician establish what the head pressure should be.

See **Figure 22.31** for an illustration of the following description of an air-cooled R-134a condenser located outside

Figure 22.31 The following points are illustrated: (1) The hot gas flowing into the first part of the condenser is highly superheated. The condensing temperature is 125°F, and the discharge gas must be cooled from 200°F to 125°F before any condensing will occur. (2) The best heat exchange is between the liquid and the air on the outside of the coil. More heat is removed during the change of state than during the desuperheating of the vapor. (3) When all of the liquid is condensed and pure liquid is in the coil, the liquid can be subcooled to below the condensing temperature.



a store. The condenser is responsible for rejecting the heat absorbed inside a medium-temperature walk-in cooler. This cooler has reach-in doors typical of those in a convenience store. In this box the beverages are on shelves and store personnel can stock the shelves from the walk-in portion behind the shelves. The cooler is maintained at 35°F. The outside air temperature is 95°F. The refrigeration system must absorb heat at 35°F and reject the same heat to the outside, where the condensing medium is 95°F.

1. The hot gas is entering the condenser at 200°F. The condensing temperature is going to be 30°F warmer than the outside (ambient) air.
2. The outside air temperature is 95°F. The condensing temperature is 95°F + 30°F = 125°F. The refrigerant must be cooled to 125°F before any actual condensing occurs. Thus the condenser has to lower the hot gas temperature 75°F (200°F − 125°F) in the first part of the coil. This is called *desuperheating*. It is the first job of the condenser.
3. Partway through the coil the superheat is removed and the refrigerant reaches the actual condensing temperature of 125°F; liquid begins to form in the coil. Liquid will continue to form at the condensing temperature of 125°F until all of the vapor has turned to 100% liquid. This is called the **latent heat** of condensation.
4. The liquid can now reject sensible heat and *subcool* to below the 125°F condensing temperature. Any liquid below the 125°F condensing temperature is referred to as a **subcooled liquid**. When the subcooled liquid refrigerant gets to the end of the coil, the condenser tubes will be full of liquid and then drain into the receiver.
5. The liquid in the bottom of the condenser draining into the receiver may cool to 110°F. This would give the liquid 15°F (125°F − 110°F) of subcooling.

In commercial and industrial applications in which the condensers are large, a pressure drop will occur as the refrigerant flows through the condenser. This pressure drop is caused by friction. When measuring condenser subcooling in these cases, the refrigerant pressure has to be read close to the condenser outlet, not at the compressor service valve, **Figure 22.32**. The condenser outlet pressure can be read at the receiver's **king valve** or at the receiver charging valve. In fact, the refrigerant pressure should be taken very near the same place the condenser outlet temperature is taken, or condenser subcooling calculations will be inaccurate. If the condenser in **Figure 22.32** was large, and the pressure was measured at the condenser outlet, the condenser subcooling calculation would be 120°F − 110°F = 10°F of condenser subcooling. The lower pressure of 171 psig at the condenser's outlet gives a lower condensing temperature of 120°F when the condenser pressure drop of 13 psig (184 psig − 171 psig) is taken into consideration.

All air-cooled condensers do not have the same 30°F relationship with the ambient air. It is good practice to determine and record the temperature relationship between the air and refrigerant at start-up time. Then if the relationship were to change, you would suspect trouble, such as a dirty condenser or an overcharge of refrigerant that has been added without your knowledge.

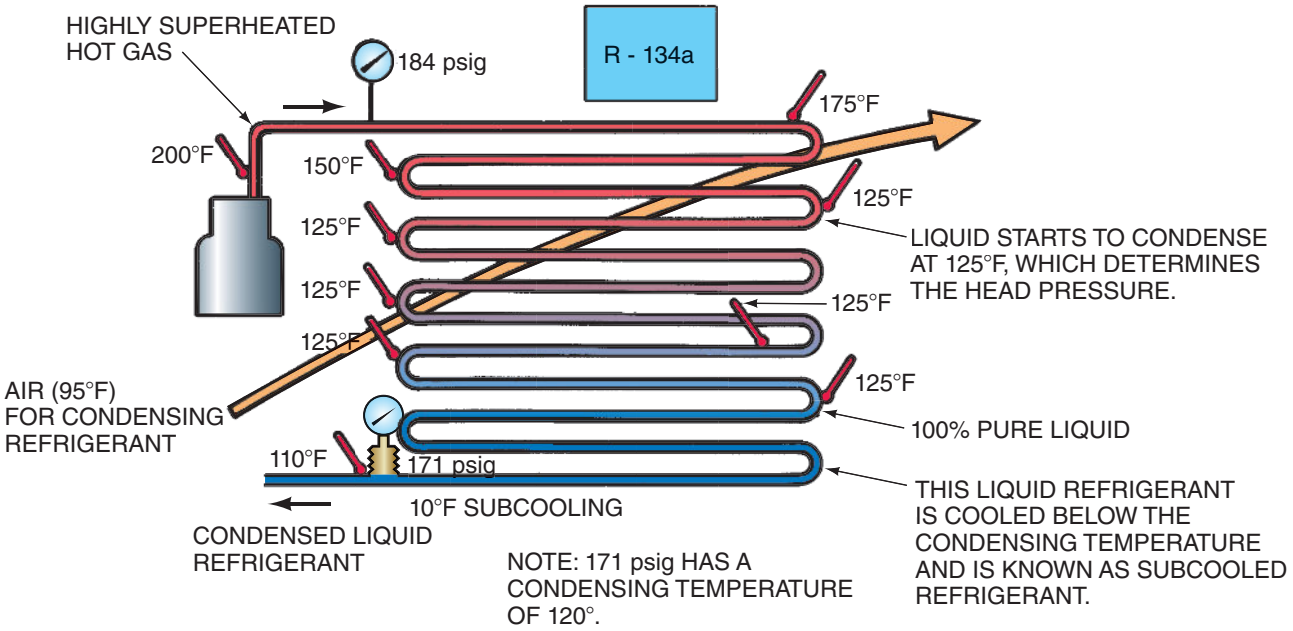
Figure 22.32 The air-cooled condenser has a 13-psig pressure drop from where the hot gas enters to where the subcooled liquid leaves the condenser. This is due to friction loss in the piping and is typical of larger condensers. The subcooling must be measured close to the same pressure location as where the temperature pressure is measured.



22.16 HIGH-EFFICIENCY CONDENSERS

Condensing temperatures can be reduced by increasing the condenser surface area. The larger the condenser surface area, the closer the condensing temperature is to the ambient temperature. A perfect condenser would condense the refrigerant at the same temperature as the ambient, but would be so large that it would not be practical. In the previous examples, we used a temperature difference of 30°F between the ambient and the condensing temperatures. **Figure 22.33** shows an example of a condenser condensing at 110°F, 15°F above the ambient temperature. The head pressure for R-134a condensing at 110°F would be

Figure 22.33 The operating conditions for a high-efficency condenser.

146.4 psig. (R-404A would be 271.4 psig.) *The reduction of head pressure provides for a more efficient system—less power is consumed for the same amount of usable refrigeration.*

Some condensers, particularly in extra-low-temperature systems, can reduce condensing temperatures to within 10°F of the ambient.

Compressors are affected by a decrease in head pressure and will be discussed in the next unit.

22.17 THE CONDENSER AND LOW AMBIENT CONDITIONS

The foregoing example described how an air-cooled condenser operates on a hot day. An example of a condenser operating under different conditions might be in a supermarket with a small package-display case located inside the store. Because this is a package-display case, the condenser is also located inside the store, **Figure 22.34**. The inlet for air to the case is in the store itself and the air may be quite cool if the air conditioner is operating—70°F or even cooler at times. This reduces the operating pressure on the high-pressure side of the system. When the condenser relationship temperature rule is applied, we see that the new condensing temperature would be 70°F + 30°F = 100°F. The head pressure would be 124 psig. This may be enough to affect the performance of the expansion device (covered in more detail later). The low-side pressure for a medium-temperature fixture using R-134a will be in the neighborhood of 18 psig at the lowest point. When the relationship of the low-side pressure of 18 psig is subtracted from the high-side pressure of 124 psig for a condenser with 70°F air passing over it, the difference is 106 psig. Should this fixture be exposed to temperatures lower than 70°F, a starved evaporator coil may be the result.

If the medium-temperature box were moved outside the store, the fixture may quit working to capacity during the winter. If the air temperature over the coil drops to 50°F outside, the head pressure is going to drop to 50°F + 30°F = 80°F condensing temperature, which corresponds to 87 psig, **Figure 22.35**. The pressure difference of 87 psig − 18 psig = 69 psig may not be sufficient to feed enough liquid refrigerant through the expansion device to properly feed the coil, **Figure 22.35**. In the figure, notice the pressure and temperature difficulties encountered. The head pressure must be regulated.

Another example of a condenser operating outside design parameters would be an ice-holding box like those found at service stations and convenience stores. These fixtures hold ice made at another location. They must keep the ice hard in all types of weather and often operate at about 0°F to 20°F inside the box. It may be 30°F outside the box where the small air-cooled condenser is rejecting the heat. The condenser would be operating at about 30°F + 30°F = 60°F,

Figure 22.34 The package-display case located inside a store with the compressor and the condenser located inside the cabinet. This is a plug-in, self-contained device; no piping is required.

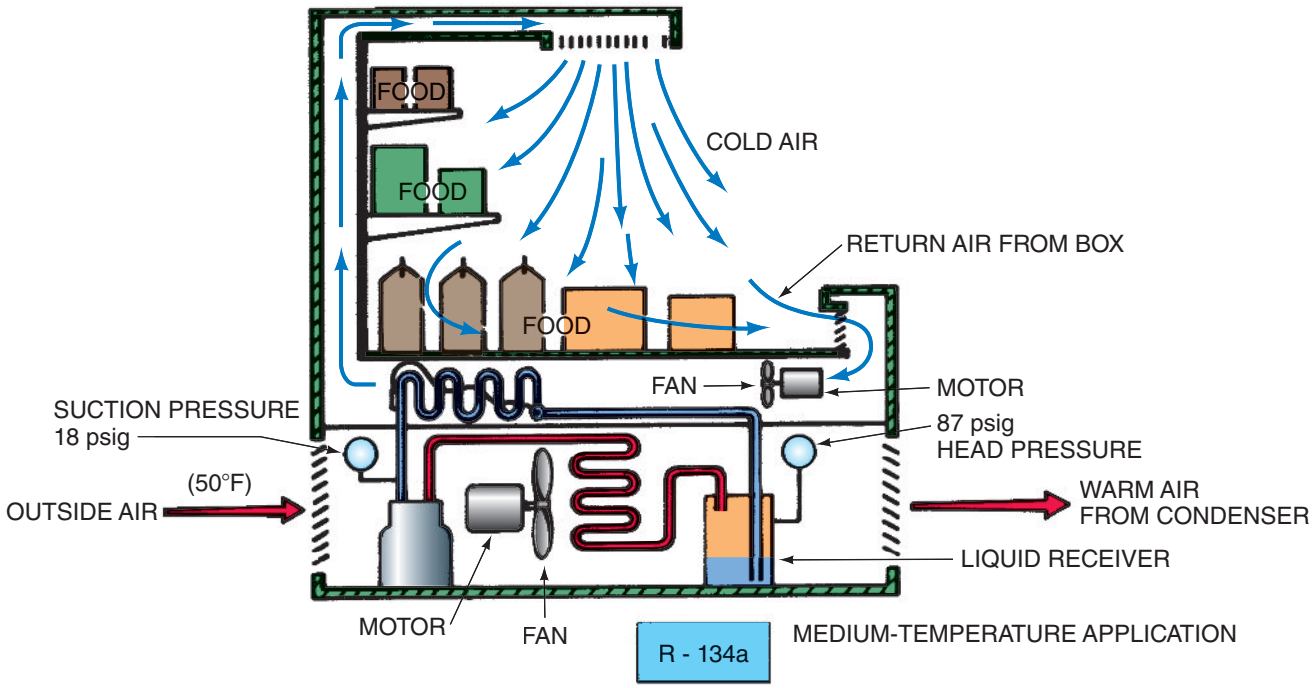
Figure 22.35 The fixture in **Figure 22.34** is relocated outside the store. Now the condenser is subject to winter conditions. Its performance will fall off if some type of head pressure control is not installed, because the head pressure is so low it cannot push enough liquid refrigerant through the expansion valve. The evaporator is starved. The unit has a reduced capacity that would be evident if a load of warm food were placed in the box. It might not pull the food temperature down, and the coil would ice up because there would be no off-cycle defrost.



or at a head pressure of 57 psig, **Figure 22.36**. The evaporator should be operating at about −15°F, or at a suction pressure of 0 psig to maintain 0°F. This gives a pressure difference of 57 psig − 0 psig = 57 psig, which will starve the evaporator. This unit has to run to keep the ice frozen, so something has to be done to get the head pressure up.

One thing that helps prevent problems in some equipment operating in low ambient conditions is that the load is reduced. The ice-holding box, for example, does not have to run as much at 30°F weather to keep the ice frozen at 0°F. It may perform poorly, but you will not know it unless it must run for a long period of time for some reason, such as if a

Figure 22.36 An illustration of how the condenser acts in a low ambient condition. Notice that this condenser has much more liquid refrigerant in it and the head pressure is very low. It may be so low that it may starve the expansion device. The condenser relies on head pressure to force liquid refrigerant through its metering device.

load of ice that is barely frozen is put into it. The unit may have run a long cycle to pull the load temperature down, and the evaporator may freeze solid.

22.18 HEAD PRESSURE CONTROLS

As the outdoor ambient temperature falls, and the temperature difference between the condensing refrigerant and the ambient temperature becomes greater, the condenser capacity will increase. In low ambient conditions, the system's condenser becomes very efficient and can be considered oversized. An oversized condenser means lower head pressures, lower compression ratios, and reduced consumption of electricity. However, there are limits to how low head pressures can be allowed to fall in order to make sure metering devices are being properly fed, evaporators remain active with proper superheats, mass flow rates or refrigerant are correct for proper oil returns to the compressor, and compressor discharge temperatures are not excessive from compressor return gas temperatures being too hot.

Practical methods to maintain the correct workable head pressure automatically and not cause equipment wear are:

- *fan-cycling controls,*
- *variable-frequency drive (VFD) condenser fan motor controls,*
- *dampers,*
- *condenser flooding, and*
- *condenser splitting.*

Each control method has different characteristics and features. Manufacturers recommend various head pressure controls for their own reasons.

FAN-CYCLING DEVICES

The air-cooled condenser uses a small fan to pass air over it. When this fan is cycled off, the head pressure will go up in any kind of weather, provided the prevailing winds do not take over and do the fan's job. To cycle the fan off, a pressure control can be piped into the high-pressure side of the system that will close a set of electrical contacts on a preset rise in pressure, **Figure 22.37**. The electrical contacts will stop and start the fan motor on pressure changes.

A common setup for R-134a may call for the fan to cut off when the head pressure falls to 135 psig and to restart the fan when the head pressure reaches 190 psig. This setting will not interfere with the summer operation of the system and will give good performance in the winter. The settings are far enough apart to keep the fan from short cycling any more than necessary. When the thermostat calls for the compressor to come on and the ambient air is cold, the head pressure would be so low that the system would never get up to good running capacity because the condenser fan would be moving more cold air over the condenser. The condenser fan-cycling control keeps the condenser fan off until the head pressure is within the correct operating range.

Figure 22.37 A condenser fan-cycling device. This control performs the same action (make on a rise in pressure) as the low-pressure control except that it operates at a much higher range.

Photo by Bill Johnson

The fan-cycling device is one method of maintaining a correct operating head pressure range. It can be added to the system without much expense, and the piping normally does not have to be altered. One problem with the device is that it has a tendency to cause the head pressure to swing up and down as the fan is stopped and started. This can also affect the operation of the expansion device because the pressure may be 190 psig for part of the cycle and then, when the fan comes on, drop rapidly to 135 psig. The pressure swing causes the expansion device to operate erratically. When the head pressure falls below certain minimums, the system's performance can be affected in three ways: underfeeding TXVs causing a starved evaporator, oil logging, and higher compressor discharge temperatures and reduced compressor efficiencies.

A head pressure reduced below a certain minimum will reduce the liquid pressure feeding the TXV and will cause the TXV to underfeed the evaporator. Pressure drop across the TXV is one of the main factors determining the capacity of the TXV. Low liquid feeding pressures will starve the evaporator and cause high superheats in the evaporator and on return to the compressor. The evaporator will become less active and starved of refrigerant. This will cause low net refrigeration effects. Because the evaporator and compressor are both starved of refrigerant, the mass flow rate of refrigerant through the system will decrease. A decreased mass flow rate of refrigerant will make it difficult for oil to return to the compressor. Because oil and refrigerant do not completely mix, a minimum refrigerant velocity in the suction line is required for proper oil return. It is refrigerant velocity that brings oil back to the compressor from the suction line and suction line risers. As mentioned, when an evaporator is starved by low head pressures feeding the TXV, high

superheats are experienced in the evaporator and coming back to the compressor. These higher-than-normal temperatures coming back to the compressor decrease the density of vapors being pumped. This in turn results in a low mass flow rate of pumped refrigerant. The higher temperature of refrigerant coming into the compressor will also cause a higher compressor discharge temperature. In fact, for every 1 degree rise in suction gas temperature returning to the compressor, there will be a 1 degree rise in the compressor's discharge temperature.

There are other means of controlling the head pressure at a steady state on air-cooled condensers. When a condenser has more than one fan, one fan can be put in the lead and the other fans can be cycled off by temperature or pressure, **Figure 22.38**. The lead fan can then be cycled off by pressure, like a single fan. Cycling multiple fans can help prevent pressure swings from being as close together as they are in the single-fan application. For example, when three fans are used, the first can cycle off at approximately 70°F, and the second can cycle off at approximately 60°F. The remaining fan may be controlled by the pressure or by a temperature sensor located on the liquid line. If a condenser had eight fans, each set of two fans could be staged off by a pressure control. Below is a typical fan-cycle control scheme with set points using pressure controls.

Condenser Set Points

Fan #	Cut-in Pressure	Cut-out Pressure
1 and 2	180 psig	160 psig
2 and 3	190 psig	170 psig
3 and 4	200 psig	180 psig
4 and 5	210 psig	190 psig

With this pressure control strategy cycling four sets of fans, the condensing pressure would never fall below 160 psig, unless the condenser experienced extremely cold winds blowing through it.

A disadvantage of this type of head pressure control is that as more fans cycle off, the head pressure (saturated condensing temperature) and receiver pressure will decrease. Any saturated liquid refrigerant in the receiver will then try to reduce its temperature by flashing into vapor to comply with the new lower condensing pressure and temperature. As some of the liquid in the receiver flashes, it absorbs heat from the surrounding liquid as it tries to reduce its temperature to the new saturation temperature in the condenser. Depending on how much liquid is in the receiver, how much subcooled liquid is in the liquid line, and how quickly the condensing pressure is falling from the cycling fans, the receiver and liquid line may not be able at all times and conditions to deliver vapor-free liquid to the TXV. There may be premature liquid flashing (liquid-line flash gas) in the liquid line all the way to the TXV. This will greatly reduce the capacity of the TXV, starve evaporators, and cause erratic TXV operation with very poor evaporator superheat control.

VARIABLE-FREQUENCY DRIVE (VFD) CONDENSER FAN MOTORS

As mentioned, one problem with cycling condenser fan motors is their tendency to cause the head pressure to swing up and down as the fan motor is started and stopped. This can cause erratic and inconsistent operation of the TXV. However, the variable-speed condenser fan motors used on larger condensing units can vary their speed gradually according to head pressure or outside ambient temperature changes. Many of these fan motors are equipped with variable-frequency drives (VFDs) controlled by electronic inverters. VFDs operate on the principle that when the frequency, or hertz (Hz), of the voltage coming into the fan motor changes, the speed of the fan motor will also change. As the voltage frequency increases, the motor speed increases; as the voltage frequency decreases, the motor speed decreases. The following formula governs the speed (rpm) of a motor. Notice that the numerator is the frequency or hertz of the incoming voltage in cycles/sec, multiplied by a factor for converting from minutes to seconds. The denominator is the number of motor pole pairs.

$$\text{rpm} = \frac{(\text{Frequency})(60\ \text{sec/min})}{(\text{Number of Motor Poles} \div 2)}$$

This simplifies to

$$\text{rpm} = \frac{(\text{Frequency})(120)}{(\text{Number of Motor Poles})}$$

Since we cannot change the number of motor poles, the frequency is the easiest variable to alter for a change in the rpm of the motor.

Through special electronic circuitry called an inverter, the voltage frequency feeding a condenser fan motor can be

altered with changing head pressure by linking the refrigeration system's high-side pressure transducer to the inverter. Another control scheme is to measure changing outdoor ambient temperatures by a temperature sensor near the condenser's air inlet. These signals can then be linked to an electronic inverter. **Figure 22.39** shows a VFD for changing the frequency of the voltage signal to a motor. The frequency change can be done in small increments, thus changing the speed of the condenser fan motors in small increments. This type of control will keep a more consistent head pressure as the outside ambient temperature changes. It will also prevent the head pressure from swinging up and down erratically, which occurs when the fan motors are cycled on and off. VFDs are covered in more detail in Unit 17, "Types of Electric Motors."

AIR SHUTTERS OR DAMPERS

Shutters may be located either at the inlet to the condenser or at the outlet. The air shutter has a pressure-operated piston that pushes a shaft to open the shutters when the head pressure rises to a predetermined pressure, **Figure 22.40**. This pressure-operated piston extends to open the shutters when the pressure rises, **Figure 22.41**. Shutters open and close slowly and provide even head pressure control. With a single fan, the shutter is installed over the inlet or over the outlet to the fan. When there are multiple fans, the shutter-covered fan is operated all the time and the other fans can be cycled off by pressure or temperature. This arrangement can give good head pressure control down to low temperatures.

CONDENSER FLOODING

Flooding the condenser with liquid refrigerant causes the head pressure to rise just as though the condenser was covered

Figure 22.40 A condenser with an air shutter. With one fan it is the only control. With multiple fans the other fans can be cycled by temperature with the shutter controlling the final fan.

with a plastic blanket. Flooding is accomplished by having enough refrigerant in the system to flood the condenser in both mild and cold weather to keep the head pressure constant. This will also assure a consistent liquid pressure for feeding the metering device in low ambient conditions. Flooding requires a large refrigerant charge and an oversized liquid receiver to store the extra charge in warmer weather when the condenser doesn't need to be flooded. In addition to the charge, there must be a valve arrangement that allows the refrigerant liquid to fill the condenser during both mild and cold weather. The flooding method is designed to maintain the correct head pressure in the coldest weather during start-up and while operating.

One big problem designers face when designing air-cooled refrigeration and air-conditioning equipment is the changing ambient of the changing seasons. A properly designed condenser will operate inefficiently during extremely high ambient conditions. The inefficiencies come from the higher head pressures and thus higher compression ratios associated with high ambient conditions. However, it is the low ambient conditions that cause more serious problems. Moreover, it is a fact that most units will be required to operate at temperatures below their design dry-bulb temperature during the fall, winter, and spring seasons. It is because of these changing ambient conditions that head pressure control valves were designed. Without these valves, head pressures would

fluctuate as widely as ambients do during the changing seasons. Both running-cycle and off-cycle problems can occur if head pressure controls are not used.

Low head pressures from low ambients can cause insufficient refrigerant flow rates through metering devices, which in turn can starve evaporators. Low suction pressures, iced coils, short cycling, and inefficient cooling can also result from low head pressures. Also, any system using hot-gas defrost or hot-gas bypass for compressor capacity control must have a minimum head pressure for proper defrosting and capacity control. With outdoor forced-air condensers, low ambient conditions also cause refrigerant to migrate to the condenser, compressor, and suction line during the off cycle.

Hard starting may also occur in a low ambient condition, causing low head pressures. Often, refrigeration systems are not able to start because most of the refrigerant has migrated to the colder condenser. The evaporator has a hard time building vapor pressure and may never get to the cut-in pressure of its low-pressure control. Even if the compressor does eventually start by reaching the cut-in pressure, it may soon short cycle. This is caused by low refrigerant flow through the metering device at the lower head pressure in the low ambient condition.

The solution to the low head pressure problem is to install a pressure-actuated "holdback" valve at the outlet of the condenser, **Figures 22.42(A)** and **(B)**. The valve throttles shut when the condenser pressure reaches a preset minimum for low ambient conditions. This allows liquid refrigerant in the condenser to be held back and actually flood portions of the condenser. The partial flooding will inactivate a portion of the condenser and cause it to have a smaller internal volume. At this point, desuperheating and condensation must take place. Condensing pressures will rise, thus giving sufficient liquid-line pressures and pressure differences across the thermostatic expansion valve (TXV) for normal system operation in the colder ambient.

The valve shown in **Figure 22.42(A)**, referred to as an ORI (open on rise of inlet pressure) valve, is an inlet-pressure regulating valve that responds to changes in inlet pressure (condensing pressure) only. A decrease in condensing pressure causes less pressure to act on the bottom of the seat disk. This action throttles the valve more in the closed position and starts to back up liquid refrigerant in the bottom of the condenser. Soon the head pressure will start to rise as a result of the condenser's reduced internal volume. Any increase in inlet (condensing pressure) above the valve setting will tend to open the valve.

The condensing pressure is opposed by the force of an adjustable spring that is on top of the valve seat disc. The setting can be changed simply by either increasing or decreasing the tension of the spring with a screwdriver or an Allen wrench. Increasing the spring pressure by turning the fitting clockwise will increase the minimum opening pressure of the valve. The outlet pressure of the valve is then cancelled out and has no bearing on valve movement because the outlet pressure is exerted on top of the bellows and on top of the seat disc simultaneously. Since the effective area of the bellows is equal to the area of the top of the seat disc, the pressures cancel one another and do not affect the valve movement, **Figure 22.43**. Only changes in condensing pressure can throttle the valve either open or closed.

An ORI valve is usually used in conjunction with an ORD (open on rise of differential pressure) valve, **Figures 22.44(A)** and **(B)**. The ORD valve is located between the discharge line and the receiver inlet, **Figure 22.42(B)**. It responds to changes in pressure differences across the valve. The ORD valve is thus dependent on the ORI valve for its operation. The ORD valve will bypass hot compressor discharge gas from the compressor to the receiver inlet when it senses a preset determined pressure difference across the valve. As the ORI valve senses a drop in condenser pressure and starts to throttle shut, a pressure difference is created across the ORD valve. The pressure difference is created by the reduced flow to the receiver due to the throttling action of the ORI valve. One outlet of the ORD valve senses receiver pressure, and the inlet side senses discharge pressure from the compressor. When the ORI valve starts to throttle shut, the receiver is still supplying refrigerant to the TXV and receiver pressure will eventually drop. If the receiver pressure drops too low, its ability to keep feeding the liquid line and the TXV will diminish. Something has to keep the receiver pressure up while the ORI valve is throttling liquid from the condenser. This is when the function of the ORD valve comes into play.

When the ORD valve senses a factory preset pressure difference of 20 psi between the receiver and compressor discharge, it will start to open and bypass hot compressor discharge gas to the receiver's inlet. If the pressure difference across the ORD valve ever reaches 30 psi, the valve will be fully open. The hot gas from the compressor, which flows through the ORD valve, serves to heat up any cold liquid refrigerant being throttled through the ORI valve at the receiver's inlet. This hot gas entering the receiver will also increase the pressure of the receiver and allow it to deliver liquid to the liquid line and TXV when the ORI valve is throttling shut on the outlet of the condenser.

Both the ORI and ORD valves will automatically work in conjunction with one another to maintain proper receiver pressure, regardless of the outside ambient conditions. The ORD valve also acts as a check valve to prevent reverse flow from the receiver to the compressor's discharge line during the off cycle. A combination ORI/ORD nonadjustable valve arrangement can also be used—which simplifies the piping arrangement, **Figures 22.45(A)** and **(B)**. These valves also limit the flow of refrigerant from the condenser to the receiver and at the same time regulate the flow of the compressor's hot gas to the receiver. The combination valve has a round dome at the top that is pressure charged. The pressurized dome will be explained in the paragraphs to come.

Figure 22.43 Cutaway view of an ORI head pressure control valve.

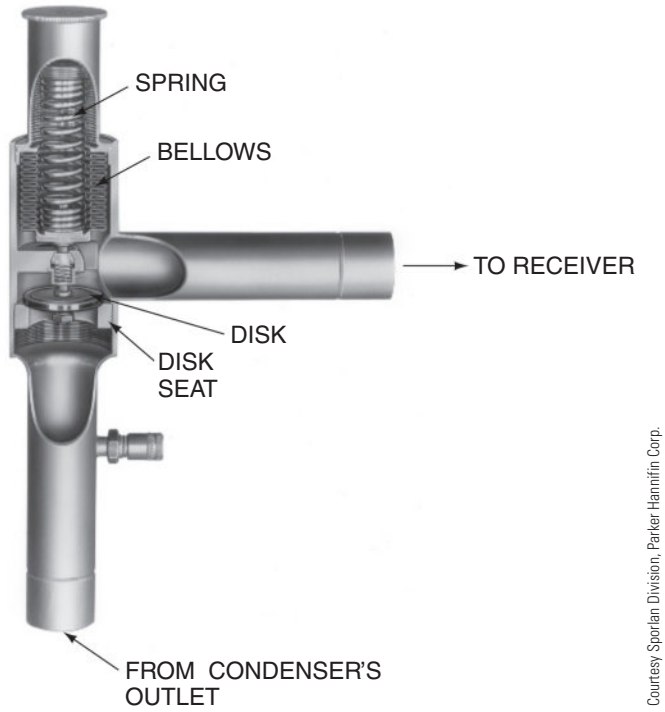

Figure 22.44 (A) Open on rise of differential pressure (ORD) head pressure control valve. (B) Cutaway view of an ORD head pressure control valve.

Figures 22.46(A) and **(B)** show another style of head pressure control valve for low ambient conditions that is often referred to as a low-ambient control (LAC) valve. It has a round, pressurized dome at the top. The charge in the dome is independent of the refrigerant charge in the actual refrigeration system. The valve is located in the condensing unit that is in the outside ambient temperature and so the charge expands and contracts in volume and acts on an internal diaphragm along with changes in the outside ambient. The expansion and contraction of the pressure charge moves the diaphragm, which in turn moves a piston in the valve and modulates the valve to either a more open or closed position. When the temperature of the condenser is above 70°F, the refrigerant flow from the compressor is directed by the mixing valve through the condenser and into the receiver. If the outside ambient temperature drops below 70°F, the condensing pressure will fall and the pressure of the liquid coming from the condenser will also fall to a point below that of the bellows in the dome of the valve. This causes a piston to move in the valve and partially restrict the flow of refrigerant leaving the condenser. The condenser will now partially flood with refrigerant to maintain a certain condensing pressure. At the same time, discharge gas will bypass the condenser and flow directly to the receiver, **Figure 22.47**. The hot, superheated discharge gas going to the receiver now mixes with liquid refrigerant coming from the condenser. This keeps the receiver pressure up and helps keep metering devices fed with refrigerant.

In low ambient conditions, these mixing valves will maintain a head pressure of approximately 190 psi for R-502 systems, a head pressure of either 240 psi or 190 psi for R-404A systems (depending on the model of the valve), and a head pressure of approximately 180 psi for R-22 systems. The dome charges can also be custom-ordered from the manufacturer to meet specific system requirements, which allows LAC valves to be used on *floating head pressure* systems. Floating head pressure is covered later in this section.

Receivers on systems having head pressure control valves must be large enough to hold the normal operating charge plus the additional charge that is necessary to totally flood the condenser for wintertime operation. In fact, the receivers should be sized so that they are about 80% full when they contain the entire system charge. This allows for a 20% vapor head for safety when pumping the system down.

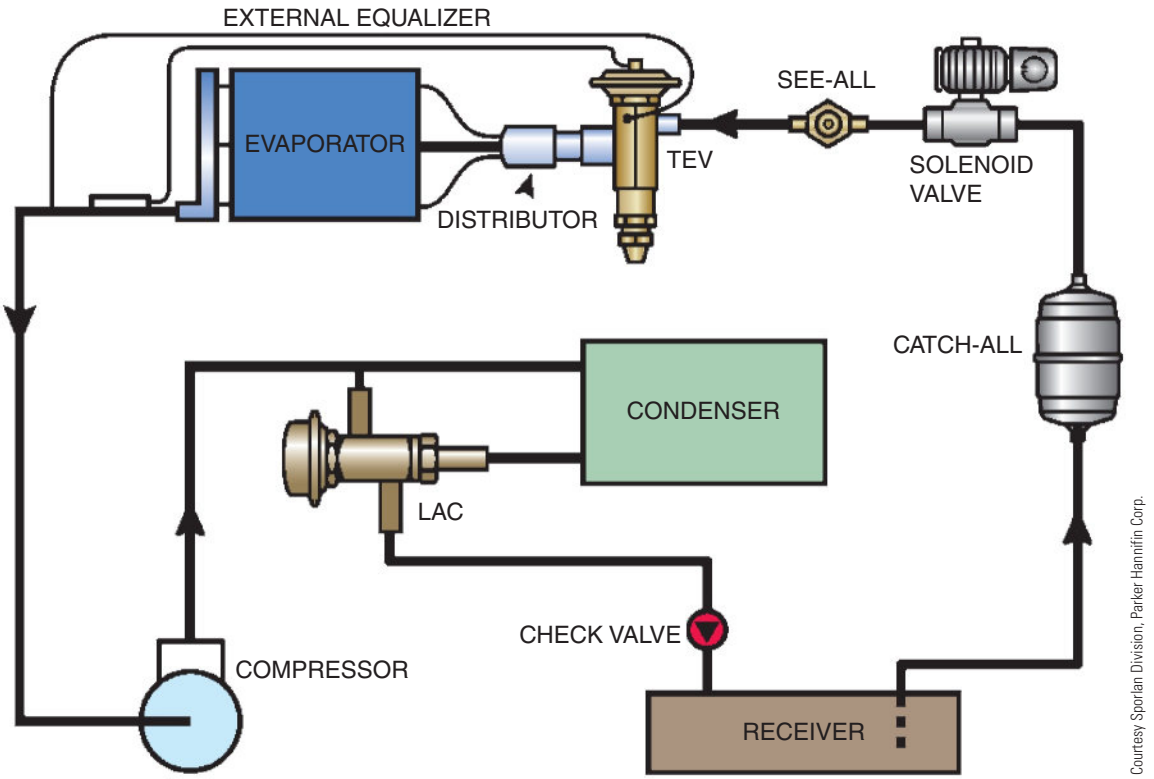
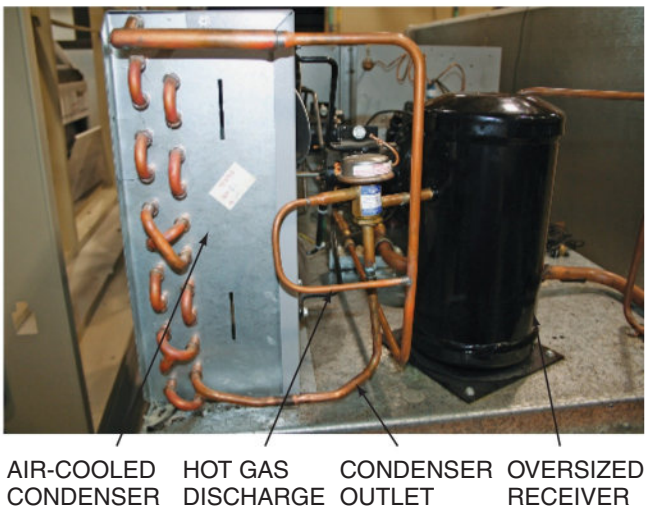
Figure 22.47 System diagram showing location of the low-ambient control (LAC) head pressure control valve.



Any refrigeration receiver should be able to hold all of the system's refrigerant charge and still have a 20% vapor head for safety. **Figure 22.48** shows a refrigeration system with a head pressure control mixing valve and an oversized receiver. Most manufacturers publish recommendations in the form of charts and tables of system charges that show the service technician how much refrigerant to add to systems having head pressure control valves designed to flood the condenser in colder weather. Nowadays, these tables and charts can be accessed on the Internet with a personal computer. If the receivers of a refrigeration or air-conditioning system haven't been oversized to accommodate the extra refrigerant needed for flooding the condenser during low ambient conditions, the technician will have to remove refrigerant every spring to prevent high head pressures at a design ambient—only to add it back again in the fall when it will be required for flooding the condenser for head pressure control, a technique often referred to as a winter/summer charge procedure. However, as one can see, oversizing the receiver can save the technician the added labor.

Figure 22.48 Low-ambient control (LAC) head pressure control valve shown piped to condenser and receiver.



As mentioned earlier, one of the advantages of condenser flooding is to keep consistent liquid pressure for feeding the metering device in low ambient conditions. Manufacturers do supply technical information on how much extra refrigerant is needed for flooding a condenser for a certain low ambient condition. However, in extreme low ambient conditions, it may be necessary to flood 80% to 90% of the condenser. On larger systems, this could require several hundred pounds of refrigerant. This is the main disadvantage of flooding a condenser. With the rising price of

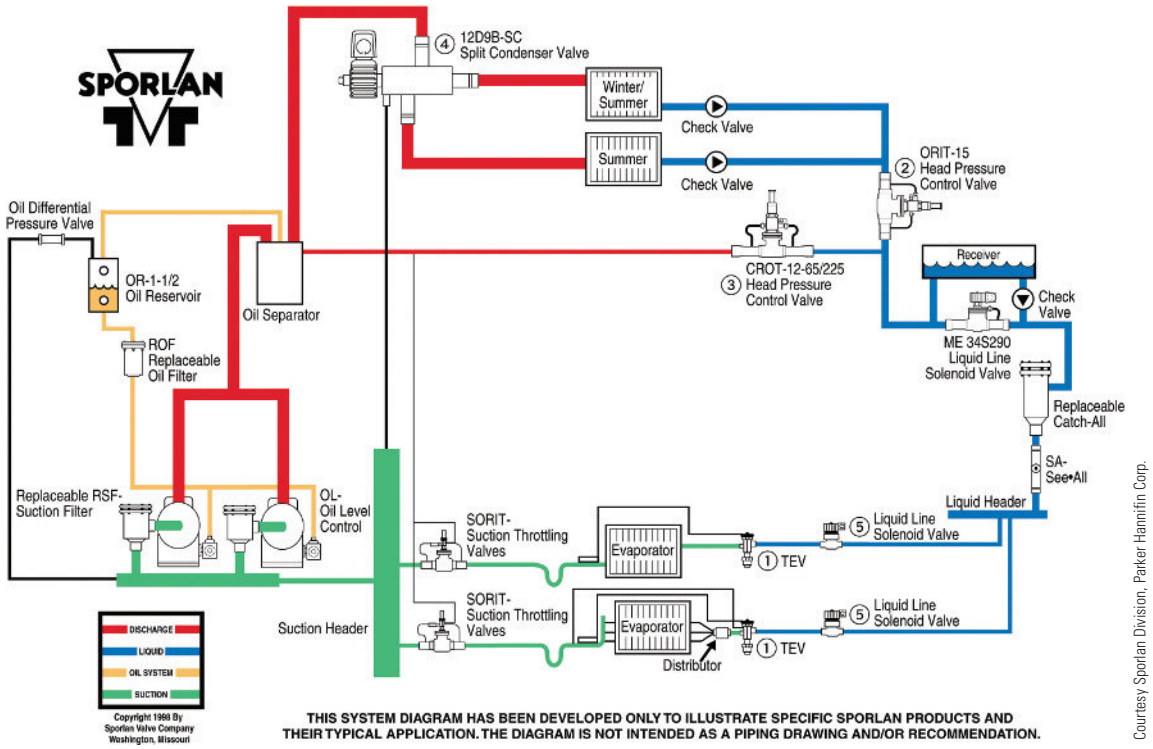
Figure 22.49 Parallel compressor supermarket refrigeration system showing split condensers. Condenser halves are labeled "Winter/Summer" and "Summer."



refrigerant and the environmental concerns of global warming and ozone depletion, condenser flooding can become quite expensive and environmentally unsound if not managed and serviced properly.

CONDENSER SPLITTING

One way to reduce the amount of extra refrigerant charge needed for condenser flooding is to split the condenser into two separate and identical condenser circuits, **Figure 22.49**. This method is referred to as **condenser splitting**. The splitting is done by installing a pilot-operated, three-way solenoid valve in the discharge line from the compressors, **Figure 22.50**. The splitting is done in such a way that only one-half of the condenser is used for winter operation and both halves are used for summer operation. The top half of the condenser is referred to as the "Summer/Winter" condenser, and the bottom half of the condenser is referred to as the "Summer" condenser, **Figure 22.49**. The three-way solenoid valve controlling the splitting of the condensers can be energized and deenergized by a controller sensing outside ambient, an outdoor thermostat, or a high-side pressure control. *During summertime operations, the added surface area and volume of both condensers are needed to maintain a reasonable head pressure at higher ambient conditions.*

Figure 22.50 Pilot-operated, three-way solenoid condenser splitting valve.

When the pilot-operated, three-way solenoid valve is deenergized, the main piston inside the valve is in position to let refrigerant flow from the compressor's discharge line to the three-way valve's inlet port and then equally to the valve's two outer ports. In other words, the refrigerant will flow to both of the condenser halves equally.

In low ambient conditions, the summer portion of the condenser can be taken out of the active refrigeration system by the three-way valve. When the coil of the pilot-operated, three-way solenoid valve in **Figure 22.50** is energized, the sliding piston inside the valve will move and close off the flow of refrigerant to the port on the bottom of the valve that feeds the summer condenser. This action will render the summer condenser inactive or idle, and the minimum head pressure can be maintained by flooding the Summer/Winter half of the condenser with conventional refrigerant-side head pressure control valves, as explained in the condenser flooding section of this unit.

In fact, during winter operations, the system's head pressure is best maintained with a combination of condenser splitting, refrigerant-side head pressure controls, and air-side controls like fan cycling or fan variable-speed devices. This combination of refrigerant-side and air-side controls will minimize the refrigerant charge even more while splitting the condenser. These combinations will also maintain the correct head pressure for better system efficiencies.

The refrigerant that is trapped in the idle summer condenser during low ambient conditions will flow back into the active system through a bleed hole in the piston of the three-way valve. The trapped refrigerant will flow through the piston's bleed hole, into the valve's pilot assembly, and back to the suction header through a small copper line that feeds all parallel compressors, **Figure 22.49**. Another scheme to rid the idle summer condenser of its refrigerant is to install a dedicated pump-out solenoid valve that will open when energized and vent the trapped refrigerant to the common suction header through a capillary tube restriction. Both the bleed hole in the piston and the capillary tube ensure that the refrigerant experiences a restriction and is mostly vaporized before reaching the common suction header, which is under low-side (common-suction) pressure. A check valve is located at the summer condenser's outlet to prevent any refrigerant from entering it while it is idle and under a low pressure condition. While not needed for back-flow prevention, a check valve is also located at the outlet of the Summer/Winter condenser simply to make the pressure drops equal in both halves of the condenser when both are being used simultaneously in summertime operations.

Troubleshooting a low-ambient head pressure control valve with a pressurized dome can be easy if the proper steps are taken. If the outdoor ambient is below 70°F and the head pressure is low, feel the line between the valve and the receiver, **Figure 22.47**. If this line is cold, the valve is not allowing the compressor's discharge gas into the receiver. The valve is defective and should be replaced. This line should be warm at an ambient below 70°F. If the head pressure is low and the ambient is above 70°F—and the line between the valve and the receiver is hot—the valve is also defective and should be replaced. The line should be a little warmer than the ambient because of the subcooled liquid coming from the condenser's outlet to the receiver at the warmer outside ambient. Discharge gas flow from the receiver should be shut off by the valve. However, the system could also be low on charge—causing a low condensing pressure that fools the valve. So, the defective valve should only be replaced after verifying that the system charge is correct.

To replace a defective low-ambient control valve with a pressurized dome charge, follow these steps:

1. Recover refrigerant.
2. Cut the process tube on the valve's charged dome to remove the pressure charge.
3. With a torch, heat the valve until the solder liquifies, then remove the valve.
4. Wrap the valve's body with a heat sink to prevent damage and silver-solder a new valve in place.
5. Install a new filter drier.
6. Leak check the system and evacuate to a deep vacuum (500 microns).
7. Charge the system and leak check again.

Systems that use condenser flooding for head pressure control have large refrigerant charges, as mentioned earlier. The total charge for the system can be determined by following the manufacturer's calculations. When a service technician is working on a unit that has a partial charge, it is very hard to charge the system without some guidelines. When the system is small—for example, under 10 tons—the technician would be advised to recover the charge that is in the system and measure in the charge that is recommended by the manufacturer. Then the system should perform in all temperature conditions.

Large systems will normally have two sight glasses on the liquid receiver, one at the bottom and one at the 80%-full level. The proper procedure for charging one of these systems is to turn off the system until the load builds up and the compressor or compressors can be run at full load. Then block the air over the condenser until the head pressure is that of a 95°F day. This will assure you that there is no excess liquid refrigerant in the condenser. Then charge the system until there is a liquid level in the sight glass at the 80% level of the liquid receiver. If the weather is warm outside, you may have to uncover the condenser if the head pressure begins to rise too high. Now you know that there is enough refrigerant to flood the condenser in cold weather and that there is not an excess of refrigerant in the condenser. The cover can then be removed from the condenser, and the system should get into balance on its own.

Figure 22.51 A heat exchanger to capture the heat from the highly superheated discharge line and use it to heat domestic water. This line can easily be 210°F and can furnish 140°F water in a supply limited by the size of the refrigeration system. The larger the system, the more heat is available.

22.19 USING THE CONDENSER SUPERHEAT

Air-cooled condensers have high discharge line temperatures even in winter. This characteristic can be used to advantage because the heat can be captured and redistributed as heat for the structure in winter or to heat water. The refrigeration system is rejecting heat from the refrigerated box, heat that leaked into the box from the structure. This heat has to be rejected to a place that is unobjectionable. In summer, the heat should be rejected to the outside of the structure or possibly into a domestic hot-water system, **Figure 22.51**. Water temperatures of 140°F are obtainable for use and can lead to big energy savings.

22.20 HEAT RECLAIM

In winter structures need heat. If heat could be rejected to the inside, heating costs could be reduced. Any heat recovered from the system is heat that does not have to be purchased, **Figure 22.52**. Heat recovery can be accomplished easily with air-cooled equipment. The discharge gas can be passed to a rooftop condenser or to a coil mounted in the ductwork that supplies heat to a structure. The condensing temperature of air-cooled equipment is high enough to be used as heat, and the quantity of heat is sizable enough to be important. Some businesses in moderate climates will be able to extract enough heat from the refrigeration system to supply the full amount of heat required. Heat reclaim is covered in detail in Unit 26, "Applications of Refrigeration Systems."

22.21 FLOATING HEAD PRESSURES

Historically, high condensing pressures and temperatures in a refrigeration system were artificially maintained with head pressure controls so that the system would function properly at low ambient temperatures. These higher pressures were considered mandatory in order for the metering device to feed the evaporator properly. However, as condensing pressures increase, the refrigeration system draws more electrical power and becomes more inefficient. At

today's power costs, these inefficiencies are becoming more and more unacceptable.

In the past, designers of air-conditioning and refrigeration systems assigned an outdoor design condition to a system. The outdoor design condition typically was a temperature that would not be reached more than 2% of the time during the life of the equipment. The condenser was then selected based on this seldom-reached condition. Today, designers of refrigeration and air-conditioning systems often try to attain the lowest possible condensing pressures and temperatures and design condensers accordingly. An industry term for attaining the lowest possible condensing pressure is **floating head pressure**. Floating head pressure systems simply let the condensing pressures follow the ambient temperature as the seasons swing from summer to winter and back again. This means that in the fall, winter, and spring, the condensing pressures will be at their lowest. It is not uncommon for condensing temperatures to be 30°F to 40°F in the winter months.

In fact, a majority of the outdoor temperatures in the United States are below 70°F more than they are above. The compressor capacity increases about 6% for every 10°F drop in condensing temperatures. Working with metering device suppliers, researchers discovered that **thermostatic expansion valves (TXVs)** would work with much less pressure drop across them than expected in the past, as long as pure liquid was supplied to them. Some newer metering devices can operate with as little as a 30-psi pressure drop. *With this new knowledge, designers are allowing condensing pressures to float downward with the ambient temperature in the spring, fall, and winter months. This gives the system higher efficiencies with less power consumption.* Low ambient controls can still be used on these systems when extreme cold temperatures are experienced. Often, their settings will have to be modified for the specific application and extreme cold ambient conditions.

When head pressures are floated in the fall, winter, and spring, condensing pressures will be lowered. This causes less heat to be available for the heat reclaim coils to heat buildings. However, it is much more efficient to heat a building with a fossil-fuel furnace than by artificially elevating head pressures with head pressure controls on a refrigeration or air-conditioning system and causing inefficiencies. Because of this, fewer heat reclaim systems are being installed.

22.22 SERVICE TECHNICIAN CALLS

SERVICE CALL 1

The owner of a small grocery store calls a service technician complaining of high water bills and warm refrigeration temperatures for a few coolers and freezers. *The problem is that two of the helical tube-within-a-tube water-cooled condensers are fouled with mineral deposits and are not transferring the condenser's rejected heat to the water,* **Figure 22.3**. This causes the condensing pressure to increase, unwanted inefficiencies in the refrigeration systems, and warmer-than-normal refrigerated-box temperatures. Because the water-regulating valve reacts to head pressure increases, the water-regulating valve remains open all of the time—wasting water down the drain.

The service technician locates all of the refrigeration equipment's condensing units and observes that five of the six condensing units used to keep the dairy and meats cool are water-cooled. The water-cooled units use water regulating valves to supply water to the five tube-within-a-tube condensers. City water is used for cooling and the used water is simply dumped down the drain after it exits the condenser. The customer explains to the technician that the water bill has always been somewhat high because of his use of water-cooled condensers, but it has gradually been increasing in the last three months. Also, refrigerated-box temperatures have been warmer than usual.

The service technician politely asks the customer some pertinent questions about the equipment in everyday language that the customer can understand and is careful not to interrupt while the customer is answering the questions. The technician wants to make the customer feel that he is helping to find a solution to the problem. After listening to the customer's account of the problem and answering any questions, the technician clearly explains what work has to be done and why it must be done. The technician explains any work options and the advantages and/or disadvantages of each option.

The technician realizes that two of the water-cooled condensers are dumping water down the floor drain very fast. He then measures the temperature difference between the water going into the condenser and the water going out of the condenser on these two units and finds that there is only a 1-degree temperature difference. This indicates that both of the tube-within-a-tube condensers are fouled with mineral deposits and are preventing heat from being transferred from the condenser to the water. Because of the severity of the fouling and because helical tube-within-a-tube water-cooled condensers are not cleanable, the service technician tells the customer that he will have to order two new condensers and then provides the customer an estimate and work orders in writing. A week later, the service technician recovers the entire refrigerant charge and replaces both of the tube-within-a-tube water-cooled condensers with more easily cleanable shell-and-tube condensers of the same capacity, **Figure 22.10(G) and Figure 22.11**. This will allow the service technician to more easily clean the condensers the next time they become severely fouled with minerals.

The service technician now double-checks the work done, cleans the work site, and explains how the problem was corrected. He then gives the final billing information with work description and costs to the customer. After making sure his hands are clean, the technician shakes the customer's hand, politely thanks the customer for the business, and quietly leaves the work site.
