A customer complains that a walk-in cooler designed to keep meats at 36°F is short cycling and not keeping the refrigerated space below 45°F. The R-134a unit has an outdoor, air-cooled condensing unit. *The problem is that the outdoor ambient is 10°F and that the low-ambient head pressure control mixing valve is defective. The valve is not allowing compressor's discharge gas into the receiver to keep the receiver pressure up to feed the metering device.* The evaporator is thus being starved of refrigerant and is running a low evaporator pressure with high superheats. This causes the low-pressure control to shut the unit off prematurely and short cycle.

After installing gauges on the unit, the service technician realizes that the head pressure is really low (50 psig) and that the evaporator superheat is really high (30°F). While the machine is still running, the technician feels the line between the head pressure control valve and the receiver and finds it to be very cold, **Figure 22.48**. This indicates that the head pressure control valve is defective and not allowing the compressor's discharge gas into the receiver to keep the receiver's pressure up in order to feed the metering device. This line should be warm at any ambient below 70°F and get warmer as the outdoor temperature drops.

When the temperature of the condenser is above 70°F, the refrigerant flow from the compressor is directed by the mixing valve through the condenser and into the receiver. If the outside ambient temperature drops below 70°F, the condensing pressure will fall and the pressure of the liquid coming from the condenser will also fall to a point below that of the bellows in the dome of the valve. This causes a piston to move in the valve and partially restrict the flow of refrigerant leaving the condenser. The condenser will now partially flood with refrigerant to maintain a certain condensing pressure. At the same time, discharge gas will bypass the condenser and flow directly to the receiver, **Figure 22.47**. This hot, superheated discharge gas going to the receiver now mixes with liquid refrigerant coming from the condenser. This keeps the receiver pressure up and helps keep metering devices fed with refrigerant.

The service technician decides to replace the valve by following these steps:

1. Recover the refrigerant.
2. Cut the process tube on the valve's charged dome to remove the pressure charge.
3. With a torch, heat the valve until the solder liquifies, then remove the valve.
4. Wrap the valve's body with a heat sink to prevent damage and silver-solder a new valve in place.
5. Install a new filter drier.
6. Leak check the system and evacuate to a deep vacuum (500 microns).
7. Charge the system and leak check again.

When the system is restarted, normal evaporator superheat and system pressures are realized. The refrigerated space pulls down in a matter of 1 hour. The technician feels the line between the low-ambient control mixing valve and the receiver and realizes that it is warm. This means the valve is allowing the compressor's discharge gas into the receiver to keep the receiver's pressure up in order to feed the metering device. At the same time, the condenser will be partially flooded with liquid refrigerant to control head pressure.

SUMMARY

- The condenser is the component that rejects the heat from the refrigeration system.
- The refrigerant condenses to a liquid in the condenser and gives up heat.
- Water is the first medium that heat is rejected into through the water-cooled condenser.
- There are three types of water-cooled condensers: the tube within a tube, the shell and coil, and the shell and tube.
- The greatest amount of heat is given up from the refrigerant while the condensing process is taking place.
- The refrigerant normally condenses about 10°F higher than the leaving condensing medium in a water-cooled condenser that uses a cooling tower.
- The first job of the condenser is to desuperheat the gas flowing from the compressor.
- After the refrigerant is condensed to a liquid, the liquid can be further cooled below the condensing temperature. This is called subcooling.
- When the condensing medium is cold enough to reduce the head pressure to the point that the expansion device will starve the evaporator, a head pressure control must be used, whether air or water is being used as the condensing medium.
- The three types of cooling towers are natural draft, forced draft, and evaporative.
- Recirculated water uses evaporation to help the cooling process.
- When water is evaporated, it will overconcentrate the minerals in it; water must be added to the system to keep this from happening.

- Five common types of head pressure controls are fan-cycling devices, variable-frequency drive (VFD) fans, air shutters and dampers, condenser flooding devices, and condenser splitting.
- The relationship of the condensing temperature to the temperature of the air passing over a condenser can help the service technician determine what the high-pressure gauge reading should be on air-cooled condensers.

REVIEW QUESTIONS

1. Why do some condensers have to be cleaned with brushes and others with chemicals?
2. The three materials of which condensers are normally made are _____, _____, and _____.
3. Who should be consulted when condenser cleaning is needed?
4. When is the most heat removed from the refrigerant in the condensing process?
5. After heat is absorbed into a condenser medium in a water-cooled condenser, the heat can be deposited in one of two places. What are they?
6. A water-cooling tower capacity is governed by what aspect of the ambient air?
   A. Dry-bulb temperature
   B. Wet-bulb temperature
   C. Enthalpy of the air
   D. Altitude
7. When a standard-efficiency air-cooled condenser is used, the condensing refrigerant will normally be _____ °F higher in temperature than the entering air temperature.
8. Four methods for controlling head pressure in an air-cooled condenser are _____, _____, _____, and _____.
9. The prevailing winds can affect which of the air-cooled condensers?
10. True or False: Air-cooled condensers are much more efficient than water-cooled condensers.
11. The type of condenser that has the lowest operating head pressure is the _____ cooled condenser.
12. Compare the standard conditions of high-efficiency and standard air-cooled condensers.
13. Name two ways in which the heat from an air-cooled condenser can be used for reclaiming heat.
14. Briefly describe what is meant by floating head pressure, and tell why it is used in refrigeration and air-conditioning systems.
15. Explain how to flush impurities from a water-regulating valve that is on a water-cooled condenser.
16. Explain the basic operation of a combination ORI and ORD low-ambient head pressure control valve.
17. Name two problems a refrigeration system may have if the condensing unit is exposed to a low-ambient condition when not equipped with a low-ambient head pressure control valve.
18. Briefly explain what is meant by condenser splitting, and list its main advantage.

UNIT 23

COMPRESSORS

OBJECTIVES

After studying this unit, you should be able to

- explain the function of the compressor in a refrigeration system.
- discuss compression ratio.
- describe four different methods of compression.
- state specific conditions under which a compressor is expected to operate.
- explain the difference between a hermetic compressor and a semihermetic compressor.
- describe the various working parts of reciprocating and rotary compressors.

SAFETYCHECKLIST

- ☑ Wear goggles and gloves when attaching or removing gauges to transfer refrigerant or to check pressures.
- ☑ Wear warm clothing when working in a walk-in cooler or freezer.
- ☑ Do not touch the compressor discharge line with your bare hands.
- ☑ Be careful not to get your hands or clothing caught in moving parts such as pulleys, belts, or fan blades.
- ☑ Wear an approved back brace belt when lifting and use your legs, keeping your back straight and upright.
- ☑ Observe all electrical safety precautions. Be careful at all times and use common sense.

23.1 THE FUNCTION OF THE COMPRESSOR

The **compressor** is considered the heart of the refrigeration system. The term that best describes a compressor is vapor pump, because it actually increases suction pressure level to the discharge pressure level. For example, in a low-temperature, R-404A refrigerant system the suction pressure may be 21 psig and the discharge pressure may be 236 psig. The compressor increases the pressure 215 psig (236 − 21 = 215) **Figure 23.1**. Another system may have a different increase in pressure. A medium-temperature system may have a suction pressure of 56 psig with a discharge pressure of 236 psig. This system has an increase of 180 psig (236 − 56 = 180) **Figure 23.2**.

Compression ratio is the technical expression for pressure difference; it is the high-side **absolute pressure** divided by the low-side absolute pressure. Absolute pressures rather than gauge pressures are used when figuring compression ratios in order to keep the calculated compression ratio from becoming a negative number. Absolute pressures keep compression ratios positive and meaningful. For example, when a compressor is operating with R-404A, a head pressure of 331.8 psig (125°F), and a suction pressure of 19.6 psig (−16°F), the compression ratio would be

$$\text{Compression Ratio} = \frac{\text{Absolute Discharge}}{\text{Absolute Suction}}$$

$$\text{CR} = \frac{331.8 \text{ psig} + 14.7 \text{ atmosphere}}{19.6 \text{ psig} + 14.7 \text{ atmosphere}}$$

$$\text{CR} = \frac{346.5}{34.3}$$

$$\text{CR} = 10.1 \text{ to } 1 \text{ or } 10.1{:}1$$

A compression ratio of 10.1:1 would indicate to a service technician that the absolute or true discharge pressure is 10.1 times as great as the absolute suction pressure.

Assume now that this same refrigeration system is operating with R-134a as the refrigerant. With the same condensing temperature of 125°F (184.6 psig) and an evaporating temperature of −16°F (0.7 in. Hg vacuum), the compression ratio would be

$$\text{CR} = \frac{184.6 \text{ psig} + 14.7 \text{ atmosphere}}{(29.92 \text{ in. Hg} - 0.7 \text{ in. Hg}) \div 2.036}$$

$$\text{CR} = \frac{199.3}{14.35}$$

$$\text{CR} = 13.89 \text{ to } 1 \text{ or } 13.89{:}1$$

NOTE: *Because the suction (evaporating) pressure of the R-134a system is in a vacuum of 0.7 in. Hg, a different calculation has to be applied to convert the vacuum reading to absolute pressure in psia. First, the gauge's vacuum measurement of 0.7 in. Hg has to be converted to in. Hg absolute. This is done by subtracting the vacuum gauge reading from the standard atmospheric pressure of 29.92 in. Hg. The result is then divided by 2.036 to convert in. Hg to psi. There are 2.036 in. Hg in every 1 psi.*

Notice that the compression ratio for the R-134a system is higher than that for the R-404A system even though both systems have the same condensing and evaporating temperatures of 125°F and −16°F, respectively. The compression ratio for the R-134a system is higher because of the higher condensing pressure and lower evaporating pressure associated with R-134a at these temperature ranges. Either an increase in head pressure or a decrease in suction pressure will cause higher compression ratios. Any time a system has high compression ratios the compressor's discharge temperature will also be elevated. This is because of the higher heat of compression during the compression stroke associated with higher compression ratios. When compression ratios are high, more energy is needed to raise the pressure of the suction gases to the discharge pressure. This means more heat is generated as heat of compression during the compression stroke.

Compression ratios are used to compare pumping conditions for a compressor. When compression ratios become too high—above approximately 12:1 for a hermetic reciprocating compressor—the refrigerant gas temperature leaving the compressor rises to the point that oil for lubrication may become overheated. Overheated oil may turn to carbon and create acid in the system. Compression ratios can be reduced by two-stage compression. One compressor discharges into the suction side of the second compressor. In **Figure 23.3**, the first-stage compressor has a compression ratio of 3.2:1 (114.7 psia ÷ 35.7 psia), and the second-stage compressor has a compression ratio of 1.6:1 (183.7 psia ÷ 114.7 psia). Both of these compression ratios are acceptable and will result in good compressor efficiencies and low compressor discharge temperatures. However, if only one compressor were used, the compression ratio would be 5.14:1. Even though a compression ratio of 5.14:1 is acceptable, the compressor would be less efficient and have higher discharge temperatures than if two compressors were used. The previous example is for illustrative purposes only. Two-stage or compound compression is not generally used until the compression ratio has exceeded 10:1. This is often experienced with low-temperature freezing applications in commercial and industrial storage facilities.

Figure 23.3 Two-stage compression. Notice that the second stage of the compressor is smaller than the first stage.

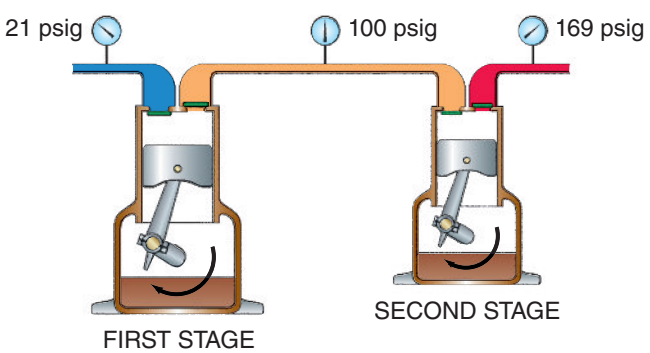

Figure 23.4 The refrigerant entering the compressor is called "heat-laden" because it contains the heat that was picked up in the evaporator from the boiling process. The gas is cool but full of heat that was absorbed at a low level of pressure and temperature. When this gas is compressed in the compressor, the heat concentrates. In addition to the heat absorbed in the evaporator, the act of compression also converts some energy to heat.

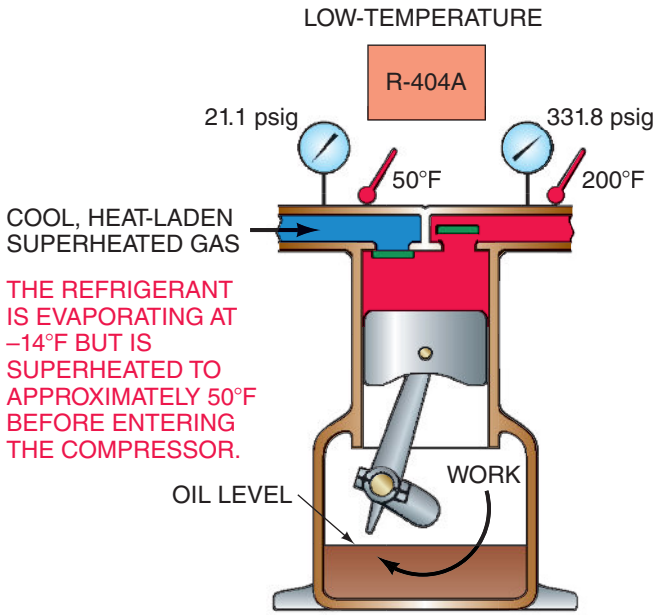

Cool refrigerant passes through the suction valve of the compressor to fill the cylinders. This cool vapor contains the heat absorbed in the evaporator. The compressor pumps this heat-laden vapor to the condenser so that can be ejected from the system. The vapor leaving the compressor can be very warm. With a discharge pressure of 169 psig, the discharge line at the compressor could easily be 200°F or higher. **SAFETY PRECAUTION:** *Do not touch the compressor discharge line—you can burn your fingers.* • The vapor is compressed with the heat from the suction gas concentrated in the gas leaving the compressor, **Figure 23.4**.

23.2 TYPES OF COMPRESSORS

Five major types of compressors are used in the refrigeration and air-conditioning industry. These are the reciprocating, screw, rotary, scroll, and centrifugal. The reciprocating compressor, **Figure 23.5**, is used most frequently in small- and medium-sized commercial refrigeration systems and will be described in detail in this unit. The screw compressor, **Figure 23.6**, is used in large commercial and industrial systems and will be described only briefly here because it is dealt with later in this text. The rotary, **Figure 23.7**, and the scroll, **Figure 23.8**, along with the reciprocating compressor, are used in residential and light commercial air-conditioning. Centrifugal compressors, **Figure 23.9**, are used extensively for air-conditioning in large buildings and are described in Section 48.7, "Fan Section."

THE RECIPROCATING COMPRESSOR

Reciprocating compressors are categorized by their housing and by their drive mechanisms. The two housings are **open** and **hermetic**, **Figure 23.10**. "Hermetic" refers to the type of housing that contains the compressor and is either fully welded, **Figure 23.11**, or serviceable or semihermetic, **Figure 23.10(B)**. The drive mechanisms may be either inside the shell or outside the shell. A hermetic compressor has a direct-drive mechanism. The same shaft drives the compressor and motor inside the compressor shell.

FULLY WELDED HERMETIC COMPRESSORS. When a welded hermetic compressor is manufactured, the motor and compressor are contained inside a single shell that is welded

(B)

closed, **Figure 23.11**. This unit is sometimes called the *tin can* compressor because it cannot be serviced without cutting open the shell. Characteristics of the fully welded hermetic compressor are as follows:

1. The only way to access the inside of the shell is by cutting the shell open.
2. Hermetic compressors can only be opened by the very few companies that specialize in this type of work. Otherwise, unless the manufacturer wants the compressor back for examination, it is a throwaway compressor.
3. The motor shaft and the compressor crankshaft are one shaft.
4. The hermetic compressor is usually considered to be a low-side device because the suction gas is vented to the whole inside of the shell, which includes the crankcase. The discharge (high-pressure) line is normally piped to the outside of the shell, so the shell only has to be rated at the low-side working-pressure value.
5. Generally, these compressors are cooled with suction gas.

Figure 23.11 The welded hermetic compressor is typical of smaller compressors, from fractional horsepower to about 50 hp. In most welded hermetic compressors, the suction line is usually piped directly into the shell and is open to the crankcase. The discharge line is normally piped from the compressor inside the shell to the outside of the shell. The compressor shell is typically thought of as a low-side component.

Source: Bristol Compressors, Inc.

6. Hermetic compressors usually have a pressure lubrication system, but smaller hermetics are splash lubricated.
7. The combination motor and crankshaft are customarily in a vertical position with a bearing at the bottom of the shaft next to the oil pump. The second bearing is located about halfway up the shaft between the compressor and the motor.
8. The pistons and rods work outward from the crankshaft, so they are working at a 90° angle in relation to the crankshaft, **Figure 23.12**.

SERVICEABLE HERMETIC COMPRESSORS. The motor and compressor of a serviceable hermetic (semihermetic) compressor are contained inside a single shell that is bolted together. This unit can be serviced by removing the bolts and opening the shell at the appropriate place, **Figure 23.13**. Following are the characteristics of the serviceable hermetic compressor:

1. The unit is bolted together at locations that facilitate service and repair. Gaskets separate the mating parts connected by the bolts.
2. The housing is normally cast iron and may also have a steel housing fastened to it. These compressors are usually heavier than the fully welded type.
3. The motor and crankshaft combination are similar to the motor and crankshaft in the fully welded compressor except that the crankshaft is usually horizontal.

Figure 23.12 The internal workings of a welded hermetic compressor.

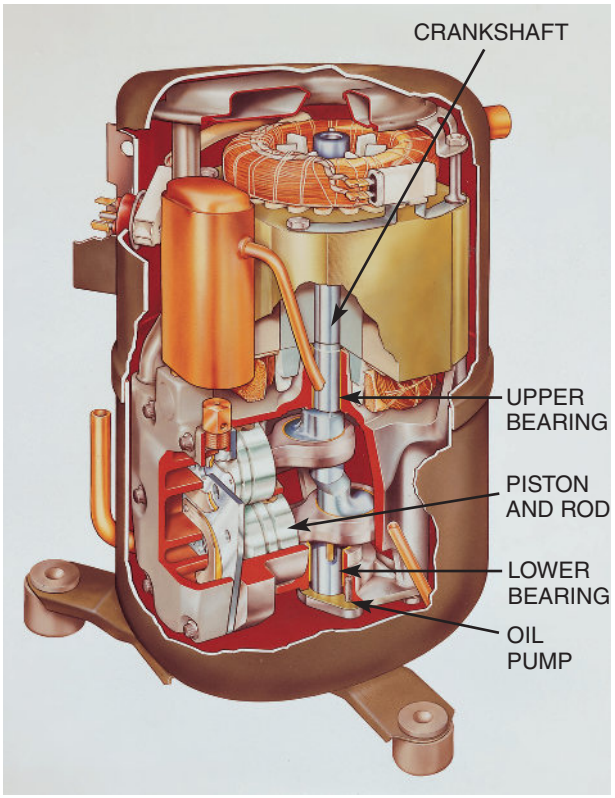

Figure 23.13 A serviceable hermetic (semihermetic) compressor designed in such a manner that it can be serviced in the field.

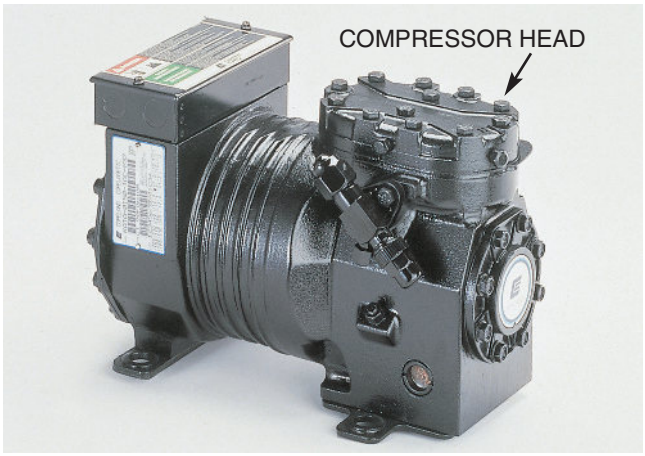
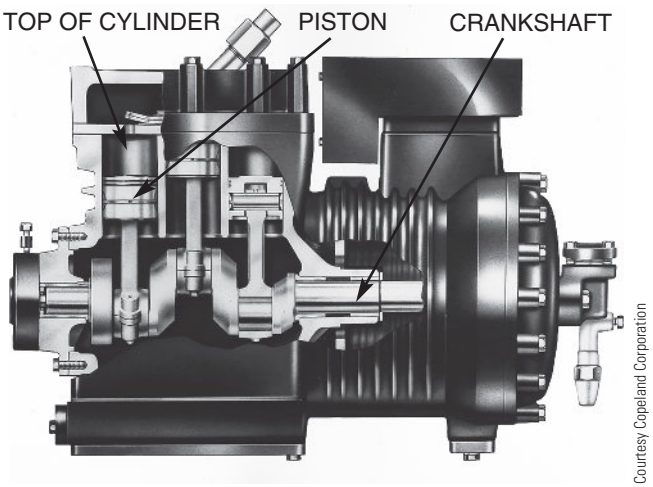


4. Smaller compressors of this type generally use a splash lubrication system; larger compressors use pressure lubrication.
5. Serviceable compressors are often air-cooled and can be identified by the fins in the casting or extra sheet metal on the outside of the housing that give the shell more surface area.

Figure 23.14 The working parts of a serviceable hermetic compressor. The crankshaft is in the horizontal position, and the rods and pistons move in and out from the center of the shaft. The oil pump is on the end of the shaft and draws the oil from the crankcase at the bottom of the compressor.



6. The piston heads are normally at the top or near the top of the compressor and work up and down from the center of the crankshaft, **Figure 23.14**.

OPEN-DRIVE COMPRESSORS. Open-drive compressors are manufactured in two styles: belt drive and direct drive, **Figure 23.15**. Any compressor with the drive on the outside of the casing must have a shaft seal to keep the refrigerant from escaping to the atmosphere. This seal arrangement has not changed much in many years. Open-drive compressors are bolted together and may be disassembled for servicing the internal parts.

BELT-DRIVE COMPRESSORS. The first type of compressor, the belt-drive compressor, is still used to some extent. In the belt-drive unit the motor and its shaft are beside the compressor and parallel to the shaft of the compressor. Notice that since the compressor and motor shaft are parallel, their sideways pull tightens the belts. This puts strain on both shafts and requires the manufacturer to compensate for the strain in the shaft bearings. **Figure 23.16** indicates correct and incorrect alignments of belt-drive compressors and motors.

DIRECT-DRIVE COMPRESSORS. The direct-drive compressor differs from the belt-drive in that the compressor shaft is placed end to end with the motor shaft. The coupling between the shafts has a small amount of flexibility, so the two shafts have to be in very good alignment to run correctly, **Figure 23.17**.

THE ROTARY SCREW COMPRESSOR

The rotary screw compressor is another mechanical method of compressing refrigerant gas and is used in larger installations. Instead of a piston and cylinder, this compressor

Figure 23.15 (A) A belt-drive compressor. (B) A direct-drive compressor. The belt-drive compressor may have different speeds, depending on the pulley sizes. The direct-drive compressor turns at the speed of the motor because it is attached directly to the motor. Common speeds are 1750 rpm and 3450 rpm. The coupling between the motor and the compressor is slightly flexible.

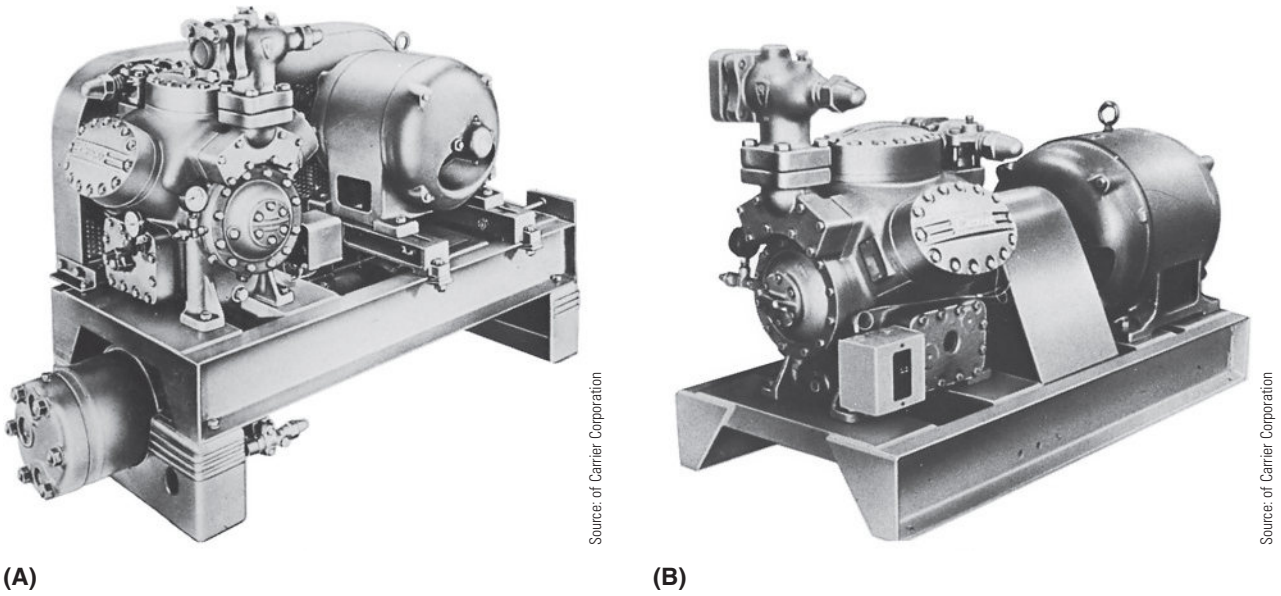

Figure 23.16 Correct and incorrect alignments of a belt-drive compressor with its motor. The belts used in a multiple-belt installation are matched at the factory for the correct length.

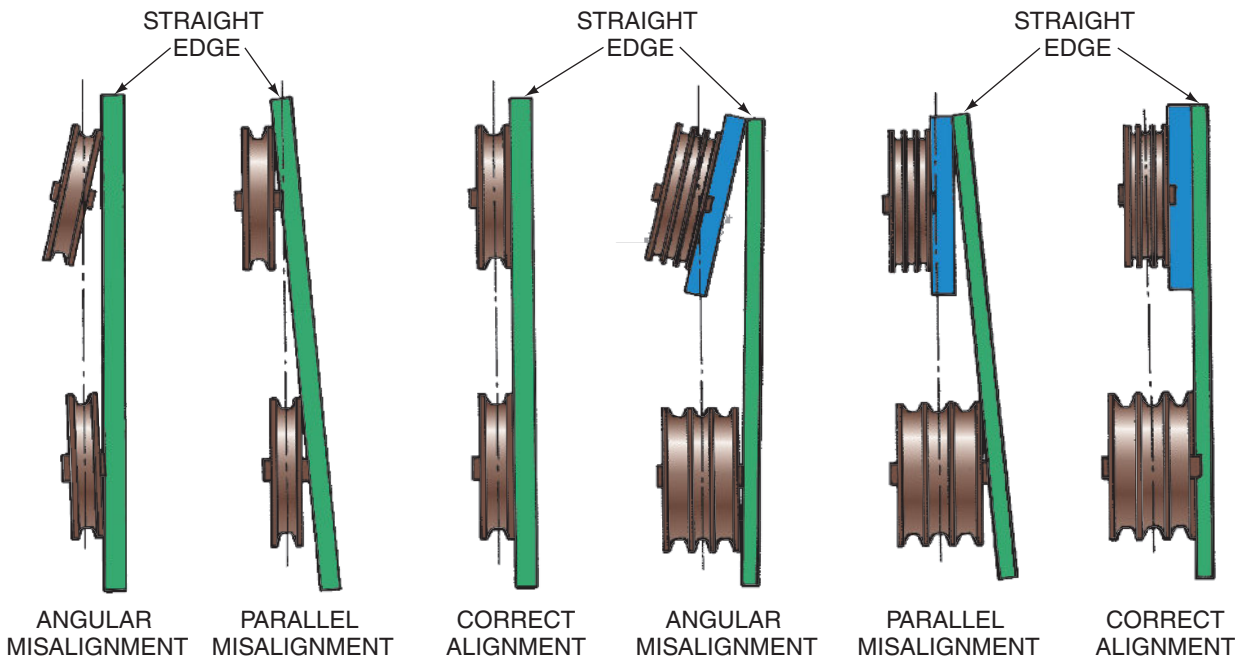

uses two tapered, machined, screw-type matching gears that squeeze the refrigerant vapor from the inlet to the outlet, **Figure 23.18**. The rotary screw compressor has an open motor instead of the hermetic design. A shaft seal traps the refrigerant in the compressor housing where the rotating shaft leaves the housing. A flexible coupling is used to connect the motor shaft to the compressor shaft to prevent minor misalignment from causing seal or bearing damage.

Screw-compressors are used in large systems (see **Figure 23.6**). The refrigerant may be any of the common refrigerants. The operating pressure on the low and high sides of the system are the same as for a reciprocating system in a similar application.

Figure 23.17 (A) and (C) Alignment of a direct-drive compressor and motor. The alignment must be within the compressor manufacturer's specifications. (B) These compressors turn so fast that if the alignment is not correct, a seal or bearing will soon fail. When the correct alignment is attained, the compressor and motor are normally fastened permanently to the base on which they are mounted. In larger installations, the motor and compressor can be rebuilt in place.

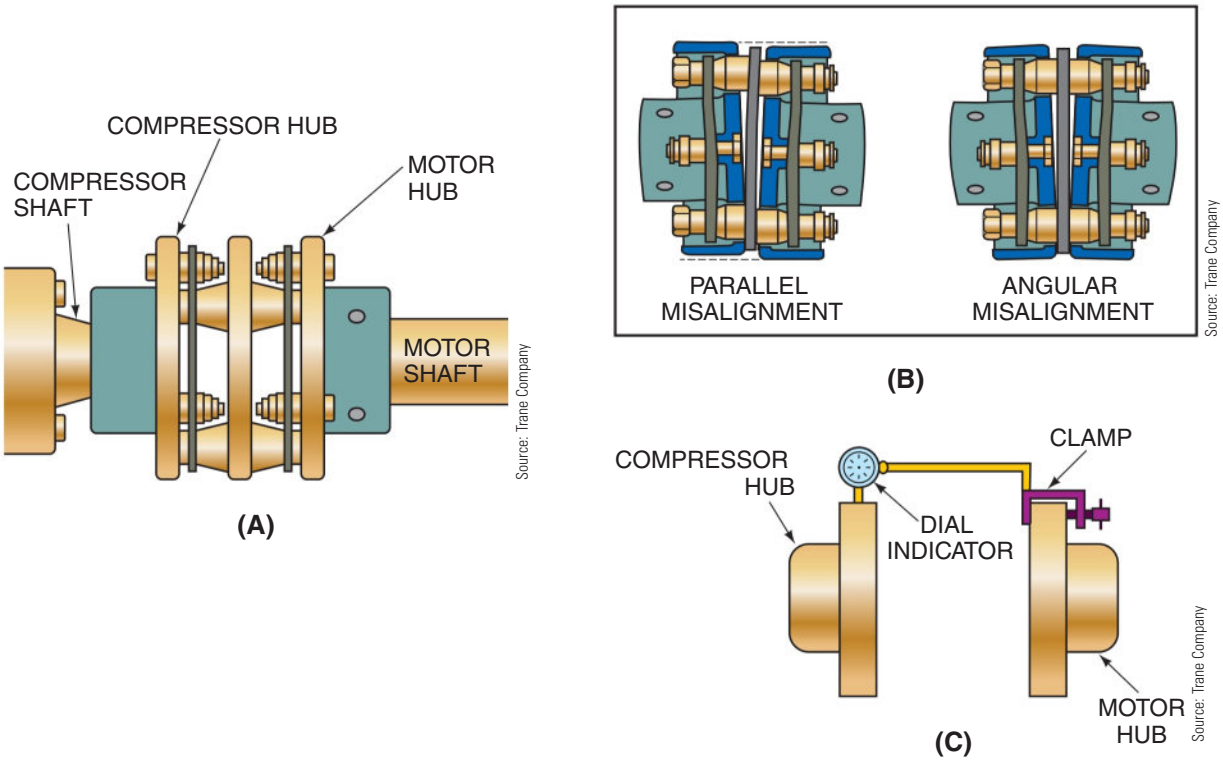

Figure 23.18 Tapered, machined, screw-type gears in a screw compressor.

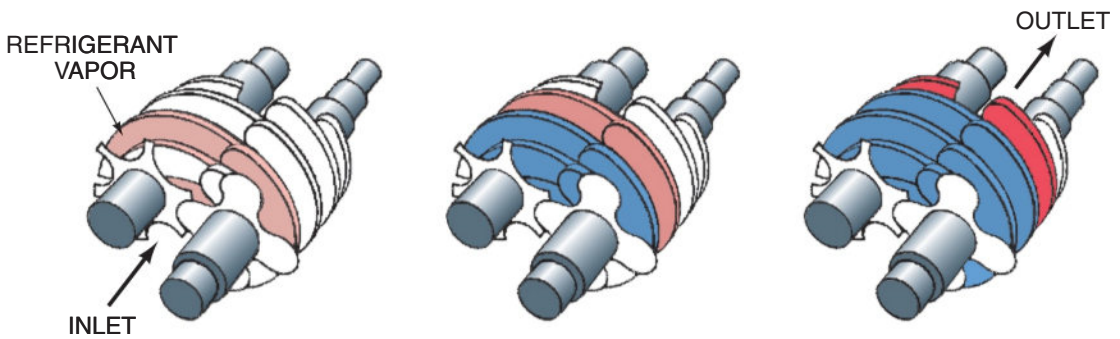

23.3 RECIPROCATING COMPRESSOR COMPONENTS

Reciprocating compressors house a vast array of moving parts. Most of these component parts have been precision machined with very tight tolerances for proper compressor efficiency and operation. Following is a list and description of the major component parts of a reciprocating compressor.

THE CRANKSHAFT

The *crankshaft* of a reciprocating compressor transmits the circular motion of the rods into a back-and-forth (reciprocating) motion for the pistons, **Figure 23.19**. Crankshafts are normally manufactured of cast iron or soft steel. They can be cast (molten metal poured into a mold) into a general shape and machined into an exact size and shape for the application. In this case, the shaft is made of cast iron, **Figure 23.20**. The machining process is critical because the

Figure 23.19 The relationship of the pistons, rods, and crankshaft.

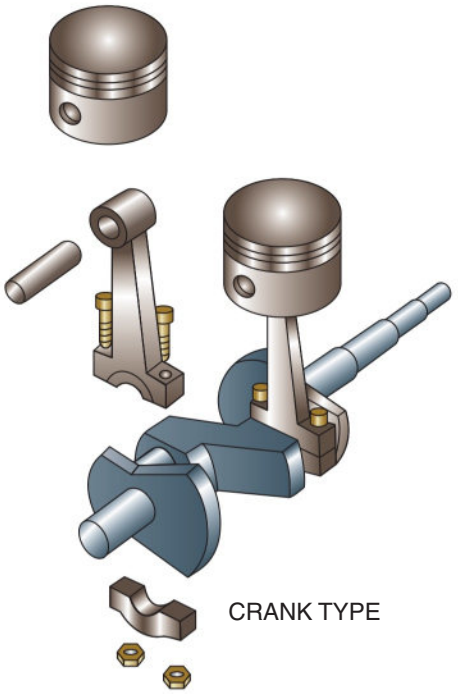

Figure 23.20 Crankshafts are cast into a general shape and machined to the correct shape in a machine shop. This crankshaft is in an open-drive compressor but is also typical of hermetic compressors.

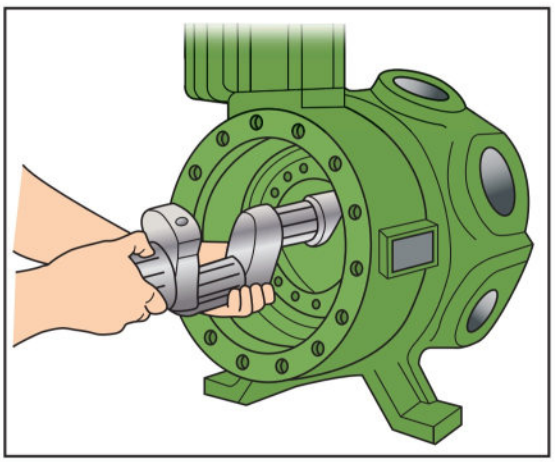
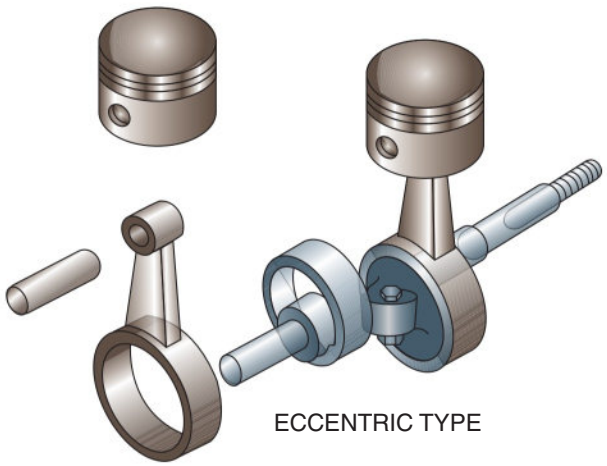


Based on Trane Company 2000.

throw (the off-center part where the rod fastens) does not turn in a circle (in relationship to the center of the shaft) when placed in a lathe. The machinist must know how to work with this type of setup. The off-center shafts normally have two main-bearing surfaces in addition to the off-center rod-bearing surfaces: One is on the motor end of the shaft, and one is on the other end. The bearing on the motor end is normally the largest because it carries the greatest load.

Some shafts are straight and have a cam-type arrangement called an **eccentric**. This allows the shaft to be manufactured

Figure 23.21 This crankshaft obtains the off-center action with a straight shaft and an eccentric. The eccentric is much like a cam lobe. The rods on this shaft have large bottom throws and slide off the end of the shaft. This means that to remove the rods, the shaft must be taken out of the compressor.



straight and from steel. The shaft may not be any more durable than the cast-iron shaft, but it is easier to machine. The eccentrics can be machined off-center to the shaft to accomplish the reciprocating action, **Figure 23.21.** Notice that the rod for the eccentric shaft is different because the end of the rod has to fit over the large eccentric on the crankshaft.

All of these shafts must be lubricated. Smaller compressors using the splash system may have a catch basin to catch oil and cause it to flow down the center of the shaft, **Figure 23.22.** When the compressor runs, the oil is then slung to the outside of the crankshaft surface. To be properly lubricated, compressors with splash-type lubrication systems must usually rotate in only one direction. This causes the oil to move to

Figure 23.22 A splash lubrication system that splashes oil up onto the parts.

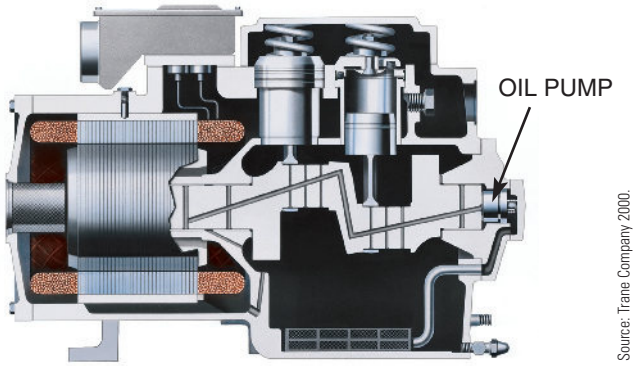
Figure 23.23 A crankshaft drilled so that an oil pump can force the oil up the shaft to the rods, then up the rods to the wrist pins. Magnetic elements are sometimes placed along the passage to capture iron filings.



Source: Trane Company 2000.

the other parts, such as the rods on both ends. Some shafts are drilled and lubricated by a pressure lubrication system. These compressors have an oil pump mounted on the end of the crankshaft that turns with the shaft, **Figure 23.23.** **NOTE:** *There is no pressure lubrication when the compressor first starts. The compressor must be running up to speed before the lubrication system is fully effective.* •

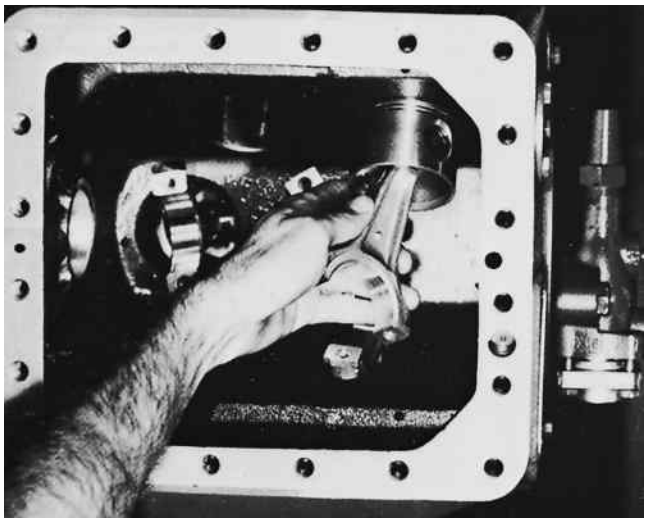
Because some compressors have vertical shafts and some have horizontal, manufacturers have been challenged to provide for proper lubrication where needed. You may have to consult the compressor manufacturer for questions about a specific application.

CONNECTING RODS

Connecting rods connect the crankshaft to the piston. These rods are normally made in two styles: one fits the crankshaft with off-center throws and the other fits the eccentric crankshaft, **Figure 23.19** and **Figure 23.21.** Rods can be made of several different metals, such as iron, brass, and aluminum. The design of the rod is important because it takes a lot of the load in the compressor. If the crankshaft is connected directly to the motor and the motor is running at 3450 rpm, the piston at the top of the rod is changing direction 6900 times per minute. The rod is the connection between this piston and the crankshaft and is the link between the changes of direction.

Rods with large holes in the shaft end are for eccentric shafts. They cannot be taken off with the shaft in place. The shaft has to be removed to take the piston out of the cylinder. Rods with smaller holes are for the off-center shafts; these are split and have rod bolts, **Figure 23.24.** These rods can be separated at the crankshaft, and the rod and piston can be removed with the crankshaft in place. They are small on the piston end and fasten to the piston differently than rods made for eccentric shafts. They normally have a

Figure 23.24 The service technician is removing the rods from a compressor. The rods have split bottoms.



Source: Trane Company 2000.

connector called a *wrist pin* that slips through the piston and the upper end of the rod. This almost always has a *snap-ring* to keep the wrist pin from sliding against the cylinder wall, **Figure 23.25.**

THE PISTON

The **piston** is the part of the cylinder assembly exposed to the high-pressure gas during compression. During the upstroke, pistons have high-pressure gas on top and suction or low-pressure gas on the bottom. They have to slide up and down

Figure 23.25 The end of the rod that fits into the piston. The wrist pin holds the rod to the piston while allowing the pivot action that takes place at the top of the stroke. The wrist pin is held secure in the piston with snaprings.

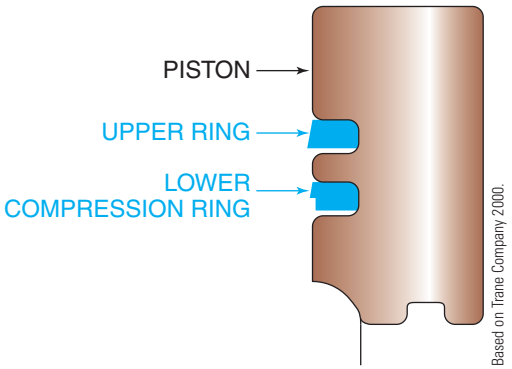
Figure 23.26 The piston rings for a refrigeration compressor resemble the rings used on automobile pistons.



in the cylinder in order to pump and must have some method of preventing the high-pressure gas from slipping by to the crankcase. Piston rings like those used in automobile engines are used on the larger pistons and are of two types: compression and oil. Smaller compressors use the oil on the cylinder walls as a seal. A cross-sectional view of these rings can be seen in **Figure 23.26.**

REFRIGERANT CYLINDER VALVES

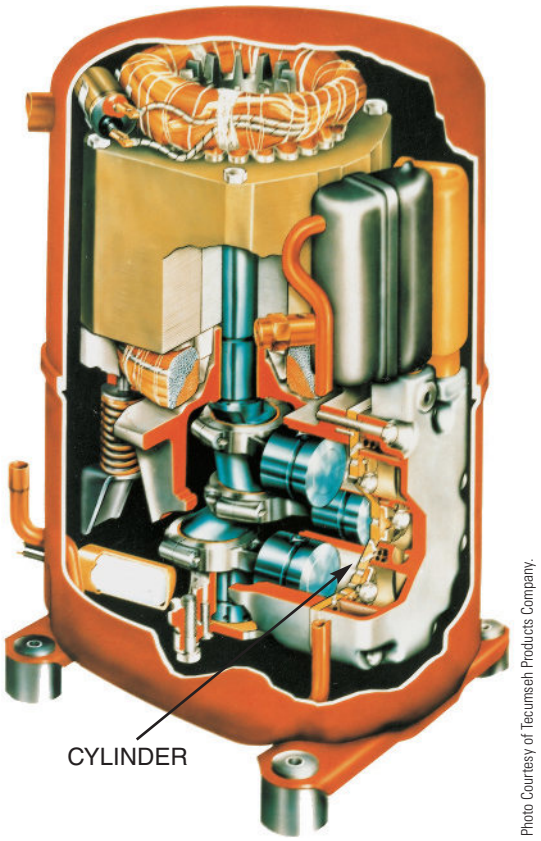
The valves in the top of the compressor determine the direction the gas entering the compressor will flow. (See the cutaway view of a compressor cylinder in **Figure 23.27.**) The valves are made of very hard steel. The majority of the valves on the market are either *ring valves* or **flapper (reed) valves**. They serve both the suction and the discharge ports of the compressor. The ring valve is circular and has springs under it. If ring valves are used for the suction and the discharge, the larger valve will be the suction valve, **Figure 23.28.** Flapper valves have been made in many different shapes. Each manufacturer has its own design, **Figure 23.29.**

THE VALVE PLATE

The **valve plate** holds the suction and discharge flapper valves. It is located between the head of the compressor and the top of the cylinder wall, **Figure 23.30.** Many different methods have been used to hold the valves in place without taking up any more space than necessary. The bottom of the plate actually protrudes into the cylinder. Any volume of gas that cannot be pumped out of the cylinder because of the valve design will reexpand on the downstroke of the piston. This makes the compressor less efficient.

There are other versions of the crankshaft and valve arrangements than those listed here, but they are not used widely enough in the refrigeration industry to justify coverage here. If you need more information, contact the manufacturer.

Figure 23.27 This cutaway view of a compressor shows a typical cylinder.



THE HEAD OF THE COMPRESSOR

The component that holds the top of the cylinder and its assembly together is the *head*. Sitting on top of the cylinder, it contains the high-pressure gas from the cylinder until it moves into the discharge line. The head often contains the suction chamber, which is separated from the discharge chamber by a partition and gaskets. Heads have many different design configurations, but they all need to accomplish two things: hold the pressure in and hold the valve plate on the cylinder. In some welded hermetic compressors, the heads are made of steel; they are made of cast iron in serviceable hermetic compressors. These cast iron heads may be in the moving airstream and have fins to help dissipate the heat from the top of the cylinder, **Figure 23.31.**

MUFFLERS

Mufflers are used in many fully hermetic compressors to muffle compressor pulsation noise. Audible suction and discharge pulsations can be transmitted into the piping if they are not muffled. Mufflers must be designed to have a low pressure drop and still muffle the discharge pulsations, **Figure 23.32.**

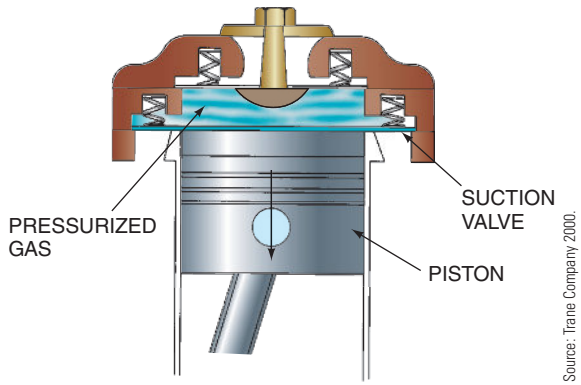
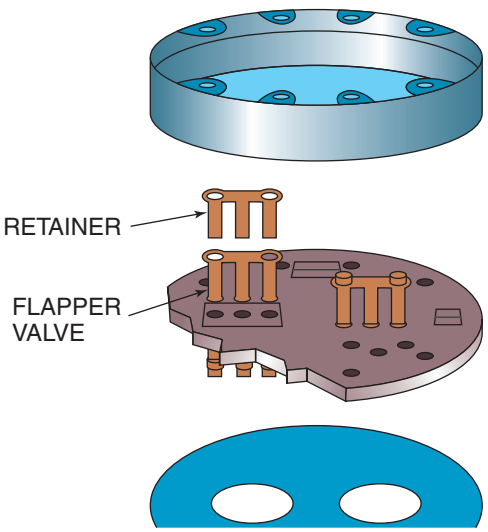
(B)



(D)

Figure 23.29 Reed or flapper valves held down on one end. This provides enough spring action to close the valve when reverse flow occurs.



THE COMPRESSOR HOUSING

The *housing* holds the compressor and sometimes the motor. It is made of stamped steel for the welded hermetic compressor and of cast iron for serviceable hermetic compressors.

The welded hermetic compressor is designed so that the compressor shell is under low-side pressure; it will often have a working pressure of 150 psig. Many compressors manufactured today must use the newer refrigerants that operate under much higher pressure; therefore, compressor shell working pressures are much higher. **SAFETY PRECAUTION:** *The technician should always check the working pressures of all system parts before applying high pressures for leak checking.* • The compressor is mounted inside the shell, and the discharge line is normally piped to the outside of the shell. This means the shell does not need to have a test pressure as high as the high-side pressure. A cutaway view of a hermetic compressor inside a welded shell and the method used to weld the shell together are shown in **Figure 23.27.**

(D)

The two methods used to mount the compressor inside the shell are *rigid mounting* and *spring mounting*. Rigid-mounted compressors were used for many years. The compressor shell was mounted on external springs that had to be bolted tightly for shipment. The springs were supposed to be loosened when the compressor was installed, **Figure 23.33**, but occasionally they were not, and the compressor vibrated because, without the springs, it was mounted rigidly to the condenser casing. External springs can also rust, especially where there is a lot of salt in the air.

In internal spring-mounting, compressors are actually suspended from springs inside the shell. There are ways of keeping these compressors from moving too much during shipment. Sometimes a compressor will come loose from one or two of the internal springs. When this happens, it will run and pump normally just like it is supposed to but will make a noise on start-up or shutdown or both. If the compressor comes off the springs and they are internal, there is nothing that can be done to make a repair in the field, **Figure 23.34**.

COMPRESSOR MOTORS IN A REFRIGERANT ATMOSPHERE

MOTORS IN A REFRIGERANT ATMOSPHERE. Special consideration must be given to compressor motors operating inside a refrigerant atmosphere. Motors for hermetic compressors

differ from standard electric motors. The materials used to make them are not the same as those that would be used for a fan or pump motor to be run in air. Hermetic motors must be manufactured of materials compatible with the system refrigerants. For instance, rubber cannot be used because the refrigerant would dissolve it. The motors are assembled in a very clean atmosphere and kept dry. When a hermetic motor malfunctions, it cannot be repaired in the field.

MOTOR ELECTRICAL TERMINALS. There must be some conductor to carry the power from the external power supply to the internal motor, and power must be carried through the compressor housing in a way that prevents the refrigerant from leaking. The connection also has to insulate the

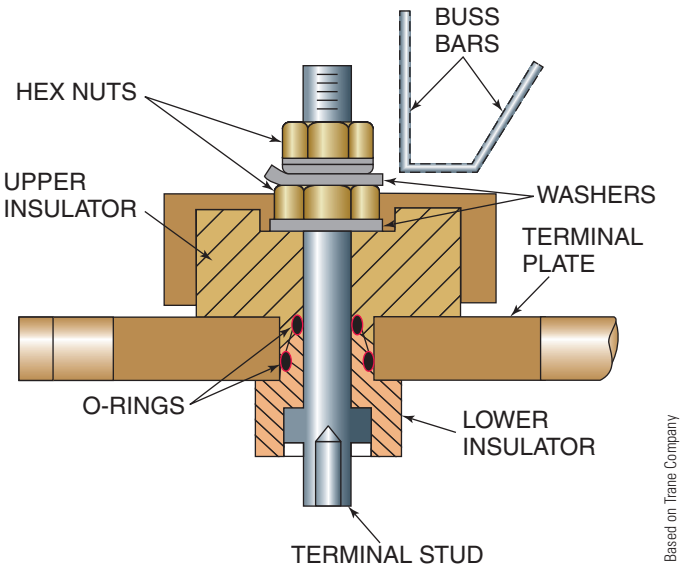
Figure 23.35 Motor terminals. The power to operate the compressor is carried through the compressor shell but must be insulated from the shell. This is a fiber block used as the insulator. O-rings keep the refrigerant in.



electric current from the compressor shell. On smaller compressors, terminals are sometimes fused glass with a terminal stud through the middle. When large terminals are required, the terminals are sometimes placed in a fiber block that is sealed with an O-ring, **Figure 23.35.** A fused-glass terminal block is hard to repair. It will stand more heat, but there is a limit to how much. The O-ring and fiber type of terminal board can tolerate less heat, but when they are damaged, they can be replaced with new parts. Refrigerant loss can result, however, before the problem is discovered. **NOTE:** *Care must be taken with electrical terminals to prevent overheating (due to loose electrical connections). Should the terminal overheat, a leak could occur.* •

INTERNAL MOTOR PROTECTION DEVICES. Internal overload protection devices in hermetic motors protect the motor from overheating. These devices are embedded in or near the windings and are wired in two different ways. One style breaks the line circuit inside the compressor. Because it is internal and carries the line current, this style is limited to smaller compressors. It has to be enclosed to prevent the electrical arc from affecting the refrigerant, **Figure 23.36(A).** If a contact in this line remains open, the compressor cannot be restarted. The compressor would have to be replaced.

Figure 23.36(B) illustrates a three-phase internal thermal overload. All three of the overload contacts will open at the same time if a motor overheating problem occurs. This prevents single phasing of the three-phase motor. The overload device is located in the compressor's shell, usually in the motor barrel compartment over the motor windings. **Figure 23.36(C)** is a photo of a three-phase overload protector that has been taken out of a working three-phase motor.

Figure 23.36 (A) An internal compressor overload protection device that breaks the line circuit. Because this set of electrical contacts is inside the refrigerant atmosphere, they are enclosed inside a hermetic container of their own. If the electrical arc were allowed inside the refrigerant atmosphere, the refrigerant would deteriorate in the vicinity of the arc. (B) A three-phase wye-wound motor with internal thermal overload protection. All three internal overload contacts will open at the same time to prevent single phasing of the three-phase motor.

(C)

Figure 23.36(D) shows a three-phase motor with internal thermistor protection. Thermistors are resistors that vary their resistance according to their temperature. If a motor overheating problem occurs, the thermistors will sense the heat, change resistance, and relay this change in resistance to a solid-state motor protection module. The thermistor circuit is usually a 24-V control circuit. The motor protection module controls the coil of the contactor or motor starter and can turn the motor off when necessary for a cool-down period. **Figure 23.36(E)** is a wiring diagram of a typical electronic motor protection package showing the motor contactor and electronic protection module.

Another type of motor overload protection device breaks the control circuit. This is wired from the outside of the compressor to the control circuit. If the pilot-duty type wired to the outside of the compressor were to remain open, an external overload device could be substituted.

THE SERVICEABLE HERMETIC COMPRESSOR. The serviceable hermetic compressor motor is rigidly mounted to the shell, and the compressor must be externally mounted on springs or other flexible mounts to prevent vibration. The compressor usually has a cast-iron shell and is considered a low-side device, **Figure 23.37.** Because of the piping arrangement in the head, the discharge gas is contained either under the head or is expelled out the discharge line. The serviceable hermetic design is used exclusively for larger compressor sizes because it can be rebuilt. The compressor components are much the same as the components in the welded hermetic type.

OPEN-DRIVE COMPRESSOR. Open-drive compressors are manufactured with the motor external to the compressor shell. The shaft protrudes through the casing to the outside, where either a pulley or a coupling is attached. The motor is either mounted end to end with the compressor shaft or alongside the compressor and uses belts to turn the compressor. This compressor is normally heavy duty in nature and must be mounted firmly to a foundation.

THE SHAFT SEAL

The pressure inside a compressor crankcase can be either a vacuum (below atmosphere) or a positive pressure. If the unit is an extra-low-temperature unit using R-12 as the refrigerant, the crankcase pressure could easily be a vacuum, so if the shaft seal were to leak, the atmosphere would enter the crankcase.

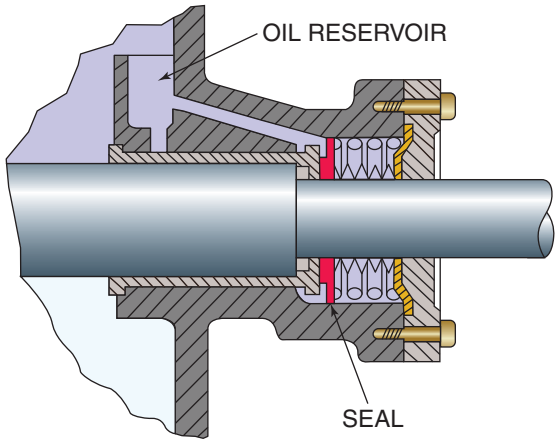
Figure 23.38 The shaft seal is responsible for keeping the refrigerant inside the crankcase and allowing the shaft to turn at high speed. This seal must be installed correctly. When the seal is installed on a belt-drive compressor, the belt tension is important. When it is installed on a direct-drive compressor, the shaft alignment is important.



When the compressor is sitting still, a high positive pressure could be exerted on it. For example, when R-502 or R-404A is used and the system is off for extended periods (the whole system may get up to 100°F in a hot climate), the crankcase pressure may go over 200 psig. The crankcase shaft seal must be able to hold refrigerant inside the compressor under all of these conditions and while the shaft is turning at high speed, **Figure 23.38.**

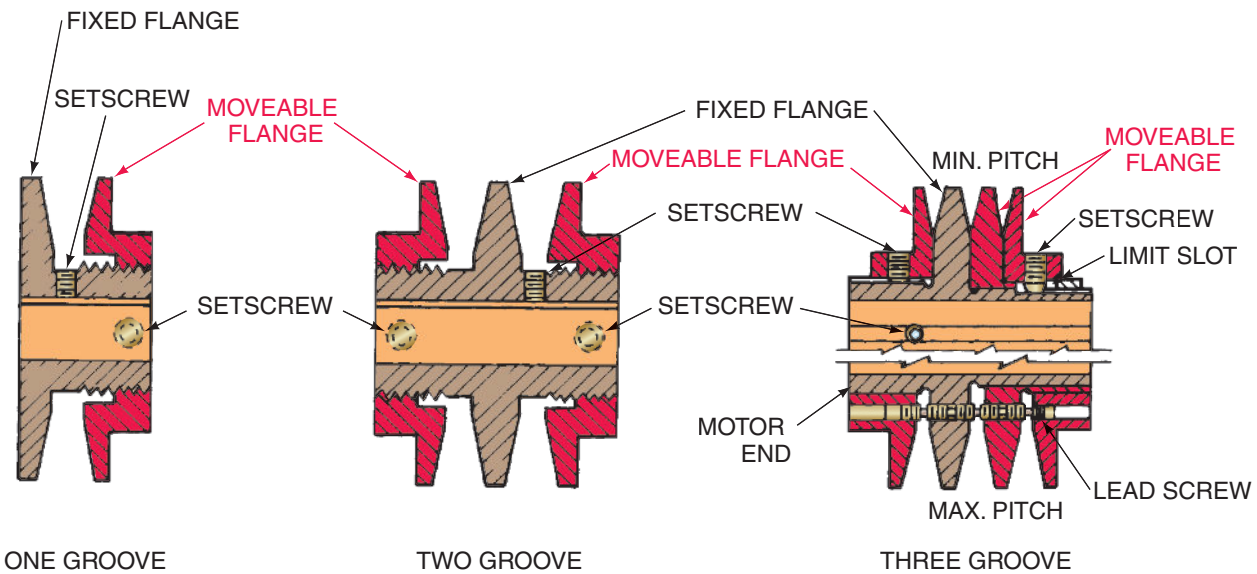
The shaft seal has a rubbing surface designed to keep the refrigerant and the atmosphere separated. This surface is usually made of a carbon or ceramic material that rubs against a steel surface. If assembled correctly, these two materials can rub together for years and not wear out. Correct assembly normally involves aligning the shafts correctly on a system where the bearings are in good working order. The belts must also have the correct tension if the unit is a belt driven. If the unit is direct drive, the shafts have to be aligned according to the manufacturer's instructions.

23.4 BELT-DRIVE MECHANISM CHARACTERISTICS

A belt-drive compressor has the motor mounted at the side of the compressor and a pulley mounted on the motor as well as on the compressor. The pulley on the motor is called the *drive pulley,* and the pulley on the compressor is called the *driven pulley.* The drive pulley is sometimes adjustable, which allows the compressor speed to be adjusted. The drive pulley can also be changed to a different size to vary the compressor speed. This can be advantageous when a compressor is too large for a job (too much capacity) and needs to be slowed down to compensate. The compressor can also be speeded up for more capacity if the motor has enough horsepower in reserve (if the motor is not already running at maximum horsepower). If a change in pulley size is needed, consult the compressor manufacturer to be sure that the design limits of the compressor are not exceeded. Different pulleys are shown in **Figure 23.39.**

The formula for determining the size of the drive pulley is determined using information gathered from the existing system. The motor speed is normally fixed, 1725 or 3450 rpm, and the pulley (flywheel) on the compressor is also normally a fixed size. The only variable is the drive pulley. A typical problem may be a motor with an rpm of 1725 and a drive pulley of 4 in. used to drive a compressor at 575 rpm

Figure 23.39 Different pulleys used on belt-drive compressors. They are single-groove and multiple-groove pulleys with different belt widths. Some pulleys are adjustable in order to change the compressor speed.



Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

with a pulley size of 12 in. It is desirable to reduce the compressor speed to 500 rpm to reduce the capacity. What would the new drive pulley size be? The formula is:

$$\text{Drive Pulley Size} \times \text{Drive Pulley rpm} =$$

$$\text{Driven Pulley Size} \times \text{Driven Pulley rpm}$$

or

$$\text{Pulley 1} \times \text{rpm 1} = \text{Pulley 2} \times \text{rpm 2}$$

Solve the problem for pulley 1, restated as:

$$\text{Pulley 1} = \frac{\text{Pulley 2} \times \text{rpm 2}}{\text{rpm 1}}$$

$$\text{Pulley 1} = \frac{12 \text{ in.} \times 500 \text{ rpm}}{1725 \text{ rpm}}$$

$$\text{Pulley 1} = 3.48 \text{ or } 3\ 1/2 \text{ in.}$$

Most compressors are not designed to operate over a certain rpm, information that is available from the compressor manufacturer. A pulley supplier can help choose the correct pulley size. Belt sizes also must be calculated. Choosing the correct belts and pulleys is important and should be done by an experienced person.

When adjusting or repairing belt-drive compressors, the compressor and motor shafts must be in correct alignment and the proper tension must be applied to the belts. The motor base and the compressor base must also be tightened rigidly so that no dimensions will vary during operation. Several belt combinations may have to be considered if the compressor drive mechanism has multiple belts, **Figure 23.40.** Even if the compressor is small and has a single belt, there are different types of belts to consider. The width of the belt, the grip type, and the material all have to be taken into account. Multiple belts have to be bought as matched sets. For example, if a particular compressor and motor drive has four V belts, which are of B width and are 88 in. long, you should order four

Figure 23.40 A multiple-belt compressor.

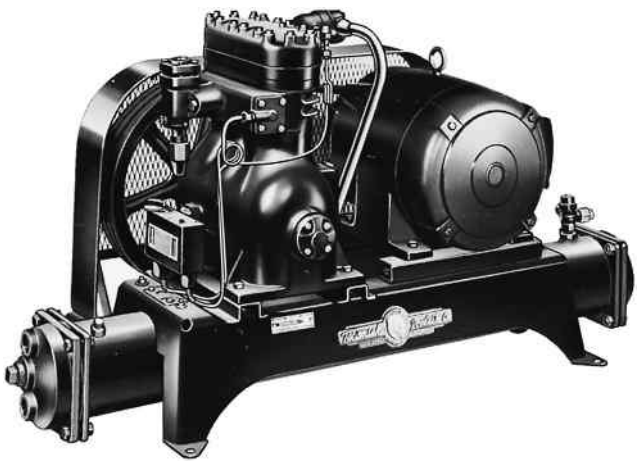


Photo Courtesy of Tecumseh Products Company.

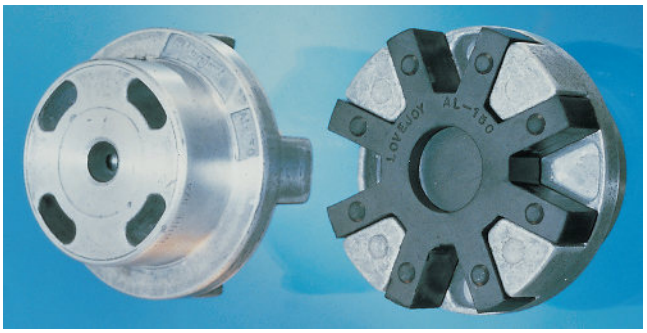
Figure 23.41 A flexible coupling. An extensive procedure is used to obtain the correct shaft alignment. This must be done, or bearings and seal will fail prematurely.



Source: Lovejoy, Inc.

88-in. belts of B width that are factory matched for the exact length. These are called *matched belts* and must be used on multiple-belt installations.

23.5 DIRECT-DRIVE COMPRESSOR CHARACTERISTICS

The direct-drive compressor is limited to the motor speed that the drive motor is turning. In this type of installation the motor and compressor shafts are end to end. These shafts have a slightly flexible coupling between them but must be in very close alignment, or the bearings and seal will fail prematurely, **Figure 23.41.** This compressor and motor combination is mounted on a common rigid base.

Both the motor and compressor are customarily manufactured so that they can be rebuilt in place. Thus, once the shafts are aligned, the shell of the motor and the shell of the compressor can be fastened down and always remain in place. If the motor or compressor has to be rebuilt, the internal parts may be removed for rebuilding, then the shafts will automatically line back up when reassembled.

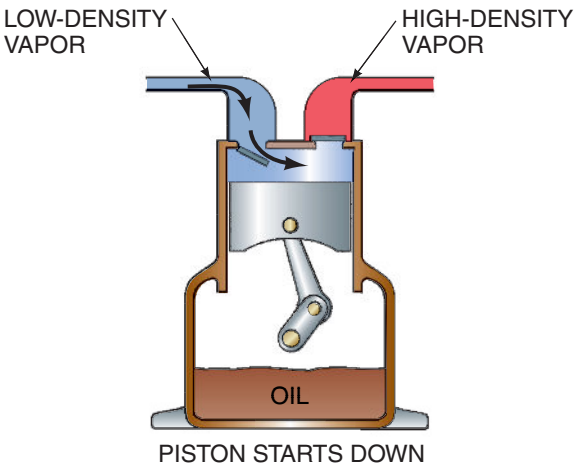
The reciprocating compressor has not changed appreciably for many years. Manufacturers continuously try to improve the motor and the pumping efficiencies. The valve arrangements can make a difference in pumping efficiency and are being studied for improvement.

23.6 RECIPROCATING COMPRESSOR EFFICIENCY

A compressor's efficiency is determined by its design. Efficiency starts with the filling of the cylinder. The following sequence of events takes place inside a reciprocating compressor during the pumping action. Our example for the pumping sequence is a medium-temperature application with R-12 refrigerant, a suction pressure of 20 psig, and a discharge pressure of 180 psig.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 23.42 An illustration of what happens inside the reciprocating compressor while it is pumping. When the piston starts down, a low pressure is formed under the suction reed valve. When this pressure becomes less than the suction pressure and the valve spring tension, the cylinder will begin to fill. Gas will rush into the cylinder through the suction reed valve.



1. **Piston at the top of the stroke and starting down.** When the piston has moved down far enough to create less pressure in the cylinder than is in the suction line, the intake flapper valve will open and the cylinder will start to fill with gas, **Figure 23.42.**
2. **Piston continues to the bottom of the stroke.** At this point the cylinder is nearly as full as it is going to get. There is a very slight time lag at the bottom of the stroke as the crankshaft carries the rod around the bottom of the stroke, **Figure 23.43.**
3. **Piston is starting up.** The rod throw is past bottom dead center, and the piston starts up. When the cylinder is as full as it is going to get, the suction flapper valve closes.
4. **The piston proceeds to the top of the stroke.** When the piston reaches a point that is nearly at the top, the pressure in the cylinder becomes greater than the pressure in the discharge line. If the discharge pressure is 180 psig, the pressure inside the cylinder may have to reach 190 psig to overcome the discharge valve's weight and spring tension, **Figure 23.44.**
5. **The piston is at exactly top dead center.** The piston is as close to the top of the head as it can go. There has to be a certain amount of clearance in the valve assemblies and between the piston and the head, or they would touch. This clearance is known as **clearance volume**. The piston is going to push as much gas out of the cylinder as time and clearance volume will allow. There will be a small amount of gas left in the clearance volume, **Figure 23.45.** This gas will be at the discharge pressure mentioned earlier. When the piston starts back down, the gas will reexpand and

Figure 23.44 When the piston starts back up and gets just off the bottom of the cylinder, the suction valve will have closed and pressure will begin to build in the cylinder. When the piston gets close to the top of the cylinder, the pressure will start to approach the pressure in the discharge line. When the pressure inside the cylinder is greater than the pressure on the top side of the discharge reed valve, the valve will open and the discharge gas will empty out into the high side of the system.

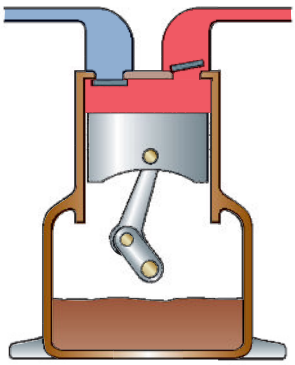


Figure 23.43 When the piston gets near the bottom of the stroke, the cylinder is nearly full. There is a short time lag as the crankshaft circles through bottom dead center, during which a small amount of gas can still flow into the cylinder.

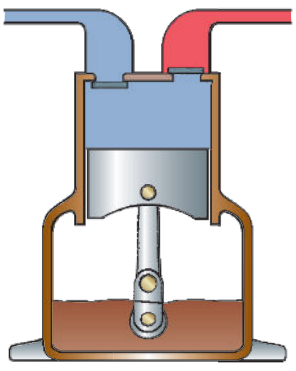

Figure 23.45 A reciprocating compressor cylinder cannot completely empty because of the clearance volume at the top of the cylinder. Manufacturers try to keep this clearance volume to a minimum but cannot completely do away with it.

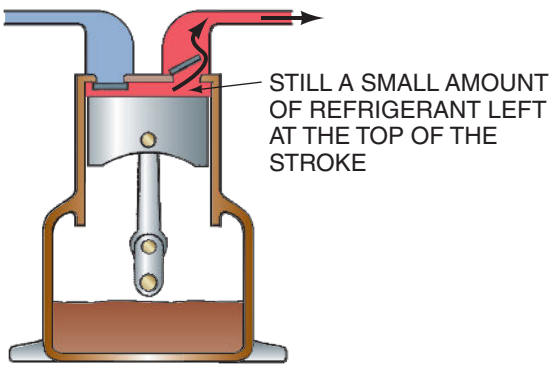

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

the cylinder will not start to fill until the cylinder pressure is lower than the suction pressure of 20 psig. This reexpanded refrigerant is part of the reason that the compressor is not 100% efficient. Valve design and the short period of time the cylinder has to fill at the bottom of the stroke are other reasons the compressor is not 100% efficient.

23.7 DISCUS VALVE DESIGN

The design of the discus valve allows a closer tolerance inside the compressor cylinder at top dead center. The closer tolerance makes the compressor more efficient because it reduces the clearance volume. The discus valve also has a larger bore and allows more gas through the port within a short period of time. **Figure 23.46** shows a discus compressor, a conventional valve design, a discus valve design, and a cutaway view of a discus compressor. Discus compressors are refrigeration compressors used in supermarkets, walk-in coolers and freezers, and industrial applications. They range in horsepower from 5 to 60 hp.

Discus compressors are available with capacity modulation that ranges from 10% to 100%. This provides the ability to match capacity to the load desired for the refrigeration equipment. Capacity modulation reduces the suction pressure and temperature variation of the refrigerated space and

allows a decrease in the compressor's cycling rate. A reduced cycling rate increases the compressor's reliability. Modulation is accomplished with a blocked suction technology by feeding a variable voltage to a solenoid for its open and closed intervals.

23.8 NEW TECHNOLOGY IN COMPRESSORS

Discus compressor technology also offers onboard diagnostics. This technology makes possible real-time monitoring to let the service technician know the status of what is happening inside the compressor before any major problems develop. Today, compressor monitoring operations can be centralized off-site, which allows service technicians to systematically troubleshoot compressor problems before arriving at the site. It also improves troubleshooting accuracy and speed of service. Centralized monitoring technology can gather data, transmit operating information, and visually display compressor status and alarm codes on the front control box. It also can record and retain a history of the compressor's operating information and past alarms and dispatch service technicians automatically if an alarm problem arises. **Figure 23.47** shows a modern discus compressor that incorporates onboard diagnostics. This new technology has the following advantages:

- Monitors the compressor's discharge temperature
- Provides contactor protection
- Enables remote diagnostics
- Integrates the compressor's system electronics—including the high- and low-pressure controls, the cooling and temperature control, oil pressure monitoring, motor protection devices, and input/output (I/O) boards

- Reduces the number of brazed joints on the compressor that can develop leaks
- Guarantees consistent field installation due to less wiring and fewer components

THE SCROLL COMPRESSOR

The concept of compressing a gas by turning one scroll against another around a common axis isn't new. Scroll compressor technology has been around for 100 years, but it did not become commercially available and cost-effective until the mid 1980s. Today, it is becoming even more fine-tuned and is available in many more applications. A major hurdle in making the scroll compressor a viable product has been the difficulty in achieving a balance between the requirement for high-volume precision manufacturing and the need for consistent high performance and efficiency, low sound levels, and great reliability. In fact, it is the scroll compressor's ability to reach higher levels of Seasonal Energy Efficiency Ratio (SEER) ratings that has helped guide the industry through government-mandated regulations. **Figure 23.48** shows a fifth-generation scroll compressor with its very few moving parts. In fact, every central split-cooling system manufactured in the United States today must have a SEER of at least 13, an energy requirement mandated by federal law as of January 23, 2006. With the phaseout of R-22 just around the corner, manufacturers of HVAC/R equipment have been looking for energy-efficient methods to apply to their equipment in order to meet the new energy requirements.

SEER is calculated on the basis of the total amount of cooling (in Btu) the system will provide over the entire season, divided by the total number of watt-hours it will consume. Higher SEER ratings reflect a more efficient cooling system. The federal mandate will impact 95% of the unitary market in the United States, which is about 8 million units at the time of this writing. To meet this new energy-efficiency requirement of 13 SEER, most air-conditioning and heat pump manufacturers are looking for more efficient evaporator and condenser designs, more efficient compressors (like the scroll compressor), and more efficient fan motors—along with more sophisticated control systems. Refer to Unit 21, "Evaporators and the Refrigeration System," and Unit 22, "Condensers," for more detailed information on evaporator and condenser designs.

Because of the scroll compressor's fewer moving parts, it operates much more quietly than other compressor designs and technologies. Less noise and higher efficiencies have become two key selling points for installing the scroll compressor in residential air-conditioning units. The scroll compressor then came to be used in commercial cooling equipment. A major development for commercial scroll compressors has been the advent of modulating technology. Modulating technology is able to maintain ideal comfort levels in buildings such as churches, where rooms can be empty for hours and then suddenly fill to capacity. Modulation technology operates in several ways, which will be covered later in the unit. Some high-end systems now have communication systems onboard that enable components to talk to each other, **Figure 23.47.**

Refrigeration has also become a major application for the scroll compressor due to its reliability and durability. It is used in walk-in coolers, reach-ins, and distributed-refrigeration systems. Beyond coolers and freezers, the scroll compressor has found its way to soft-serve ice cream machines, frozen carbonated beverage machines, and other types of machines. Scroll compressors are also being utilized in cryogenic equipment, magnetic resonance imaging (MRI) machines, and even some dental equipment.

SCROLL COMPRESSOR OPERATION

The operation of a scroll compressor is relatively simple. Two spiral-shaped scrolls fit inside one another, **Figure 23.49.** These two mating parts are often referred to as *involute spirals*. One of the spiral-shaped parts stays stationary while the other orbits around the stationary member. The orbiting motion is created by the offset operation of the centers of the journal bearings and the motor, **Figure 23.50.**

The motion is a true orbital motion, not a rotational motion. The orbiting motion causes continuous crescent-shaped gas pockets to form, **Figure 23.51**, then draws gas into the outer pocket and seals it as the orbiting continues. The continuous orbiting motion reduces the crescent-shaped gas pocket to a smaller and smaller volume as it nears the center of the scroll form. When the gas pocket is fully compressed, it is discharged out of a port of the nonorbiting (fixed) scroll member, **Figure 23.52.** Several crescent-shaped gas pockets are compressed at the same time, which provides for a smooth and continuous compression cycle. Thus, the scroll compressor conducts its intake, compression, and discharge phases simultaneously.

The scroll compressor always takes a fixed volume of gas at suction pressure and then decreases the same gas volume, which increases its pressure. In fact, during the discharge phase, the scroll compressor compresses the discharge gas to a zero volume, eliminating any carryover of trapped discharge gas into a clearance volume that is characteristic of piston-type compressors. Because of this, the scroll compressor is often referred to as a "fixed compression ratio" compressor. Piston-type compressors are often referred to as "variable compression ratio" compressors. Reexpansion of discharge gas contributes to low volumetric efficiencies in piston-type compressors.

SCROLL COMPRESSOR ADVANTAGES

The ways in which the two scroll members interact and operate provide several advantages. When liquid refrigerant, oil, or small solid particles enter between the two scrolls, the mating scroll parts can actually move apart in a sideways direction, referred to as "radial" movement. Radial movement eliminates high-stress situations and allows for just the right

Figure 23.51 Continuous crescent-shaped gas pockets being formed in the scroll.

1 GAS ENTERS AN OUTER OPENING AS ONE SCROLL ORBITS THE OTHER.

2 THE OPEN PASSAGE IS SEALED AS GAS IS DRAWN INTO THE COMPRESSION CHAMBER.

3 AS ONE SCROLL CONTINUES ORBITING, THE GAS IS COMPRESSED INTO AN INCREASINGLY SMALLER "POCKET."

4 GAS IS CONTINUALLY COMPRESSED TO THE CENTER OF THE SCROLLS, WHERE IT IS DISCHARGED THROUGH PRECISELY MACHINED PORTS AND RETURNED TO THE SYSTEM.

5 DURING ACTUAL OPERATION, ALL PASSAGES ARE IN VARIOUS STAGES OF COMPRESSION AT ALL TIMES, RESULTING IN NEAR-CONTINUOUS INTAKE AND DISCHARGE.

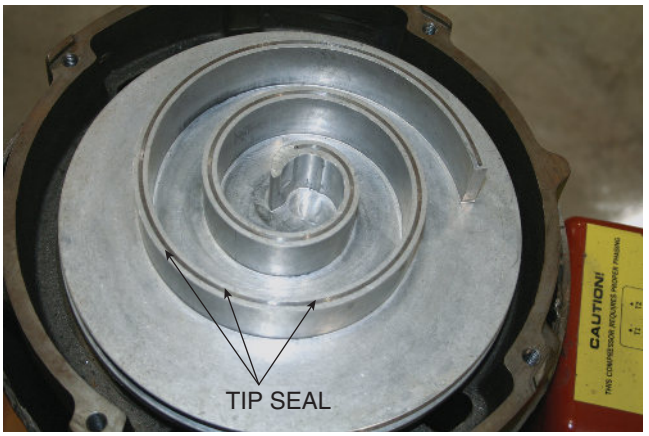
(B)

amount of contact force between mating scroll surfaces. This action allows the compressor to handle some liquid. When the compressor experiences a liquid slug, the scroll's mating parts will separate slightly and allow the pressurized gas to vent to suction pressure. This allows the liquid slug to be swept from the mating scroll surfaces to the suction pressure and be vaporized. A gurgling noise may be heard during this process. The compressor may even stop pumping briefly and then restart as the excess liquid is purged from the scrolls. Although scroll compressors handle liquid better than other compressors, they can still require additional accessories like crankcase heaters and suction-line accumulators for added protection.

As the orbiting scroll orbits, centrifugal forces on the sides of the mating scrolls, along with some lubricating oil, form a seal that prevents gas-pocket leakage. This is often referred to as "flank sealing," a major contributor to the scroll's high efficiency. A small amount of lubricating oil is usually entrained in the suction gases and, along with the centrifugal forces, provides the flank sealing. Tight up-and-down mating or sealing of the tips of each scroll prevents any compressed gas-pocket leakage and adds to efficiency. Up-and-down sealing is often referred to as "axial" sealing. Some scroll manufacturers use tip seals for axial sealing, **Figure 23.53.** Scroll-tip seals serve the same purpose as the piston rings in a reciprocating piston-type compressor. The tip seals ride on the surface of the opposite scroll and provide a seal so that gases cannot escape between mating scroll parts and the tips of the scrolls.

The scroll compressor requires no reed valves, so it does not have valve losses that contribute to inefficiencies as piston-type compressors do. As mentioned, there is no reexpansion of discharge gases, which can be trapped in a clearance volume and cause low volumetric efficiencies. This is why the scroll compressor has a very high capacity in high-compression-ratio applications. In addition, a considerable distance separates the scroll compressor's suction and discharge ports or locations, which greatly reduces the transfer of heat between the suction and discharge gases. Because suction gases have less heat transferred into them, they have a higher density, which increases the mass flow rate of refrigerant through the scroll compressor.

Figure 23.53 Scroll member showing a tip seal for axial sealing.



Courtesy Ferris State University. Photo by John Tomczyk.

Because of its continuous compression process and the fact that it has no reed valves to create valve noise, the scroll compressor has very soft gas-pulsation noises and very little vibration as compared with piston-type compressors. Scroll compressors also have a check valve in the discharge chamber that prevents high-side gas from flowing into the low side when the compressor stops. This valve opens by pressure difference when the compressor restarts. Finally, the simplicity of the scroll compressor's design requires only the stationary and the orbiting scroll for compressing gas.

Piston-type compressors require about 15 parts to do the same task.

In summary, the main reasons scroll compressors are gaining popularity over piston-type compressors in energy efficiency, reliability, and quieter operation are as follows:

- There are no volumetric losses through gas reexpansion as with piston-type compressors.
- The scroll compressor requires no reed valves, so it does not have valve losses that contribute to inefficiencies as piston-type compressors do.
- Separation of suction and discharge gases reduces heat-transfer losses.
- Centrifugal forces within the mating scrolls maintain nearly continuous compression and constant, leak-free contact.
- Radial movement eliminates high-stress situations and allows for just the right amount of contact force between mating scroll surfaces. This action allows the compressor to handle some liquid.
- Scroll compressors maintain a continuous compression process and have no reed valves to create valve noise. This creates very soft gas-pulsation noises and very little vibration as compared with piston-type compressors.

TWO-STEP CAPACITY CONTROL FOR SCROLL COMPRESSORS

A cooling system that can modulate capacity within the compressor and a variable-speed blower motor for the conditioned air will deliver much tighter temperature control and a reduced humidity level within the conditioned space than will a standard cooling system. The overall comfort level for occupants will be much higher because the compressor will run longer at part load to reduce humidity levels and maintain very precise temperature levels.

A new technology in scroll compressor design allows the compressor to have a two-step capacity of either 67% or 100%. A modern, two-step scroll compressor, shown in **Figure 23.54**, has an internal unloading mechanism in the scroll compressor that opens a bypass port or vent at the end of the first compression pocket. This internal unloading mechanism is a direct-current (DC) solenoid controlled by the second stage of a conditioned space thermostat in either the heating or cooling modes. The DC solenoid, which is controlled by a rectified, external, 24-V alternating-current (AC) signal initiated by the conditioned space thermostat, moves a slider that covers and uncovers the bypass ports or vents, **Figures 23.55(A)** and **(B)**. The compressed gas is then vented into the beginning of a suction pocket within the scroll. When the bypass or vent port is opened by deenergizing the DC solenoid, the effective displacement of the scroll is reduced to 67%. When the DC solenoid is energized by the second stage of the conditioned space thermostat, the bypass ports are blocked or

Figure 23.54 A modern, two-step modulating scroll compressor with either 100% or 67% capacity.

Courtesy Emerson Climate Technologies

closed and the scroll is at 100% capacity. Again, this opening and closing of the bypass ports or vents is controlled by an internal, electrically operated DC solenoid. The unloading and loading of the two-step scroll compressor is done while the compressor's motor is running—and without cycling the motor on and off. The compressor motor is a single-speed, high-efficiency motor that will continue to run while the scroll alternates between the two capacity steps. Whether in the high-capacity (100%) or low-capacity (67%) mode, the two-step scroll operates like a standard scroll compressor.

As mentioned earlier, the internal DC solenoid in the compressor that operates the internal unloading mechanism is energized by the second stage of a conditioned space thermostat. It is expected that the majority of run hours will be at low capacity (unloaded at 67%). It is in this mode that the solenoid is deenergized. This allows the two-stage thermostat to control capacity through the second stage of the thermostat in both cooling and heating, **Figure 23.55(C).** An extra external electrical connection is made with a molded plug assembly that contains a full-wave rectifier to supply direct current to the solenoid unloaded coil, **Figure 23.54.** The rectifier is actually located in the external power plug on the compressor.

DIGITAL CAPACITY CONTROL FOR SCROLL COMPRESSORS

As mentioned, compressor capacity control is desirable for optimum system performance when loads vary over a wide range. Compressor capacity control through modulation can reduce power consumption, produce better dehumidification control, and reduce compressor cycling along with starting currents in smaller compressors. This is especially important when trying to cool an area that has different cooling needs throughout the day. With a digital capacity scroll doing the cooling, constant temperatures of ±0.5°F can be accomplished in every room, at any time of the day, whether the room is mostly empty or standing-room-only.

If the mating scroll members of a scroll compressor are separated axially, no refrigerant gas will be compressed and there will be only 10% power usage. If axial separation of the mating scrolls can be controlled by varying the amount of time they are separated, capacity control can be achieved at percentages between 10% and 100%. The separation of the mating scrolls is achieved by bypassing a controlled amount of discharge gas to the suction side of the compressor through a solenoid valve, **Figure 23.56.** When the pressure in the modulating chamber is lowered by energizing the solenoid valve, discharge gas will be metered through a bleed hole and the scrolls will separate axially, **Figure 23.57.** No flow of refrigerant gas will take place when the mating scrolls are separated, which will unload the scroll compressor. The scroll compressor is shown in both the loaded and unloaded positions in **Figure 23.58.**

A modulating capacity is achieved by either energizing or deenergizing the solenoid valve. An energized solenoid will unload the compressor by axially separating the scrolls, making the compressor's capacity zero. When the solenoid valve is deenergized, the compressor's capacity is 100%. Solenoid cycle times of between 10 and 30 seconds should be used to minimize solenoid-valve cycling and to make the system more responsive. One complete "cycle time" is a combination of solenoid-valve energized (unloaded) time plus deenergized (loaded) time. It is suggested that the solenoid never be deenergized less than 10% of the cycle time; this will ensure that there is enough refrigerant gas flow for motor cooling, since the digital scroll is a refrigerant-cooled compressor.

Example: If you have a 30-second cycle time and the solenoid is deenergized for 20 seconds and then energized for 10 seconds, the resulting capacity will be

$$20 \div 30 = 66.6\%$$

Any normal control parameter (including the surrounding air temperature, humidity, or suction pressure) can unload the compressor. A compressor discharge-line thermistor is required with a cut-out temperature of 280°F. The solenoid valve must have 15 watts of power at the appropriate voltage.

A controller that is used with the digital scroll compressor offers many protective features, such as phase control, short-cycling control, amperage and voltage imbalance, and high-amperage monitoring, to name a few. The controller can also supply a variable voltage to the unloading solenoid valve for open/closed time intervals, **Figure 23.59(A).**

(B)

Figure 23.59(B) illustrates an electronic compressor protection module that uses the compressor as a sensor. The module monitors and interprets system and electrical information within the compressor, shutting it down before damage occurs. The module alerts service technicians to the most serious faults first, so they can accurately and rapidly correct problems and prevent compressor failures that could suddenly generate product spoilage. The electronic module also offers a safeguard against insufficient oil pressure and high motor temperatures, and is also capable of high compressor discharge temperature protection. User-friendly diagnostics optimize the service technician's time, saves money, and ultimately frees operators to focus on other priorities. Fault history and LED indicators allow service technicians to diagnose the past and present state of the system for rapid, accurate troubleshooting and increased uptime. When the module senses that the compressor is running in an unsustainable condition, it responds by shutting down the compressor to avoid damage. Based on fault severity, the compressor will either reset itself when the condition is cleared, or require a service technician to troubleshoot the fault before restarting. Its communication capability also makes it possible to retrieve information and take action remotely.

In summary, the digital scroll compressor can offer the following advantages:

- Ability to hold a precise temperature and humidity level
- Full-load and part-load efficiencies
- Ability to be 30% more efficient than traditional compressor modulation methods
- Less compressor cycling for longer compressor life
- Delivery of maximum comfort, efficiency, and reliability in one compressor

Many refrigeration and air-conditioning compressors today can employ electronic variable frequency drives (VFDs) to vary the frequency feeding their electric motors. VFDs work by converting the motor's input alternating current (AC) to direct current (DC). From the direct current, the VFD will generate a simulated AC signal at varying frequencies. Motor speed is directly proportional to the electrical frequency used by the motor. So, by varying the frequency to the compressor's motor, the compressor's motor speed, thus compressor capacity, can be controlled. This is a very effective way to accurately match compressor capacity to a load requirement. Refer to Unit 17, "Types of Electric Motors" for more in-depth coverage on variable frequency drives. Matching a compressor's capacity to the evaporator heat loading offers many advantages:

- Better efficiency at part load
- Less cycling on and off, which contributes to longer compressor life
- Less fluctuation in evaporator temperatures and pressures
- Gradual speed increases at start-up, meaning less liquid refrigerant and oil return to the compressor

Many modern VFDs can generate frequencies from 3.0 to over 350 hertz, which is outside the operating ranges of modern refrigeration and air conditioning compressors. This is why compressor manufacturers will state minimum and maximum allowable frequencies and frequency ranges for their compressor motors when using a VFD. Many compressor operational characteristics can be affected if a compressor motor does not operate within a certain frequency range. These may include:

- Compressor lubrication and cooling at low speeds
- Proper oil pump operation
- Compressor overheating
- Increased electrical motor losses

- Increased vibration
- Reed valve performance

NOTE: *Always consult with the specific compressor manufacturer before using a VFD controller on any compressor.*

SCROLL COMPRESSOR PROTECTION

Many modern scroll compressors incorporate a variety of internal safety controls that can activate the internal line-break motor protection, **Figure 23.60.** Some safety features found in an air-conditioning scroll with less than 7 tons of capacity may include the following:

- Temperature-operated disc (TOD)—A bimetallic disc that senses compressor discharge temperature and opens at 270°F.
- Internal pressure relief (IPR)—Opens at an approximate 400 ± 50 psi differential between high- and low-side pressures for R-22, and at a 500 to 625 psi differential for R-410A.
- Floating seal—Separates the high side from the low side. Also prevents the compressor from drawing into a deep vacuum and damaging the fusite electrical terminal.
- Internal motor protection—Senses both internal temperatures and amperages.

Another innovative scroll compressor protection device is used to ensure better reliability, diagnostic accuracy, speed of service, and a reduction in the number of callbacks when the technician is systematically troubleshooting the compressor. The diagnostic controller is installed in the electrical box of a commercial condensing unit or residential unit or inside a rooftop unit. It is completely self-contained and has no external sensors, **Figure 23.61.** In fact, it actually uses the compressor as a sensor because the compressor's electrical lines run through the device, which acts as a current transformer. It monitors vital information from the scroll compressor that will help pinpoint the root cause of cooling system problems, such as electrical problems, compressor defects, and other general system faults. Phase dropouts,

miswiring, and short cycling can also be detected with this device. A flashing light-emitting diode (LED) will quickly communicate the alert code and direct the service technician to the problem.

CENTRIFUGAL COMPRESSOR

A revolutionary oil-free centrifugal compressor has been designed for the HVAC/R industry. This centrifugal compressor has magnetic bearings, variable speeds, and digital electronic technology and achieves very high efficiencies, **Figure 23.62.**

The rotor shaft and impellers are the only moving parts in this compressor. The shaft acts as the rotor for the permanent-magnet synchronous motor. The rotor shaft has magnetically levitated bearings for frictionless operation, **Figures 23.63(A)** and **(B)**. The magnetic bearings and bearing sensors are composed of both permanent magnets and electromagnets. They precisely control the frictionless compressor shaft rotation on a levitated magnetic cushion, **Figure 23.63(B).** Bearing sensors, located at each magnetic bearing, feed back rotor orbit information in real time to the bearing control system, **Figure 23.64.**

The permanent-magnet synchronous motor is powered by a pulse-width-modulated (PWM) voltage supply. High-speed variable frequency drive (VFD) operation allows for high efficiency, compactness, and soft-start capability. Soft starting reduces high in-rush currents at start-up. The variable frequency drive has an inverter that converts a DC voltage into an adjustable three-phase AC voltage. Signals from the motor/bearing controller determine the inverter output frequency, torque, and voltage phase—all of which regulate the motor speed. The compressor motor can reduce speed as the condensing temperatures or heat loads are reduced. This allows the variable-speed compressor to optimize energy performance from 100% to 20% of rated capacity.

The centrifugal compressor has onboard digital control electronics that oversee its operation. The electronic package also provides for Web-enabled monitoring access and external control. This provides valuable performance and reliability information. It also reduces costs because it replaces the power and control panel functions seen on traditional chillers and rooftop packages.

23.9 LIQUID IN THE COMPRESSOR CYLINDER

The piston-type reciprocating compressor is known as a positive displacement device. This means that when the cylinder starts on the upstroke, it is going to empty itself or stall. **SAFETY PRECAUTION:** *If the cylinder is filled with liquid refrigerant that does not compress (liquids are not compressible), something is going to break. Piston breakage, valve breakage, and rod breakage can all occur if a large amount of liquid reaches the cylinder,* **Figure 23.65.** •

Liquid in compressors can be a problem from more than one standpoint. Large amounts of liquid, called a *slug* of liquid or **liquid slugging**, usually cause immediate damage. Small amounts of liquid floodback can be just as detrimental but take more time to cause damage. When small amounts of liquid enter the compressor, they dilute the oil. If the compressor has no oil lubrication protection, this may not be noticed until the compressor fails. One of the results is that marginal oil pressure may cause the compressor to throw a rod, a mechanical failure that may cause motor damage and burn out the motor. The technician may erroneously diagnose this as an electrical problem. If the compressor is a welded hermetic, the technician may have difficulty diagnosing the problem until another failure occurs. Many electrical failures are caused by mechanical failures. Following are some causes that may lead to liquid slugging a compressor with liquid refrigerant, which in turn may lead to electrical failures because of a motor seizure:

- Metering device overfeeding
- Low air circulation over evaporator
- Low heat load
- Evaporator fan motor not working
- Dirty or iced-up evaporator coil
- Defrost heaters or defrost timer not working
- Dirty or blocked evaporator filters

NOTE: *Never take a compressor failure for granted. Give the system a thorough check on start-up and actively look for a problem.* •

23.10 SYSTEM MAINTENANCE AND COMPRESSOR EFFICIENCY

The compressor's overall efficiency can be improved by maintaining the correct working conditions. This involves keeping the suction pressure as high as practical and the head pressure as low as practical within the design parameters.

A dirty evaporator will cause the suction pressure to drop. When the suction pressure goes below normal, the vapor that the compressor is pumping becomes less dense and gets thin (sometimes called rarified vapor). The compressor performance declines. Low suction pressures also cause the high-pressure gases caught in the clearance volume of the compressor to expand more during the piston's downstroke. This gives the compressor a lower volumetric efficiency. These gases have to expand to a pressure just below the suction pressure before the suction valve will open. Because more of the downward stroke is used for reexpansion, less of the stroke can be used for suction. Suction ends when the piston reaches bottom dead center.

In the past, not much attention was paid to dirty evaporators. Technicians are now beginning to realize that low evaporator pressures cause high compression ratios. For example, if an ice cream storage walk-in cooler is designed to operate at −5°F room temperature, it would result in a coil temperature of about −20°F (using a coil-to-return-air temperature of 15°F). If the refrigerant is R-134a, the suction pressure would be 3.6 psig, slightly above atmospheric pressure. Assume the condenser will operate with a 25°F temperature difference between the outside air and the condensing temperature. If the outside air is 95°F, the condensing temperature would be 120°F (95°F + 25°F). The condensing pressure would then be 171.2 psig. The following calculation would show the compression ratio to be 10:1, **Figure 23.66(A)**.

Compression Ratio = Absolute Discharge Pressure ÷ Absolute Suction Pressure

CR = [171.2 psig + 15 (atmosphere)] ÷ [3.6 psig + 15 (atmosphere)]

CR = 10.01:1

If the coil were old and dirty, **Figure 23.66(B)**, and the coil temperature reduced to −30°F, assuming the head pressure remained the same, a new refrigerant boiling temperature of −30°F would produce a suction pressure of 9.7 in. Hg vacuum. This is below atmospheric pressure. It is an absolute pressure of 9.93 psia. (This was arrived at by converting inches of mercury vacuum to inches of mercury absolute, then converting this to psia.)

29.92 in. Hg absolute − 9.7 in. Hg vacuum = 20.22 in. Hg absolute

20.22 in. Hg absolute ÷ 2.036 in. Hg per psi = 9.93 psia

The new compression ratio is 18.75:1

CR = [171.2 + 15 (atmosphere)] ÷ 9.93 psia

CR = 18.75:1

This compression ratio is too high. Most manufacturers recommend that the compression ratio not be more than 12:1.

The same situation could occur if the store manager were to turn the refrigerated box thermostat down to −15°F. The coil temperature would go down to −30°F and the compression ratio would be 18.75:1. This is too high. Many low-temperature coolers are operated at temperatures far below what is necessary. This condition often causes compressor problems.

Dirty condensers also cause compression ratios to rise, but they do not rise as fast as with a dirty evaporator. For example, if the ice cream storage box above were operated at 3.6 psig and the condenser became dirty to the point that the head pressure rose to 190 psig, the compression ratio would be 11.02:1, **Figure 23.66(C).** This is not good but not as bad as the 18.75:1 ratio in the previous example.

CR = [190 psig + 15 (atmosphere)] ÷ [3.6 psig + 15 (atmosphere)]

CR = 11.02:1

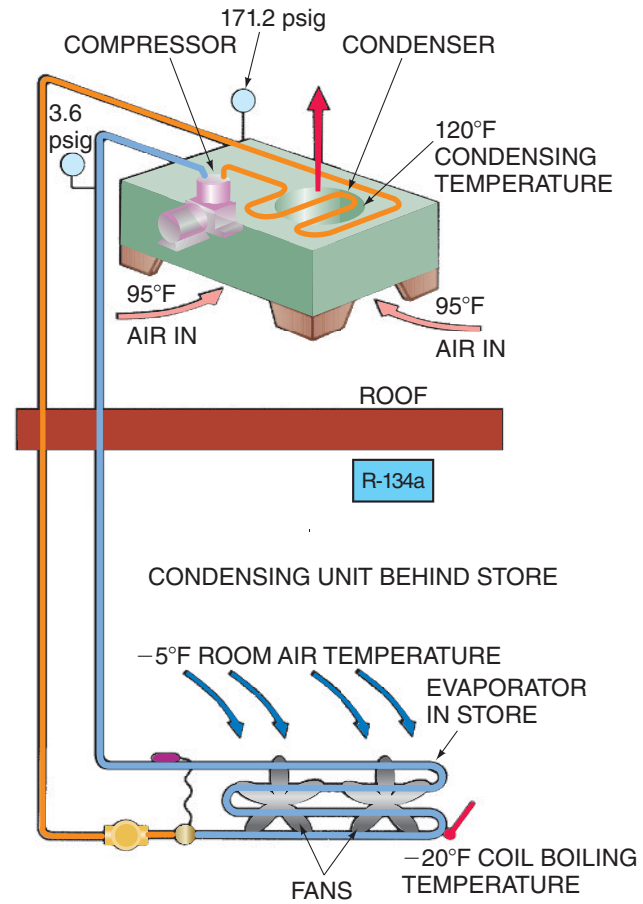
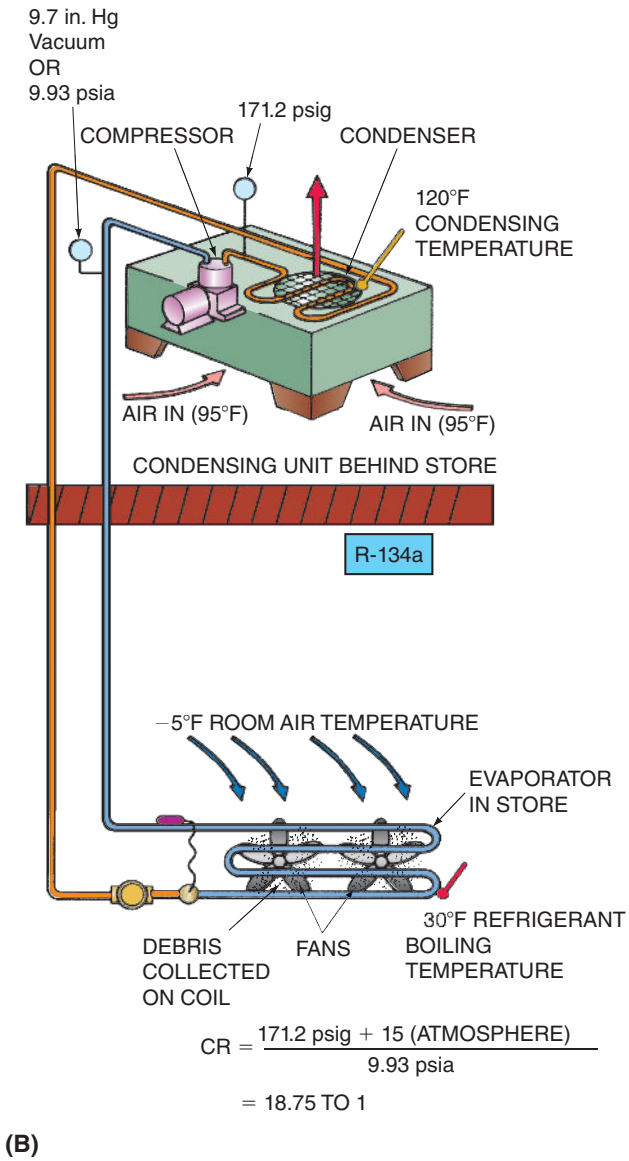
Figure 23.66 (A) A system operating with a normal compression ratio. Notice that the condenser is large enough to keep the head pressure low. (B) This system has a dirty evaporator.





If both situations were to occur at the same time, as in **Figure 23.66(D)**, the compressor would have a compression ratio of 20.64:1. The compressor would probably not last very long under these conditions.

$$CR = [190 \text{ psig} + 15 \text{ (atmosphere)}] \div 9.93 \text{ psia}$$

$$CR = 20.64{:}1$$

The technician has a responsibility to maintain equipment to obtain the greatest efficiency and to otherwise protect the equipment with a maintenance program. Clean coils are part of this program. The owner usually does not know the difference. A dirty condenser makes the head pressure rise. This causes the amount of refrigerant in the clearance volume (at the top of the compressor cylinder) to be greater than the design conditions allow and the compressor efficiency to drop. If there is a dirty condenser (high head pressure) and a dirty evaporator (low suction pressure), the compressor will run longer to keep the refrigerated space at the design temperature. The overall efficiency drops. A customer with a lot of equipment may not be aware of this if only part of the equipment is not efficient. When the efficiency of a compressor drops, the owner is paying more money for less refrigeration. A good maintenance program is economical in the long term.

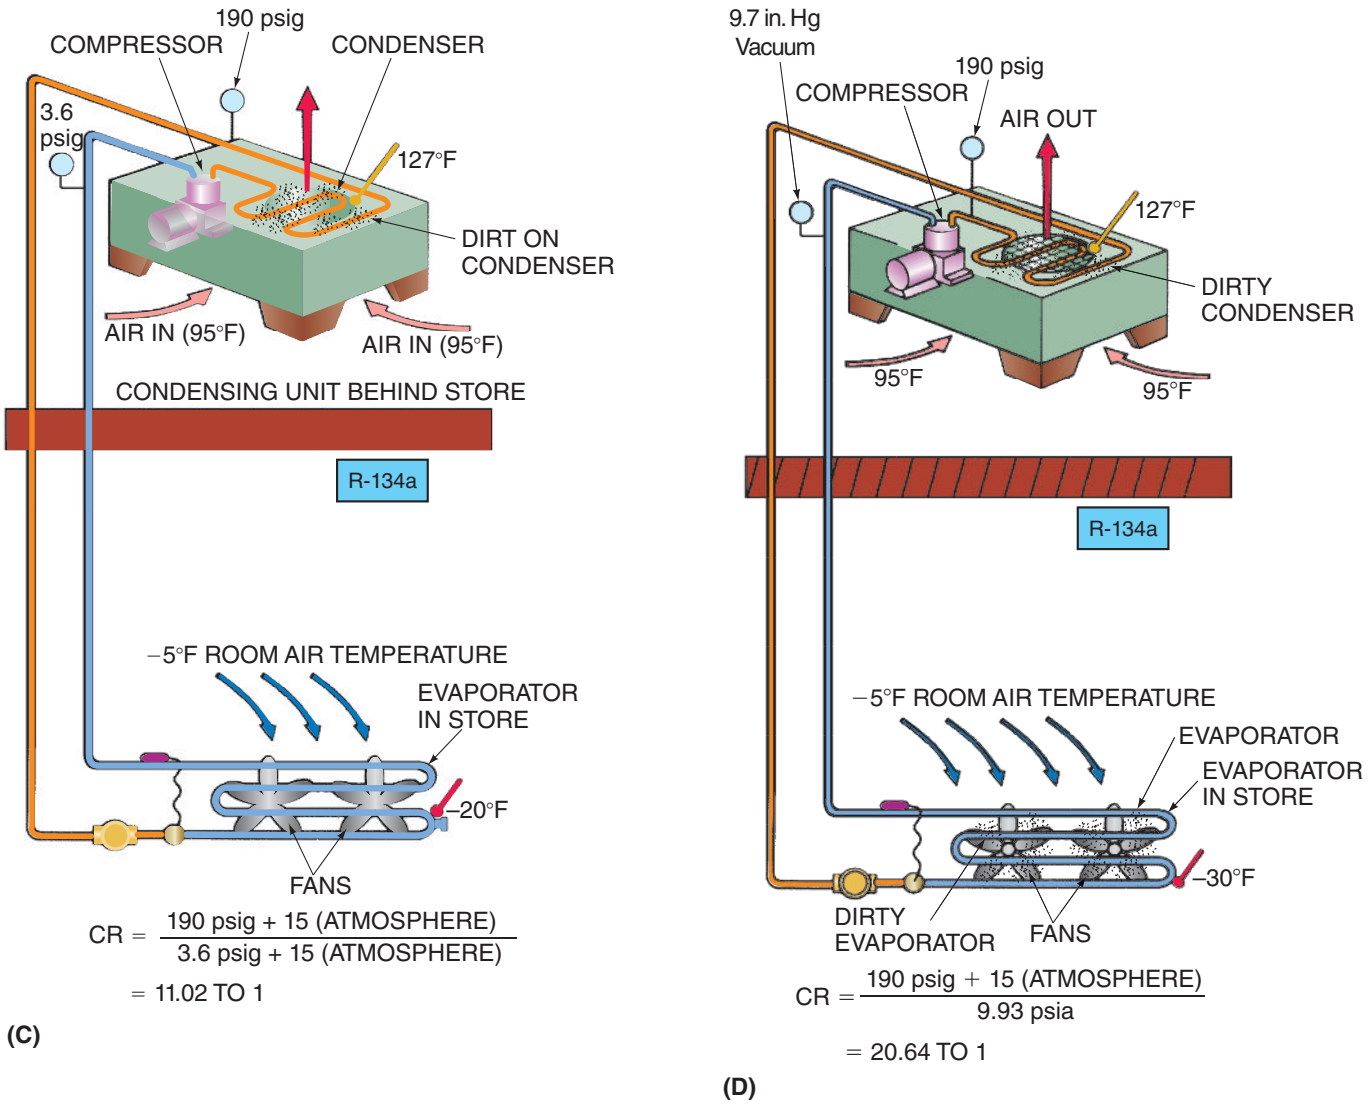
Figure 23.66 (*Continued*) (C) A system with high head pressure because the condenser is dirty. (D) This system has a dirty condenser and a dirty evaporator.



SUMMARY

- The discharge gas can be quite hot because the heat contained in the cool suction gas is concentrated when compressed in the compressor.
- Three types of compressors are usually used to achieve compression in commercial refrigeration: the reciprocating, rotary screw, and scroll compressor.
- Hermetic and open-drive are two types of reciprocating compressors.
- Two types of hermetic compressors are welded hermetic and serviceable hermetic or semihermetic.
- The shell of the serviceable hermetic or semihermetic compressor is bolted together and can be disassembled in the field.
- Most reciprocating compressor motors are cooled by suction gas. Some are air-cooled.
- The motors of all hermetic compressors operate in a refrigerant and oil atmosphere and special precautions must be taken in their manufacture and servicing.
- Special internal overload devices are used on hermetic motors that operate inside a refrigerant atmosphere.
- One type of internal overload protection device interrupts the actual line current. If this overload device does not close when it should, the compressor is defective.
- Another internal overload device is a pilot-duty type that interrupts the control voltage.

- Some compressors use thermistors in or near the motor windings to sense motor heat. The thermistors are then wired to a solid-state electronic compressor protection module, which will decide when the compressor should be cycled off because of excessive heat.
- Reciprocating compressors are positive displacement pumps, meaning that when they have a cylinder full of gas or liquid, the cylinder must be emptied or damage will occur.
- Open compressors have a motor on the outside of the refrigeration or air-conditioning system.
- The motor can be mounted beside a compressor, the compressor and motor shafts may be side by side, or the motor may be mounted at the end of the compressor shaft with a flexible coupling between them.
- Shaft-to-motor alignment is very important.
- Belts for belt-drive applications come in different types.
- Discus valve design provides for smaller clearance volume, a greater area through which the gas can flow, and consequently greater efficiency.

REVIEW QUESTIONS

1. Describe the operation of a compressor.
2. Name five types of compressors.
3. True or False: A compressor can compress a liquid.
4. What would be considered a higher-than-normal temperature for a discharge gas line on a reciprocating compressor?
   A. 190°F
   B. 215°F
   C. 250°F
   D. All of the above
5. Which compressor type uses pistons to compress the gas?
   A. Scroll
   B. Reciprocating
   C. Rotary
   D. Screw
6. Which compressor type uses tapered, machined gear components to trap the gas for compression?
   A. Scroll
   B. Reciprocating
   C. Rotary
   D. Screw
7. Which style of compressor uses belts to turn the compressor?
   A. Open drive
   B. Closed drive
   C. Chassis drive
   D. Hermetic drive
8. What would be done to increase the compressor speed on a belt-driven compressor?
   A. Decrease drive pulley size
   B. Increase drive pulley size
   C. Increase driven pulley size
   D. Both A and C
9. Describe the reciprocating compressor piston, rod, crankshaft, valves, valve plate, head, shaft seal, internal motor overload device, pilot-duty motor overload device, and coupling.
10. Name two things in the design of a reciprocating compressor that control the efficiency of the compressor.
    A. _____
    B. _____
11. At what speeds in rpm does a hermetic compressor normally turn?
    A. 1750
    B. 3450
    C. 4500
    D. Both A and B
12. What effect does a slight amount of liquid refrigerant have on a compressor over a long period of time?
13. What lubricates the refrigeration compressor?
    A. Refrigerant
    B. Moisture
    C. Desiccants
    D. Oil
14. What can the service technician do to keep the refrigeration system operating at peak efficiency?
15. State the main advantage that a discus compressor's valve plate design has over a conventional piston-type compressor.
16. Briefly describe how the scroll compressor compresses refrigerant gas.
17. List four main advantages a scroll compressor has over a conventional piston-type compressor.
18. What are two main reasons why a compressor should have modulating capacity control?
19. Briefly describe how the digital capacity control for a scroll compressor works.
20. List the three main advantages of having digital capacity control on a scroll compressor.
21. Explain how a compressor can be oil-free.

UNIT 24

EXPANSION DEVICES

OBJECTIVES

After studying this unit, you should be able to

- describe the three most popular types of expansion devices.
- describe the operating characteristics of the three most popular expansion devices.
- describe how the three expansion devices respond to load changes.
- describe the operation of a balanced-port expansion valve.
- describe how electronic expansion valves and their controllers operate.
- explain the operation and operating charge of a system incorporating a capillary tube metering device.

SAFETYCHECKLIST

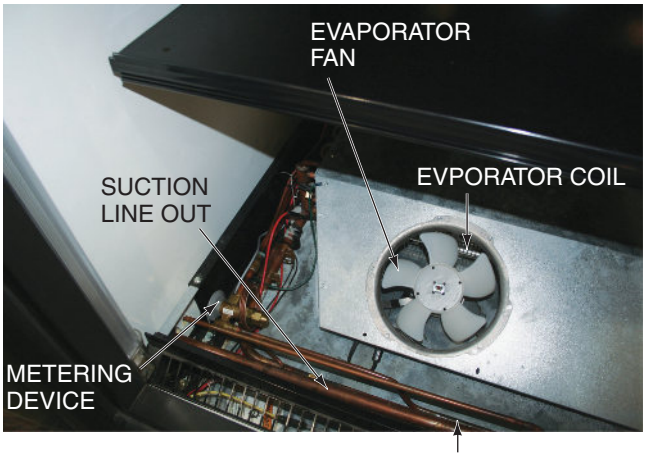
☑ Wear warm clothing when working in a walk-in cooler or freezer.

24.1 EXPANSION DEVICES

The **expansion device**, often called the metering device, is the fourth component necessary for the compression refrigeration cycle to function. The expansion device is not as visible as the evaporator, the condenser, or the compressor. Generally, it is concealed inside the evaporator cabinet and not obvious to the casual observer. The device can be either a valve or a fixed-bore. **Figure 24.1** illustrates an expansion valve installed inside an evaporator cabinet.

The expansion device is one component that divides the high side of the system from the low side (the compressor is the other). **Figure 24.2** shows its location. It is responsible for metering the correct amount of refrigerant to the evaporator. The evaporator performs best when it is as full of liquid refrigerant as possible with none left in the suction line. Liquid refrigerant that enters the suction line may reach the compressor because only a small amount of heat is added in the suction line. Later in this section we will discuss a suction-line heat exchanger for special applications that is used to boil away liquid that may be in the suction line. Usually, liquid in the suction line is a problem.

Figure 24.1 Metering devices installed on a refrigerated case. The valve is not out in the open and is not as visible as the compressor, condenser, or evaporator.



Courtesy Ferris State University. Photo by John Tomczyk

The expansion device is normally installed in the liquid line between the condenser and the evaporator. On a hot day, the liquid line may be warm to the touch and thus can be followed quite easily to the expansion device, where there is a pressure drop and an accompanying temperature drop. For example, the liquid line entering the expansion device may be 110°F on a hot day. In a low-temperature cooler using R-134a, the low-side pressure on the evaporator side may be 3 psig at a temperature of –8°F. This dramatic temperature drop can be easily detected when found. The device may be warm on one side and frosted on the other, **Figure 24.3**. Because some expansion devices are valves and some are fixed-bore devices, the temperature change can occur in a very short distance—less than an inch on a valve or a more gradual change on some fixed-bore devices.

24.2 THERMOSTATIC EXPANSION VALVE

Expansion devices can be one of the following different types: (A) thermostatic expansion valve, (B) automatic expansion valve, and (C) fixed bore, such as the capillary

Figure 24.2 The complete refrigeration cycle with the four basic components: compressor, condenser, evaporator, and expansion device.

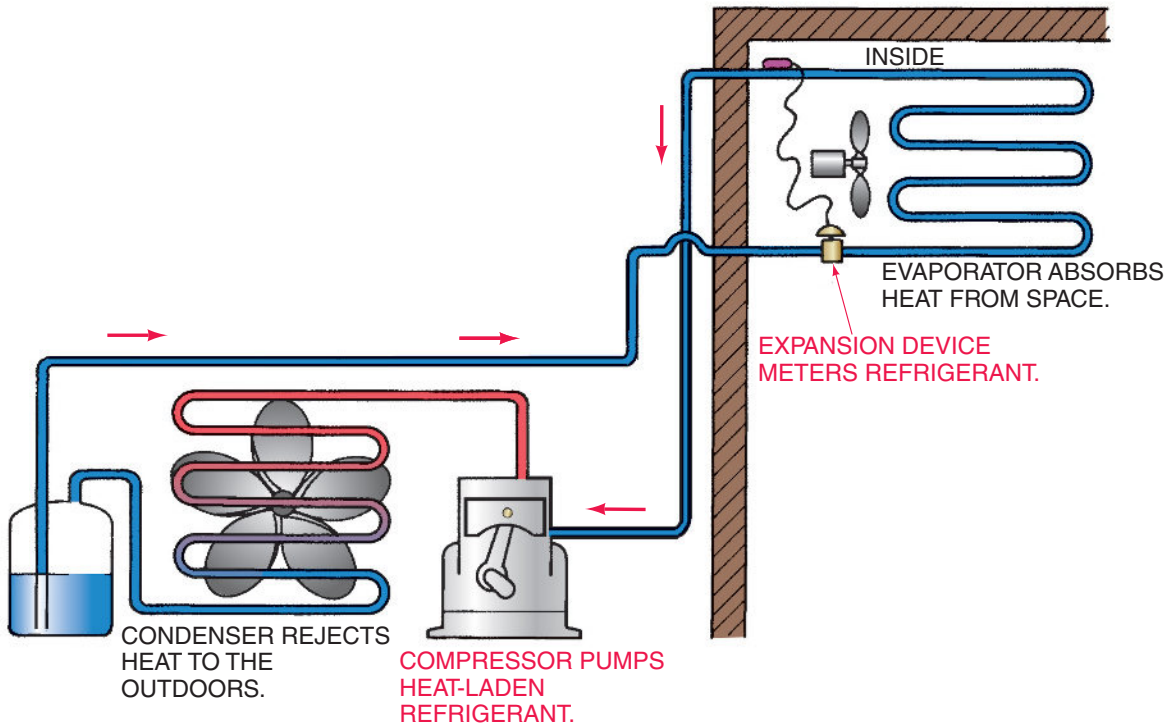

Figure 24.3 The expansion device has a dramatic temperature change from one side to the other.

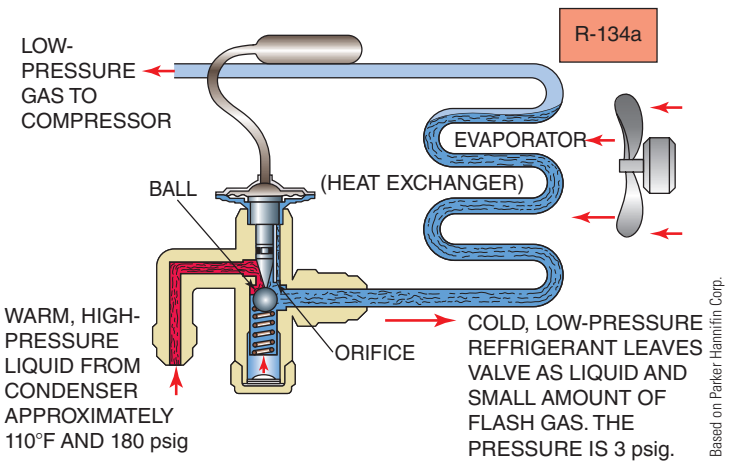

tube, **Figure 24.4**. The *thermostatic expansion valve* (TXV) meters the refrigerant to the evaporator by using a thermal sensing element to monitor the superheat. This valve opens or closes in response to a thermal element. The TXV maintains a constant superheat in the evaporator. Remember, when there is superheat, there is no liquid refrigerant. Excess superheat is *not* desirable, but a small amount is necessary with this valve to ensure that no liquid refrigerant leaves the evaporator. *The TXV can be adjusted to maintain a low superheat to ensure that the majority of the evaporator surface is being used. This will give the refrigeration system a higher net refrigeration effect and higher capacities and efficiencies.*

The service technician should always check evaporator superheat to make sure the evaporator is being fully utilized. When adjusting the TXV, care should be taken to do so slowly. The superheat spring adjustment should be turned in the counterclockwise direction about one-half to one full turn at a time. The system should then be allowed to operate for approximately 15 min before making additional adjustments. Evaporator superheat measurements should be taken after each adjustment to help ensure that liquid refrigerant is not leaving the evaporator. Recommended evaporator superheat settings are as follows:

- High-temperature evaporators (30°F) 10–12°
- Medium-temperature evaporators (0°–30°F) 5–10°
- Low-temperature evaporators (below 0°F) 2–5°

The lower the evaporator temperature, the more necessary it is to keep the evaporator active with refrigerant and to reduce superheat. At the lower evaporator temperatures, system efficiencies and capacities are at their lowest and there is a greater need for an active evaporator.

24.3 TXV COMPONENTS

The TXV consists of the valve body, diaphragm, needle and seat, spring, adjustment and packing gland, and the sensing bulb and transmission tube, **Figure 24.5**.

24.4 THE VALVE BODY

On common refrigerant systems the *valve body* is an accurately machined piece of solid brass or stainless steel that holds the rest of the components and fastens the valve to the refrigerant piping circuit, **Figure 24.6**. Notice that the valves have different configurations. Some of them are single-body pieces and cannot be disassembled, and some are made so that they can be taken apart.

TXV valves may be fastened to a system by one of three methods: flare, solder, or flange. Future service should be considered when installing a valve in a refrigeration system, so a flare connection or a flange-type valve should be used, **Figure 24.7**. If the connection is to be soldered, a valve that can be disassembled and rebuilt in place is desirable, **Figure 24.8**. The valve often has an inlet screen with a very fine mesh to strain out any small particles that may stop up the needle and seat, **Figure 24.9**.

Some valves have a third connection called an **external equalizer** on the side of the valve close to the diaphragm, **Figure 24.10**. This connection is normally a 1/4-in. flare or 1/4-in. solder. As will be discussed later, the diaphragm of the expansion valve registers the evaporator pressure. A pressure connection at the end of the evaporator supplies the evaporator pressure to the diaphragm. If an evaporator has a very long circuit, a pressure drop may occur; an external equalizer is used to correct this. Some evaporators also have several circuits and the method of distributing the refrigerant will cause a pressure drop between the expansion valve outlet and the evaporator inlet. This type of installation also must have an external equalizer for the expansion valve to provide correct control of the refrigerant, **Figure 24.11**.

24.5 THE DIAPHRAGM

The diaphragm is located inside the valve body and moves the needle in and out of the seat in response to system load changes. The diaphragm is made of thin metal and is under the round, dome-like top of the valve, **Figure 24.12**.

Figure 24.6 TXVs have remote sensing elements. (A) Some of these valves are one-piece valves that are thrown away when defective. (B) Some of the remote sensing elements can be replaced. This feature is particularly good when the valve is soldered into the system.

Figure 24.11 An evaporator with circuits and an external equalizer line to account for pressure drop. When an evaporator becomes so large that the length would create pressure drop, the evaporator is divided into circuits, and each circuit must have the correct amount of refrigerant.

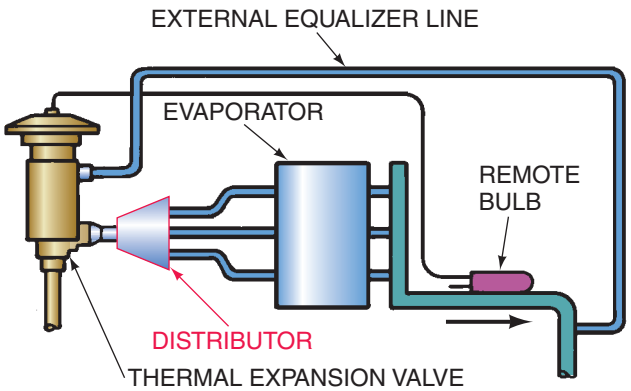

Figure 24.12 The diaphragm in the expansion valve is a thin membrane that has a certain amount of flexibility. It is normally made of a hard metal such as stainless steel.

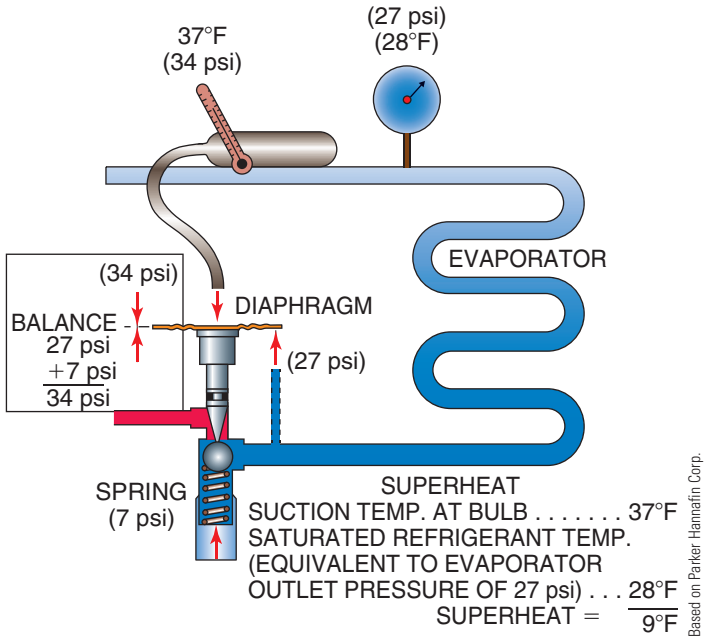

Based on Parker Hannafin Corp.

24.6 NEEDLE AND SEAT

The *needle* and **seat** control the flow of refrigerant through the valve. They are used in a metering device to maintain close control of the refrigerant, **Figure 24.13**, and are normally made of some type of very hard metal, such as stainless steel, to prevent the passing refrigerant from eroding the seat. Some valve manufacturers make needle and seat mechanisms that can be changed for different capacities or to correct a problem.

The size of the needle and seat determines how much liquid refrigerant will pass through the valve under a specific pressure drop. For example, when the pressure is 170 psig on one side of the valve and 2 psig on the other side, a certain measured and predictable amount of liquid refrigerant will pass through the valve. If this same valve were used when the pressure is 100 psig and 3 psig, the valve would not be able to pass as much refrigerant. So the conditions under which the valve will operate must be considered when selecting the valve. The manufacturer's manual for a specific valve is the best place to get the proper information to make these decisions.

The pressure difference from one side of the valve to the other is not necessarily the discharge versus the suction pressure. Pressure drop in the condenser and interconnecting piping may be enough to cause a problem if it is not taken into consideration, **Figure 24.14**. Notice in the figure that the actual discharge and suction pressure are not the same as the pressure drop across the expansion valve. The pressure drop across the distributor would be 25 psig (62 psig−37 psig). The pressure drop across the TXV, not considering the distributor, would be 58 psig (120 psig−62 psig).

Figure 24.13 Needle and seat devices used in expansion valves.

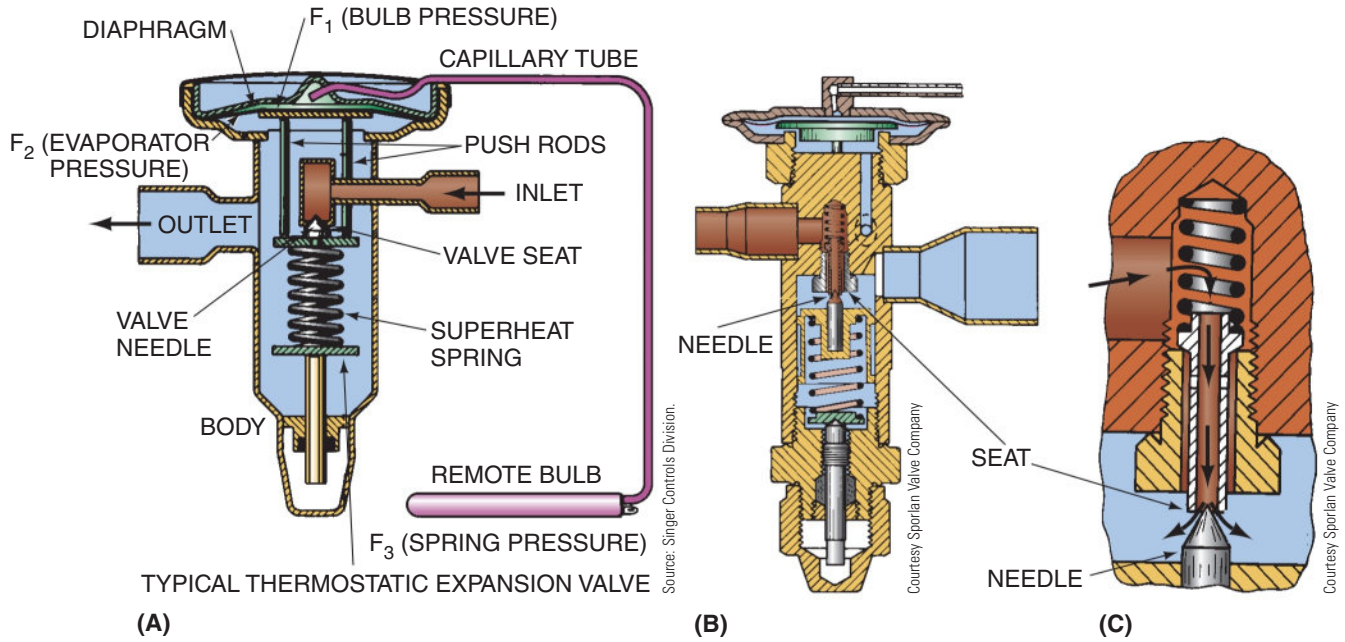

Figure 24.14 Real pressures as they would appear in a system. The pressure drop across the expansion valve is not necessarily the head pressure versus the suction pressure. The pressure drop through the refrigerant distributor is one of the big pressure drops that has to be considered. The refrigerant distributor is between the expansion valve and the evaporator coil.

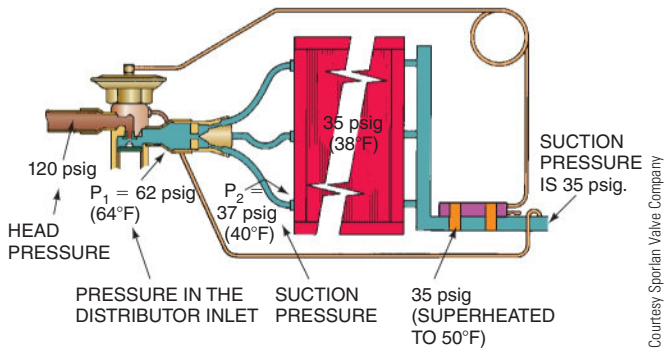

The capacity of thermostatic expansion valves is rated in tons of refrigeration under a particular pressure drop condition. To determine the appropriate size of the valve, the capacity of the system and the working conditions must be known. For example, using the manufacturer's catalog data for sizing a TXV in the table in **Figure 24.15**, we see that a 1-ton R-134a TXV is needed in a medium-temperature cooler with a 20°F evaporator (18.4 psig) and a 1-ton (12,000 Btu/h) capacity. This system is going to operate inside a store, which is expected to stay at 75°F year-round. The head pressure is expected to remain constant at 124 psig (100°F). Assuming negligible pressure drops in the associated piping and accessories in the system, the TXV would be operating with a pressure drop across the valve of 105.6 psig (124 psig − 18.4 psig). Since the 100-psig column in the table is closest to the 105.6-psig calculated pressure drop, that is the one we will use. A 1-ton nominal capacity valve has a capacity of 1.34 tons under these conditions.

If the same cooler is moved outside where the temperature is warmer and the condensing pressure rises to 145 psig, the new pressure drop across the TXV would be 126.6 psig (145 psig − 18.4 psig). We will use the 120-psig pressure drop column in the table because it is closest to our calculated 126.6-psig pressure drop across the valve. A 1-ton nominal capacity valve has a capacity of 1.47 tons under this new condition of 120-psig pressure drop across the valve. The increase in capacity of the 1-ton nominal TXV from 1.34 to 1.47 is due to the increase in head pressure, which causes an increase in the pressure drop across the valve.

These examples of TXV capacity ratings assumed that the subcooled liquid temperature coming into the TXV was 100°F. The bottom of the table in **Figure 24.15** includes liquid correction factors for liquid temperatures other than 100°F. Notice that the correction factor for 100°F liquid is 1.00. Correction factors greater than 1.00 will increase the valve's capacity, and correction factors less than 1.00 will decrease the valve's capacity. In our first example, the nominal 1-ton TXV at a 20°F evaporating temperature and a 100-psig pressure drop across the valve had a capacity of 1.34 tons. This is assuming 100°F liquid temperatures entering the valve. However, if the liquid temperature entering the valve were 80°F, the valve would have a new capacity of 1.34 tons × 1.14 = 1.52 tons. A correction factor of 1.14 from the table was used for the 80°F liquid temperature entering the valve.

Liquid Temperature (°F)	0°	10°	20°	30°	40°	50°	60°	70°	80°	90°	100°	110°	120°	130°	140°
Correction Factor	1.70	1.63	1.56	1.49	1.42	1.36	1.29	1.21	1.14	1.07	1.00	0.93	0.85	0.78	0.71

These factors include corrections for liquid refrigerant density and net refrigerating effect and are based on an average evaporator temperature of 0°F. However they may be used for any evaporator temperature from 40°F to 0°F since the variation in the actual factors across this range is insignificant.

EXAMPLE: 2 ton valve at 20°F evaporator, 80 psi pressure drop, 90°F liquid temperature = 2.39 × 1.07 = 2.56 tons.

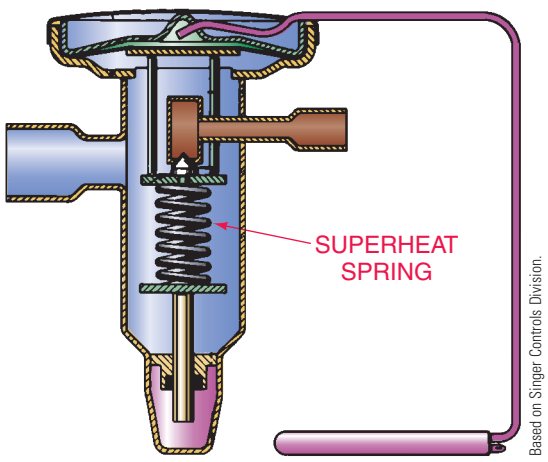
Courtesy Sporlan Valve Company

The colder the liquid temperature entering the TXV, the more capacity in tons the TXV will have. *As the liquid temperature gets colder, the less flashing (loss effect) there will be at the entrance of the evaporator in cooling the liquid down to the evaporating temperature. The more liquid subcooling there is, the lower the loss effects at the evaporator entrance. This will increase the net refrigeration effect and the capacity of the system.* Because increased subcooling increases the refrigeration effect, many systems put the suction lines in contact with the liquid line to increase the subcooling effect. This also helps reduce the possibility of liquid refrigerant entering the compressor by adding heat to the refrigerant in the suction line.

24.7 THE SPRING

The *spring* is one of the three forces that act on the diaphragm. It raises the diaphragm and closes the valve by pushing the needle into the seat. When a valve is adjusted, more or less pressure is applied to the spring to change the tension for different superheat settings. The spring is often referred to as the superheat spring. The spring tension is factory set for a predetermined superheat of 8°F to 12°F, **Figure 24.16.**

Figure 24.16 The spring used in the TXV.



Based on Singer Controls Division.

The adjustment part of the valve can have either a screw slot or a square-headed shaft. Both are normally covered by a cap to prevent water, ice, or other foreign matter from collecting on the stem. The cap also serves as backup leak prevention. Most adjustment stems on expansion valves have a

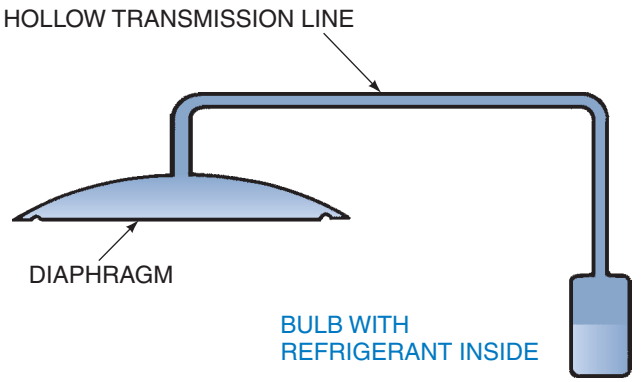
packing gland that can be tightened to prevent refrigerant from leaking. The cap covers the gland as well, **Figure 24.17**. One complete turn of the stem usually changes the superheat reading significantly, depending on the manufacturer. It is good field practice not to adjust the spring unless you are a seasoned technician. If the valve is adjusted improperly, compressor damage can occur.

24.8 THE SENSING BULB AND TRANSMISSION TUBE

The *sensing bulb* and *transmission line* are extensions of the valve diaphragm. The bulb detects the temperature at the end of the evaporator on the suction line and transmits this temperature, converted to pressure, to the top of the diaphragm. The bulb contains a fluid, such as refrigerant, that follows the relationships in a temperature/pressure chart just like any refrigerant. When the suction line temperature goes up, the temperature change occurs inside the bulb as well. As the temperature of the TXV's sensing bulb increases, the valve will gradually open, letting more refrigerant into the

Figure 24.18 An illustration of the diaphragm, the bulb, and the transmission tube.



evaporator. This increases both the evaporating pressure and the compressor's suction pressure, while attempting to reduce the amount of superheat in the evaporator. When the pressure changes, the transmission line (which is nothing more than a small-diameter hollow tube) allows the pressure between the bulb and diaphragm to equalize back and forth, **Figure 24.18**.

The seat in the TXV valve is stationary in the valve body, and the needle is moved by the diaphragm. One side of the diaphragm gets its pressure from the bulb, and the other side gets its pressure from the evaporator and the spring. The diaphragm moves up and down in response to three different pressures, which act at the proper time to open, close, or modulate the valve needle between open and closed. The three pressures are the *bulb pressure*, the *evaporator pressure*, and the *spring pressure*. They all work as a team to position the valve needle correctly to meet the load conditions at any particular time. **Figure 24.19** is a series of illustrations that show the TXV functions under different load conditions.

24.9 TYPES OF BULB CHARGE

The fluid inside the expansion valve bulb is known as the *charge* for the valve. Four types of charge can be used in the TXV:

- Liquid charge
- Cross liquid charge
- Vapor charge
- Cross vapor charge

24.10 THE LIQUID CHARGE BULB

The **liquid charge bulb** is charged with a fluid characteristic of the refrigerant in the system. The diaphragm and bulb are not actually full of liquid, but they have enough so as to always have some liquid inside them. The liquid will not entirely boil away.

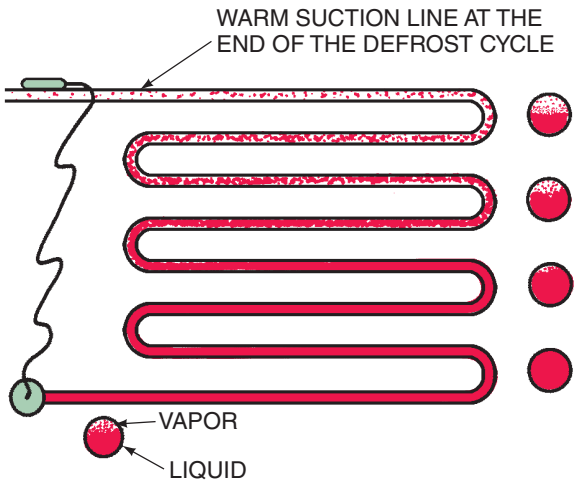
Figure 24.20 The valve is open because the evaporator suction line is warm after the defrost cycle. This allows the liquid in the evaporator to spill over into the suction line before the expansion valve can gain control. The bulb can become quite hot in an extended defrost cycle, and the remaining liquid can move on to the suction line, causing possible compressor damage.

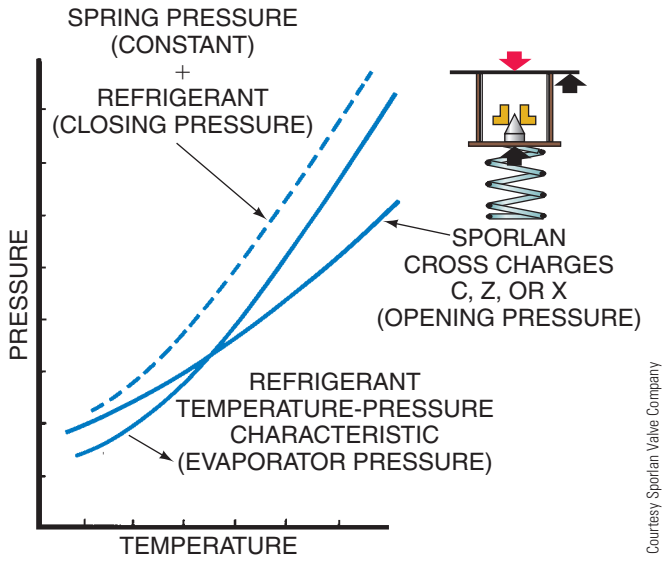


The temperature/pressure relationship in the bulb is almost a straight line on a graph. When the temperature goes up a degree, the pressure goes up a specific amount that can be followed on a temperature/pressure chart. When high temperatures are encountered, high pressures will exist. During defrost, the expansion valve bulb may reach high temperatures, which can cause two things to happen. The pressures inside the bulb can cause excessive pressures over the diaphragm, and the valve will open wide when the bulb gets warm. This will overfeed the evaporator and can cause liquid to flood the compressor when defrost is terminated, **Figure 24.20**. This can lead the service technician or manufacturer to change to the cross liquid charge bulb. The liquid charge bulb is usually limited to applications that have narrow operating ranges or to special functions like desuperheating on the high side of the system.

24.11 THE CROSS LIQUID CHARGE BULB

The **cross liquid charge bulb** is filled with a fluid that is different from the system fluid. It does not follow the system's temperature/pressure relationship but has a flatter curve and will close the valve faster on a rise in evaporator pressure. The cross-charged liquid bulb on a TXV will not open the valve as fast when the remote bulb gets real warm. Cross-charged liquid bulbs are good for low-temperature applications. They will usually give high evaporator superheats under high evaporator-heat load conditions. Normal evaporator superheats will be experienced within the operating range of the valve. The valve closes during the off cycle when the compressor shuts off and the evaporator pressure rises. This helps prevent liquid refrigerant from flooding over into the compressor at startup, **Figure 24.21**.

Figure 24.21 This cross charge valve has a flatter temperature/pressure curve. The pressure rise after defrost or at the end of the cycle will have a tendency to close the valve and prevent liquid floodback problems.



24.12 THE VAPOR (GAS) CHARGE BULB

The **vapor charge bulb**, *or gas-charged bulb*, has only a small amount of liquid refrigerant in the bulb, **Figure 24.22**. It is sometimes called a *critical charge bulb*. When the bulb temperature rises, more and more of the liquid will boil to a vapor until there is no more liquid. When this point is reached, an increase in temperature will no longer bring an increase in pressure. The pressure curve will be flat, **Figure 24.23(A)**. This acts to limit the maximum operating pressure the valve will allow the evaporator to experience, and so these valves are also often referred to as maximum operating pressure (MOP) valves. Notice that the TXV in **Figure 24.23(B)** has a MOP of 15. This means that when the evaporator pressure reaches 15 psig, all of the liquid in the remote bulb will be vaporized and no more opening pressure will be exerted on the diaphragm of the valve. The evaporator pressure will never go higher than 15 psig. Limiting the evaporator pressure will protect the compressor

Figure 24.22 This gas charge bulb is actually a liquid charge bulb with a critical charge. When the bulb reaches a predetermined temperature, the liquid is boiled away, and the pressure will not rise any further.

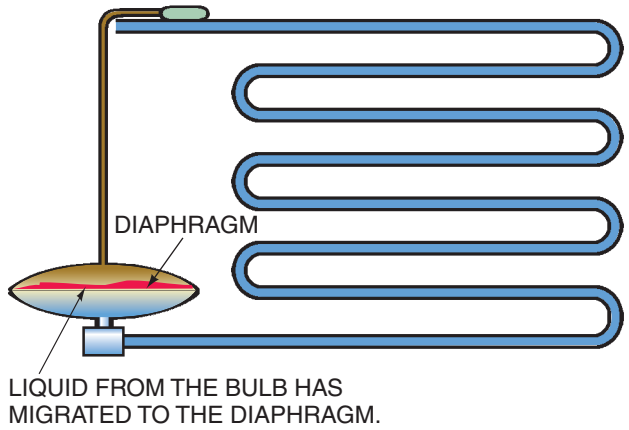
(B)

from an overloading condition resulting from excessively high pressures. Pressure entering the compressor that is too high causes the density of suction gases entering the compressor to increase. This in turn causes an increase in the mass flow rate of refrigerant through the compressor. High mass flow rates of refrigerant will overload the compressor by causing high compressor-motor amperage draws, which can overheat compressor motors and open motor overload protection devices, which will take the compressor out of service temporarily.

Figure 24.24 The liquid can migrate to the valve body when the body becomes cooler than the bulb. When this happens, the valve body can be heated with warm cloth, and the liquid will move back to the bulb.



When the vapor charge bulb is installed, care must be taken that the valve body does not get colder than the bulb; if it does, the vapor in the bulb will condense to liquid above the diaphragm. When this happens, the control at the end of the evaporator will migrate to the valve diaphragm area, **Figure 24.24.** Since the valve is operated by the temperature of the liquid at the diaphragm, control will be lost. Small heaters have been installed at the valve body to keep this from happening.

24.13 THE CROSS VAPOR CHARGE BULB

The **cross vapor charge bulb** is similar to the vapor charge bulb, but is charged with a fluid different from the refrigerant in the system. This creates a different pressure and temperature relationship under different conditions. These special valves are applied to special systems. Manufacturers or suppliers should be consulted when questions are encountered.

24.14 EXAMPLE OF A TXV FUNCTIONING WITH AN INTERNAL EQUALIZER

When all of these components are assembled, the expansion valve will function as follows. **NOTE:** *This example is based on a liquid-filled bulb.* •

1. **Normal load conditions.** The valve is operating in equilibrium (no change, stable), **Figure 24.25**. The evaporator is operating in a medium-temperature application and just before the cutoff point. The suction pressure is 18.4 psig, and the refrigerant, R-134a, is boiling (evaporating) in the evaporator at 20°F. The expansion valve is maintaining 10°F of superheat, so the suction-line temperature is 30°F at the bulb location. The bulb has been on the line long

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Figure 24.25 A TXV under a normal load condition. The valve is said to be in equilibrium. The needle is stationary.

enough that it is the same temperature as the line, 30°F. For now, suppose that the pressure of the liquid in the bulb is 26.1 psig, corresponding to 30°F. The spring is exerting a pressure equal to the difference in pressure to hold the needle at the correct position in the seat to maintain this condition. The spring pressure in this example is 7.7 psi.

2. **Load changes with food added to the cooler.** See **Figure 24.26(A)**. When food that is warmer than the inside of the cooler is added to the cooler, the load on the evaporator changes. The warmer food warms the air inside the cooler, and the load is added to the refrigeration coil by the air. This warmer air passing over the coil causes the liquid refrigerant inside the coil to boil faster. The suction pressure will also rise. The net effect of this condition will be that the last point of liquid in the coil will be farther from the end of the coil than it is when the coil is under normal working conditions. The coil will start to starve for liquid refrigerant. The TXV will start to feed more refrigerant to compensate for this shortage. This happens because the increased superheat in the evaporator causes the temperature of the remote bulb to rise. Since the pressure in the remote bulb is the only opening pressure in the TXV, the valve will open to feed more refrigerant to the evaporator. The rate of vaporization of the refrigerant in the evaporator will increase and cause the evaporator pressure to increase. In fact, the pressure on the whole low side of the system will increase all the way down to the compressor. When this condition of increased load has gone on for an extended time, the TXV will stabilize and reach a new point of equilibrium in the feeding of refrigerant, where no adjustment occurs.
3. **Load changes with food removed from the cooler.** See **Figure 24.26(B)**. When a large portion of the food is removed from the cooler, the load will decrease on the evaporator coil. There will no longer be enough load to boil the amount of refrigerant that the expansion valve is feeding into the coil, so the expansion valve will start overfeeding the coil. The coil is beginning to flood with liquid refrigerant. The TXV needs to throttle the refrigerant flow. When the TXV has operated at this condition for a period of time, it will stabilize and reach another point of equilibrium at or near 10°F of evaporator superheat. When the condition exists for a long enough time, the thermostat will stop the compressor because the air in the cooler is reduced to the thermostat cut-out point.

24.15 TXV FUNCTIONING WITH EXTERNAL EQUALIZERS

Evaporators are often designed and applied with pressure drop from the inlet to the outlet. This pressure drop may be created by a distributor located after the expansion valve or a long piping circuit. An external equalizer is required whenever the pressure drop in the evaporator exceeds

- 3 psig (air-conditioning applications).
- 2 psig (medium temperature refrigeration applications).
- 1 psig (low-temperature applications).

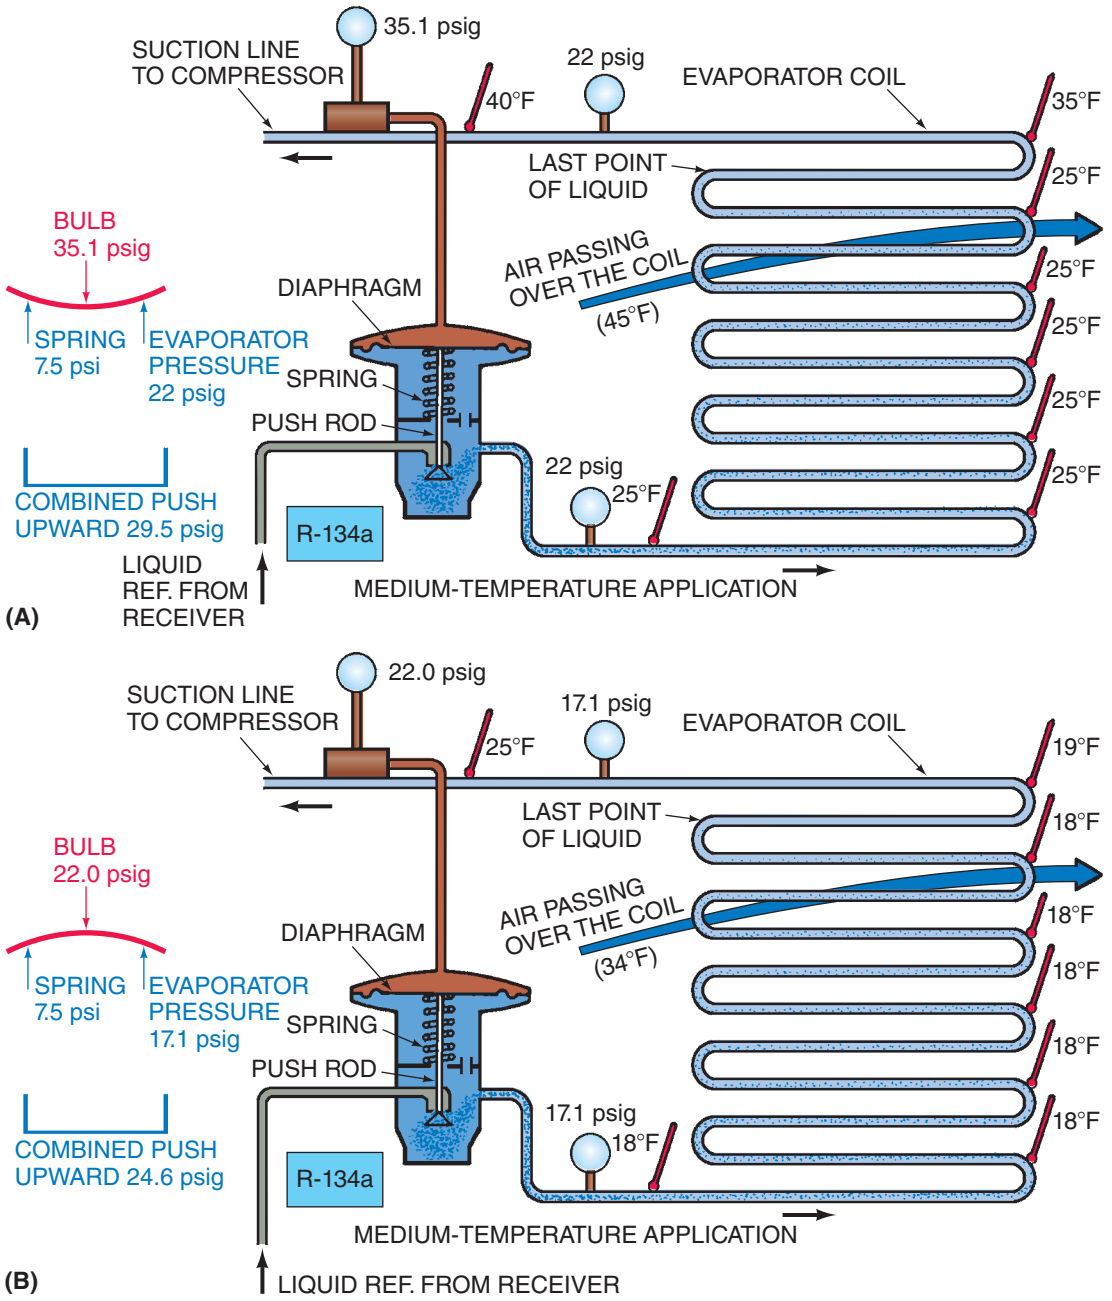
Figure 24.26 (A) When food is added to the cooler, the load on the coil goes up. The extra Btu added to the air in the cooler are transferred into the coil, which causes a temperature increase in the suction line. This causes the valve to open and feed more refrigerant. If this condition is prolonged, the valve will reach a new equilibrium point with the needle remaining steady, not moving. (B) When there is a load decrease, such as when some of the food is removed, the refrigeration machine now has prolonged time; the valve will reach a new point of equilibrium at a low-load condition. The thermostat will cut the unit off if this condition goes on long enough. The equilibrium point in (A) and (B) is the valve superheat set point of 10°F superheat. The valve should always return to this 10°F set point with prolonged steady-state operation.



The external equalizer on a TXV is used to compensate for, not get rid of, pressure drops from the inlet to the outlet of the evaporator. As mentioned, the pressure drops could be caused by a refrigerant distributor located after the TXV or simply by long evaporator piping circuits with a lot of U bends. **An external-equalized TXV must always be installed when a refrigerant distributor is used because of the distributor's large pressure drop characteristics.** Excess pressure drop in a coil with a TXV will cause the valve to starve the coil of refrigerant, **Figure 24.27**. When evaporator outlet pressure is sensed, less pressure is on the bottom of the TXV bellows than if evaporator inlet

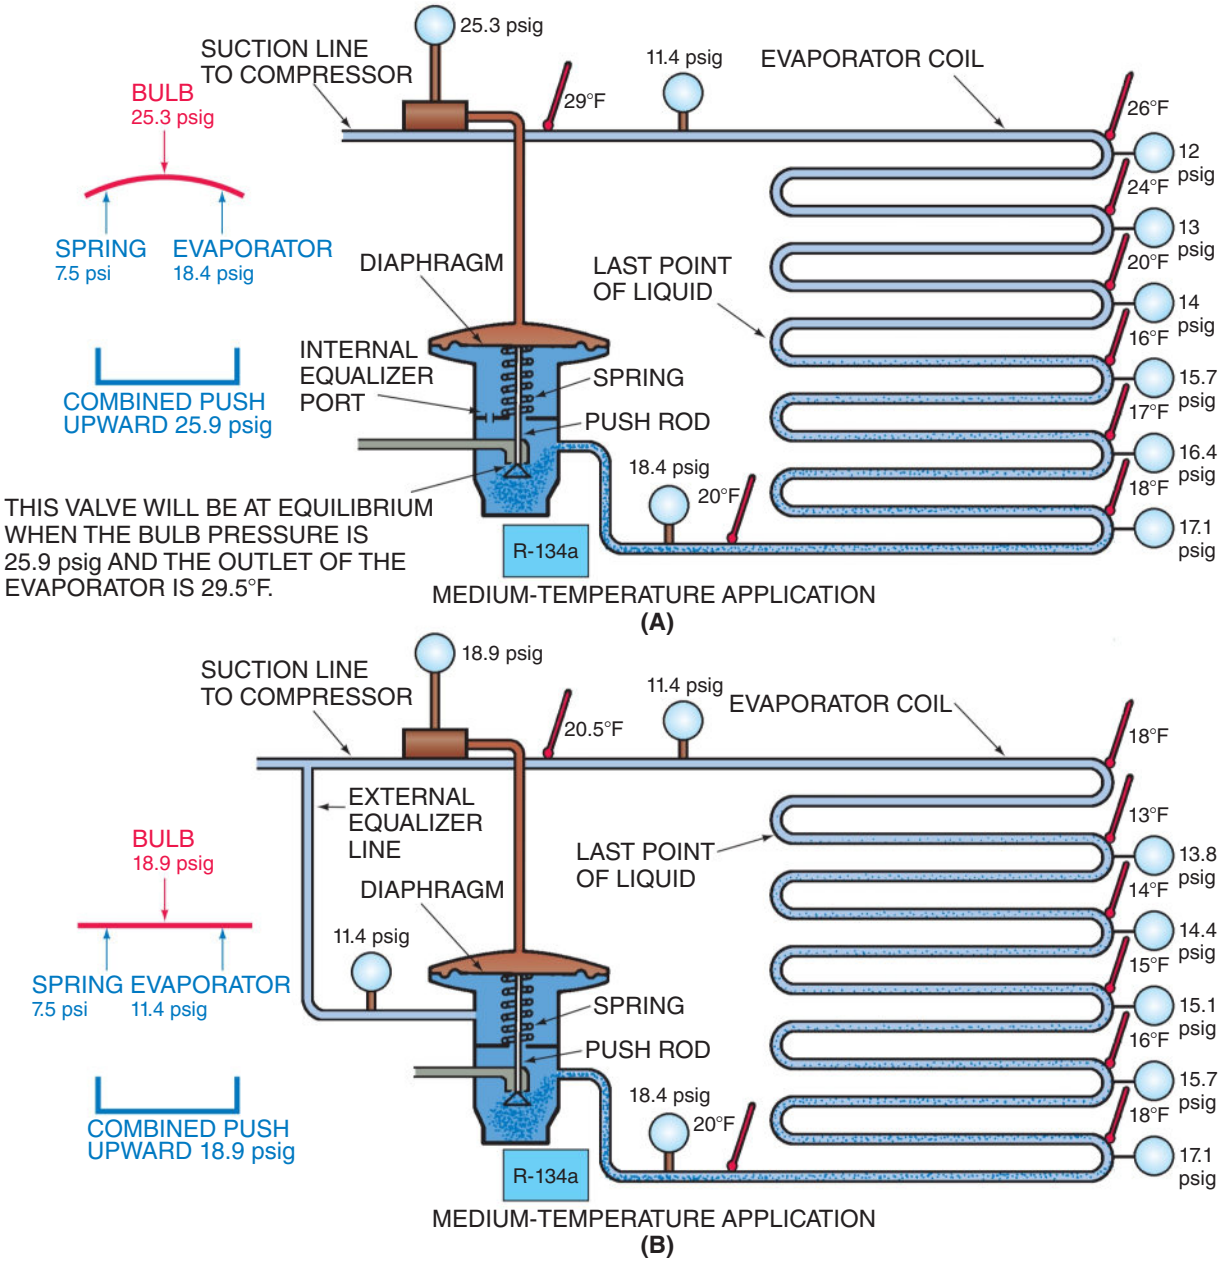
Figure 24.27 (A) This evaporator has 7-psig pressure drop, which starves the evaporator. (B) When a TXV with an external equalizer is added, the coil has the correct amount of refrigerant for best coil efficiency.



pressure is sensed. *This lower pressure causes a smaller closing force, so the valve remains more open and fills out more of the evaporator with refrigerant by compensating for the pressure drop through the evaporator. Remember, the evaporator is more efficient when it has the maximum amount of refrigerant without flooding any back to the compressor.* An expansion valve with an external equalizer was shown in **Figure 24.10**.

The external equalizer line should always be piped to the suction line after the expansion valve sensing bulb to prevent superheat problems from internal leaks in the valve, **Figure 24.28**. If a TXV with an external equalizer line were to have an internal leak, very small amounts of liquid would vent to the suction line through the external equalizer line. If the sensing bulb for the valve were to be touched by this small amount of liquid, it would throttle toward closed because this would simulate a flooded coil, **Figure 24.29**. Sometimes this condition can be sensed by feeling the line leading to the suction line. It should not become cold as it leaves the expansion valve.

24.16 TXV RESPONSE TO LOAD CHANGES

The TXV responds to a change in load in the following manner. When the load is increased—for example, when a load of food warmer than the cooler (refrigerated box) is placed inside the cooler—the TXV opens, allowing more refrigerant into the coil. The evaporator needs more refrigerant at this time because the increased load is evaporating the refrigerant in the evaporator faster. The suction pressure increases, **Figure 24.26(A)**. When there is a load decrease—for example, when some of the food is removed from the cooler—the liquid in the evaporator evaporates more slowly and the suction pressure decreases. At this time the TXV will throttle back by slightly closing the needle and seat to maintain the correct superheat. **The TXV responds to a load increase by metering more refrigerant into the coil. This causes an increase in suction pressure from the refrigerant boiling at a faster rate.**

24.17 SELECTION OF TXV VALVES

The TXV must be carefully chosen for a particular application. **Each TXV is designed for a particular refrigerant or group of refrigerants.** Many newer TXVs entering the market are manufactured to handle some of the newer, alternative refrigerants and refrigerant blends and are designed to be used with more than one refrigerant. This helps in the selection process and makes it a lot easier for service technicians when retrofitting a system.

The capacity of the system is very important. If the system calls for a 1/2-ton expansion valve and a 1-ton valve is used, the valve will not control correctly because the needle and seat are too large. If a 1/4-ton valve were used, it would not pass enough liquid refrigerant to keep the coil full, and a starving coil condition would occur.

24.18 BALANCED-PORT TXV

In response to need, manufacturers have developed TXVs that will feed refrigerant at the same rate when ambient temperatures are low. When the head pressure is low in mild weather, these valves do not reduce refrigerant flows, so the evaporator then has the correct amount of refrigerant and is able to operate at design conditions under lower outdoor temperatures. The flow of liquid on the face of the needle valve on larger TXVs tends to open the valve, which can cause erratic superheat control. With the **balanced-port TXV**, the liquid pressure is actually cancelled out because it acts on equal areas but in opposite directions. **Figure 24.30(A)** illustrates the liquid force on the face of the needle valve. For a larger TXV, this can be a significant opening force because of the larger surface area associated with the needle valve faces. This liquid or opening force also becomes significant with a large pressure drop across the valve from either high head pressures, low suction pressures, or a combination of both. **Figure 24.30(B)** illustrates how the liquid force on a balanced-port TXV is cancelled out. If this force is not cancelled out, the TXV would operate erratically, and the valve could not hold its original superheat setting. This can cause compressor damage if certain system parameters change, such as head pressure or suction pressure.

As compared to a conventional TXV, balanced-port valves have a large orifice or needle valve area. The needle valve also operates very close to its seat, which provides a very stable control of evaporator superheat with a minimum movement of the valve. This allows a large orifice or needle valve assembly to handle both large and small loads. This type of design can help refrigeration equipment pull down faster. The larger orifice or needle valve assembly can also handle some liquid-line bubbles or flash gas if they happen. This is where the term *balanced port* originates. Balanced-port TXVs should be used if any of the following conditions exist:

- Large varying head pressures
- Larger varying pressure drops across the TXV
- Widely varying evaporator loads
- Very low liquid-line temperatures

You cannot tell a balanced-port expansion valve from a regular expansion valve by its appearance. It will have a different model number, and you can look it up in a manufacturer's catalog to determine the type of valve it is.

24.19 THE PRESSURE-LIMITING TXV

The pressure-limiting TXV has another bellows that will only allow the evaporator to build to a predetermined pressure, and then the valve will throttle the flow of liquid. This valve is desirable on low-temperature applications because it keeps the suction pressure to the compressor down during a hot pulldown that could overload the compressor. For example, when a low-temperature cooler is started with the inside of the box hot, the compressor will operate under an overloaded condition until the box cools down. The pressure-limiting TXV valve will prevent this from happening, **Figure 24.31**. The vapor charge bulb TXV also has pressure-limiting qualities, **Figure 24.23(B)**.

24.20 SERVICING THE TXV

Care should be taken when selecting any TXV that the valve will be serviceable and perform correctly. Several things should be considered: (1) type of fastener (flare, solder, or flange), (2) location of the valve for service and performance,

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 24.30 (A) The liquid force on the face of the needle valve, which can be a significant opening force for the TXV. (B) Equal liquid forces, but opposite in direction, can cancel one another out in a balanced-port TXV.

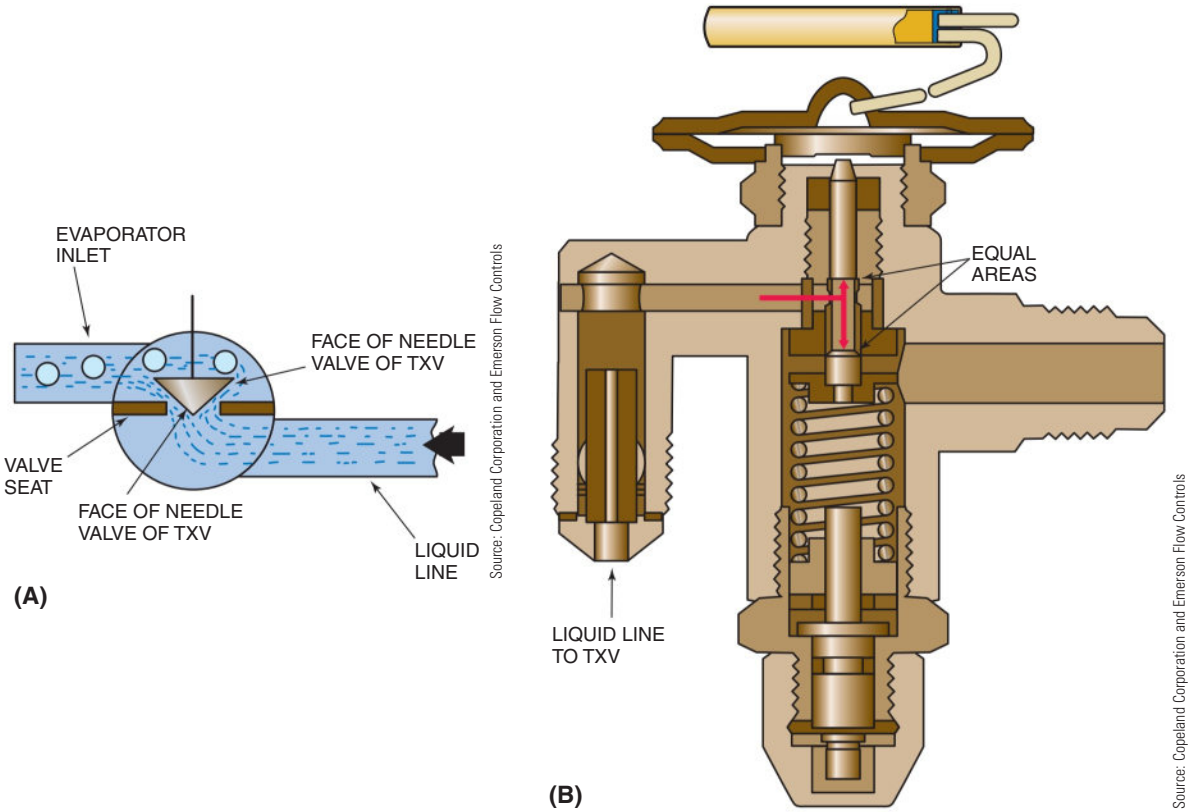

Figure 24.31 A pressure-limiting expansion valve. When the pressure is high in the evaporator, such as during a hot pulldown, this valve will override the thermostatic element with a pressure element and throttle the refrigerant.

and (3) location of the expansion valve bulb. The valve has moving parts that are subject to wear. When a valve must be replaced, an exact replacement is usually best. When this is not possible, a supplier can furnish you with the information needed to select another valve.

Many technicians (and owners) will adjust a TXV. This may cause problems because pressures and temperatures in the coil will be changed. If the valve sensing element is mounted properly and in the correct location where it can sense refrigerant vapor, the valve should work correctly as shipped from the factory. The valves are very reliable and normally do not require any adjustment. If there are signs that the valve has been adjusted, look for other problems, because the valve probably did not need adjustment to begin with. Many manufacturers are producing nonadjustable valves to prevent people from adjusting the valve unnecessarily.

24.21 INSTALLING THE SENSING ELEMENT

Particular care should be taken when installing the expansion valve sensing element. Each manufacturer has a recommended method for installation, but all are similar. The valve sensing bulb has to be mounted at the end of the evaporator on the suction line. The recommended location for the thermal bulb on smaller suction lines is near the top of the line. The best location for larger suction lines is near the bottom of the line on a horizontal run where the bulb can be mounted flat and not be raised by a fitting, **Figure 24.32**. The bulb should not be located at the bottom of the line because returning oil will act as an insulator to the sensing element. The objective of the sensing element is to sense the temperature of the refrigerant gas in the suction line. To do this, the line should be very clean and the

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Figure 24.32 The best positions for mounting the expansion valve sensing bulb.

bulb should be fastened to this line very securely. Normally, the manufacturer suggests that the bulb be insulated from the ambient temperature if the ambient is much warmer than the suction-line temperature, because the bulb will be influenced by the ambient temperature as well as by the line temperature.

24.22 STEP-MOTOR EXPANSION VALVES

The *step-motor valve* uses a small motor to control the valve's port, which in turn controls evaporator superheat. A solid-state controller instructs the step motor to rotate a fraction of a revolution, or step, for each signal sent by the controller, **Figure 24.33**. The controller has a temperature sensor, or thermistor, as one of its inputs, **Figure 24.34**. Thermistors, solid-state devices that will change their electrical resistance in response to a change in temperature, are used because they are accurate, readily available, and reasonably priced. Once the electrical signal is taken away, the motor stops; it does not rotate continuously. The motor can return the valve to any previous position at any time because the controller can remember the number of steps it has taken. Many of these motors can operate at a rate of 200 steps per second. Most modern step motors used in electronic expansion valve applications have a bipolar motor design. Multiple electromagnets, as many as 100, are placed around a permanent magnet acting as the motor's rotor, **Figure 24.35**. They can produce step increments as small as 3.6° in rotation (this figure comes from a total of

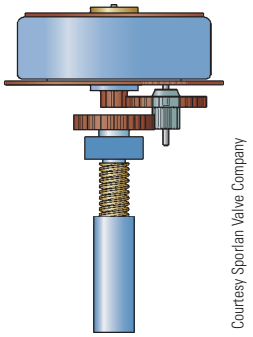
360° divided by 100 magnets). The pin or valve port piston of the electronic step-motor expansion valve can move in a linear motion of 0.0000783 in./step.

The motor is powered by signals that change in polarity. This creates a push/pull action within the motor's magnetic fields and increases the torque and efficiency of the motor and so permits a very small motor. The torque, or rotational force, is then translated into linear motion by a digital linear actuator, **Figure 24.36**. The motor and valve thus make up a true modulating device comparable to the dimmer switch on a typical household light, which has thousands of steps. The step motor is not a pulsing digital motor or a common light switch that has only two steps, on or off.

The controller consists of many transistors for each switching function. Transistors are solid-state switches that are made from a solid chip of silicon and have no moving parts. They act as relays by using small electrical signals to turn a larger electrical signal on and off. The small electrical signal enters the base of the transistor, which allows flow

Figure 24.36 A digital linear actuator.



Courtesy Sporlan Valve Company

from emitter to collector. A small microcomputer in the controller has a programmed algorithm, which can control or sequence the electrical signal given to the base of each transistor, **Figure 24.37**. An algorithm is simply a program or set of instructions resident in the **microprocessor** of the controller. The transistors are usually turned on and off in pairs, which step the electronic valve in either the open or the closed direction in small increments to control evaporator superheat.

The controls of electronic expansion valves (EEVs) use algorithms, and a set of electronic instructions, along with a *proportional, integral, and derivative (PID) controller.* (PID controllers will be explained in the next section.) The valve's hardware includes the step motor, the controller, transistors, and the microprocessor. As mentioned earlier, algorithms, or sets of instructions, often referred to as **software**, must be resident in the microprocessor.

Feedback loops are used to let the controller know that the process of controlling evaporator superheat needs to be changed or modified. This means that when the controller opens the EEV too much, which in turn overcools the thermistor sensor on the evaporator outlet, the sensor will feed back this information so the controller can start to close the valve, **Figure 24.38**. The sensor in the feedback loop is usually a thermistor that is located on the evaporator outlet. Often, two thermistors, located on the evaporator's inlet and outlet, are used to calculate evaporator superheat.

The difference in temperature would be the calculated evaporator superheat. With this method, there is no need for temperature/pressure tables or for a pressure transducer to sense pressure. This greatly simplifies the superheat calculation process.

24.23 ALGORITHMS AND PID CONTROLLERS

As mentioned earlier, the EEV controls use many different algorithms or sets of instructions along with a PID controller. The following paragraphs will explain the PID controller. Although we start with explaining proportional, integral, and derivative controls separately, in reality they work together to modify the controller's output signal to the EEV for less error.

Proportional controllers refer to a modulating controller mode. Proportional controllers generate an immediate change in the position of the expansion valve in response to changes in the evaporator superheat of the system. They generate an analog (modulating) output signal instead of a binary (on/off) output signal. The output signal of a proportional controller is always present, but its magnitude will vary. Proportional modes can only be used in closed-loop, feedback applications like that of the EEV. In proportional mode, the actual evaporator superheat will "approach" the evaporator superheat set point of the controller but may never reach it in all applications. The difference between the superheat set point of the controller and the actual superheat is called **offset** or **error**, **Figure 24.39**. Proportional-mode controllers change or modify the controller's output signal to the expansion valve in proportion to the size of the change in the error. It cannot sense, and has no control over, any timespan that the superheat error has been in existence. For example, if the thermistor on the evaporator's outlet is very warm, meaning high superheat to the controller, a large movement of the expansion valve in the opening direction would follow. In this example, the controller saw a large error between the evaporator superheat set point and the actual evaporator superheat and compensated for it with a large valve movement.

A typical programmed algorithm for a proportional controller follows:

If evaporator superheat is 20°F, then open the valve 175 steps.
If evaporator superheat is 15°F, then open the valve 125 steps.
If evaporator superheat is 10°F, then open the valve 0 steps.
If evaporator superheat is 6°F, then close the valve 75 steps.
If evaporator superheat is 0°F, then close the valve 1000 steps.

This algorithm will change the output (motor steps) in direct relation to the input (superheat). However, if the algorithm is used, the valve will slowly reach the controller's superheat set point, especially if the step motor has over 5000 steps. This is why a more sophisticated algorithm including integral and derivative functions must be used.

If the offset or error was a constant value, as shown in **Figure 24.39**, this constant difference could simply be preprogrammed into the controller. However, offset will change over time as refrigeration system parameters change with changing heat loads. This is why some means of predicting the offset must be used to lessen its value and let the controller reach its evaporator superheat set point value. This is where the integral controller comes into play.

Integral controller modes can be added to a proportional controller to modify the controller's output signal, which will help force the offset value error to zero. The integral mode will change the controller's output signal in proportion to the size of the error or offset and the length of time it exists. The integral mode will calculate the amount of error that exists over a specific time interval. The integral controller actually calculates the area under the curve of the temperature/time graph, **Figure 24.40**. In mathematical terms, finding an area under a curve is often called integration. Integration, or the integral mode, of a controller will sense the average deviation of the actual evaporator superheat from the controller's superheat set point. Following is an example of a typical integral algorithm:

If the average superheat for 60 seconds is 6°F high, then open the valve 50 steps.

Figure 24.39 This temperature/time graph shows set point and offset, or "error."

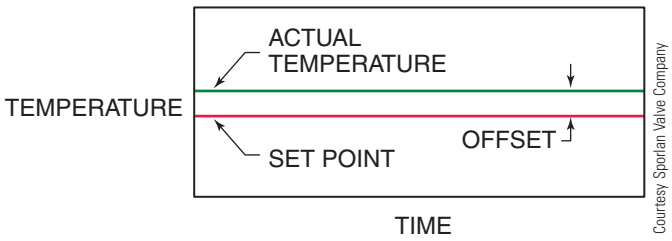

Figure 24.40 The temperature/time graph of an integral controller showing set point, offset, and reset.

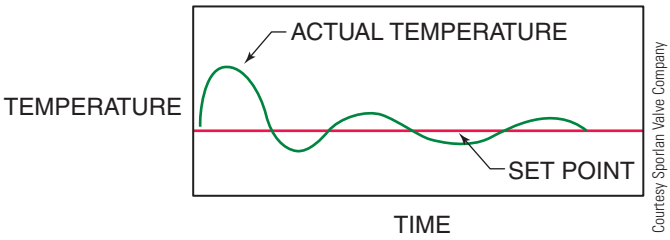
Figure 24.41 The temperature/time graph of a derivative, or differential, controller showing slopes or rates of change.



Thus, the offset or error in superheat is constantly being changed as heat load and refrigeration system parameters change. The changing amount of offset is calculated by the control algorithm and is then added to the set point. Another name for integral control is reset control. The calculation of the time-weighted offset (error), or the area under the curve of the time/temperature graph, occurs over a period of time referred to as the reset time. The controller will constantly try to reset the measured evaporator superheat to the superheat set point of the controller.

Derivative (differential) controller modes can also be added to a proportional controller, which will ensure even closer evaporator superheat control. The terms *derivative* and *differential* are used interchangeably. Derivative algorithms estimate the slope, or rate of change, of the temperature/time curve, **Figure 24.41**. If the rate of change (slope) is great, then the controller will make larger changes. If the slope is small, the controller will make small changes. Derivative control actually calculates the instantaneous rate of change of the error with respect to time. It can tell how fast the process error is changing. The controller can then adjust the magnitude of its output signal to the EEV in proportion to the rate of change of the error in evaporator superheat of the system. This type of control reacts quickly to changes and will reduce any effect that changes in evaporator loads or system parameters have on the evaporator superheat set point. A typical derivative algorithm is shown here:

If superheat has dropped 0.2°F in 10 seconds, then close the valve 15 steps.
If superheat has dropped 2.0°F in 2 seconds, then close the valve 50 steps.

24.24 THE AUTOMATIC EXPANSION VALVE

The **automatic expansion valve (AXV)** is an expansion device that meters the refrigerant to the evaporator by using a pressure-sensing device. This device is also a valve that changes in inside dimension in response to its sensing element. **The AXV maintains a constant pressure in the evaporator. Notice that superheat is not mentioned.** This device has a needle and seat like the TXV that is fastened to a diaphragm,

Figure 24.42 The automatic expansion valve uses the diaphragm as the sensing element and maintains a constant pressure in the evaporator but does not control superheat.

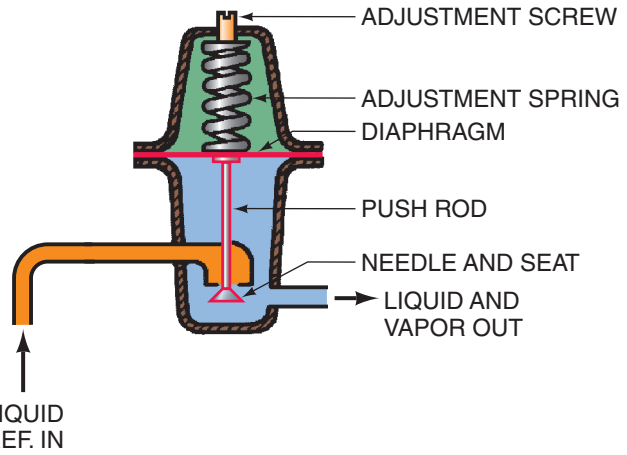


Figure 24.42. One side of the diaphragm is common to the evaporator and the other side to the atmosphere. When the evaporator pressure drops for any reason, the valve begins to open and feed more refrigerant into the evaporator.

The AXV is built much the same as the TXV except that it does not have a sensing bulb. The body is normally made of machined brass. The adjustment for this valve is normally at the top of the valve. There may be a cap to remove, or there may be a cap to turn. This adjustment changes the spring tension that supports the atmosphere in pushing down on the diaphragm. When the tension is increased, the valve will feed more refrigerant and increase the suction pressure, **Figure 24.43**.

Figure 24.43 Automatic expansion valves. They resemble the TXV, but they do not have the bulb for sensing temperature at the suction-line end of the evaporator.

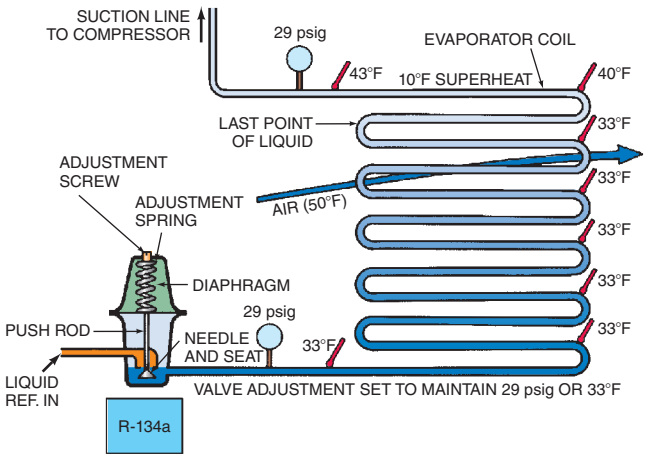
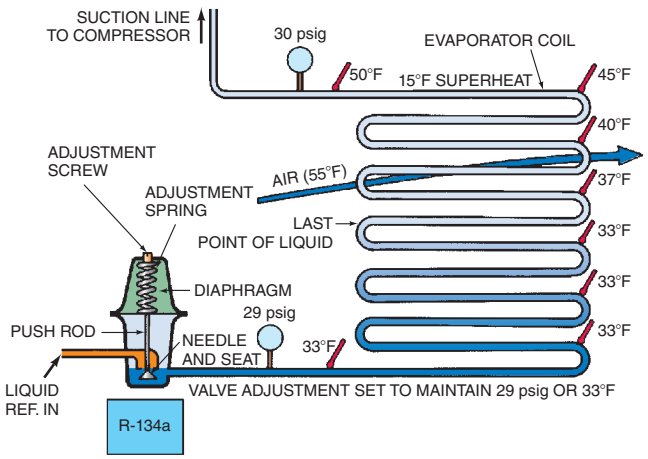
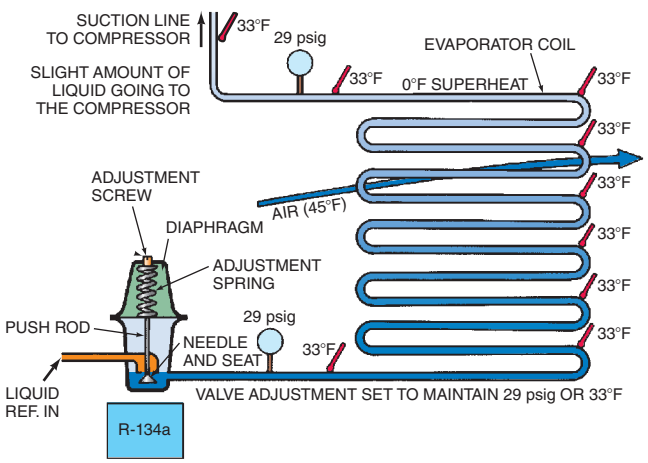
Figure 24.44 An automatic expansion valve under varying load conditions. This valve responds in reverse to a load change. (A) Normal operation. (B) When the load goes up, the valve closes down and starts to starve the coil slightly to keep the evaporator pressure from rising. (C) When the load goes down, the valve opens up to keep the evaporator pressure up. This valve is best applied where the load is relatively constant. When applied to a water-type evaporator, the valve's freeze protection can be a big advantage.



(A)



(B)



(C)

24.25 AUTOMATIC EXPANSION VALVE RESPONSE TO LOAD CHANGES

The AXV responds differently than the TXV to load changes. It actually acts in reverse. When a load is added to the coil, the suction pressure starts to rise. The AXV will start to throttle the refrigerant by closing enough to maintain the suction pressure at the set point. This has the effect of starving the coil slightly. A large increase in load will cause more starving. When the load is decreased and the suction pressure starts to fall, the AXV will start to open and feed more refrigerant into the coil. If the load reduces too much, liquid could actually leave the evaporator and proceed down the suction line, **Figure 24.44**.

Because the AXV can maintain constant pressure, it cannot be used with a low-pressure motor control. When the AXV is used with a thermostat, the thermostat should be adjusted to shut the compressor off before flooding of the entire evaporator occurs. The AXV should be adjusted to maintain an evaporator pressure that corresponds to the lowest evaporator temperature desired through the entire running cycle of the compressor. AXVs are usually found on smaller equipment with somewhat constant evaporator loads, including ice cream freezers and makers and drinking fountains.

24.26 SPECIAL CONSIDERATIONS FOR THE TXV AND AXV

Both the TXV and the AXV are expansion devices that allow more or less refrigerant flow, depending on the load. Both need a storage device (receiver) for refrigerant when it is not needed. The receiver is a small tank located between the condenser and the expansion device. Normally, the condenser is close to the receiver. It has a *king valve* that functions as a service valve. This valve stops the refrigerant from leaving the receiver when the low side of the system is serviced. The receiver can serve both as a storage tank for different load conditions and as a tank into which the refrigerant can be pumped when servicing the system, **Figure 24.45**.

Figure 24.45 A refrigerant receiver. When the load increases and more refrigerant is needed, it moves from the receiver into the system.

24.27 THE CAPILLARY TUBE METERING DEVICE

The **capillary tube** metering device controls refrigerant flow by pressure drop. It is a copper tube with a very small, calibrated, inside diameter, **Figure 24.46(A)**. The diameter and the length of the tube determine how much liquid will pass through the tube at any given pressure drop, **Figure 24.46(B)**. It is much like a garden hose: The larger the hose, the more gallons of water will pass at 100 psig pressure at the hose inlet, **Figure 24.46(C)**.

Figure 24.46 (A) A capillary tube metering device. (B) The length of the capillary tube as well as the bore determines the flow rate of the refrigerant, which is rated in pounds per minute.

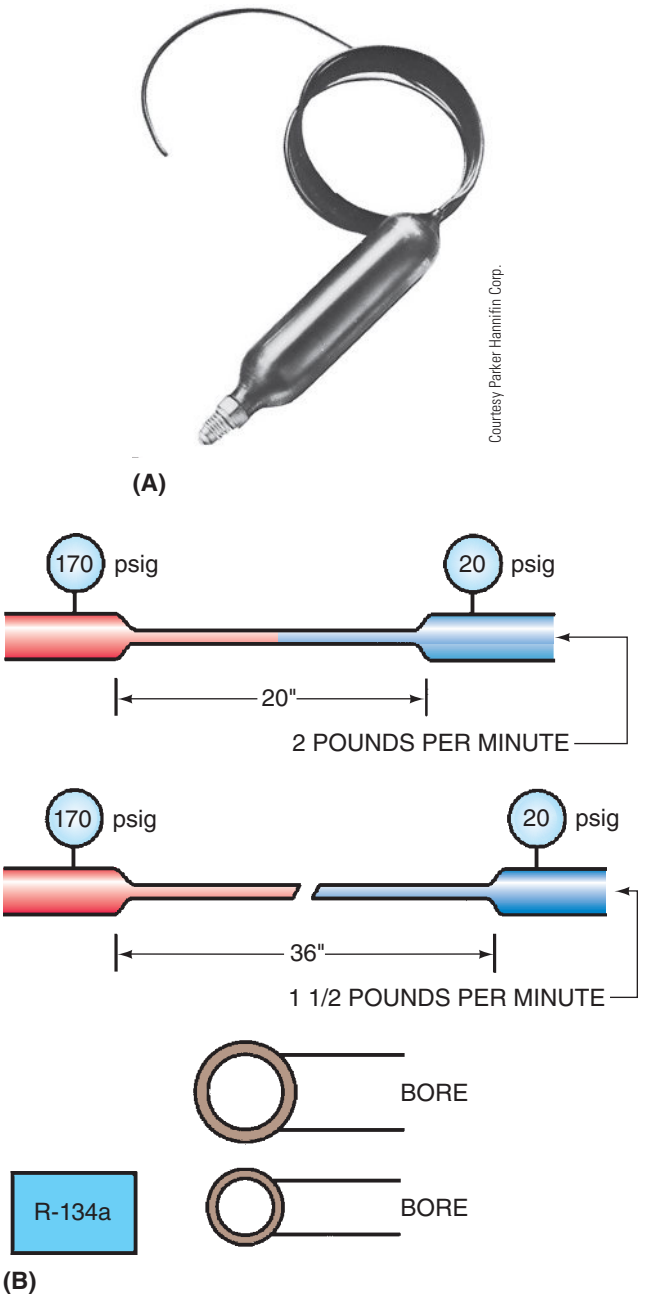

Figure 24.46 (C) The longer the hose, the less water pressure at the end. A capillary tube functions the same way.

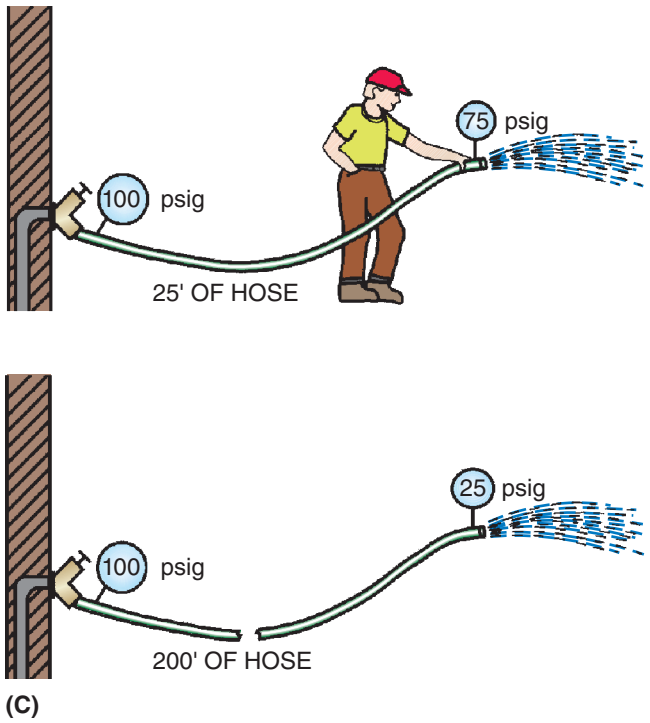

The water hose has pressure drop all along its length, so a longer hose will have less pressure at the outlet even though the pressure at the inlet is 100 psig. This length-to-pressure drop relationship is used by manufacturers to arrive at the pressure drop that will allow the correct amount of refrigerant to pass through the capillary tube to correctly fill the evaporator. The capillary tube can be quite long on some installations and may be wound in a coil to store the extra tubing length.

The capillary tube does not control superheat or pressure. It is a fixed-bore device with no moving parts. Because this device cannot adjust to load change, it is usually used where the load is relatively constant with no large fluctuations. It is an inexpensive device for the control of refrigerant and is often used in small equipment. This device does not have a valve and does not stop the liquid from moving to the low side of the system during the off cycle, so pressures will equalize during the off cycle. This reduces the motor-starting torque requirements for the compressor. **Figure 24.47(A)** illustrates a capillary tube in place at the inlet of the evaporator.

Because the capillary tube has no moving parts, it will not wear out. About the only problems it may have would come from small particles that may block or partially block the tube. The bore is so small that a small piece of flux, carbon, or solder would cause a problem if it were to reach the tube inlet. Manufacturers always place a strainer or strainer-drier just before the capillary tube to prevent this from happening, **Figure 24.47(B)**. Capillary tube metering devices can also become oil logged, which can cause a partial or complete blockage of the tube. Too much oil, or the wrong viscosity of

(B)

oil, in the refrigeration system can cause oil logging. Another cause of oil logging is liquid refrigerant entering the crankcase of the compressor and then flashing. This is referred to as **flooding** the crankcase when it occurs during the run cycle. It is called **migration** when it occurs during the off cycle. The flashing of refrigerant in the warm compressor's crankcase causes the oil in the crankcase to foam and be sucked into the suction valve of the compressor during the run cycle. The oil is then circulated until it eventually reaches the capillary tube. Oil-logged capillary tubes cause sluggish operations and systems usually run with high superheats as a result, causing inefficiencies and damage to compressors from overheating due to lack of refrigerant in circulation for cooling. Often, long running cycles will return the oil to the compressor's crankcase. If oil in the capillary tube is suspected, force the

Figure 24.48 Hydraulic capillary-tube cleaning kit.

system to run for several hours. This may resolve the problem of an oil-logged capillary tube. There are hydraulic capillary tube cleaners on the market, but they should be used as a last resort, **Figure 24.48**.

24.28 OPERATING CHARGE FOR THE CAPILLARY TUBE SYSTEM

The capillary tube system requires only a small amount of refrigerant because it does not modulate (feed more or less) refrigerant according to the load. Capillary tube systems are known as critically charged systems. When the refrigerant charge is analyzed and when the unit is operating at the design conditions, a specific amount of refrigerant is in the evaporator and a specific amount of refrigerant is in the condenser. This is the amount of refrigerant required for proper refrigeration. Any other refrigerant that is in the system is in the pipes for circulating purposes only.

The amount of refrigerant in the system is critical in capillary tube systems. It is easy for technicians to overcharge if they are not careful and familiar with the system. In most capillary tube systems, the charge is printed on the nameplate of the equipment. The manufacturer always recommends measuring the refrigerant into these systems either by scales or by liquid-charging cylinders. A properly charged system would maintain about 10°F superheat at the end of the coil once the system is pulled down to the desired box temperature, **Figure 24.47(A)**. A characteristic of a capillary tube metering device system is to run high evaporator superheat under high evaporator heat loads. However, once the system is pulled down near the desired refrigerated box temperature, an evaporator superheat of about 8°F to 12°F will be reached if the system is critically charged properly.

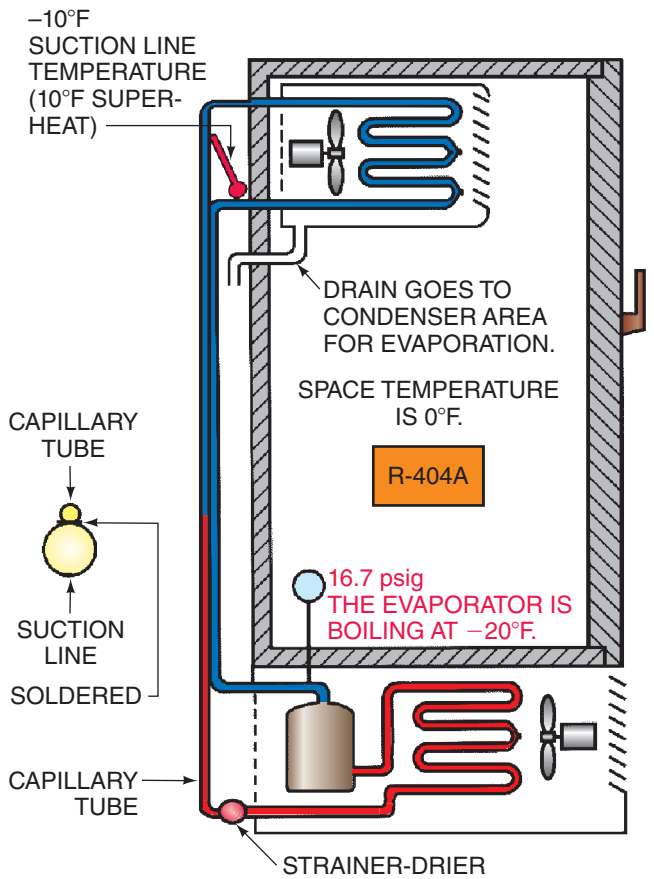
Figure 24.49 Checking the superheat before the suction–liquid heat exchange.



In many capillary tube systems, the capillary tube is fastened to the suction line between the condenser and the evaporator to exchange heat between the capillary tube and the suction line. To troubleshoot a possible capillary tube problem, the correct superheat reading must be taken. The capillary tube should hold the refrigerant to about 10°F superheat at the end of the evaporator once the box temperature is pulled down and the heat load is at a minimum. *To obtain the correct superheat reading it must be taken before the capillary tube/suction line heat exchanger,* **Figure 24.49**.

The capillary tube is very slow to respond to load changes or charge modifications. For example, if a technician were to add a small amount of refrigerant to the capillary tube system, it would take at least 15 min for the charge to adjust. The reason for this is that the refrigerant moves from one side of the system to the other through the small bore, and this takes time. When refrigerant is added to the low side of the system, it moves into the compressor and is pumped into the condenser. It now must move to the evaporator before the charge is in balance. Many technicians get in a hurry and overcharge this type of system. Manufacturers do not recommend adding refrigerant to top off the charge; they recommend starting over from a deep vacuum and measuring a complete charge into the system.

Under high evaporator loads, capillary tube systems will often cause high evaporator superheats of 40°F or 50°F. This is because the refrigerant in the evaporator will vaporize rapidly, and the last point of liquid will be toward the middle of the evaporator. This makes the system very inefficient. Many technicians have the urge to add more refrigerant to the system at these high loads because of the high superheat readings. Adding refrigerant at this point will, in time, only overcharge the system. Before adding refrigerant, check the superheat at the normal evaporator load to see whether it is normal. It should be from 8°F to 12°F at the normal evaporator load. If unsure, recover the refrigerant, evacuate the system, and add the specified nameplate critical charge of refrigerant. Under low evaporator heat loads, the refrigerant in the evaporator will not vaporize as fast. Low evaporator loads are usually experienced just before the desired box temperature is reached. The last point of liquid will now be toward the end of the evaporator. The system will still have a normal superheat of about 8°F to 12°F because of its critical charge characteristics.

The capillary tube metering device is used primarily on small fractional-horsepower refrigeration systems that have somewhat constant evaporator heat loads. These systems are hermetically sealed; have no bolted, gasketed connections; and are leak-free systems. They are factory assembled in a very clean environment and should run trouble-free for many years.

SUMMARY

- The expansion device is one of the dividing points between the high and low sides of the system.
- The TXV valve maintains a constant *superheat* in the evaporator.
- The bulb pressure is the only force that acts to open the TXV valve.
- The forces inside the expansion valve all work together to hold the needle and seat in the correct position so that the evaporator will have the correct amount of refrigerant under all load conditions.
- The liquid temperature entering the TXV, the evaporator temperature, and the pressure drop across the TXV all determine the capacity of the TXV in tons.
- Balanced-port TXVs are used where low ambient temperatures exist, head pressures vary widely, evaporator loads

vary widely, large pressure drops exist across the TXV, or low liquid-line temperatures exist.
- Maximum operating pressure (MOP) TXVs limit the evaporating pressure to prevent the compressor from overloading.
- Electronic expansion valves (EEV)s use proportional, integral, and derivative (PID) controllers for their operations.
- The automatic expansion valve responds in reverse to a load change; when the load increases, the automatic expansion valve throttles the refrigerant instead of feeding more refrigerant as the TXV does.
- The capillary tube expansion device is a fixed-bore metering device usually made of copper, with a very small inside diameter and no moving parts.
- The capillary tube system uses a very limited amount of refrigerant compared with other metering devices and is popular in small systems.

REVIEW QUESTIONS

1. Which is not a pressure or force acting on a TXV diaphragm?
   A. Head pressure
   B. Evaporator pressure
   C. Spring pressure
   D. Bulb pressure
2. The needle and seat of a TXV are normally made of _____.
3. The TXV tries to maintain a constant _____ in the evaporator.
4. The four types of charges that the TXV uses to control refrigerant flow are _____, _____, _____, and _____.
5. The bulb of the TXV is mounted on the
   A. compressor inlet.
   B. compressor outlet.
   C. evaporator inlet.
   D. evaporator outlet.
6. When do some TXVs require an external equalizer?
7. Draw a diagram showing how an external equalizer line is connected into a system.
8. The TXV responds to an increased heat load by
   A. decreasing refrigerant flow.
   B. keeping refrigerant flow constant.
   C. increasing refrigerant flow.
   D. not reacting to changing heat loads.
9. The three factors that determine the capacity of a TXV are _____, _____, and _____.
10. Explain why the entering liquid pressure has no effect on the opening force of a balanced-port TXV.
11. Explain how a PID controller works.
12. Explain the following terms as they apply to electronic expansion valves:
    step motor
    offset
    error
    algorithm
    microprocessor
    feedback loop
13. What condition does the automatic expansion valve maintain in the evaporator?
14. How does the automatic expansion valve respond to a load increase?
15. What determines the amount of refrigerant that flows through a capillary tube metering device?
16. Explain what is meant by a maximum operating pressure (MOP) TXV.

UNIT 25

SPECIAL REFRIGERATION SYSTEM COMPONENTS

OBJECTIVES

After studying this unit, you should be able to

- distinguish between mechanical and electrical controls.
- explain how and why mechanical controls function.
- describe an automatic pumpdown system.
- define low-ambient operation.
- describe electrical controls that apply to refrigeration.
- describe off-cycle defrost.
- describe random, planned, hot gas, cool gas, and external heat defrost.
- explain temperature-terminated defrost.
- describe the various refrigeration accessories.
- describe the low-side components.
- describe the high-side components.
- explain the function of a compressor oil pump and oil check valve.
- describe the function of a partition wall in a compressor.

SAFETYCHECKLIST

- ☑ Wear goggles and gloves when attaching or removing gauges to transfer refrigerant or to check pressures.
- ☑ Wear warm clothing when working in a walk-in cooler or freezer. A technician does not think properly when chilled.
- ☑ Be careful not to get your hands or clothing caught in moving parts such as pulleys, belts, or fan blades.
- ☑ Wear an approved back brace belt when lifting and use your legs, keeping your back straight and upright.
- ☑ Observe all electrical safety precautions. Be careful at all times and use common sense.
- ☑ Never work near live electrical circuits unless absolutely necessary. Turn the power off at the nearest disconnect, lock and tag the panel, and keep the only key in your possession.

25.1 THE FOUR BASIC COMPONENTS

The compression refrigeration cycle must have four basic components to function: the compressor, the condenser, the evaporator, and the expansion device. However, many more devices and components can enhance the performance and the reliability of the refrigeration system. Some of these protect the components, and some improve the reliability under various conditions. Special refrigeration system components can be divided into two broad categories: controls and accessories. Control components are divided into mechanical, electrical, and electromechanical.

25.2 MECHANICAL CONTROLS

Mechanical controls generally stop, start, or modulate fluid flow and can be operated by pressure, temperature, or electricity. These controls can usually be identified by their location, because they are almost always found in the piping.

25.3 TWO-TEMPERATURE CONTROLS

When two-temperature operation is desirable, more than one evaporator is used with a compressor. Two or more evaporators may be designed to operate in different temperature ranges, such as an evaporator operating at 30°F used on the same compressor as an evaporator operating at 20°F, **Figure 25.1**. Two-temperature operation is normally accomplished by means of a purely mechanical valve operating within another, temperature-controlled valve.

25.4 EVAPORATOR PRESSURE CONTROL

The **evaporator pressure-regulating valve (EPR valve)** is a mechanical control that keeps the refrigerant pressure in the evaporator from going below a predetermined point. The EPR valve is installed in the suction line at the evaporator outlet. The bellows in the EPR valve senses evaporator pressure and throttles (modulates) the suction gas to the compressor. This will then allow the evaporator pressure to go as low as the pressure setting on the valve. When the EPR valve is used with the *thermostatic expansion valve* (TXV), the system can maintain a constant superheat and keep the pressure from going too low, **Figure 25.2**.

Figure 25.1 Two-temperature operation. Two evaporators are operating with one compressor. One evaporator operates at 20°F (18.4 psig), the other at 30°F (26.1 psig).

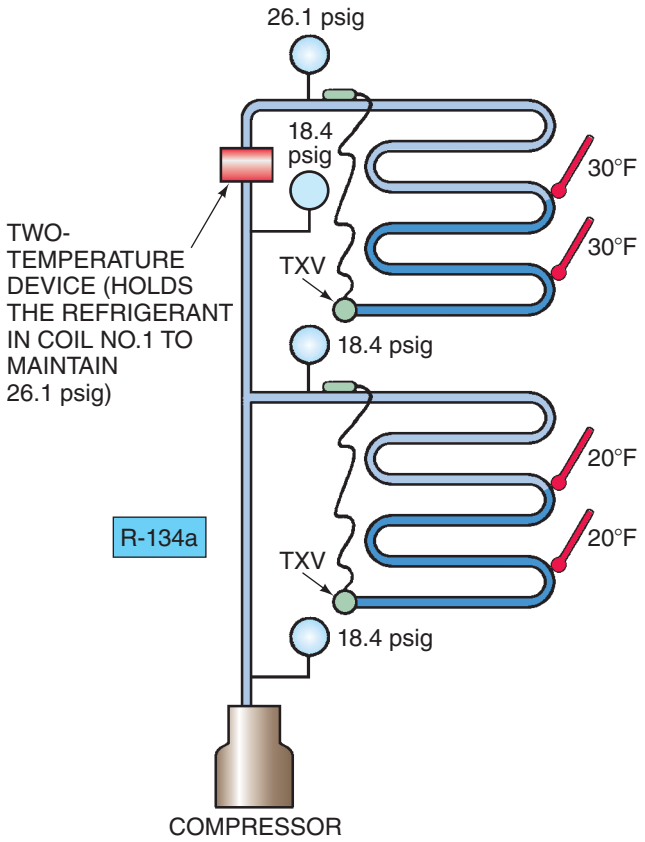

Figure 25.2 The EPR valve modulates the flow of vapor refrigerant leaving the evaporator. It limits the pressure in the evaporator and keeps it from dropping below the set point.

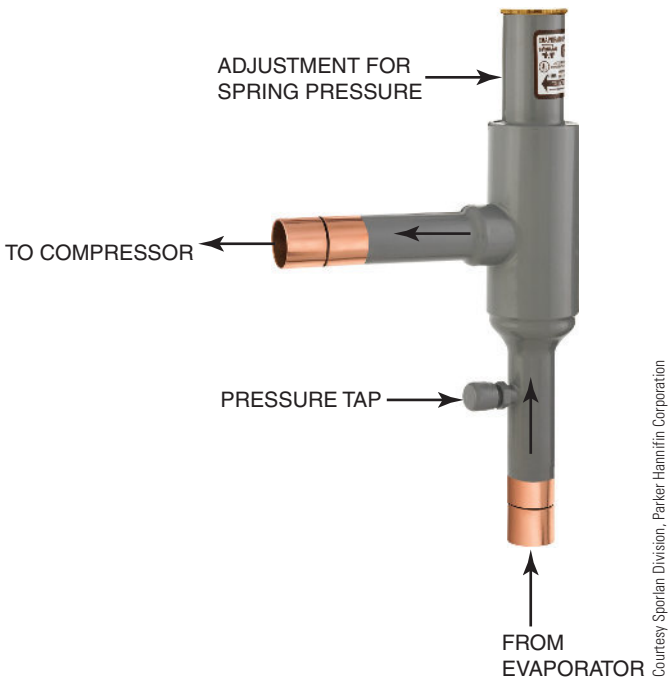

The EPR valve can be used in a system that cools water to keep the evaporator from going below a predetermined point, which could be freezing. For example, if there is a load on the system at start-up, the EPR valve will be wide open, and the TXV will be throttling the flow of liquid refrigerant into the evaporator. When the evaporator pressure reaches the point at which the EPR valve is set, the valve will begin to throttle a slow flow of refrigerant. If the setting is just above freezing, the valve will throttle off enough to keep the evaporator from freezing until the thermostat responds and shuts the system off, **Figure 25.3**. The EPR valve is often called a "holdback valve" in the industry because it holds the refrigerant back in the evaporator to prevent the suction pressure in the evaporator from going below a set point.

The EPR valve may operate for an extended period of time while in the throttled-down position in order to satisfy the cooling load and keep the pressure in the evaporator from falling below a minimum set point. Many times, the evaporator pressure will be near the valve's set minimum pressure, but some refrigeration is still needed due to a small heat load on the evaporator. The flow of refrigerant will be minimal, and the TXV may not be able to keep a constant evaporator superheat because of the reduced mass flow rate of refrigerant. High evaporator superheat readings are often encountered at these throttled-down conditions. However, once the heat load on the evaporator increases and the EPR valve opens more to increase the mass flow rate of refrigerant, the TXV will regain control of evaporator superheat.

The two forces that control the EPR valve are the evaporator pressure, which is the valve's inlet pressure, and the

Figure 25.3 The TXV keeps the proper level of refrigerant in the evaporator while the EPR valve keeps the evaporator from getting too cold. The EPR valve may be used on a water-type evaporator to keep it from operating below freezing. The thermostat should cut off the compressor soon after the EPR valve starts to throttle.

valve's spring pressure. Evaporator pressure and spring pressure counteract one another: The spring pressure is a closing force, and the evaporator pressure is an opening force. The outlet pressure is effectively cancelled out and does not affect the valve operation because the area of the bellows is equal to the area of the inlet port. The outlet pressure acts on these equal areas, but in opposite directions, thus they cancel one another, **Figure 25.4(A)**.

EPR valves are also referred to as *open on rise of inlet pressure (ORI)* valves, because they will throttle open on a

rise in their inlet (evaporator) pressure. When the evaporator is under a high load, the EPR valve will be fully opened—in effect, act as if it were not there. The spring pressure can be adjusted with a screwdriver or Allen wrench to allow the setting of a minimum evaporator pressure. Remember, these valves simply establish a minimum evaporator pressure; they do not hold a constant pressure or limit maximum pressure in the evaporator.

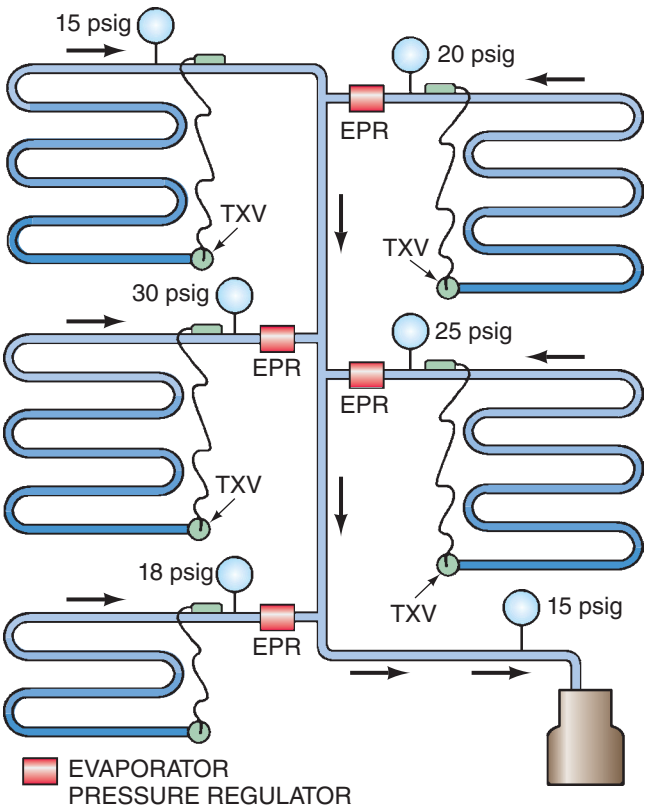
Larger Btu capacities, as in supermarket installations, call for larger EPR valves or pilot-operated valves, **Figure 25.4(B)**. Some normally open pilot EPR valves operate by high-pressure gas. These valves are held open by a spring and are forced closed by high-side gas pressure, **Figure 25.4(C)**. Three pressures control the modulation of the main valve piston: the high-pressure source, the evaporator pressure, and a spring pressure. A pilot port that is controlled by a pilot regulator valve indirectly controls the operation of the main regulating valve. These valves include a solenoid stop feature when hot gas defrost is used because the hot gas is injected into the suction line between the EPR valve and the coils being defrosted. A solenoid valve in the EPR valve will be deenergized, shutting off the suction inlet pressure. This allows the internal pilot spring to force the EPR valve closed. At the same time, a hot gas defrost solenoid valve will open; the evaporator fans will stop; and the hot gas will flow in reverse through the evaporators, around the expansion valves, through a check valve, and then around a liquid-line solenoid valve. The condensed hot gas, which is now cool liquid, will then feed into a liquid header to supply other evaporators with subcooled liquid refrigerant, **Figure 25.4(D)**.

25.5 MULTIPLE EVAPORATORS

When two or more evaporators are used with one compressor, they may sometimes be at different temperature and pressure ranges. For example, when an evaporator that needs to operate at 15.1 psig (15°F for R-134a) is piped to the same compressor with another evaporator of 22 psig (25°F for R-134a), an EPR valve is needed in the highest-temperature evaporator's suction line. The true suction pressure for the system will be the low value of 15.1 psig, but the other evaporator will operate at the correct pressure of 22 psig. Several evaporators with different pressure requirements can be piped together using this method, **Figure 25.5**.

It is desirable to know the actual pressure in the evaporator because that is not the same as the true suction pressure. Normally, a gauge port, known as a Schrader valve port, is permanently installed in the EPR valve body, which allows the service technician to take gauge readings on the evaporator side of the valve. The true suction pressure can be obtained at the compressor service valve, **Figure 25.2**.

Figure 25.5 Evaporators piped together and one compressor used to maintain a suction pressure for the lowest-pressure evaporator. The evaporators that have pressures higher than the true suction pressure of the lowest-pressure evaporator have EPR valves set to their individual needs.



25.6 ELECTRIC EVAPORATOR PRESSURE-REGULATING VALVE

Due to new regulations issued in the U.S. Food and Drug Administration's Food Code concerning product temperature in supermarkets, a more sophisticated and accurate way was needed for controlling the discharge air temperatures in the evaporator section of display cases. Electric evaporator pressure-regulating (EEPR) valves were designed for the close temperature control required, **Figure 25.6**.

For single evaporator applications, EEPR valves are located at the evaporator outlet; in multiple evaporator applications, they are located on the suction line before the common suction header as in parallel compressor systems, **Figure 25.7**. EEPR valves and a refrigerated case discharge air sensor are wired to a microprocessor board for control purposes.

The EEPR valve can move in very small increments, either opening or closing the suction line in response to the discharge air temperature of the refrigerated case. Although these valves

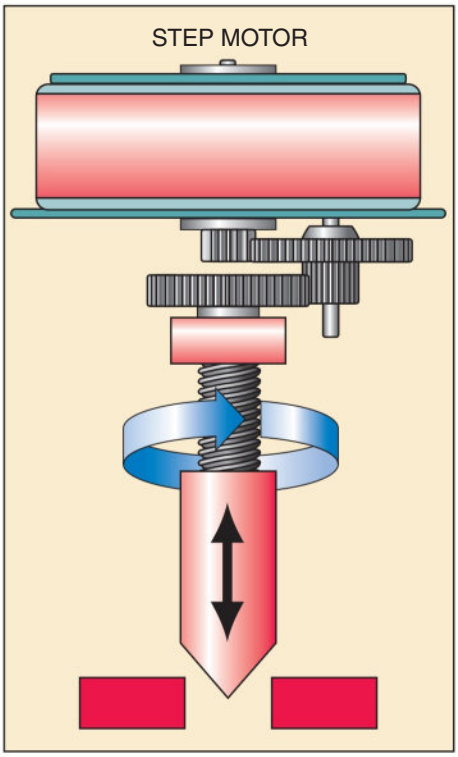
are referred to as evaporator pressure regulators, they do not serve the same purpose as the standard EPR valve mentioned earlier. A standard mechanical EPR valve prevents pressure, and thus temperature, from falling below a minimum in the evaporator. EEPR valves, on the other hand, control the discharge air temperature in the refrigerated case. They regulate the saturated pressure in the evaporator in order to provide the temperature required at the discharge air sensor. EEPR valves can deliver a quick temperature pulldown since they

Figure 25.8 A step motor showing how the lead screw is driven through gear reduction for providing additional power to the valve.



Courtesy RSES Journal

are sensing discharge air instead of evaporator pressure. They will remain fully open until the temperature of the discharge air in the case drops to the valve's set point.

A bipolar step motor operates the EEPR valve. The step motor operates by moving the motor in discrete steps instead of in a continuous rotation. The motor can step in either direction because it has two different windings. A step motor may have as many as 100 electromagnets around the rotor, resulting in an angular rotation that can be as small as 3.6° per step. The motor drives a lead screw that converts the angular motion into straight-line, or linear, motion, **Figure 25.8**, with a resolution that can be as fine as 0.0000783 in. per step. An algorithm programmed into a controller or microprocessor controls the direction and position of the step motor. Refer to Unit 24, "Expansion Devices," for a more detailed explanation of bipolar step-motor operation and control.

25.7 CRANKCASE PRESSURE REGULATOR

The **crankcase pressure-regulating valve (CPR valve)** looks much the same as the EPR valve, but it has a different function. The CPR valve is in the suction line also, but it is usually located close to the compressor rather than at the

evaporator outlet. The CPR valve sensing bellows are on the true compressor suction side of the valve and would normally have a gauge port on the evaporator side of the valve, **Figure 25.9**.

The CPR valve is used to keep a low-temperature compressor from overloading on a hot pulldown. A hot pulldown would occur

- when the compressor has been off for a long enough time and the foodstuff has risen in temperature,
- on start-ups with a warm box temperature, and
- after a defrost period.

In any case, the temperature in the refrigerated box or the evaporator influences the suction pressure. When the temperature is high, the suction pressure is high. When the suction pressure goes up, the density of the suction gas goes up. The compressor is a constant-volume pump and does not know when the gas it is pumping is dense enough to create a motor overload.

When a compressor is started and the refrigerated cooler is warmer than the design range of the compressor, an overload occurs. The refrigeration compressor motor can be operated at about 10% over its rated capacity without harm during this pulldown. For example, when a motor has a full-load amperage rating of 20 A, it could run at 22 A for an extended pulldown and no harm would occur to the motor. If the temperature in the cooler were to be 75°F or 80°F, the motor would be overloaded to the point that its overcurrent protection would shut it off. But this protection device automatically resets, so the compressor would try to restart immediately, causing it to short cycle. This type of operation could continue until the manual reset motor control, the fuse, or the breaker stopped the compressor, or until the system slowly pulls down during the brief running times. The CPR valve throttles the suction gas entering the compressor to keep the compressor current at no more than the rated value, **Figure 25.10**. Before CPR valves came into use, on a hot start-up the service technician had to start the system manually by throttling the suction service valve.

The CPR valve is often referred to as a *close on rise of outlet pressure (CRO)* valve. This is because it closes when its outlet (crankcase) pressure rises to a predetermined pressure. The CPR valve is controlled by crankcase (outlet) pressure

Figure 25.9 Three modern CPR valves that prevent the compressor from running in an overloaded condition during a hot pulldown.

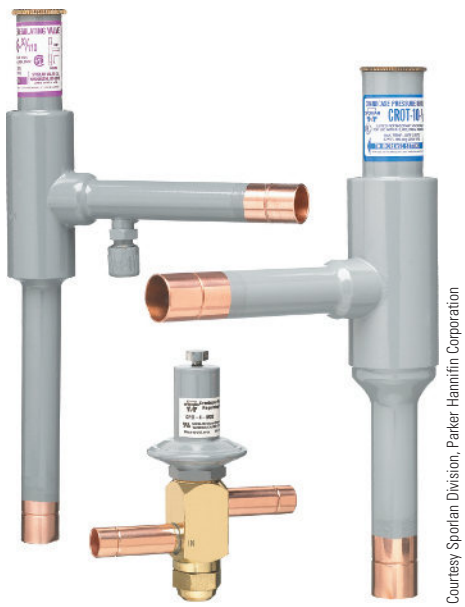

Figure 25.10 The CPR valve throttles the vapor refrigerant entering the compressor. There will be a pressure drop across the valve when the evaporator is too warm. This valve is adjusted and set up according to the compressor full-load amperage on a hot pulldown. The CPR valve can be set to throttle the suction gas to the compressor to prevent a high suction pressure on the compressor side of the valve so that the compressor will not overload. When the refrigerated box temperature is pulled down to the design range, the suction gas pressure in the evaporator will be the same as the pressure at the compressor because the valve is wide open.

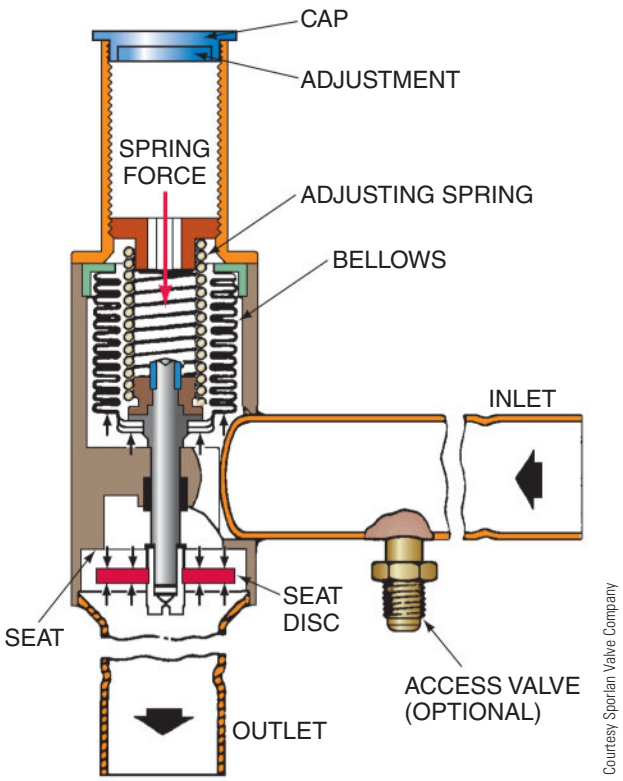
Figure 25.11 The cutaway view of a crankcase pressure-regulating (CPR) valve.



and its spring pressure. The crankcase pressure is a closing force, and the spring pressure is an opening force. The inlet pressure of the CPR valve is actually cancelled out because of the equal areas of the bellows and the seat disc. The inlet pressure exerts an equal pressure on both the bellows and seat disc, but these pressures are in opposite directions and cancel one another out, **Figure 25.11**. The spring pressure can be adjusted with a screwdriver or an Allen wrench to set the maximum desired crankcase pressure.

25.8 ADJUSTING THE CPR VALVE

The setting of the CPR valve should be accomplished on a hot pulldown or at least when the compressor has enough load that it is trying to run overloaded. This can be done by shutting off the unit until the box or cooler is warm enough to create a load on the evaporator. This loads up the compressor enough to cause it to run at a high current. Use the ammeter on the compressor while adjusting the CPR valve to the full-load amperage of the compressor. For example, if the compressor is supposed to draw 20 A at fully loaded conditions, throttle the CPR valve back until the compressor amperage is 20 A and the valve is set.

25.9 RELIEF VALVES

Relief valves are designed to release refrigerant from a system when predetermined high pressures exist. Refrigerant relief valves come in two different types: the spring-loaded type that will reseat and the one-time type that does not close back. Spring-loaded relief valves are mainly used in today's applications because of the increased cost of refrigerants and ozone depletion scares.

The *spring-loaded* relief valve is normally brass with a neoprene seat. This valve is piped so that it is in the vapor space of the condenser or receiver. The relief valve must be in the vapor space, not in the liquid space, for it to relieve pressure. The object is to let vapor off in order to vaporize some of the remaining liquid and lower its pressure, **Figure 25.12**. The top of the valve normally is threaded so that the refrigerant can be piped to the outside of the building. **SAFETY PRECAUTION:** *When relief valves are used to protect vessels in a fire, it is desirable for the refrigerant to be removed from the area. Refrigerant gives off a noxious gas when it is burned. Some systems pipe the relief valve into a large, evacuated tank. The refrigerant will not be vented if the relief valve opens in this case.* •

Temperature causes the *one-time* relief valve to relieve. These valves, often called fusible plugs, are designed in one of the following ways: with a fitting filled with a low melting-temperature solder, a patch of copper soldered on a drilled hole in the copper line using low-temperature solder, or a fitting that has been drilled out at the end with a spot of low-temperature solder over the hole, **Figure 25.13**. Sometimes

Figure 25.12 The spring-loaded relief valve used to protect the system from very high pressures that might occur if the condenser fan were to fail or if a water supply were to fail on a water-cooled system. This relief valve is designed to reseat after the pressure is reduced. The threads on the valve outlet enable the valve to be piped to the outside if needed.

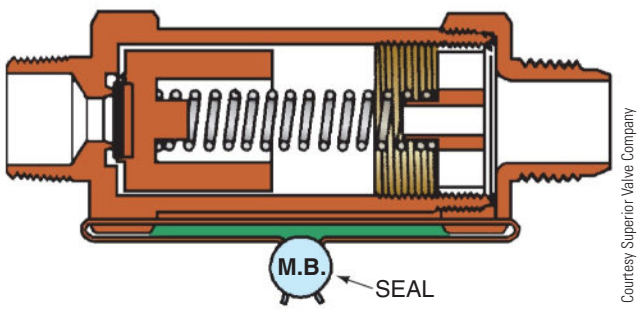


Figure 25.13 The fusible relief valve may be a low-temperature solder patch that covers a hole drilled in a fitting or pipe. Care should be taken when soldering in the vicinity of this relief device, or it will melt.

the melting temperature will be very low, about 220°F. When soldering around the compressor, make sure that the solder in the fusible plug is not melted away. This type of device will normally never relieve unless there is a fire. It can often be found on the suction side of the system close to the compressor to protect the system and the public. This will keep the compressor shell from experiencing high pressures and temperatures and rupturing during a fire. Remember, the compressor shell can have a working pressure as low as 150 psig. The plug blows at approximately 220°F.

LOW-AMBIENT CONTROLS

This section is an overview of low-ambient controls. For more detailed coverage, please refer to the section "Head Pressure Controls" in Unit 22, "Condensers." *Low-ambient controls* are important in refrigeration systems because refrigeration is needed all year. When the condenser is located outside, the head pressure will go down in the winter to the point that the expansion valve will not have enough pressure drop across it to feed refrigerant correctly. When this happens, some method must be used to keep the head pressure up to an acceptable level. The most common methods are as follows:

1. Fan cycling using a pressure control
2. Fan speed control
3. Air volume control using shutters and fan cycling
4. Condenser flooding and condenser splitting

25.10 FAN-CYCLING HEAD PRESSURE CONTROLS

Fan cycling has been used for years because it is simple and reliable. When there is more than one fan, the extra fans may be cycled by temperature, and the last fan can be cycled by head pressure. The control used is a pressure control that closes on a rise in pressure to start the fan and opens on a fall in pressure to stop the fan when the head pressure falls. When fan cycling is used, the fan will cycle in the winter but will run constantly in hot weather, **Figure 25.14(A)**. On multiple-fan condensing units, one or many ambient temperature controls may accomplish condenser fan cycling. The controls are usually thermal disks located somewhere on the condensing unit's frame, **Figure 25.14(B)**. As the outside ambient temperature drops, the fans begin to turn off. As the outside ambient temperature rises, the fans begin to turn on. Frequently on smaller condensing units, one fan will run continuously and the other fan will be cycled on and off with an ambient temperature controller.

Controls using fans can be hard on a motor because of all the cycling. The fan motor needs to be a type that does not have a high starting current. To be reliable, the control must have enough contact surface area to be able to start the motor many times. The motor current should be carefully compared with the control capabilities. Fan cycling can vary the pressure to the expansion device a great deal. The technician must choose whether to have the control set points close together for the best expansion device performance or far apart to keep the fan from short cycling. The best application for fan-cycling devices is the use of multiple fans, where the last fan has a whole condenser to absorb the fluctuation.

Vertical condensers may be affected by the prevailing winds. If these winds are directed into the coil, they can provide airflow similar to that of a fan. Sometimes a shield is installed to prevent this, **Figure 25.15**. When an air-cooled

Figure 25.14 (A) A pressure control with the same action as a low-pressure control; it takes a rise in head pressure to start the condenser fan. This pressure control operates at a higher pressure range than the low-pressure control normally used on the low side of the system. Fan-cycling devices will cause the head pressure to fluctuate up and down, which can affect the operation of the expansion device. (B) A thermal disk-type fan speed control.

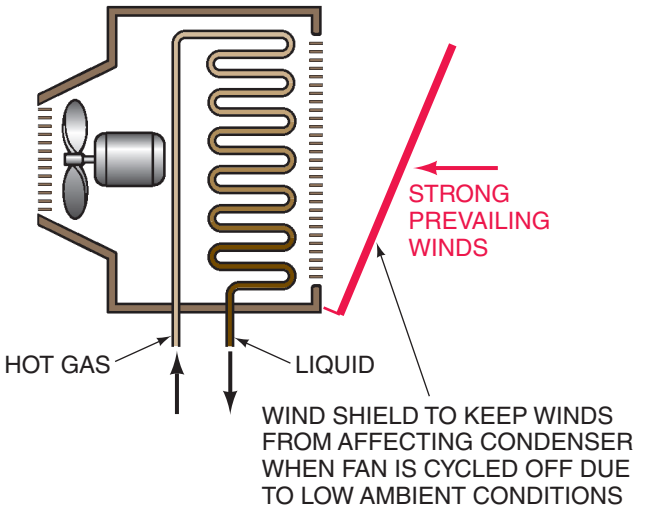
Figure 25.15 When fan-cycling controls are used, care must be taken if the condenser is vertical. The prevailing winds can cause the head pressure to be too low even when the fan is off. A shield can be used to prevent the wind from affecting the condenser.



condenser is installed either on the ground or on the roof, the direction of airflow across the condenser's face should be in the prevailing wind direction. This way, when the condenser's fan is operating, it will not be bucking the prevailing winds and decreasing airflow volume (cfm) through the condenser.

25.11 FAN SPEED CONTROL FOR CONTROLLING HEAD PRESSURE

Devices that control fan speed have been used successfully in many installations. These devices can be used with multiple fans, where the first fans are cycled off by temperature and the last fan is controlled by head pressure or condensing temperature. The device that controls the last fan is normally a transducer that converts a pressure or temperature signal to an electrical signal that feeds a motor speed controller. As the temperature drops on a cool day, the motor speed is reduced. As the temperature rises, the motor speed increases. At some predetermined point the additional fans are started. On a hot day all fans will be running, with the variable-speed fan running at maximum speed. Some fan speed controls use a temperature sensor to monitor the condenser's temperature, **Figure 25.16(A)**.

Variable frequency drives (VFDs) are becoming much more popular for controlling fan speeds because they are more affordable today than they were 10 years ago, **Figure 25.16(B)**. A condenser fan motor is much more energy efficient at reduced capacities and speeds. Fan motors with VFDs

Figure 25.16 (A) A control used to vary the fan speed on a special motor based on condenser temperature. (B) Four VFDs used to control the speed of a motor by varying the frequency delivered to the motor.

(B)

have the ability to deliver variable air volume (VAV) flows. This allows the airflow to exactly match the airflow through the condenser that is needed under a certain ambient condition. VFDs can control the speed of a condenser fan motor by controlling the frequency fed to the motor. The lower the frequency, the slower the motor, and vice versa. For a more detailed explanation of VFD motors, refer to Section 17.28, "Inverters and Variable Frequency Drives (VFDs)" in Unit 17, "Types of Electric Motors."

25.12 AIR VOLUME CONTROL FOR CONTROLLING HEAD PRESSURE

Air volume control using shutters is accomplished with a piston-driven damper driven with the high-pressure refrigerant. When there are multiple fans, the first fans can be cycled off using temperature, and the shutter can be used on the last fan, as in the previous two systems. This system results in a steady head pressure, as with fan speed control. The expansion valve inlet pressure does not fluctuate as it does when

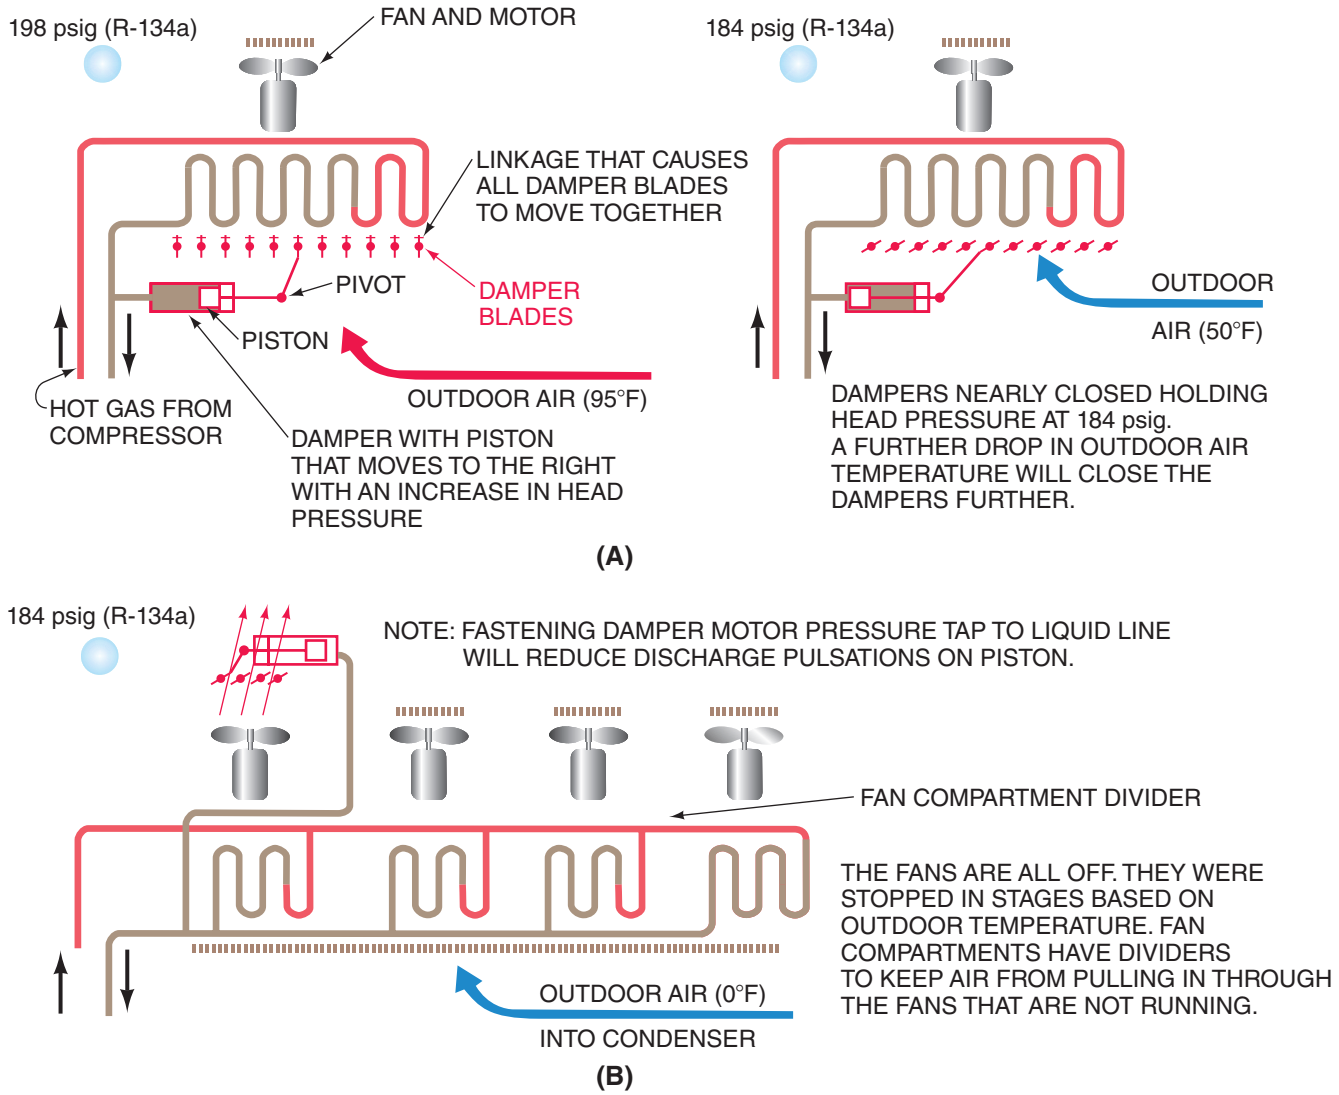
Figure 25.17 (A) Installation using dampers to vary the air volume instead of fan speed. This is accomplished with a refrigerant-operated damper that operates the shutters. This application modulates the airflow and gives steady head pressure control. (B) If more than one fan is used, the first fans can be cycled off based on ambient temperature. Care should be taken not to overload the condenser fan when the shutters are placed at the fan outlet.



one fan is cycled on and off. The shutter can be located either on the fan inlet or on the fan outlet, **Figure 25.17**. Be careful that the fan motor is not overloaded with a damper.

25.13 CONDENSER FLOODING AND CONDENSER SPLITTING FOR CONTROLLING HEAD PRESSURE

Condenser flooding devices are used in both mild and cold weather to cause the refrigerant to move from an oversized receiver into the condenser, **Figure 25.18**. This excess refrigerant in the condenser acts like an overcharge and causes the head pressure to be much higher than it normally would be on a mild or cold day. The head pressure will remain the same as it would on a warm day. This method gives very steady control with no fluctuations while running. The system requires a large amount of refrigerant because in addition to the normal operating charge, there must be enough refrigerant to flood the condenser in the winter. A large receiver is used to store the refrigerant in the summer, when valves will divert the excess liquid into the receiver. Condenser flooding has one added benefit in the winter. Because the condenser is nearly full of refrigerant, the liquid refrigerant that is furnished to the expansion devices is well below the condensing temperature. Remember, subcooling will help improve the efficiency of the system. The liquid may be subcooled to well below freezing for systems operating in a cold climate.

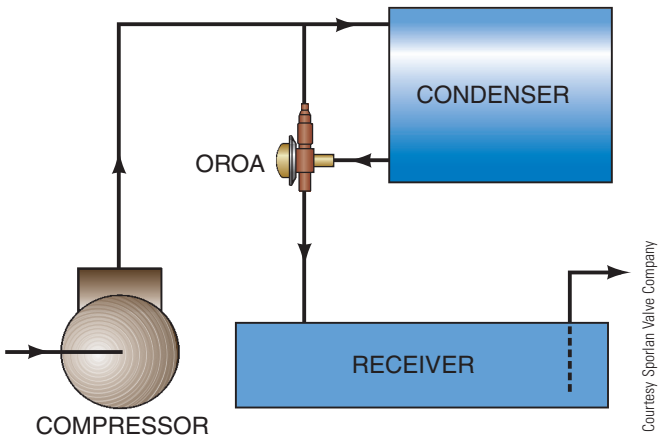
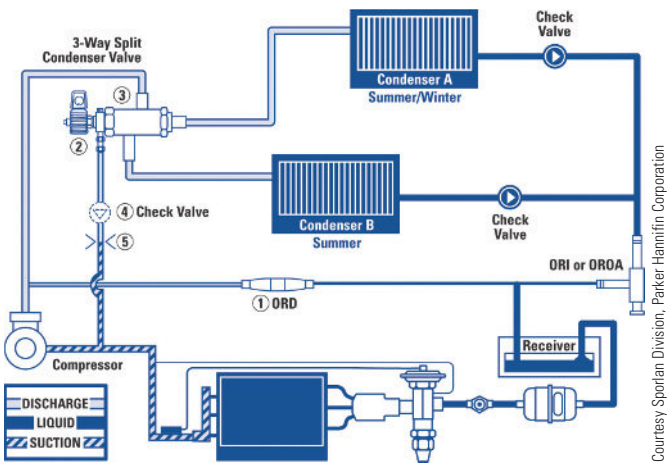
Figure 25.18 Low-ambient head pressure control accomplished with refrigerant. A large receiver stores the refrigerant when it is not needed (the summer cycle). (A) The valve in the system diverts the hot gas to the condenser during summer operation, and the system acts like a typical system with a large receiver. In the winter cycle, part of the gas goes to the condenser, depending on the outdoor temperature, and part of the gas goes to the top of the receiver. (B) The gas going to the receiver keeps the pressure up for correct expansion valve operation. The gas going to the condenser is changed to a liquid and subcooled in the condenser. It then returns to the receiver to subcool the remaining liquid. (C) Split condensers with a three-way, solenoid-operated split condenser valve incorporated into a refrigeration system.

(A)



(B)



(C)

One way to reduce the amount of extra refrigerant charge needed for condenser flooding is to split the condenser into two separate and identical condenser circuits, **Figure 25.18(C)**, referred to as condenser splitting. The splitting of the condensers is done with the addition of a pilot-operated, three-way solenoid valve installed in the discharge line from the compressors. The splitting of the identical condensers is done in such a way that only one half of the condenser is used for winter operation, and both halves are used for summer operation. The top half of the condenser is referred to as the "Summer/Winter" condenser, and the bottom half of the condenser is referred to as the "Summer" condenser. The three-way solenoid valve controlling the splitting of the condensers can be energized and deenergized by a controller sensing outside ambient, an outdoor thermostat, or a high-side pressure control. For a more detailed explanation of head pressure controls, refer to Section 22.18, "Head Pressure Controls" in Unit 22, "Condensers."

25.14 ELECTRICAL CONTROLS

THE SOLENOID VALVE

The *solenoid valve* is the component most frequently used to control fluid flow. The valve has a magnetic coil that when energized will lift a plunger into the coil, **Figure 25.19**. This valve can be either normally open (NO) or normally closed (NC). The NC valve is closed until energized; then it opens. The NO valve is normally open until energized; then it closes. The plunger is attached to the valve so that the plunger action moves the valve. Solenoid valves must be sized correctly for their particular application. For the refrigerant liquid line, they are sized according to refrigerant tonnage and a pressure drop through the valve that is acceptable. If a valve needs to be replaced, the manufacturer's data will help you choose the correct valve.

Solenoid valves can be used to control either liquid or vapor flow. They are snap-acting valves and open and close very fast when electrical energy is applied to the coil. The snap action can cause liquid hammer when installed in a liquid line, however, so care must be taken when locating the valve. Liquid hammer occurs when the fast-moving liquid is shut off by the solenoid valve, causing the liquid to stop abruptly. The solenoid valve must be fastened to the refrigerant line in a way that will not leak refrigerant. It can be fastened by flare, flange, or solder connections. Most valves have to be serviced at some time. The valves that are soldered in the line can be serviced easily if they can be disassembled.

The manufacturer's instructions as to the location and placement of solenoid valves should be followed. Two common mistakes in installation can prevent the solenoid valve from functioning correctly: the direction in which the valve is mounted and the position in which the valve is installed. A solenoid valve must be oriented in the correct

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. (B)

direction to the fluid flow or the valve may not close tightly, **Figure 25.20**. The valve is mounted correctly when the fluid helps to close the valve. If the high pressure is under the valve seat, the plunger may have a tendency to lift the valve off the seat. The valve has an arrow that indicates the direction of flow. When placing the solenoid valve in the correct direction, the position of the valve must be considered. Most solenoid valves have a heavy plunger that is lifted to open the valve. When the plunger is not energized, its weight holds the valve on its sealing seat. If this type of valve is installed on its side or upside down, the valve will remain in the energized position when it should be closed, **Figure 25.21**.

Figure 25.20 The fluid flow in a solenoid valve must be in the correct direction, or the valve will not close tight. If the high-pressure fluid is under the seat, it will have a tendency to raise the valve off the seat. When installed correctly, the fluid helps to hold the valve on the seat.

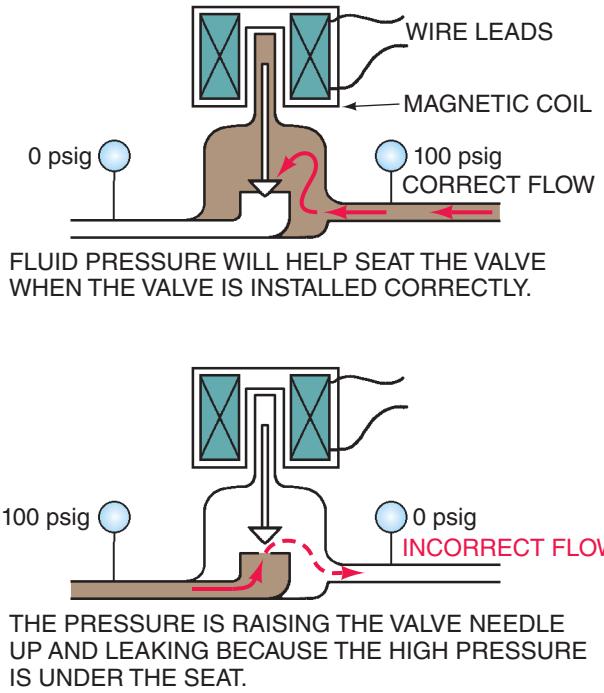

Figure 25.21 A solenoid valve installed in the correct position. Most valves use gravity to seat, and a magnetic force raises the valve off its seat. If the valve is installed on its side or upside down, the valve will not seat when deenergized.

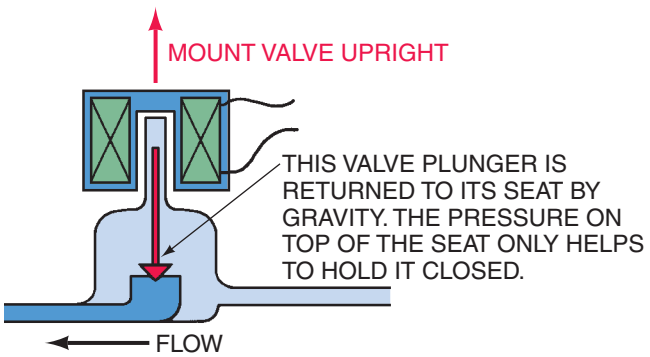

A special solenoid valve known as *pilot acting* is available for controlling fluid flow in larger applications. This valve uses a very small valve seat to divert high-pressure gas that causes a larger valve to change position, thus using the difference in pressure to cause a large movement while the solenoid's magnetic coil only has to lift a small seat. An electrical coil large enough to cause the switching action of a large valve would be very big and draw too much current for

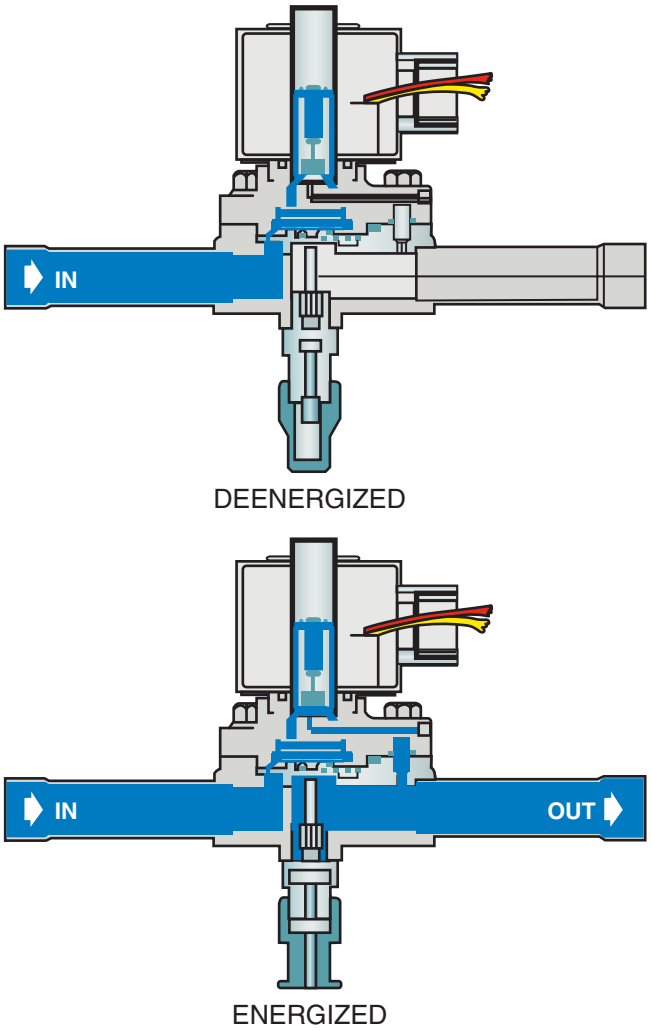
Figure 25.22 A pilot-operated solenoid valve. The magnetic coil controls a small line that directs the high-pressure refrigerant to one end of a sliding piston. The magnetic coil has to do only a small amount of work, and the difference in pressure does the rest.



practical use, **Figure 25.22**. Pilot action reduces the size of the electrical coil and the overall size of the valve. Pilot-acting valves are used when large vapor or liquid lines must be switched and can have more than one inlet and outlet. Some are known as *four-way* valves; others as *three-way* valves. These have special functions.

25.15 PRESSURE SWITCHES

Pressure switches are used to stop and start electrical current flow to refrigeration components. They play a very important part in the function of the equipment. The typical pressure switch can be

1. a low-pressure switch—closes on a rise in pressure,
2. a high-pressure switch—opens on a rise in pressure,
3. a low-ambient control—closes on a rise in pressure, or
4. an oil safety switch—has a time delay; opens on a rise in pressure.

25.16 LOW-PRESSURE SWITCH

The low-pressure switch or control is used in the following two major refrigeration applications:

- Low-charge protection
- Control of space temperature

The low-pressure control can be used as a low-charge protection by setting the control to cut out at a value that is below the typical evaporator operating pressure. For example, in a medium-temperature cooler the air temperature may be expected to be no lower than 34°F. When this cooler uses R-134a for the refrigerant, the lowest pressure at which the evaporator would be expected to operate would be around 18 psig because the coil would normally operate at about 15°F colder than the air temperature in the coil (34°F − 15°F = 19°F). The refrigerant in the coil should not operate below this temperature of 19°F, which converts to 18 psig. The low-pressure cut-out should be set below the expected operating condition of 18 psig and above the atmospheric pressure of 0 psig. A setting that would cut off the compressor at 5 psig would keep the low-pressure side of the system from going into a vacuum in the event of refrigerant loss. This setting would be well below the typical operating condition. The control would normally be automatically reset. When a low-charge condition exists, the control would cut the compressor off and on and maintain some refrigeration. A store owner may call with a complaint that the unit is cutting off and on but not lowering the cooler temperature properly.

The cut-in setting for this application should be a pressure that is below the pressure corresponding to the highest temperature the cooler is expected to experience in a typical cycle and just lower than the pressure corresponding to the thermostat cut-in point. For example, the thermostat may be set at 45°F, which would mean that the pressure in the evaporator may rise as high as 40 psig. The low-pressure control should be set to cut in at about 25 psig. The previous example of a low-pressure control set to cut out at 5 psig and to cut in at 40 psig means that the control differential is 35 psig. Remember that the compressor is not running. The wide differential helps to prevent the compressor from coming back on too soon or from short cycling, **Figure 25.23**.

25.17 LOW-PRESSURE CONTROL APPLIED AS A THERMOSTAT

The low-pressure control setup described in the previous example is for low-charge protection only, to keep the system from going into a vacuum. The same control can be set to operate the compressor to maintain the space temperature

Figure 25.23 The low-pressure control. The control contacts close on a rise in pressure and open on a fall in pressure. If the low-side pressure goes below the control's set point, the control will open its contacts to the compressor's control circuit.

Photo by Bill Johnson

in the cooler and to serve as a low-charge protection as well. Using the same temperatures as in the preceding example as the operating conditions, 34°F and 45°F, the low-pressure control can be set to cut out when the low pressure reaches 18 psig. This corresponds to a coil temperature of 19°F. When the air in the cooler reaches 34°F, the coil temperature should be 19°F, with a corresponding pressure of 18 psig. This system has a room-to-coil temperature difference of 15°F (34°F room temperature − 19°F coil temperature = 15°F temperature difference). When the compressor cuts off, the air in the cooler is going to raise the coil temperature to 34°F and a corresponding pressure of 30 psig. As the cooler temperature goes up, it will raise the temperature of the refrigerant. When the temperature of the air increases to 45°F, the coil temperature should be 45°F with a corresponding pressure of 40 psig. This could be the cut-in point of the low-pressure control. The settings would be cut out at 18 psig and cut in at 40 psig. This is a differential of 22 psig and would maintain a cooler temperature of 34°F to 45°F. You could say that you are using the refrigerant in the evaporator coil as the thermostat sensing fluid.

One of the advantages of this type of control arrangement is that no interconnecting wires are between the inside of the cooler and the condensing unit. If a thermostat is used to control the air temperature in the cooler, a pair of wires must be run between the condensing unit and the inside of the cooler. In some installations, the condensing unit is a considerable distance from the cooler, which makes running wires impractical. With the temperature being controlled at the condensing unit, an owner is less likely to turn the control and cause problems.

As many low-pressure control settings exist as there are applications. Different situations call for different settings. **Figure 25.24** is a chart of settings recommended by one company.

Low-pressure controls are rated by their pressure range and the current draw of the contacts. A low-pressure control that is suitable for R-12 or R-134a may not be suitable for R-502, R-507, or R-404A because of their different pressure ranges. For the same application in the previous paragraph using R-502, the cut-out would be 51 psig, and the cut-in would be 88 psig. If R-404A were the refrigerant, the cut-out would be 55 psig and the cut-in would be 95 psig. The correct control for the pressure range must be chosen. Some controls

Figure 25.24 This table is to be used as a guide for setting low-pressure controls for the different applications.

APPROXIMATE PRESSURE CONTROL SETTINGS

Pressure — Pounds Per Square Inch Gauge

APPLICATION	TEMP RANGE (°F)	EVAP TD (°F)	REFRIGERANT

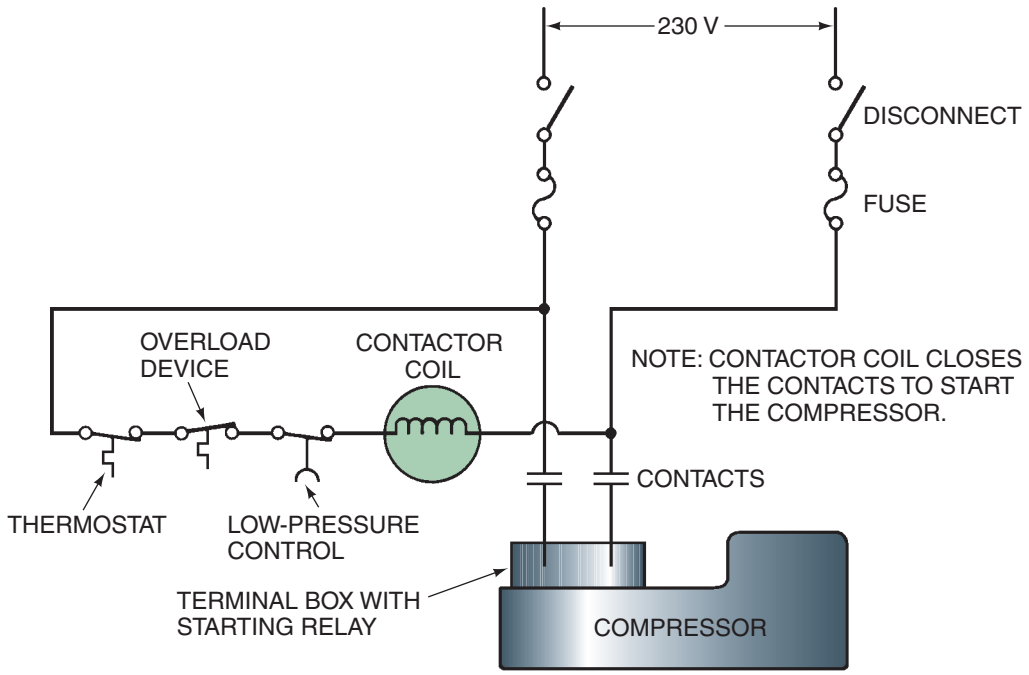
Figure 25.25 When a compressor that is larger than the electrical rating of the pressure control contacts is encountered, the compressor has to be started with a contactor. The wiring diagram shows how this is accomplished.



are single-pole–double-throw, which can make or break on a rise. Such controls can serve as one component serving two different functions.

The contact rating for a pressure control has to do with the size of electrical load the control can carry. If the pressure control is expected to start a small compressor, the inrush current should also be considered. Normally a pressure control used for refrigeration is rated so that it can directly start up to a 3-hp single-phase compressor. If the compressor is any larger, or three phase, a contactor or motor starter is normally used. The pressure control then can control the contactor or motor starter coil, **Figure 25.25**.

25.18 AUTOMATIC PUMPDOWN SYSTEMS

The **automatic pumpdown system** consists of a normally closed liquid-line solenoid valve installed in the liquid line of a refrigeration system. The direction of flow of the solenoid valve should be in the direction of the evaporator. The solenoid is a normally closed electric shutoff valve that is controlled by a thermostat. The thermostat is located somewhere in the refrigerated space. When the desired box temperature is reached in the refrigerated space, the thermostat will open and deenergize and close the liquid-line solenoid valve. The compressor will continue to run and will evacuate any refrigerant from the solenoid valve's outlet to and including the compressor. This includes part of the liquid line, evaporator, suction line, and crankcase. **Figure 25.26** is an electrical schematic diagram of an automatic pumpdown system using a liquid-line solenoid valve, thermostat, and low-pressure control. **Figure 25.27(A)** is a system diagram showing the electrical hookup of an automatic pumpdown system.

Refrigerant is stored in the condenser and receiver on the high side of the refrigeration system, with most stored in the receiver. The compressor will then be shut off by the action of a low-pressure control set to open at about 5 to 10 psig, which ensures that no refrigerant migrates during the off cycle to the compressor. The practice years ago was to let the compressor pump down to 0 psig, but this proved to be hard on compressors because they reach such high compression ratios at 0-psig suction pressure. Also, a refrigerant-cooled compressor could be starved of refrigerant every time it pumped down and suffer possible damage from overheating. On a call for cooling, the thermostat closes and energizes the liquid-line solenoid valve. This action sends liquid refrigerant to the expansion valve and into the empty evaporator, thus increasing evaporator pressure. Once the cut-in pressure of the low-pressure control is reached, the compressor will easily start and resume a normal refrigeration cycle. Automatic pumpdown systems do not need a larger receiver since the receiver is designed to hold the entire refrigerant charge and still have a 20% vapor head for safety.

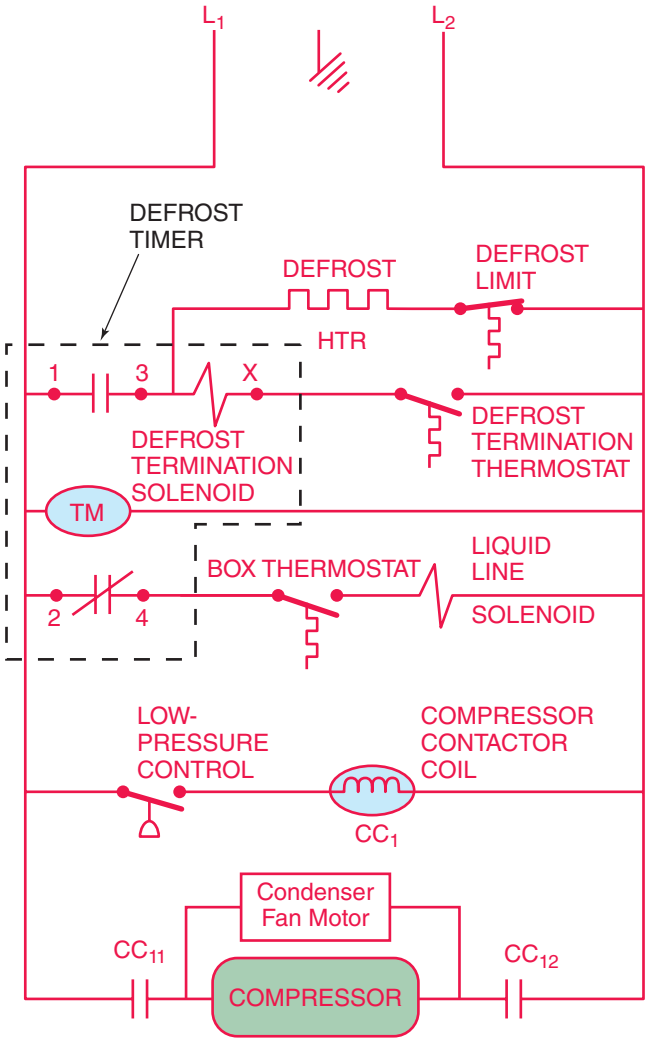
Figure 25.26 An electrical schematic diagram of an automatic pumpdown system.



The cut-in pressure of the low-pressure control should be set high enough to ensure that the system will not short cycle if residual pressure does remain in the low side of the system once it is pumped down. Compressor short cycling can be devastating to motor windings and starting controls because of overheating. However, the cut-in pressure has to be low enough to ensure the system will cut in once the liquid-line solenoid is energized by the thermostat to start the next on cycle. These pressures are dependent on refrigerant type and desired box temperatures. A pressure-setting guide like the one in **Figure 25.24** should be sufficient to determine the correct pressures for an automatic system. Compressor short cycling during the off cycle can also be caused by a leaky liquid-line solenoid valve or the compressor discharge valve leaking high pressure back into the compressor during the pumpdown phase. An important thing to remember when leak testing a system with automatic pumpdown is that the solenoid circuit must be energized to prevent trapping of refrigerant in the condenser and receiver.

It is a good practice to install automatic pumpdown systems on all refrigeration systems employing large amounts of refrigerant and oil. Automatic systems are not used on systems with small amounts of oil or refrigerant because there is not enough refrigerant to migrate to the oil and cause any damage if migration does occur during the off cycle. For example, a domestic refrigerator or freezer may have a refrigerant charge of only 8 to 16 oz and an oil charge from 12 to 20 oz. There is often more oil than refrigerant in these systems. Even if the entire refrigerant charge migrates to the crankcase during an off cycle, no real damage will be done because the refrigerant flashes off during the next on cycle. So, only if the refrigerant-to-oil ratio is large should automatic pumpdown systems be employed.

Figure 25.27(B) illustrates a wiring scheme for an automatic pumpdown system that will not short cycle the compressor during a pumpdown phase caused by a leaking solenoid valve or compressor discharge valve. This type of system is often referred to as a non-short-cycling or "one-time" automatic pumpdown system. Only the thermostat calling again for cooling will take the refrigeration system out of pumpdown. The diagram shows the system in a pumpdown with the compressor off. On a call for cooling, the thermostat closes and energizes the liquid-line solenoid valve. This allows the low side of the system to experience refrigerant pressure, which allows the low-pressure switch to close, **Figure 25.27(C).** The latching relay coil (LRC) is energized through the normally closed (NC) contacts A and B. Once the LRC is energized, it closes contacts B and C and contacts C and D, while opening contacts A and B. With the LRC energized, the compressor contactor coil (CC) is energized through contacts C and D and the low-pressure switch. This starts the compressor and then the system is in a normal cooling mode, **Figure 25.27(D)**.

When the thermostat opens, the liquid-line solenoid valve is deenergized, **Figure 25.27(E)**. This physically closes off the liquid line and initiates an automatic pumpdown. The low-pressure switch now opens from the low pressure, deenergizing the LRC coil, which opens contacts C and D and B and C. The opening of the low-pressure switch also deenergizes the compressor contactor coil (CC), which shuts off the compressor. The system is pumped down and the compressor remains off until there is another call for cooling from the thermostat. However, if the low-pressure switch closes because of a leaking component while the thermostat is still open and not calling for cooling, the compressor contactor coil (CC) will not be energized because of the normally open (NO) contacts C and D of the latching relay. This prevents the compressor from short cycling while in the pumpdown mode. The LRC will also not be energized because of the NO contacts B and C of the latching relay. In summary, when components leak, these latching relay contacts prevent the compressor

(A)

from short cycling during pumpdown, which causes low-side pressures to increase and low-pressure switches to close prematurely.

The following are three main reasons automatic pumpdown systems are employed on refrigeration systems:

- *To rid the evaporator, suction line, and crankcase of refrigerant before the off cycle and defrost cycle so that migration of refrigerant to the compressor and/or compressor crankcase cannot occur*
- *To prevent surges of liquid refrigerant from entering the suction port of the compressor (slugging) during start-ups*
- *To rid the crankcase of refrigerant to prevent oil from foaming during start-ups and robbing lubrication from the compressor's mechanical parts*

25.19 HIGH-PRESSURE CONTROL

The high-pressure control is usually not as complicated as the low-pressure control (switch). It is used to keep the compressor from operating with a high head pressure. This control is necessary on water-cooled equipment because an interruption of water is more likely than an interruption of air. This control opens on a rise in pressure and should be set above the typical high pressure that the machine would normally encounter. The high-pressure control may be either automatic or manual reset.

When an air-cooled condenser is placed outside, it can be expected to operate at no more than 30°F warmer than the ambient air. This condition is true after the condenser has run long enough to have a coat of dirt built up on the coil. A clean condenser is important, but it is more often slightly dirty than clean. If the ambient air is 95°F, the condenser would be operating at about 170 psig if the system used R-12 (95°F + 30°F = 125°F condensing temperature, which corresponds to 169 psig). The high-pressure control should be set well above 170 psig for the R-12 system. If the control were set to cut out at 250 psig, there should be no interference with normal operation, and it still would give good protection, **Figure 25.28**. If the system incorporates R-134a as the refrigerant, the high-pressure control should be set well above 185 psig, which corresponds to a 125°F condensing temperature. Again, if the high-pressure control were set to cut out at 250 psig, it would still protect the system. Most condensers operate at a 30°F temperature difference as shipped from the factory and will continue to operate under this condition when properly maintained. Many condensers for low-temperature applications may operate at temperature differences as low as 15°F to maintain low compression ratios.

Figure 25.28 A high-pressure switch to keep the compressor from running when high system pressures occur.

The control cut-in point must be above the pressure corresponding to the ambient temperature of 95°F. If the compressor cuts off and the outdoor fan continues to run, the temperature inside the condenser will quickly reach the ambient temperature. For example, if the ambient is 95°F, the pressure will quickly fall to 108 psig for an R-12 system. If the high-pressure control were set to cut in at 125 psig, the compressor could come back on with a safe differential of 125 psig (cut-out 250 − cut-in 125 = 125 psig differential). Some high-pressure controls have a fixed differential of 50 psig. This means they will cycle the compressor back on at 50 psig lower than the cut-out setting. For example, if a system cycles off on the high-pressure control at 250 psig, it will come back on at 200 psig (250 psig − 50 psig).

Some manufacturers specify a manual reset high-pressure control. When this control cuts out, someone must press the reset button to start the compressor. This calls attention to the fact that a problem exists. The manual reset control provides better equipment protection, but the automatic reset control may save the food by allowing the compressor to run at short intervals. An observant owner or operator should notice the short cycle of the automatic control if the compressor is near the workspace.

25.20 LOW-AMBIENT FAN CONTROL

The low-ambient fan control has the same switch action as the low-pressure control but operates at a higher pressure range. This control stops and starts the condenser fan in response to head pressure. This control must be coordinated with the high-pressure control to keep them from working against each other. The high-pressure control stops the compressor when the head pressure gets too high, and the low-ambient control starts the fan when the pressure gets to a predetermined point before the high-pressure control stops the compressor.

When a low-ambient control is used, the high-pressure cut-out should be checked to make sure that it is higher than the cut-in point of the low-ambient control. For example, if the low-ambient control is set to maintain the head pressure between 125 psig and 175 psig, a high-pressure control setting of 250 psig should not interfere with the low-ambient control setting. This can easily be verified by installing a gauge and stopping the condenser fan to make sure that the high-pressure control is cutting out where it is supposed to.

Figure 25.29 The low-ambient control used to open the contacts on a drop in head pressure to stop the condenser fan.

With the gauge on the high side, the fan action can also be observed to see that the fan is cutting off and on as it should. The fan will operate all of the time on high-ambient days, and the fan control will not stop the fan. The low-ambient pressure control can be identified by the terminology on the control's action. It is described as "close on a rise" in pressure, **Figure 25.29**. This is the same terminology used on a low-pressure control. The difference is that the low-ambient fan control has a higher operating pressure range.

25.21 OIL PRESSURE SAFETY CONTROL

Many larger compressors in the refrigeration and air-conditioning field have forced oiling systems. These compressors are usually over 3 hp. They contain an oil pump located at the end of the compressor crankshaft, **Figure 25.65**. The crankshaft is connected to the oil pump and supplies power, which turns the oil pump, which can be either of the gear or eccentric type. **Figure 25.65** shows a gear type oil pump and **Figure 25.67** illustrates an eccentric type oil pump. The oil pump forces oil through holes drilled in the crankshaft and delivers it to bearings and connecting rods. The oil then drops to the crankcase to be picked up again by the oil pump. Smaller compressors usually have a splash-type oiling system with an scoop that scoops and flings the oil throughout the crankcase, causing an oil fog as the crankshaft turns.

The oil pressure safety control (switch) is used to ensure that the compressor has oil pressure when operating, **Figure 25.30(A)**.

The oil pressure control is used on larger compressors and has a different sensing arrangement than do the high- and low-pressure controls. The high- and low-pressure controls are single-diaphragm or single-bellows controls because they are comparing atmospheric pressure with the pressures inside the system. Atmospheric pressure can be considered a constant for any particular locality because it does not vary more than a small amount.

The oil pressure safety control is a pressure differential control. It measures a difference in pressure to establish that positive oil pressure is present. The pressure in the compressor crankcase (this is the oil pump suction inlet) is the same as the compressor suction pressure, **Figure 25.30(B)**. The suction pressure will vary from the off or standing reading to the actual running reading, not to mention the reading that would occur when a low charge is experienced. For example, when a system is using R-22 as the refrigerant, the pressures may be similar to the following: 125 psig while standing, 70 psig while operating, and 20 psig during a low-charge situation.

A plain low-pressure cut-out control would not function at all of these levels, so a control had to be devised that would. When dealing with compressors that employ an oil pump, many service technicians confuse net oil pressure with oil pump discharge ("outlet") pressure. However, it is of utmost importance that technicians understand the difference between these two pressures when servicing compressors with oil pumps. The oil pump's rotating gear or eccentrics add a certain pressure to the oil pumped through the crankshaft. This pressure is considered net oil pressure. Net oil pressure is *not* the pressure that can be measured at the discharge or outlet of the oil pump. The oil pump picks up oil at suction or crankcase pressure from the compressor's crankcase through a screen or filter. The oil pump discharge port's pressure includes both crankcase pressure and the oil pump gear pressure it adds to the oil. This is why net oil pressure cannot be measured directly with a gauge. A gauge at the oil pump's discharge port would register a combination of crankcase pressure and oil pump gear pressure. The technician must subtract the crankcase pressure from the discharge port pressure to get the net oil pressure. The following is an equation for net oil pressure:

$$\text{Oil Pump Discharge Pressure} - \text{Crankcase Pressure} = \text{Net Oil Pressure}$$

Example: The oil pump discharge pressure is 80 psig. The crankcase pressure is 20 psig. What would be the net oil pressure?

Solution: Simply subtract the crankcase pressure from the oil pump discharge pressure to get net oil pressure.

$$80 \text{ psi} - 20 \text{ psi} = 60 \text{ psid net oil pressure}$$

This means the oil pump is actually putting 60 psid of pressure into the oil when delivering it into the crankshaft's drilled passages. Notice that the net oil pressure is expressed in *pounds per square inch differential (psid)* because it is a difference between two pressures.

Figure 25.30 (A) Oil safety controls have a bellows on each side. They are opposed in their forces and measure the net oil pressure: the difference in the suction pressure (oil pump inlet) and the oil pump outlet pressure. This control has a 90-sec time delay to allow the compressor to get up to speed and establish oil pressure before it shuts down. (B) Two views of an oil pressure safety control. This control satisfies two requirements: how to measure net oil pressure effectively and how to get the compressor started to build oil pressure.

Photo by Bill Johnson

(A)

Photo by Bill Johnson

(B-1)

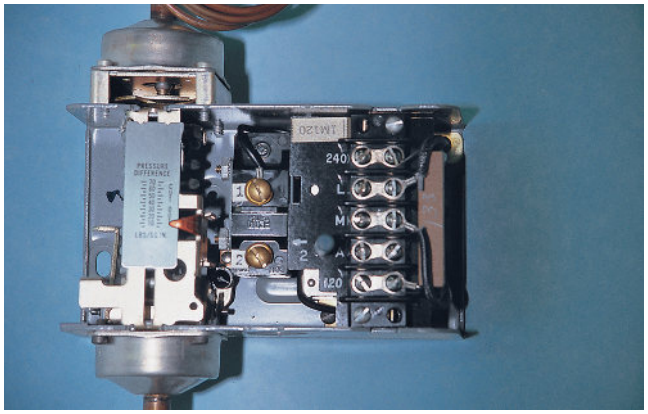

Photo by Bill Johnson

(B-2)

Sometimes the compressor's crankcase may be operating in a vacuum. In this case, the crankcase pressure is negative. Remember that every 2 in. of mercury vacuum is equivalent to approximately 1 psi.

Example: What is the net oil pressure if the oil pump discharge pressure is 35 psig and the crankcase pressure is 6 in. of vacuum (−3 psi)?
Solution: Again, we must subtract the crankcase pressure from the oil pump discharge pressure to get the net oil pressure.

35 psi − (−3 psi) = 38 psid net oil pressure.

This means that the oil pump is delivering 38 psi of net oil pressure through the crankshaft and bearings. **NOTE:** *The terms suction pressure and crankcase pressure are often used interchangeably in the HVAC/R industry. However, on some larger refrigerant-cooled compressors there is a partition wall between the crankcase and motor barrel. During start-up periods or when system problems occur, there could be a slight difference in pressure between crankcase pressure in the crankcase and suction pressure in the motor barrel. Because of this, it is of utmost importance to use the crankcase pressure, not the suction pressure, when connecting an oil safety controller to these types of compressors.* •

In the basic low-pressure control, the pressure is under the diaphragm or bellows and the atmospheric pressure is on the other side. The oil pressure control uses a double bellows—one bellows opposing the other—to detect the net or actual oil pressure. The pump inlet pressure is under one bellows, and the pump outlet pressure is under the other bellows. These bellows are opposite each other either physically or by linkage. The bellows with the most pressure is the oil pump outlet, and it overrides the bellows with the least amount of pressure. This override reads out in net pressure and is attached to a linkage that can stop the compressor when the net pressure drops for a predetermined time.

Because the control needs a differential in pressure to allow power to pass to the compressor, it must have some means of allowing the compressor to start. There is no pressure differential until the compressor starts to turn because the oil pump is attached to the compressor crankshaft. A time delay is built into the control to allow the compressor to get started and to prevent unneeded cut-outs when oil pressure may vary for only a moment. This time delay is normally about 90 to 120 sec. It is accomplished with a heater circuit and a bimetal device or electronically, **Figure 25.30(C)**. The delay also gives the crankcase time to clear any unwanted refrigerant during periods when refrigerant migration or flooding has occurred. Furthermore, it avoids nuisance shutdowns during short fluctuations in net oil pressure on start-ups.

Net oil pressures vary from compressor to compressor. They usually range from 20 to 40 psi. Most oil pressure safety controllers will shut the compressor down if the net oil

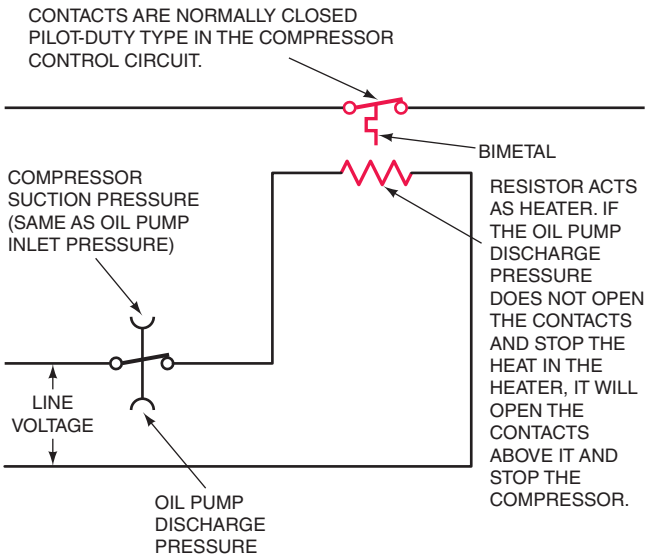
Figure 25.30 (C) The oil pressure control is used for lubrication protection for the compressor. The oil pump that lubricates the compressor is driven by the compressor crankshaft. Therefore, there has to be a time delay to allow the compressor to start and build oil pressure. This time delay is normally 90 sec. The time delay is accomplished with either a heater circuit heating a bimetal device or an electronic circuit.



(C)

pressure falls below 10 psi. The following variables affect the net oil pressure:

- Compressor size
- Oil viscosity
- Oil temperature
- Bearing clearance
- Percent of refrigerant in the oil

Larger compressors need more net oil pressure because they have more surface areas to lubricate, and the oil pumps must pump and carry the oil greater distances. As the oil gets hotter and its viscosity drops, the net oil pressure will also usually drop. As a compressor wears, its tolerances become greater and it becomes easier for the oil to escape through its clearances.

TRANSDUCER-TYPE OIL SAFETY CONTROLLERS

Transducer-type oil safety controllers use a pressure transducer, which senses a combination of oil pump discharge pressure and crankcase pressure. The pressure transducer has two separate ports to sense both crankcase pressure and oil pump discharge pressure. The subtraction or difference between these two pressures (net oil pressure) is mechanically accomplished by the pressure transducer. The transducer is connected to an electronic controller by wires, **Figure 25.31(A)**. The pressure transducer is shown connected to the compressor in **Figure 25.31(B)**. It then transforms a pressure signal to an

Figure 25.31 (A) The pressure transducer wired to an electronic controller. (B) The pressure transducer connected to the compressor.

(B)

electrical signal for the electronic controller to process. The advantage of an electronic oil safety controller is that it eliminates capillary tubes. Thus, there is less chance for refrigerant leaks. Also, the electronic clock and circuitry are much more accurate and reliable. Remember, when the compressor is off, the net oil pressure is 0 psi and the differential pressure switch contacts are closed. The heater in the oil safety controller will not be energized during the off cycle because it is wired to the load side of the motor starter contacts, **Figure 25.32**. When the motor starter contacts are opened, this action takes L_2 out of the heater circuit. At start-up, when the motor starter contacts close and the compressor starts, the differential pressure switch contacts will stay closed and the heater will be energized until

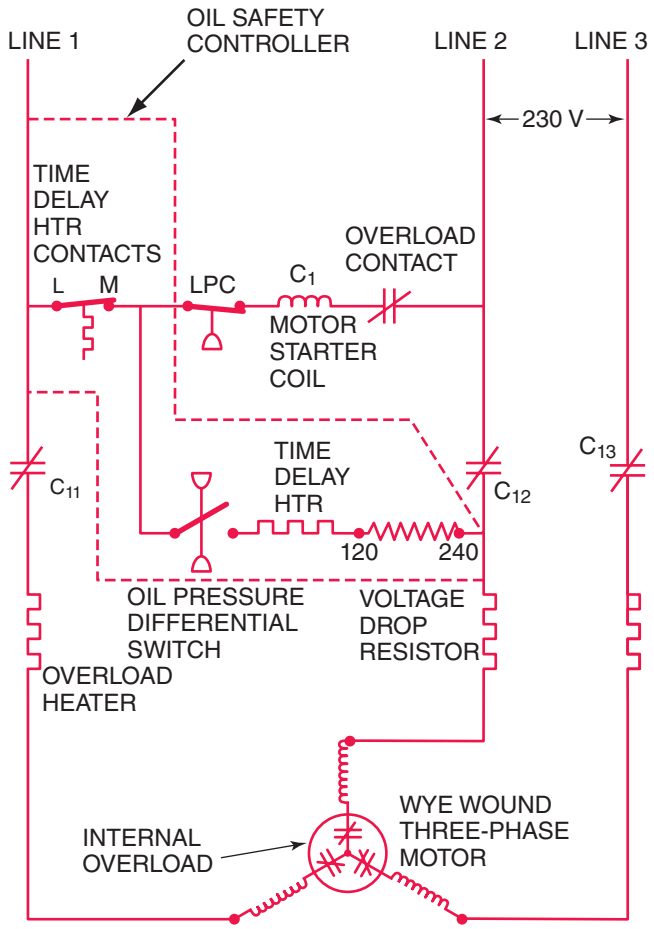
Figure 25.32 The schematic diagram of an oil safety control circuit and a three-phase motor with internal overload.



at least 9 psid of net oil pressure is developed on most controllers. As mentioned before, this time delay will prevent nuisance trips to the controller at compressor start-ups or when system problems like floodback and migration occur.

INTERNAL OVERLOADS

If a motor is equipped with both an internal inherent motor protector and an oil safety controller, the oil safety controller may trip on some systems due to a motor overheating or overloading problem. When the internal overload opens, the motor is shut off but the motor starter coil remains energized with contacts closed. The 2-min timing circuit would be activated due to the lack of net oil pressure. This will trip the oil safety controller in a matter of 2 min because the heater will still be energized through the load side of the motor starter, **Figure 25.32**. Remember, there is no net oil pressure when the compressor is shut off by its internal overload protector. In time, the compressor will cool off and the internal overload will reset (close). But the compressor will not restart until pushing the reset button manually resets the oil safety controller. This condition can be prevented by the use of a current sensing relay.

The **current sensing relay** allows the compressor to cycle on the internal overload while not affecting the operation of the oil safety controller. The current sensing relay is wired to the load side of the contactor or motor starter. It acts like an inductive-type ammeter. One leg of the load side of the compressor motor is passed through the relay inductive coil. The inductive coil controls a normally open set of contacts in series with the time delay heater, **Figure 25.33(A)**. One leg of the compressor motor is shown passing through the inductive coil in **Figure 25.33(B)**. The contacts are closed when normal motor current is sensed. When the current drops quite low, or reduces to zero because of the motor being off, the contacts of the current relay will open and take power away from the time delay heater. This prevents a tripping of the oil safety controller in case the internal overload opens (compressor off) but the motor starter's coil is still energized. The voltage-dropping resistor in **Figure 25.33(A)** makes the control more versatile for use on 230-V or 115-V systems.

In these situations it is often necessary to incorporate another field-wired relay when dealing with an electronic oil safety controller. The reason for this is that the electronic oil safety module requires power to the module for proper reset. The added relay simply provides this power to the module during an oil safety trip. However, always consult with the compressor and control manufacturer before applying or wiring any of these controls or devices. **SAFETY PRECAUTION:** *The manufacturer's instructions should be consulted when working with any compressor that has an oil safety control.*•

25.22 THE DEFROST CYCLE

Any evaporator that operates below 32°F, the freezing point of water, will need some sort of method of defrosting. This also holds true when products must be stored above freezing temperatures, because the evaporators that cool them are often below freezing. For example, dairy products are often kept refrigerated at 35°F to 36°F, while their evaporator surface temperatures will range between 25°F to 30°F. When the surface of the evaporator falls below freezing, it will begin to build a coating of ice—"frost." Frost can occur on the surface of the evaporator in a number of forms. The layer of frost closest to the evaporator coil will be a very hard form of ice, similar to what you would see in an ice cube. The other layers of frost that form on this hard surface of ice covering the coil often resemble snow or flaked ice and will hold a lot of entrained air. This layer is often referred to as "**hoar frost**." The amount of hoar frost depends on:

- Humidity levels
- Airflow amounts
- Evaporator temperatures

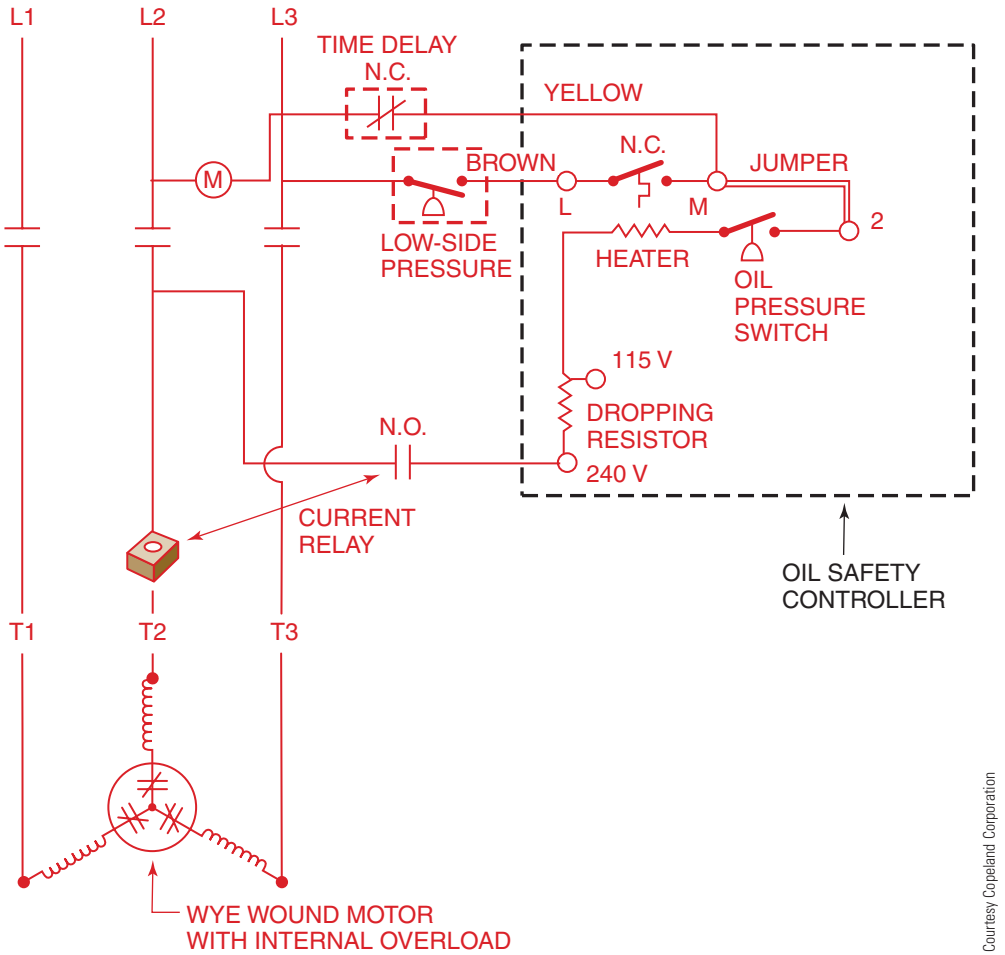
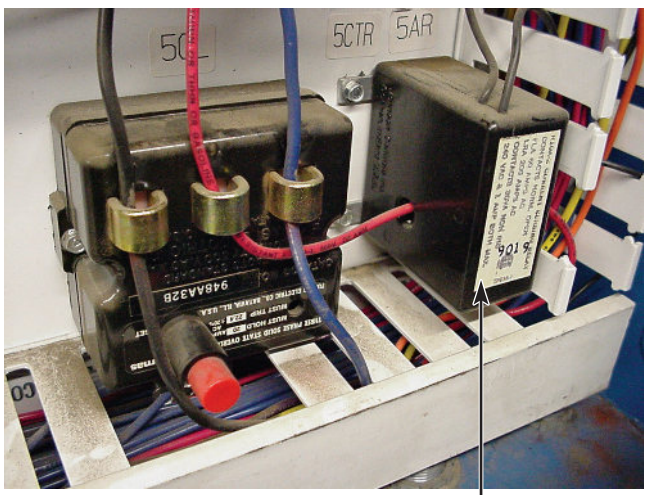
Figure 25.33 (A) An oil safety circuit showing a current sensing relay with motor and internal overload. (B) A current sensing relay.



(A)



(B)

As humidity levels and airflow amounts increase, so does the amount of hoar frost. As evaporator temperatures decrease, the hoar frost will also increase.

Although ice will conduct heat four times as well as water, the air entrained in the porous hoar frost will insulate the evaporator and severely reduce its heat-absorbing abilities. The suction pressure will now drop and the evaporator will become even colder. The colder evaporator and lower suction pressures cause the refrigeration system to have a higher compression ratio. Higher compression ratios cause lower volumetric efficiencies within the compressor. Lower suction pressures also cause the return gas coming back to the compressor to be less dense, reducing the mass flow rates of refrigerant. If the evaporator is severely insulated in frost to the point that hardly any heat load is reaching the coil, the TXV metering device may lose control and flood the compressor.

Evaporator fin spacing is very important in handling hoar frost. The colder the operating temperature of the evaporator, the more space there needs to be between

the fins. This provides space for frost to accumulate and at the same time not slow down or block the evaporator's airflow. Some typical fin spacing for different evaporators are as follows:

- Low-temperature evaporators: 4 to 6 fins per inch
- Medium- and high-temperature evaporators: 6 to 10 fins per inch
- Air-conditioning evaporators: 12 to 15 fins per inch

However, an evaporator that has fewer fins per inch will need to be larger. This is because these evaporators have less surface area for heat transfer to take place. So, if frost can be minimized, fins can be more closely spaced and a smaller, more economical evaporator can be used. Defrosting the evaporator and eliminating frost from its surface will accomplish this task.

Laboratory testing has shown that a thin layer of frost will actually increase heat transfer in an evaporator. The thin layer of frost will somewhat reduce the area for airflow, causing a slight increase in the air's velocity which will increase heat transfer to the evaporator. Also, a thin layer of frost will increase the surface area of the evaporator tubes, which will also enhance heat transfer. These same tests also show that the best time to defrost is when the evaporator has lost about 10% of its efficiency. It is for these reasons that service technicians must follow the manufacturer's recommendation for defrost period intervals and defrost period durations to get maximum efficiency out of an evaporator surface and a defrost period. The defrost cycle in refrigeration is divided into medium-temperature and low-temperature ranges; the components that serve these defrost cycles are different.

25.23 MEDIUM-TEMPERATURE REFRIGERATION

The medium-temperature refrigeration coil normally operates below freezing and rises above freezing during the off cycle. A typical temperature range would be from 34°F to 45°F inside the cooler. The coil temperature is normally 10°F to 15°F cooler than the space temperature in the refrigerated box. This means that the coil temperatures would normally operate as low as 19°F (34°F − 15°F = 19°F). The air temperature inside the box will always rise above the freezing point during the off cycle and can be used for the defrost. This is called **off-cycle defrost** and it can be either random or planned.

25.24 RANDOM OR OFF-CYCLE DEFROST

Random or off-cycle defrost is the most common type of defrost. Random defrost will occur when the refrigeration system has enough reserve capacity to cool more than the load requirement. When the system has reserve capacity, it will be shut down from time to time by the thermostat, and the air in the cooler can defrost the ice from the coil. When the compressor is off, the evaporator fans will continue to run and circulate the air in the cooler. The air that is circulated must be warmer than 32°F to defrost the coil. The main advantage of off-cycle defrost is its simplicity and economy of installation. When the refrigeration system does not have enough capacity or the refrigerated box has a constant load, there may not be enough off time to accomplish defrost. This is when the defrost cycle must be planned.

Figure 25.34 A timer to program off-cycle defrost. This is a 24-hour timer that can have several defrost times programmed for convenience.

Photo by Bill Johnson

25.25 PLANNED DEFROST

Planned defrost is accomplished by forcing the compressor to shut down for short periods of time so that the air in the cooler can defrost the ice from the coil. A timer that can be programmed stops the compressor during times that the refrigerated box is under the least amount of load. For example, a restaurant unit may defrost at 2 AM and 2 PM to avoid the rush hours, **Figure 25.34**. Again, always consult with the refrigerated case manufacturer for defrost period intervals and durations.

25.26 LOW-TEMPERATURE EVAPORATOR DEFROST

Low-temperature evaporators all operate below freezing and must have planned defrost. Because the air inside the refrigerated box is well below freezing, heat must be added to the evaporator for defrost, which is accomplished using *internal heat* or *external heat*.

25.27 INTERNAL HEAT DEFROST (HOT GAS AND COOL GAS DEFROST)

Hot and cool gas defrost is the least common type of defrost when compared to random or off-cycle defrost and electric defrost. In cool gas defrost, the gas used for defrosting the evaporator comes from the top of the receiver. Even though this gas has a cooler temperature, it often has more heat content, or enthalpy, because it is a more dense, saturated gas. The internal heat method of defrost normally uses the hot gas from the compressor. The hot gas can be introduced into the evaporator from the compressor discharge line to the inlet of the evaporator and allowed to flow until the evaporator is defrosted, **Figure 25.35**. *Because a portion of the energy used for hot gas defrost is available in the system, this method is attractive from an energy-saving standpoint.*

Injecting hot gas into the evaporator is rather simple if the evaporator is a single-circuit type because inserting a T in the expansion valve outlet is all that is necessary. With a multicircuit evaporator, the hot gas must be injected between the expansion valve and the refrigerant distributor. This gives an equal distribution of hot gas to defrost all of the coils equally. Often, the hot gas is 200°F or above, and as it rejects its heat to the frosted evaporator coil from the inside of the coil, it will cool enough to condense to a liquid. The liquid is often caught by the accumulator in the suction line before it enters the compressor, **Figure 25.35**. Once the frost on the evaporator is melted to water, the water must have time to drip and drain off the evaporator. It is important to keep the fans off during this "**drip time**" and for some time after the defrost to prevent moisture from being blown off the coil and on to the product.

In space temperature applications, where forced air is used to cool the product, the defrost cycle is normally started with a timer. The cycle can be terminated by time or temperature. The amount of time it takes to defrost the coil must be known before time alone can be used efficiently to terminate defrost. Because this can vary from one situation to another, if the timer is set for too long a time the unit would run in defrost when it is not desirable, causing energy loss and possible product spoilage. Defrost can also be started with time and terminated by temperature. A temperature-sensing device is used to determine that the coil is above freezing. The hot gas entering the evaporator is stopped, and the system goes back to normal operation, **Figure 25.36**.

During the hot gas defrost cycle, several things must happen at the same time. The timer is used to coordinate the following functions:

1. The hot gas solenoid must open.
2. The evaporator fans must stop, or cold air will keep defrost from occurring.
3. The compressor must continue to run.
4. A maximum defrost time must be determined and programmed into the timer in the event the defrost termination switch fails to terminate defrost.
5. Drain pan heaters may be energized.

Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

25.28 EXTERNAL HEAT DEFROST

The external heat method of defrost is often accomplished by electric heating elements that are factory mounted next to the evaporator coil. Electric defrost is the second most common type after random or off-cycle defrost and hot gas or cool gas defrost. It is also a planned defrost that is controlled by a timer. The external heat method is usually not as efficient as the internal heat method because energy must be purchased for it. Even though it is one of the simpler methods to install, electric defrost can be very expensive in terms of energy usage. The electric heaters often use 1 kW per foot of evaporator length, and there can be 3 to 5 defrost periods per day, of 45 to 60 minutes in duration. The heaters often reach 300°F and can scorch components on or near the evaporator if not carefully used and controlled. Often, melted frost that touches the element will flash to steam and recondense on any cold surface, as evidenced by layers of ice on the ceilings of refrigerated rooms. This may require extending the defrost periods and run into unwanted costs. Thus, electric defrost must be closely controlled to make it safe, efficient, and effective. However, if long runs are required for the hot gas lines, electric defrost may be the more efficient method. The long runs can cause refrigerant to condense, slowing the defrost process, and liquid refrigerant could reach the compressor, causing slugging and compressor damage.

When electric defrost is used, it is critical that the cycle be terminated at the earliest possible time. The timer controls the following events:

1. Stopping the evaporator fan in most cases
2. Stopping the compressor (with a possible pumpdown cycle to pump the refrigerant out of the evaporator to the condenser and receiver)
3. Energizing the electric heaters
4. Energizing drain pan heaters

Figure 25.37 A sensor used with the timer in **Figure 25.36** (A and B). The sensor has three wires and is a single-pole–double-throw device. It has a hot contact (made from the common to the terminal that is energized on a rise in temperature) and a cold contact (made from the common to the terminal that is energized when the coil is cold). This control is in either the hot or the cold mode. It is often referred to as a defrost termination and fan delay (DTFD) switch.

Courtesy Ferris State University. Photo by John Tomczyk

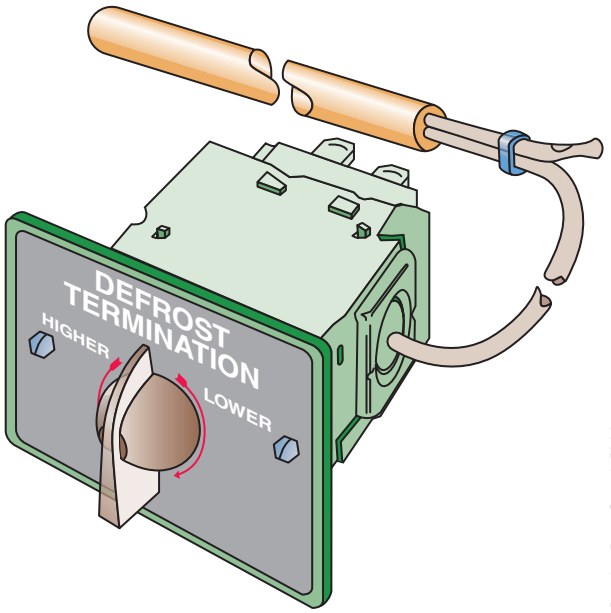
NOTE: *A temperature sensor may be used to terminate defrost when the coil is above freezing. A maximum defrost time should be programmed into the timer in the event the defrost termination switch fails to terminate defrost,* **Figure 25.37.** • The programmed defrost duration time is often referred to as the **fail-safe** time.

25.29 DEFROST TERMINATION AND FAN DELAY CONTROL

The defrost termination/fan delay control is a temperature-activated, single-pole–double-throw switch controlled by a remote sensing bulb. The control shown in **Figure 25.38(A)** also happens to be adjustable. The control installed on an evaporator is shown in **Figure 25.38(B)** and is wired into the refrigeration circuit as shown in **Figure 25.36(B)**. The control's remote sensing bulb is located high on the evaporator where the frost is likely to clear last. The function of this temperature-activated switch is to terminate defrost when the evaporator coil has been defrosted and also to delay the evaporator fans from coming on immediately after defrost.

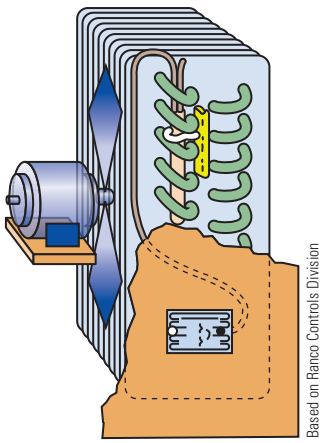
Defrost time clocks can be programmed to control the length of defrost periods in increments of minutes. For example, a defrost time clock on a freezer could be programmed to defrost every 6 hours (four times daily) for periods of 40 min. However, there will be times throughout the year when the coil does not need

Figure 25.38 (A) A defrost termination/fan delay control. (B) A defrost termination/fan delay control installed on a forced air evaporator.



(A)

Based on Ranco Controls Division



(B)

Based on Ranco Controls Division

the entire 40 min of defrost heat, for example, when low freezer usage keeps door openings to a minimum or when the humidity is low and not much frost accumulates on the coil. This is where the defrost termination part of the control comes into play. The following paragraphs explain the defrost termination function.

Let us assume that the system does not have a defrost termination/fan delay control. Once the normally open (NO) contacts of the defrost time control have closed and the unit is in defrost, the defrost heaters will emit heat and frost will melt off the evaporator coil, **Figure 25.36(B)**. If it takes only 10 min for all of the frost to leave the evaporator coil, there will still be 30 min left (40 min–10 min) in the programmed defrost period. If the system has an optional heater safety switch (sometimes referred to as a defrost limit control) wired in series with the defrost heater, as shown in **Figure 25.36(B)**, the limit switch

will open and take the defrost heaters out of the active circuit. However, the system's defrost timer will still have 30 min left in the defrost period. The system will simply sit idle, and because there will be no refrigeration for 30 min the product load will suffer an increase in temperature. After 30 min, the defrost timer switches over to refrigeration mode and the fans will start immediately. They will blow the moist, residual defrost heat through the refrigerated space and the evaporator coil while the system is in refrigeration mode. This puts the system, and thus the compressor, under an extremely high load from high suction pressures. The compressor will experience high suction pressures and dense vapors coming to its cylinders, which will cause high amperage draws and may overload the compressor to a point where its internal or external overload may open.

To prevent a long defrost period and compressor overload after defrost, a defrost termination/fan delay switch can be installed on the system, as shown in **Figure 25.36(B)**. If it takes only 10 min for the ice to leave the coil, the remote bulb of the defrost termination control will sense the defrost heat and close the contacts between 2 and 3 on the control. This energizes a defrost termination solenoid (release solenoid) in the time clock, which will mechanically put the system back into refrigeration mode. The solenoid action and levers will mechanically close the NC contacts and open the NO contacts of the defrost time control, **Figure 25.36(B)**. This action prevents the system from sitting idle for 30 min in defrost with the heaters off. It terminates the defrost mode and puts the refrigeration mode back into service. The fan delay part of the sequence will be explained in the following paragraph.

Now that the system is in refrigeration mode, the evaporator fans will be delayed until the contacts between 2 and 1 of the defrost termination/fan control close. This usually happens at about +20°F to +30°F, a setting that is adjustable on most controls, and is sensed and controlled by the control's remote bulb. This allows the evaporator coil to prechill itself and get rid of some of the defrost heat still in the coil. *Delaying the fans prevents the suction pressure from getting too high after defrost and overloading the compressor when an automatic pumpdown cycle is not being used. It also prevents warm, moist air and droplets of moisture from accumulating on the evaporator coil. The end of the fan delay period is often referred to as a "drip time." It allows the evaporator coil to drip and drain its melted frost from the coil and keep it from being blown on the product in the refrigerated space.*

25.30 REFRIGERATION ACCESSORIES

Accessories in refrigeration systems are devices that improve the performance and service functions. We will start at the condenser, where the liquid refrigerant leaves the coil, and will describe the various accessories as they are encountered in systems. All systems do not have each of the accessories.

25.31 RECEIVERS

The *receiver* is located in the liquid line and is used to store the liquid refrigerant after it leaves the condenser. The receiver should be lower than the condenser so that the refrigerant has an incentive to flow into it naturally, but this is not always possible. The receiver is a tanklike device that can be either upright or horizontal, depending on the installation, **Figure 25.39**. Receivers can be quite large on systems that need to store large amounts of refrigerant. **Figure 25.40** is a photo of a large receiver that will hold several hundred pounds of refrigerant.

The receiver inlet and outlet connection can be at almost any location on the outside of the tank body. On the inside of the receiver, however, the refrigerant must enter the receiver

Figure 25.39 Vertical and horizontal receivers.

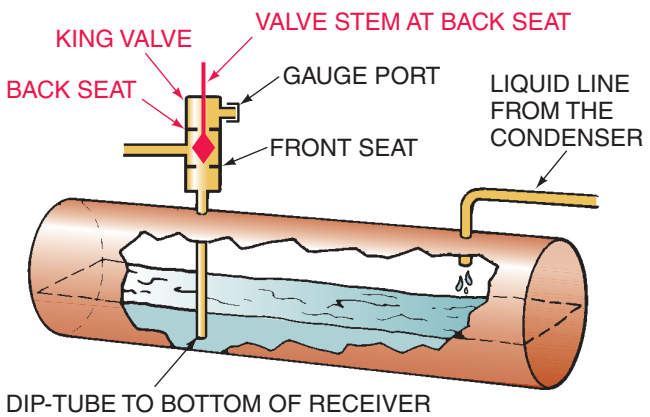
at the top in some manner. The refrigerant that is leaving the receiver must be taken from the bottom to ensure that it is 100% liquid. This is accomplished with a dip tube if the outlet line is at the top.

25.32 THE KING VALVE ON THE RECEIVER

The *king valve* is located in the liquid line between the receiver and the expansion valve. It is often fastened to the receiver tank at the outlet, **Figure 25.41**. The king valve is important in service work because when it is front-seated, no refrigerant can leave the receiver. If the compressor is operated with this valve front-seated, all the refrigerant will be pumped into the condenser and receiver. Most of it will flow into the receiver. The receiver should be sized to hold approximately 20% more than the system's full charge of refrigerant. This leaves a vapor head for safety reasons during system pumpdowns. The other valves in the system can then be closed, and the low-pressure side of the system can be opened for service. When service is complete and the low side of the system is ready for operation, the king valve can be opened, and the system can be put back into operation.

The king valve has a pressure service port to which a gauge manifold can be fastened. When the valve stem is turned away from the back seat, this port will give a pressure reading in the liquid line between the expansion valve and the compressor high-side gauge port. When the valve is front-seated and the system is being pumped down, this gauge port is on the low-pressure side of the system common to the liquid line (this becomes the low side because the king valve is trapping the high-pressure refrigerant in the receiver). If there is any pressure in the liquid line, removing the gauge line may be difficult until the king valve is back-seated after the repair is completed, **Figure 25.41**. Another component that can be found in many systems is a solenoid valve. This was covered in the section "The Solenoid Valve," earlier in this unit. It is a valve that stops and starts the liquid flow.

Figure 25.41 A king valve piped in the circuit. The back seat is open to the gauge port when the valve is front-seated. This valve has to be back-seated to remove the gauge if refrigerant is in the system.



25.33 FILTER DRIERS

The *refrigerant filter drier* can be found at any point on the liquid line after the king valve.

The filter drier is a device that removes foreign matter from the refrigerant. This foreign matter can be dirt, flux from soldering, solder beads, filings, moisture, parts, and acid caused by moisture. Some sources of moisture in refrigeration systems include poor service practices, air trapped from improper evacuation techniques, leaky systems, and improper handling of polyolester (POE) lubricants. The device has a fine screen at the outlet to catch any small particles that may be moving in the system, **Figure 25.42(A)**.

Figure 25.42 (A) A filter drier. This device removes particles and moisture from a liquid line. The moisture removal is accomplished with a desiccant in bead or block form inside the drier shell. (B) Cutaway view of a filter drier showing the desiccant core and prefilters.

(C)

Filter-drying operations are accomplished with a variety of materials that are packed inside the drier. Some manufacturers use chemical beads and some use porous blocks made from a drying agent. The most common agents found in filter driers are activated alumina, molecular sieve, or silica gel. Silica gel, a noncrystalline material with molecules formed by bundles of polymerized silica, forms a weaker bond with water, which is why silica gels are not widely used in modern filter driers.

Molecular sieve desiccants are sodium alumina-silicates in cubic crystalline form. The crystal structure is honeycombed with cavities that are uniform in size that can selectively absorb molecules based on their charge (polarity) and size. These properties allow water to be absorbed while still permitting the larger molecules like refrigerants and their lubricants to pass by. The surface of the desiccant is coated with cations, which are positively charged and act like magnets to attract polarized molecules such as water. Molecular sieves retain the highest amount of water and keep the concentration of water in the refrigerant low. The molecular sieve filter is recommended for use as liquid-line filter driers because of these good water-removal capabilities. The strong bond between water and the molecular sieve thus keeps the occurrence of system corrosion, acid formation, and freeze-ups very low.

Inorganic acids like hydrochloric and hydrofluoric acids are formed when high system temperatures break down refrigerants and water. These acids can attack metal surfaces in the system and destroy the crystalline structure of the molecular sieve. In the presence of the wrong desiccant and water, organic acids can then form from the broken down refrigerant lubricant. Organic acids, a sludgelike material, can plug up metering devices. Activated alumina is more effective than the molecular sieve for removing organic acid molecules. Activated alumina is formed from aluminum oxide. It is not a highly crystalline structure like a molecular sieve; its pores vary in size and do not absorb molecules based on pore size. Because of this, it can absorb much larger molecules like refrigerants and lubricants along with water. Activated alumina is even more effective in removing organic acids when it is used in the suction line of the refrigerant system. This is why some manufacturers recommend using a suction-line filter drier made of activated alumina for acid cleanups.

Filtration, another main function of a filter drier, can also be done with a screen. A screen will filter or catch particles that cannot fit through its wire mesh. As particles and contaminants start to cover the mesh of the screen, they act as a fine filter that removes even smaller particles. The accumulation of particles will soon cause enough pressure drop that the refrigerant will flash into a vapor. This will often cause a local cold spot on the filter drier and it may even sweat. Filters may also include the following:

- Bonded desiccant cores
- Fiberglass pads
- Rigid fiberglass with a resin coating

Bonded desiccant cores have smaller openings than fiberglass pads. As refrigerant passes through, the channels trap the particles. As the channels fill, a pressure drop occurs and the refrigerant will vaporize or flash. Fiberglass pads are less compressed than rigid fiberglass with resins. As refrigerant and particles flow through the pads, their speed decreases and they deposit themselves in the openings of the fiberglass. As the pads fill with more particles, the filtration becomes finer, soon becoming similar to a rigid fiberglass filter. A fiberglass pad can hold up to four times as many particles and contaminants as the bonded desiccant core drier can and still retain the same filtration capacity.

The filter drier comes in two styles: permanent and replaceable core. Both types of driers can be used in the suction line as well as the liquid line, and this application will be discussed in more detail later. Filter driers in the smaller sizes up to 5/8 in. can be fastened to the liquid line by a flare connection. Solder connections can be used for a full range of sizes, from 1/4 to 1 5/8 in. The larger, soldered filter driers have replaceable cores. Replaceable-core filter driers as well as plain filters can be easily serviced, **Figure 25.42(C)**. The king valve is front-seated to pump the refrigerant into the condenser and receiver to replace the drier cores. An evacuation to at least 500 microns with a vacuum pump is then

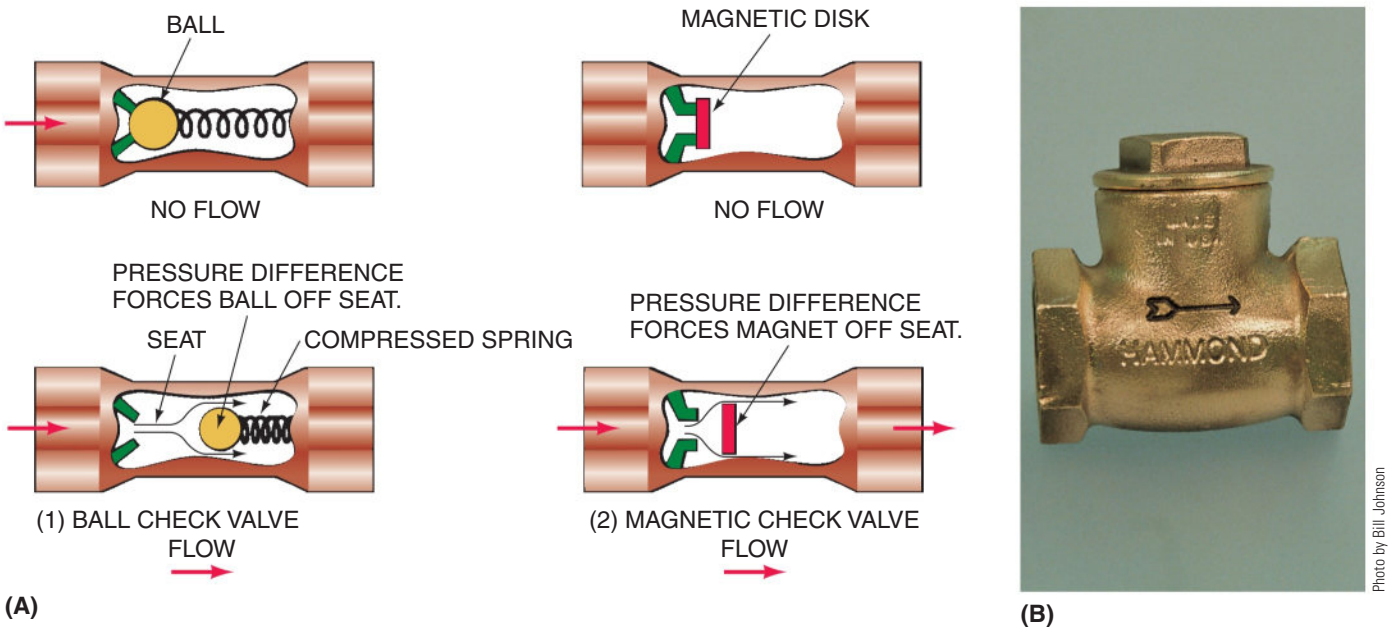
Figure 25.43 (A) Two types of check valves. (B) Photo of valve.



applied to the pumped-down part of the system before putting the new filter or core back into service.

Filter driers can be installed anywhere in the liquid line. The closer it is to the metering device, the better it cleans the refrigerant before it enters the tiny orifice in the metering device. The closer it is to the king valve, the easier it is to service. Service technicians and engineers choose their own placement, based on experience and judgment.

25.34 REFRIGERANT CHECK VALVES

A *check valve* is a device that will allow fluid to flow in only one direction. It is used to prevent refrigerant from backing up in a line by means of several types of mechanisms. Two common types of check valves are the ball check and magnetic check, **Figure 25.43(A)**. Both of these check valves cause some pressure drop, depending on the flow rate. The technician must consult the manufacturer's catalog for flow rate and application. The check valve can be identified by an arrow on the outside that indicates the direction of flow, **Figure 25.43(B)**.

25.35 REFRIGERANT SIGHT GLASSES

The *refrigerant* **sight glass** is normally located anywhere liquid flow exists and anywhere it can serve a purpose. *When it is installed just prior to the expansion device, the technician can be assured that a solid column of liquid is reaching the device. When it is installed at the condensing unit, it can help with troubleshooting.* More than one sight glass, one at each place, is sometimes a good investment. Sight glasses come in two basic styles: plain and with a moisture indictor. The plain sight glass is used to observe the refrigerant as it moves along the line. The sight glass with a moisture indicator can tell the technician what the moisture content is in the system. It has a small element in it that changes color when moisture is present. An example can be seen in **Figure 25.44**.

25.36 LIQUID REFRIGERANT DISTRIBUTORS

The refrigerant **distributor** is used on multicircuit evaporators. It is fastened to the outlet of the expansion valve and distributes the refrigerant to each individual evaporator circuit. This is a precision-machined device that ensures that the refrigerant is divided equally to each circuit, **Figure 25.45**. This is not a simple task because the refrigerant is not all liquid or all vapor. It is a mixture of liquid and vapor. A mixture has a tendency to stratify and feed more liquid to the bottom and the vapor to the top. Choosing the correct size of distributor for a system can be a complex decision because the distributor must have the exactly right pressure drop to perform correctly. The expansion valve and the distributor must be considered together because of the pressure reduction through the distributor. For a new installation,

the manufacturer determines the sizing of the distributor. 4R *In the future, as chlorofluorocarbon refrigerants are changed to the new refrigerants, the refrigerant distributor will need to be considered. Without a close relationship with manufacturers, distributors may be mismatched to expansion valves.* 4R Some distributors have a side inlet for the injection of hot gas for hot gas defrost, **Figure 25.46.**

25.37 HEAT EXCHANGERS

The **heat exchanger** is often placed in or at the suction line leaving the evaporator. The heat exchange is between the suction and the liquid lines, **Figure 25.47(A)**, and serves two purposes:

1. *It improves the capacity of the evaporator by subcooling the liquid refrigerant entering it, which can allow a smaller evaporator to be used in the refrigerated box. The cooler the refrigerant entering the expansion device, the more net refrigeration effect in the evaporator.* This is not necessarily a net system efficiency improvement because the heat is given up to the suction gas and is still in the system. The heating of the suction gas expands the gas, giving it a lower density before it enters the cylinders of the compressor. This can reduce the refrigerant flow rate pumped by the compressor.

Figure 25.45 (A) A multicircuit refrigerant distributor used to feed equal amounts of liquid refrigerant to the different refrigerant circuits. The combination of liquid and vapor refrigerant has a tendency to stratify, with the liquid moving to the bottom. This is a precision-machined device for separating the mixture evenly. 2. *It prevents liquid refrigerant from moving out of the evaporator to the suction line and into the compressor.*

Most heat exchangers are simple and straightforward. The heat exchanger has no electrical circuit or wires. It can be recognized by the fact that the suction line and the liquid line are piped to the same device. In some small refrigeration systems, a capillary tube is soldered to the suction line, which accomplishes the same thing that a larger heat exchanger does, **Figure 25.47(B)**.

Figure 25.46 The same type of distributor as in **Figure 25.45** except that it has a side inlet for allowing hot gas to enter the evaporator evenly during defrost.

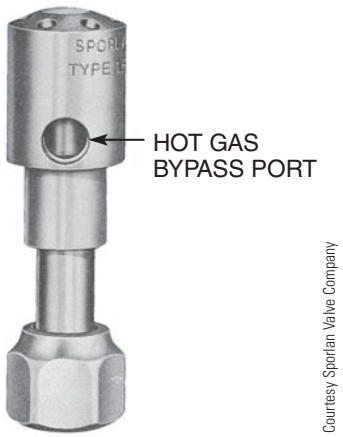

Figure 25.47 Heat exchangers. (A) Plain liquid-to-suction type. (B) Capillary tube fastened to the suction line; it accomplishes the same thing as the heat exchanger.

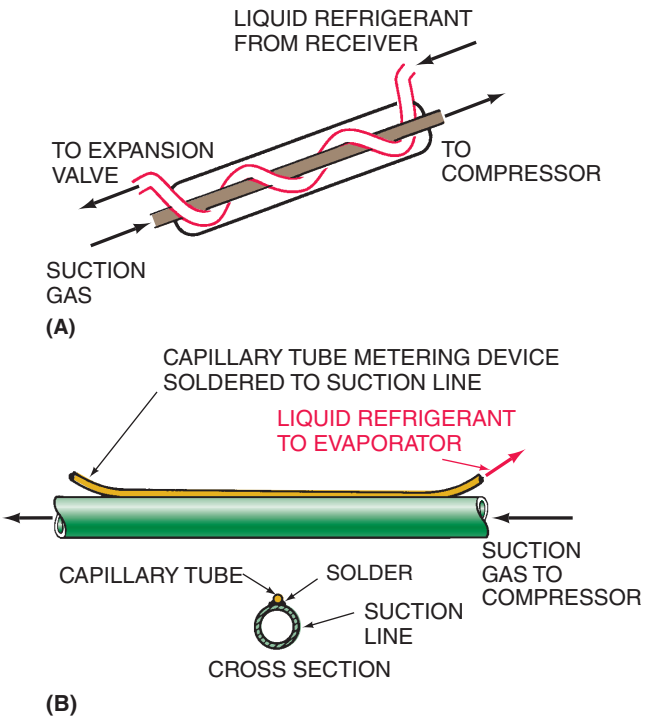

The next two components that could be installed in the suction line are the EPR valve and the CPR valve. These were discussed earlier in this unit as control components.

25.38 SUCTION-LINE ACCUMULATORS

The **suction-line accumulator** can be located in the suction line to prevent liquid refrigerant from passing into the compressor. As discussed earlier, liquid refrigerant floodback causes serious problems for a compressor. Floodback dilutes the compressor's oil with liquid refrigerant and causes foaming in the crankcase, resulting in bearing washout. Under certain conditions, usually during defrost, liquid refrigerant may leave the evaporator. The suction line is insulated and will not evaporate much refrigerant. *The suction-line accumulator collects this liquid and gives it a place to boil off (evaporate) to a gas before continuing on to the compressor.*

As mentioned, liquid entering a compressor during the running cycle is called liquid floodback. The following are some causes of floodback:

- Wrong TXV setting (low or no compressor superheat)
- Overcharge
- Evaporator fan not operating
- Low load on evaporator
- End of cycle (lowest load)
- Defrost clock or heater not operating, causing an iced coil
- Dirty or blocked evaporator coil
- Capillary tube overfeeding
- Capillary tube system overcharged
- Loose TXV bulb on evaporator outlet
- Oversized expansion valve
- Flooding after hot gas termination
- Heat pump changeover
- Defrost termination

When liquid is present in the bottom of the accumulator, most accumulators are designed to meter both the liquid refrigerant and the oil back to the compressor at an acceptable rate that will not damage compressor parts or cause oil foaming in the crankcase. This is done with a small metering orifice at the bottom of the outlet tube while the compressor is running, **Figure 25.48(A)** and **Figure 25.48(B)**. However, even though suction line accumulators assist in refrigerant flooding and migration problems, if flooding is severe the accumulator may also flood and cause compressor damage. The only 100% safe accumulator is one that can hold the entire system charge. Always consult with the manufacturer when sizing a suction accumulator for specific catalog numbers and tonnage ratings.

High compressor amperage draws may occur when liquid refrigerant is in the bottom of an accumulator and being vaporized because the compressor now sees dense, saturated or near-saturated gas coming into it and being compressed. Little or no superheat will be in the vapor coming off the

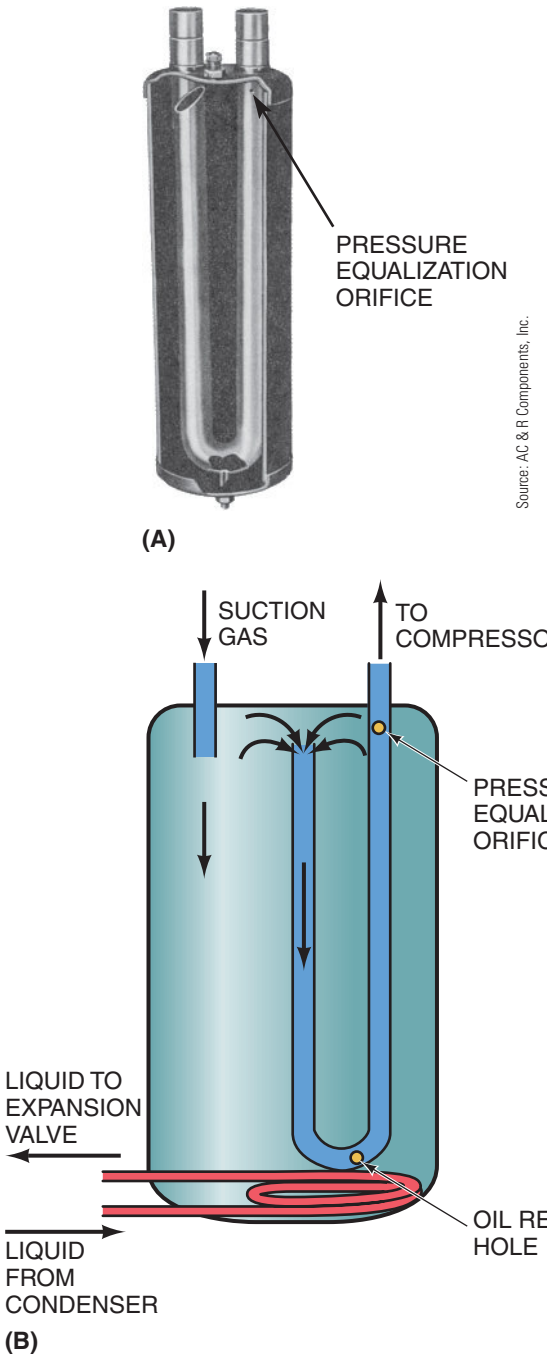
liquid in the accumulator and into the compressor. This causes high mass flow rates of refrigerant and can overload a compressor to the point of overheating.

Many indoor compressor installations have problems with suction accumulators sweating and dripping on floors. The only way around this problem is for the accumulator to be insulated completely and vapor sealed to prevent condensate from forming under the insulation. Because they are made of steel, accumulators can rust if exposed to moisture for any long period of time. The rusting usually happens at the seams or at the piping stubs after about 6 to 8 years of use. Although manufacturers do supply accumulators with rust-preventive paints, during the welding processes these paints can be burned off, leaving exposed metal. If an accumulator is resoldered because of pinhole leaks, usually near the seams or piping stubs, the residual soldering flux should be washed away and the area cleaned with emery cloth or steel wool. The surfaces should then be covered with a silicone rubber or roofing tar for a waterproof seal. The suction lines connected to the accumulator should also be insulated to prevent sweat from forming on them and dripping onto the accumulator.

During an off cycle, some liquid refrigerant may move into the accumulator by gravity from the evaporator and suction line, especially when the system does not have an automatic pumpdown cycle for its off cycles. This refrigerant will flow through the metering orifice for liquid refrigerant and oil return and seek its own level both inside and outside the U-tube formation of the suction piping of the accumulator. This means that the piping inside the accumulator will have a column of liquid refrigerant in it during the off cycle simply because of liquid inside the accumulator seeking its own level. When the compressor starts up, this column of liquid refrigerant would be sucked out of the accumulator and into the compressor if it were not for a pressure equalization orifice at the outlet of the accumulator, **Figure 25.48(C)**. This orifice will equalize pressure on both sides of the liquid column when the compressor is on or off. In other words, the liquid column will have accumulator pressure on both sides of it because of the orifice. This prevents the column of liquid from being sucked out of the U-tube of the accumulator and possibly damaging the compressor during the running cycle. The liquid column will momentarily hang in the U-tube and rapidly vaporize on a compressor start-up. This is a time where saturated gas could enter the compressor. Once the column of liquid in the accumulator is cleared or vaporized, the compressor will again see superheated gas.

Since compressors are extremely susceptible to liquid coming back to their crankcases or valves, accumulators add an extra safety precaution. Suction accumulators can assist in flooding and migration conditions. However, if flooding or migration problems are severe, suction-line accumulators have been known to flood and fail to prevent compressor damage. This is why the only 100% safe accumulator is one that can hold 100% of the entire system's refrigerant charge.

Figure 25.48 (A) A suction-line accumulator. Liquid refrigerant returning down the suction line can be trapped and allowed to boil away before entering the compressor. The oil bleed hole allows a small amount of any liquid in the accumulator to be returned to the compressor. If the liquid is refrigerant, not enough of it will get back through the bleed hole to cause damage. (B) A suction-line accumulator with heat exchanger.



Also, refrigerant vapor can migrate through the accumulator during the off cycle and still get to the compressor and condense. So, the accumulator is not the cure-all for refrigerant migration problems.

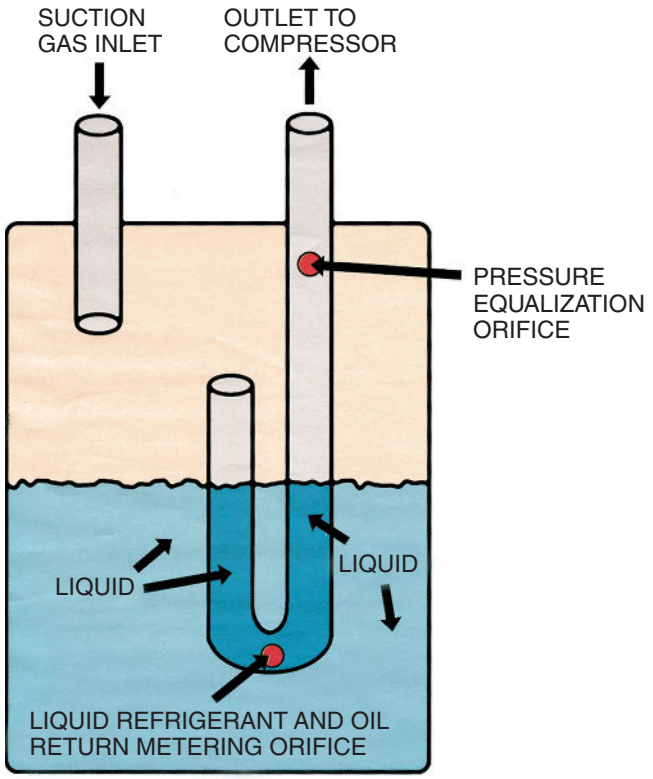
Figure 25.48 (C) A suction-line accumulator showing a pressure equalization orifice at the outlet of the accumulator.



(C)

Accumulators should be selected with three basic considerations in mind. Consult with the manufacturer for specific catalog numbers and tonnage ratings.

1. The accumulator should have adequate liquid holding capacity, not less than 50% of the entire system charge.
2. The accumulator should not add excessive pressure drop to the system.
3. The selection of an accumulator should not be based on the line size of the suction line. Many times an accumulator will not have the same line size as the suction line.

The accumulator is usually located close to the compressor. It should not be insulated so that any liquid that is in it may have a chance to vaporize.

The suction-line accumulator may have a small coil in the bottom where liquid from the liquid line may be routed to boil off the refrigerant in the bottom of the accumulator, **Figure 25.48(B)**. Otherwise, part of the refrigerant charge for the system will stay in the accumulator until the heat from the vapor passing through boils it to a vapor. Actually, not much heat will exchange unless liquid is in the accumulator, so there is not much effect on the system while only vapor is in the accumulator. The liquid-line coil in the accumulator also will help subcool the liquid refrigerant before it reaches the metering device. This will increase the net refrigeration effect in the evaporator.

Suction-line accumulators are typically made of steel. They also sweat, which causes rust. Older accumulators should be observed from time to time for refrigerant leaks. Cleaning and painting the solder connection will help to prevent rust.

25.39 SUCTION-LINE FILTER DRIERS

The *suction-line filter drier* is similar to the drier in the liquid line. It is rated for suction-line use. A filter drier is placed in the suction line to protect the compressor—and it is good insurance in any installation. It is essential to install a suction-line filter drier after any failure that contaminates a system. A motor burnout in a compressor shell usually moves acid and contamination into the whole system. When a new compressor is installed, a suction-line filter drier can be installed to clean the refrigerant and oil before they reach the compressor, **Figure 25.49(A)**. *Driers that have the capability to remove high levels of acid are typically used after motor burnout problems.*

Figure 25.49 (A) A suction-line filter drier. This device cleans any vapor that is moving toward the compressor. (B) A suction-line filter drier with access ports for checking pressure drop.

Most suction-line filter driers have some means for checking pressure drop across the cores. This is important because even a small pressure drop can cause the suction pressure to decrease to the point that the compression ratio is increased, which will reduce the efficiency of the compressor. **Figure 25.49(B)** shows the pressure fittings on a typical suction-line drier. From a sizing standpoint, the suction line is the most critical refrigerant line. Any accessories—such as evaporator pressure regulators, suction filters, suction accumulators, or crankcase pressure regulators—must also be sized correctly when installed in the suction line. The right refrigerant velocity must be maintained in the suction line, whether it is a level line or a suction-line riser, to make sure there is proper oil return. Refrigerant velocity is what sweeps oil through the suction line and back to the compressor. If the suction line is oversized, refrigerant velocity will be low and oil return will be hindered. If the suction line or its accessories are undersized, excessive pressure drop will reduce suction pressure, which will cause higher compression ratios and lower volumetric efficiencies.

25.40 SUCTION SERVICE VALVES

Refrigeration equipment usually has service valves. This is not always the case on air-conditioning equipment. The **suction service valve** is normally attached to the compressor on one side. The refrigerant piping from the evaporator fastens to the other side of the valve. The piping can be either flanged, flared, or soldered where fastened to the service valve. The valve can never be totally closed because of the valve's seat design. The service valve is either back-seated, front-seated, or midseated. A position of "just cracked" off the back seat is often used for reading system pressures and charging. An example of these functions is shown in **Figure 25.50**. The suction service valve is used

1. as a gauge port,
2. to throttle the gas flow to the compressor,
3. to valve off the compressor from the evaporator for service, and
4. to charge the system with refrigerant.

The service valve consists of the valve cap, valve stem, packing gland, inlet, outlet, and valve body, **Figure 25.51**. The *valve cap* is used as a backup to the packing gland to prevent refrigerant from leaking out around the stem. It is normally made of steel and should be kept dry on the inside. An oil coating on the inside will help prevent rust. *Valve covers should always be in place except during service operations.* The *valve stem* has a square head to accommodate the valve wrench. This stem is normally steel and should be kept rust-free. If rust does build up on the stem, a light sanding and a coat of oil will help. The valve turns in and out through the valve packing gland. Rust on the stem will destroy the packing in the gland. The *packing gland* can be either permanent or adjustable. If the gland is not adjustable and a leak starts,

only the valve cap will stop. If the gland is adjustable, the packing can be replaced. Normally, packing is graphite rope, **Figure 25.52**. Any time the valve stem is turned, the gland should be first loosened if it is adjustable. This will keep the valve stem from wearing the packing when the stem is turned.

Because the suction valve sweats, it is not uncommon for rust to cause pits in the valve stem, but this occurs only when poor service practices have been followed. A pitted valve stem should be carefully sanded smooth, then coated with refrigerant oil before turning. *If the stem is not smoothed, the packing will be damaged. The technician should always dry the valve stem and the inside of the protective cap and apply a light coat of oil before placing the cap on the valve stem.*

25.41 DISCHARGE SERVICE VALVES

The *discharge service valve* is the same as the suction service valve except that it is located in the discharge line. This valve can be used as a gauge port and to valve off the compressor for service **SAFETY PRECAUTION:** *The compressor cannot be operated with this valve front-seated. An exception is closed-loop capacity checks that take place under experienced supervision. Extremely high pressures will result if the test equipment is not properly applied to the valve.*

Compressor service valves are used for many service functions. One of the most important of these functions is the changing out of a compressor. *When both service valves are front-seated, the refrigerant may be recovered from between the valves where it is trapped inside the compressor,* **Figure 25.53**. When the refrigerant is recovered, the isolated compressor can be removed. When a new one is installed, the only part of the system that must be evacuated is the new compressor. A compressor can be changed in this fashion with no loss of refrigerant.

25.42 REFRIGERATION LINE SERVICE VALVES

Refrigeration line service valves are hand-operated specialty valves used for service purposes. These valves can be used in any line that may have to be valved off for any reason. They come in two types: the diaphragm valve and the ball valve.

25.43 DIAPHRAGM VALVES

The *diaphragm valve* has the same internal flow pattern that a "globe" valve does. The fluid has to rise up and over a seat, **Figure 25.54**. There is a measurable pressure drop through this type of valve. It can be tightened by hand enough to hold back high pressures. The valve can be installed in a system by either a flare or soldered connection. When soldered, care should be taken that it is not overheated because most of these valves have seats made of materials that would melt when being soldered into a line. The diaphragm valve can be taken apart and the internal parts removed for soldering purposes.

25.44 BALL VALVES

The **ball valve** is a straight-through valve with little pressure drop. This valve can also be soldered into the line, but temperature has to be considered. All manufacturers furnish directions that show how to install this valve, **Figure 25.55**. One of the advantages of the ball valve is that it can be opened or closed easily because it takes only a 90° turn to do either. Thus it is known as a "quick open or close" valve.

Figure 25.54 The diaphragm hand valve used when servicing a system. This valve is either open or closed, unlike the suction and discharge valves with a gauge port. The valve has some resistance to fluid flow, called pressure drop. It can be used anywhere a valve is needed. The larger sizes of this valve are soldered into the line. Care should be taken that the valve is not overheated when being soldered.

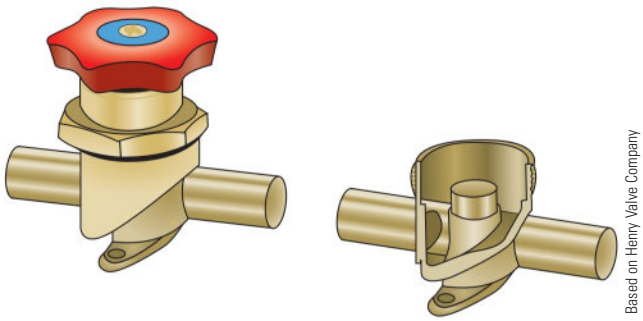

Figure 25.55 The ball valve. This valve is open straight through and creates very little pressure drop or resistance to the refrigerant flow.

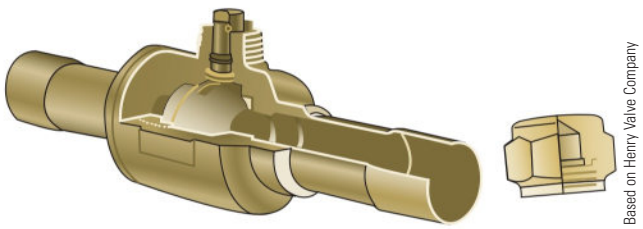

25.45 OIL SEPARATORS

The **oil separator** *is installed in the discharge line to separate the oil from the refrigerant and return the oil to the compressor crankcase.* All reciprocating and rotary compressors allow a small amount of oil to pass through into the discharge line. Once the oil leaves the compressor, it would have to go through the entire system to get back to the compressor crankcase by way of the system piping and coils. The oil separator has a reservoir and float to shortcut this oil flow and return it to the crankcase, **Figures 25.56(A)** and **(B)**. Oil separators work on the principle of low refrigerant and oil velocity. As oil-laden discharge gas enters the oil separator, its velocity is immediately slowed. This slowing of velocity happens because of an abrupt change of direction, impingement screens, internal baffling, or a large opening or transitioning of the piping at the entrance of the oil separator. Oil is usually mixed with the hot discharge gas in the form of a fog. This refrigerant/oil fog runs into the internal baffling or screens, which cause the refrigerant and oil fog to change direction and rapidly slow down. Very fine particles of oil collide with one another and form larger, heavier particles. Fine mesh impingement screens separate the oil and refrigerant even more, causing large oil droplets to form and drop to the bottom of the separator. The oil collects in a sump or reservoir at the bottom of the separator. A magnet is often connected to the bottom of the oil sump to collect any metallic particles.

When the oil level becomes high enough to raise a float, an oil return needle valve is opened, and the oil is returned to the compressor crankcase or oil reservoir through a small return line. This return line should be just above room temperature most of the time. If it is always hot, the float could be stuck open, allowing hot gas to enter the crankcase, which

Figure 25.56 (A) The oil separator used in the discharge line of a compressor to return some of the oil to the compressor before it gets out into the system. (B) This is a float-action valve that will return liquid refrigerant as well as oil. It must be kept warm to keep refrigerant from condensing in it during the off cycle.

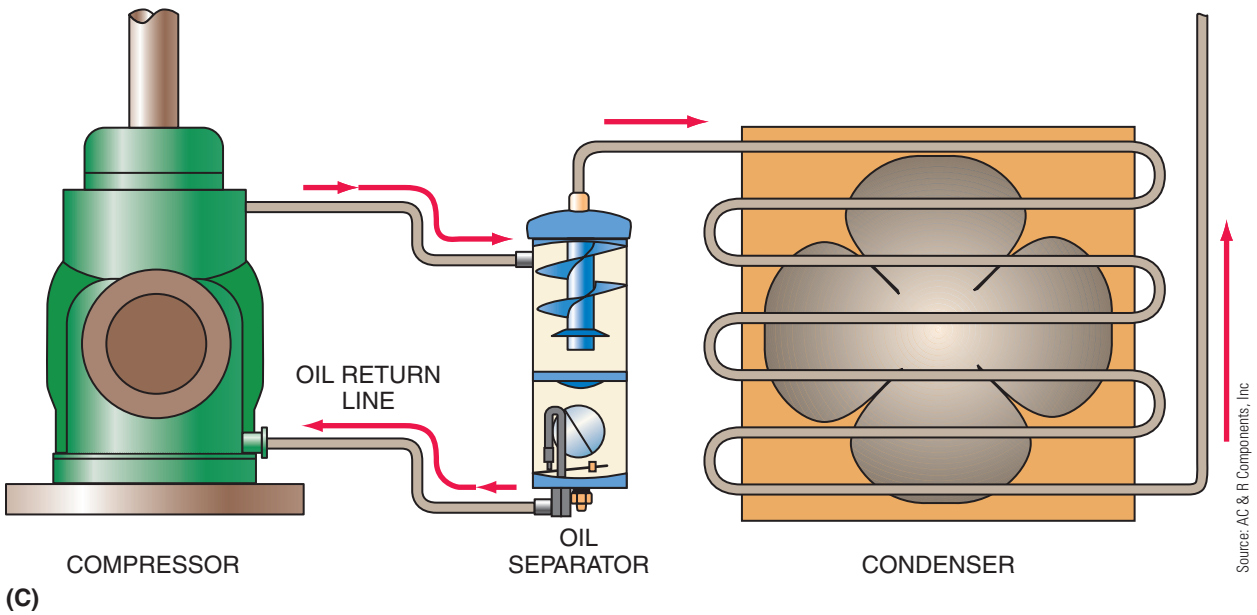
Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 25.56 (*Continued*) (C) Shows a helical oil separator. Helical oil separators are about 98% efficient in separating oil. When the oil and refrigerant fog enters the oil separator, it hits the leading edge of a helical flighting. The fog mixture is centrifugally forced along the spiral path of the helix. This causes the heavier oil particles to be forced to the perimeter of the separator's shell, where it is impinged by a screen layer. The screen layer acts as an oil stripping and draining medium. The liquid oil then flows through a baffle and into an oil collection area at the bottom of the separator and the oil-free refrigerant gas exits the separator just below the flighting. A float-activated oil return valve allows the captured oil to return to the compressor's crankcase or oil reservoir.



would also cause excessively high crankcase pressures and could overheat the compressor, resulting in serious damage. Because the oil separator is in the high side of the system and the crankcase is in the low side, a pressure difference naturally exists. This pressure difference drives the oil to travel from the separator to the crankcase when the float is in the right position. Only a small amount of oil is needed to actuate the float mechanism. This ensures that only a small amount of oil is ever absent from the compressor crankcase at any given time.

Figure 25.56(C) shows a helical oil separator. Helical oil separators are about 98% efficient in separating oil. When the oil and refrigerant fog enters the oil separator, it hits the leading edge of a helical flighting. The fog mixture is centrifugally forced along the spiral path of the helix. This causes the heavier oil particles to be forced to the perimeter of the separator's shell. This is where impingement with a screen layer occurs. The screen layer acts as an oil stripping and draining medium. The liquid oil then flows through a baffle and into an oil collection area at the bottom of the separator, and the oil-free refrigerant gas exits the separator just below the flighting. A float-activated oil return valve allows the captured oil to return to the compressor's crankcase or oil reservoir.

The oil separator should be kept warm to keep liquid refrigerant from condensing in it during the off cycle. The float does not distinguish between oil and liquid refrigerant. If liquid refrigerant were in the separator, it would return the refrigerant to the compressor crankcase, which would dilute the oil and cause marginal lubrication. If liquid refrigerant is returning to the compressor crankcase, the return line between the separator and the crankcase will be cold from refrigerant vaporizing due to the pressure drop. A damaged, leaking, or collapsed float in the oil separator will cause the orifice to stay closed and excessive amounts of oil will accumulate in the oil separator. This situation could rob the system of its valuable lubricant and cause compressor damage.

25.46 VIBRATION ELIMINATORS

Compressors produce enough vibration while running that it is often necessary to protect the tubing at the suction and discharge lines. Vibration can be eliminated on small compressors successfully with vibration loops. Large tubing cannot be routed in loops, so special vibration eliminators are often installed. These are constructed with a bellows-type lining and a flexible outer protective support, **Figure 25.57(A)**. These devices must be installed correctly, or other problems may occur, such as extra vibration. The typical recommendation is that they be installed close to the compressor and in parallel with the compressor's crankshaft, **Figure 25.57(B)**. If mounted crossways or perpendicular to the crankshaft, excess vibration may occur. Follow the manufacturer's directions.

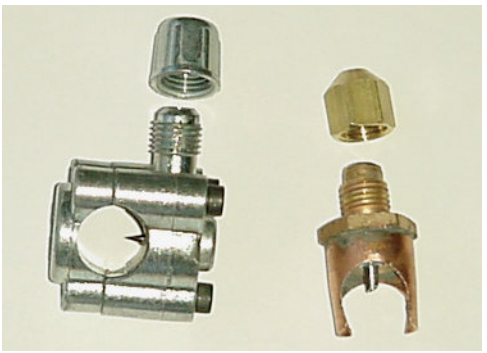
25.47 PRESSURE ACCESS PORTS

Pressure access ports provide a method of taking pressure readings at places that do not have service ports. Several types can be used effectively. Some can be attached to a line while the unit is operating. This can be helpful when a pressure reading is needed in a hurry and the system needs to keep on running. One of these types has a gasket and is bolted on the line. When the valve is bolted in place, a pointed plunger is forced through the pipe to make a very small hole in the line, just large enough to take pressure readings and transfer small amounts of refrigerant, if needed, **Figure 25.58**. The other type of valve that can be installed while the system is running requires the valve to be soldered onto the line with a low-temperature solder. This can only be done on a vapor line because a liquid line will not heat up as long as there is liquid in it. Manufacturers claim that this type of soldering application does no damage to the refrigerant in the line. This valve may be more free of leaks because it is soldered. After the valve is soldered onto the line, a puncture is made in a manner similar to the valve previously described, **Figure 25.59**.

Figure 25.58 Pressure tap devices used to obtain pressure readings when there are no gauge ports.



Courtesy Ferris State University. Photo by John Tomczyk

Figure 25.59 This valve can be soldered on a vapor line while the system has pressure in it. Low-temperature solder is used. It cannot be soldered to a line with liquid in it because the liquid will not allow the line to get hot enough.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

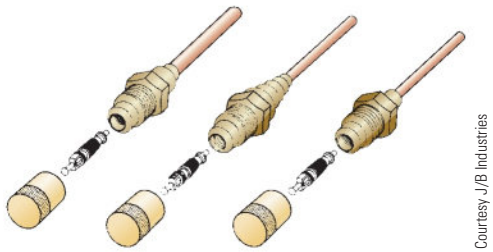
Figure 25.60 This valve port must have a hole drilled in the line and can be installed only with the system at atmospheric pressure.

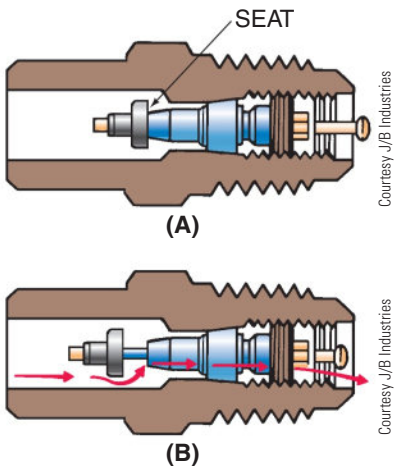


Line-piercing valves should be installed according to the manufacturer's directions or a leak is likely to occur. It is good practice not to locate a line tap valve on the hot gas line if a gasket is involved because, in time, the heat will deteriorate the gasket and a leak will occur. If a high-side pressure reading is required, use the liquid line; it is much cooler and less likely to leak. A line tap valve with a gasket should not be left on the line as a permanent gauge port.

For other valves used as ports a hole must be drilled in the refrigerant line. All copper filings should be removed from the line to prevent system damage. A copper tee also can be installed in the line to house the valve. This can be done without drilling. The valve stem is inserted into the line and soldered when there is no pressure in the line, **Figure 25.60**.

Attaching a gauge hose to these pressure access ports can be done in two ways. Some of the valves have handles that shut off the valve to the atmosphere. The others normally use a *Schrader* connection, which is like a tire valve on a car or bicycle except that it has threads that accept the 1/4-in. gauge hose connector from a gauge manifold, **Figure 25.61**.

Figure 25.61 The Schrader valve is similar to the valve on a car tire. It has threads to accept the service technician's gauge line threads, (A)–(B).



25.48 CRANKCASE HEAT

The crankcase heater is a resistance heater that is strapped on, inserted, or connected in some way to the compressor's crankcase. The crankcase heater is designed to help combat refrigerant migration. Migration is refrigerant liquid or vapor migrating to the compressor's crankcase during the compressor's off-cycle. The function of the crankcase heater is to hold the oil in the compressor's crankcase at a temperature higher than the coldest part of the system. Refrigerant entering the crankcase will then be vaporized and driven back into the suction line. However, the next on cycle could draw this refrigerant from the suction line and liquid slugging of the compressor can occur. Again, crankcase heaters do help in combating migration, but do not prevent slugging at start-ups or liquid floodback to compressors once the compressor is running. However, a crankcase heater used in conjunction with an automatic pumpdown cycle and/or suction line accumulator will help remedy many of these start-up problems.

Crankcase heat is common in air-conditioning (cooling) systems. The homeowner often shuts off the disconnect to the outdoor condensing unit for the winter, leaving the compressor without crankcase heat. If the homeowner then starts the unit without allowing some time for the heat to boil the refrigerant out of the oil, damage will likely occur to the compressor. On start-up, the crankcase pressure reduces as soon as the compressor starts to turn. The refrigerant will boil and turn the oil to foam. The oil and refrigerant (some of the refrigerant may be in the liquid state) will be pumped out of the compressor. Valve and bearing damage may occur and the compressor may be operated with a limited oil charge until the oil returns to the crankcase from the evaporator. Refrigeration compressors typically operate all season and will not have this seasonal shutdown, but if they are shut down for a period of time, the preceding situation will occur.

Crankcase heat can be applied in several ways. Sometimes it is applied by heaters that are inserted into a well located on the shell of the compressor's crankcase where the compressor's oil can be heated, and sometimes by external heaters at the base of the compressor adjacent to the oil, **Figure 25.62**. When the heater is external, the heating element must be in good contact with the compressor housing or it will overheat the element and not transfer heat into the compressor. The risk is that these heaters can be installed incorrectly—that is, not tight enough—unless directions are followed.

Because the crankcase heat is only needed (and desired) during the off cycle, manufacturers are likely to use relays to shut the heat off during the running cycle. (Heat added during the running cycle only reduces system efficiency.) This can also be accomplished with a set of NC contacts in the compressor contactor, contacts that are closed when the contactor is deenergized. The technician should be well aware of crankcase heat. If a compressor has been off for a long time, the housing should be warm to the touch if it has crankcase heat. If the manufacturer has installed crankcase heat, do not

(C)

start the compressor when it is cold, or damage may occur. In order to avoid carbonization of the oil from excessive heat, the wattage inputs of the crankcase heater must be limited. In very cold ambient or when exposed to cold winds, the crankcase heater may be overpowered and refrigerant migration to the compressor's crankcase may still occur.

25.49 OIL PUMPS

Smaller refrigeration compressors, typically under 3 horsepower, usually have splash-type lubrication systems without an oil pump. These compressors often have an oil scoop that flings oil throughout the compressor's crankcase causing an oil fog that lubricates the bearings, wrist pins, pistons, and rings. However, larger compressors in the refrigeration and air conditioning fields have forced oiling systems. These compressors are usually over 3 horsepower. They contain an oil pump located at the end of the compressor's crankshaft, **Figure 25.63**. The oil pump is actually keyed into the compressor's crankshaft which supplies power to turn the oil pump, **Figure 25.64**. Oil pumps can be of the gear or eccentric type. **Figure 25.65** shows a gear type oil pump. The star gear in this type of pump actually squeezes the oil to a higher pressure. The added pressure that the star gear puts into the oil can

be referred to as the net oil pressure. **Figure 25.66** shows the star gear disassembled from the oil pump and out of its seat within the oil pump.

One has to remember that the oil pump picks up the oil from the compressor's crankcase (under crankcase pressure), adds pressure to the oil, and then delivers the oil into drilled holes in the crankshaft. The oil is then delivered to the compressor's bearings and connecting rods through these drilled holes or oil galleys. The oil now drops to the crankcase to be picked up again by the oil pump. Notice that the oil was first picked up by the oil pump from the compressor's crankcase, and after lubricating essential compressor parts, ends up back in the crankcase. **Figure 25.67** shows an eccentric type oil pump which uses an eccentric type of mechanism to squeeze the oil to a smaller and smaller volume, which adds pressure to the oil. Again, this squeezing action is referred to as net oil pressure.

25.50 COMPRESSOR OIL CHECK VALVE AND PARTITION WALL

Many compressors have a partition wall which separates the crankcase from the motor barrel. On refrigerant gas-cooled compressors, the motor barrel is where the motor windings and stator reside and where oil entrained suction gasses enter the compressor's end bell through the suction service valve. Because the motor barrel has a large diameter compared to the suction line, oil-entrained suction gasses will lose velocity and slow down significantly as they enter the motor barrel. This loss of velocity will cause the oil in the suction gasses to drop out and collect at the bottom of the motor barrel. The partition wall separating the motor barrel from the compressor's crankcase has an oil check valve which will only let oil pass from the compressor's motor barrel to its crankcase, **Figure 25.68**. When the compressor is running and no system

problems exist, there is usually a 1 to 2 psi pressure drop from the motor barrel and the crankcase. This pressure difference allows the oil check valve to be open, which allows any collected oil in the bottom of the motor barrel to return to the compressor's crankcase. The returned oil can now be picked up by the oil pump and delivered throughout the compressor's moving parts to provide lubrication.

However, during start-up periods or when some system problems occur, the compressor's crankcase could experience a slightly higher pressure than the motor barrel. It is in these cases where the oil check valve will be closed thus preventing any oil return to the crankcase for use by the oil pump. An accumulation of oil will now occur in the motor barrel which will prevent the compressor's crankcase from receiving any new oil from the motor barrel. If the system problem is not cleared up or remedied soon after start-up, the oil check valve will remain closed and the crankcase will soon be starved of oil causing loss of lubrication and a tripping of the oil safety control. Some system problems that may cause this situation to happen are:

- Liquid refrigerant floodback during the on cycle from the motor barrel to the crankcase.
- Compressor start-ups with liquid refrigerant in the crankcase.
- Refrigerant migration to the crankcase from the suction line and motor barrel during the off cycle causing start-up pressurization of the crankcase. Refrigerant loves oil and will migrate to it because of the oil's lower vapor pressure.
- No automatic pumpdown system to prevent refrigerant migration.
- Compressor located outside in a cold ambient, causing refrigerant migration during the off cycle from suction line through the motor barrel to the crankcase. This causes oil foaming and crankcase pressurization at start-ups.

SUMMARY

- Four basic components of the compression cycle are the compressor, condenser, evaporator, and expansion device.
- Two other types of components that enhance the refrigeration cycle are control components and accessories.
- Two-temperature operation may utilize an evaporator pressure regulator.
- Relief valves prevent high pressures from occurring in the system.
- Electrical controls stop, start, or modulate electron flow for the control of motors and fluid flow.
- When energized, the solenoid valve, a valve with a magnetic coil, will open or close a valve to control fluid flow.
- Pressure switches stop and start system components.
- The low-pressure switch can be used for low-charge protection and as a thermostat.
- The high-pressure switch protects the system against high operating pressures. This control can be either manual or automatic reset.
- The low-ambient control (switch) maintains the correct operating head pressures on air-cooled equipment in both mild and cold weather by cycling the condenser fan.
- The oil safety switch ensures that the correct oil pressure is available 90 to 120 sec after start-up on larger compressors (normally above 3 hp).
- Defrost with internal heat can be accomplished with hot gas from the compressor.
- Defrost with external heat is normally done with electric heaters in the vicinity of the evaporator.
- Refrigeration system accessories can be service valves, filter driers, sight glasses, refrigerant distributors, heat exchangers, storage tanks, oil separators, vibration eliminators, or pressure taps.
- Crankcase heat is required for many refrigeration systems, because of refrigerant migration during downtime.
- Oil pumps are located at the end of the compressor's crankshaft and can be either gear type or eccentric type.
- Refrigerant-cooled compressors have a partition wall that separates the motor barrel from the crankcase.
- An oil check valve is located on the partition wall and will only let oil flow from the motor barrel to the crankcase.

REVIEW QUESTIONS

1. Which is not a basic component of the compression refrigeration cycle?
   A. Compressor
   B. Condenser
   C. Evaporator
   D. Suction filter
2. Describe modulating fluid flow.
3. The purpose of the crankcase pressure-regulating valve is to
   A. maintain constant pressure in the crankcase.
   B. maintain constant pressure in the evaporator.
   C. prevent a compressor from going into a vacuum.
   D. prevent a compressor overload condition.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

4. Describe the function of an electric evaporator pressure-regulating (EEPR) valve.
5. What are three main reasons why automatic pumpdown systems are used on refrigeration systems?
6. Briefly describe the function of a non-short-cycling, or "one-time," automatic pumpdown system.
7. Two types of relief valves are _____ and _____.
8. Why is low-ambient control necessary?
9. Which is not a method of low-ambient control on air-cooled equipment?
   A. Modulating TXV
   B. Fan-cycling controls
   C. Flooding a condenser
   D. Fan speed control

Describe the devices in questions 10–13.

10. Low-pressure switch
11. High-pressure switch
12. Low-ambient control (switch)
13. Oil safety switch
14. What is the function of the current sensing relay in an oil safety control scheme?
15. Why is there a time delay in an oil safety control?
16. What is off-cycle defrost?
17. Two types of off-cycle defrost are _____ and _____.
18. Two methods for accomplishing defrost on low-temperature refrigeration systems are _____ and _____.

Describe how the components in questions 19–23 enhance the refrigeration cycle.

19. Filter drier
20. Heat exchanger
21. Suction accumulator
22. Receiver
23. Pressure taps
24. Describe the function of an oil separator.
25. What will happen if the float in an oil separator collapses?
26. The function of the evaporator pressure regulator is to
    A. maintain a constant evaporator pressure.
    B. prevent a minimum pressure in the evaporator.
    C. maintain a constant evaporator temperature.
    D. prevent a maximum pressure in the evaporator.
27. What is the function of the oil return hole or orifice in a suction accumulator?
28. What is the function of the pressure equalization orifice at the outlet of an accumulator?

UNIT 26

APPLICATIONS OF REFRIGERATION SYSTEMS

OBJECTIVES

After studying this unit, you should be able to

- describe the different types of display equipment.
- discuss heat reclaim.
- describe a parallel refrigeration system.
- describe a secondary-fluid refrigeration system.
- discuss different types of carbon dioxide refrigeration systems.
- explain what is meant by preserving liquid subcooling.
- describe a pressurized liquid system.
- describe a distributed refrigeration system.
- describe package versus remote-condensing applications.
- describe mullion heat.
- describe the various defrost methods.
- discuss walk-in refrigeration applications.
- explain basic refrigerated air-dry unit operation.

SAFETYCHECKLIST

- ✔ Wear goggles and gloves when attaching or removing gauges and when using gauges to transfer refrigerant or check pressures.
- ✔ Be careful not to get your hands or clothing caught in moving parts such as pulleys, belts, or fan blades.
- ✔ Observe all electrical safety precautions. Be careful at all times and use common sense.
- ✔ Follow manufacturers' instructions when using any cleaning or other types of chemicals. Many of these chemicals are hazardous, so make sure that they are kept away from ice, drinking water, and other edible products.

26.1 APPLICATION DECISIONS

When refrigeration equipment is needed, a decision must be made as to the specific equipment to install. The factors that enter into the decision process are, first, purchase cost of the equipment, the conditions to be maintained, the operating cost of the equipment, and the long-term intent of the installation. When purchase cost alone is considered, the equipment chosen may not perform acceptably. For example, if the wrong equipment is chosen for storing meat, the humidity may be too low in the cooler and dehydration may occur—too much moisture may be taken out of the meat, causing a weight loss. This weight loss is actually part of the condensate that goes down the drain during defrost.

This unit provides information regarding some of the different options to consider when equipment is purchased or installed. The service technician should know these options in order to help make service decisions.

26.2 REACH-IN REFRIGERATION

Retail stores use reach-in refrigeration units for merchandising their products. Customers can go from one section of the store to another and choose items to purchase. These reach-in display cases are available in high-, medium-, and low-temperature ranges. Each has open-display and closed-display cases from which to choose. The open and closed styles may be of the chest type, upright type with display shelves, or upright type with doors. The boxes can be placed end-to-end for a continuous display. Thus, the frozen food is kept together and fresh foods (medium-temperature applications) are grouped, **Figure 26.1(A)**, **Figure 26.1(B)**, and **Figure 26.1(C)**.

Figure 26.1 (A) Display cases are used to safely store food displayed for sale. Some display cases are open to allow the customer to reach in without opening a door; some have doors. Closed cases are the most energy efficient.

(C)

All of these combinations of reach-in displays add to the customer's convenience and enhance the sales appeal of the products. The two broad categories of open and closed displays are purely for merchandising the product. A closed case is more efficient than an open case, but the open case is more appealing to the customer because the food is more visible and easier to reach. Open-display cases can maintain temperature conditions because the refrigerated air is heavy and settles to the bottom. Even upright display cases can store low-temperature products. This is accomplished by designing and maintaining air patterns to keep the refrigerated air from leaving the case, **Figure 26.2**. When reach-in refrigerated cases are used as storage, such as in restaurants, they do not display products, although they have the same components, and doors are used to keep the room air out. Restaurant

Figure 26.2 Open display cases maintain even, low-temperature refrigeration because cold air can be controlled. It falls naturally. Air patterns are formed to create air curtains for shelves that are up high. These air curtains must not be disturbed by the air-conditioning system's air discharge. All open cases have explicit directions as to how to load them, with load lines conspicuously marked.

equipment is usually located in a hot, humid kitchen, whereas supermarket equipment is located in a temperature- and humidity-controlled atmosphere.

26.3 SELF-CONTAINED REACH-IN FIXTURES

Reach-in refrigeration fixtures can be either self-contained, with the condensing unit built inside the box, or they may have a remote condensing unit. Deciding which type of fixture is best to purchase depends on several factors.

Self-contained equipment rejects heat at the case. The compressor and condenser are located at the fixture, and the condenser rejects its heat back into the store, **Figure 26.3**. This is good in winter; in summer it is desirable in warmer climates to reject the heat to the outside. Self-contained equipment can also be moved around to new locations without much difficulty. It normally plugs into either a 120-V or 230-V electrical outlet. Only the outlet may have to be moved. **Figure 26.4** shows examples of wiring diagrams for medium- and low-temperature fixtures. When service problems arise, only one fixture is affected, and the food can be moved to another cooler. However, self-contained equipment is located in the conditioned space, and the condenser is subject to any airborne particles in that space. Keeping several condensers clean at a large installation may be

Figure 26.3 This self-contained refrigerated box has its condensing unit built in. Refrigeration tubing does not have to be run. This box rejects the heat it absorbs back into the store. It is moveable because it needs only an electrical outlet and, sometimes, a drain, depending on the box.

Courtesy Hill Refrigeration

difficult. In a restaurant kitchen, for example, large amounts of grease will deposit on the condenser fins and coil, which will then collect dust. The combination of grease and dust is not easy to clean in the kitchen area without contaminating other areas. The versatility of self-contained equipment is good for a kitchen, but remote condensing units may be easier to maintain. The warm condensers are also a natural place for pests to locate.

All refrigeration equipment must have some means for disposing of the condensate that is gathered on the evaporator. The condensate must be either piped to a drain or evaporated. Self-contained equipment can use the heat that the compressor gives off to evaporate the condensate, provided the condensate can be drained to the area of the condenser. This also helps to desuperheat the hot gas leaving the compressor, which will lower discharge line temperatures. To do

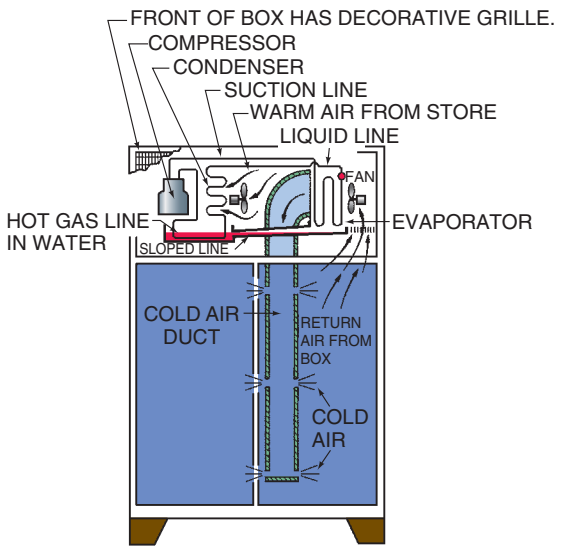
this, the condenser must be lower than the evaporator. This is not easy to arrange when the condenser is on top of the unit, **Figure 26.5**.

Figure 26.5 The evaporator can be high enough on a self-contained cooler so that the condensate will drain into a pan and be evaporated by heat from the hot gas line. No drain is needed in this application.



26.4 INDIVIDUAL CONDENSING UNITS

When individual condensing units are used and trouble is encountered with the compressor, or when a refrigerant leak occurs, only one system is affected. The condensing unit can be located outside, with proper weather protection, or in a common equipment room, where all equipment can be observed at a glance for routine service. The air in the room can be controlled with dampers for proper head pressure control. The equipment room can be arranged so that it recirculates store air in the winter and reuses the heat that it took out of the store through the refrigeration system. This saves buying heat from a local utility.

26.5 SINGLE-COMPRESSOR APPLICATIONS AND MULTIPLE EVAPORATORS

Using one compressor for several fixtures has its advantages:

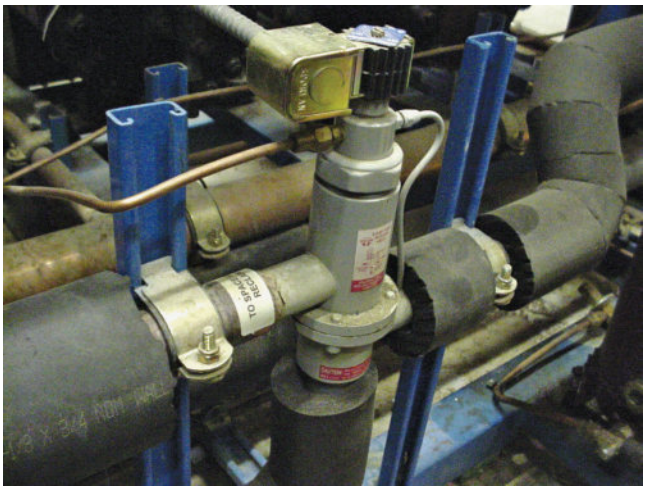
1. The compressor motors are more efficient because they are larger.
2. More heat from the equipment can be captured for use in heating the space or for hot water, because larger compressors give off more heat.

The three-way heat reclaim valves in most heat reclaim systems are activated by a solenoid operated by a pilot, **Figure 26.6**. Pilot operation means that the valve uses the refrigeration system's pressures to move a sliding mechanism when the solenoid is energized. Because the heat reclaim valve experiences very hot compressor discharge gases, it must be mounted properly and securely to counteract any expansion and contraction forces from heating and cooling effects, **Figure 26.7**. Its operation is simple. The first stage of a two-stage thermostat in the store calls for heat. *The three-way heat reclaim valve is energized and enables hot gas from the discharge header to flow to an auxiliary condenser or heat reclaim coil located in the store's ductwork,* **Figure 26.8**. If this reclaimed heat is not enough to satisfy the first call for heat, the second stage of the thermostat will call. This will initiate the primary heating equipment, which could be a fossil-fuel furnace, a heat pump, or electric heat. The heat reclaim coil, cooling coil, air filters, and primary heating source are located in the ductwork, usually in series with one another, **Figure 26.9**. Heat reclaim coils can be used in parallel or in series with the normal condensers.

Figure 26.6 This three-way heat reclaim valve is pilot operated and solenoid activated.

Courtesy Sporlan Division, Parker Hannifin Corporation

Figure 26.7 A heat reclaim valve shown mounted securely to handle any expansion and contraction forces.



Source: Meijer Corporation. Photo by John Tomczyk

Figure 26.10 shows a heat reclaim system both in parallel and in series. In a parallel heat reclaim system, the heat reclaim condenser must be sized to handle 100% of the refrigeration system's rejected heat when in the heat reclaim mode. The normal condenser is inactive during the heat reclaim mode and will not hold any refrigerant. It is pumped out through a normally closed solenoid valve that is energized during the heat reclaim mode. The refrigerant that is pumped out of the normal or inactive condenser also passes through a restrictor before entering the suction line. This restrictor vaporizes any liquid refrigerant coming out of the inactive condenser before it enters the suction line and also controls the pumpout rate of the inactive condenser. By pumping out the inactive condenser in the heat reclaim mode, a proper system refrigerant charge is maintained and refrigerant is also prevented from sitting idle and condensing in the inactive condenser. If the liquid were left in the inactive coil to condense, once the system switched out of the heat reclaim mode the mixing of hot gas with subcooled or saturated liquid could cause **liquid hammer**, which can create tremendous forces, causing refrigerant lines and valves to rupture. Refrigerant must also be pumped out of the heat reclaim coil when the system is not calling for heat reclaim. Some heat reclaim valves have bleed ports built into the valve for the sole purpose of removing refrigerant from the heat reclaim coil when it is not being used, **Figure 26.11**. A check valve is usually installed in the heat reclaim pumpout or bleed line to prevent migration of refrigerant to the coldest location when the heat reclaim coil is exposed to temperatures that are lower than the saturated suction temperatures of the refrigeration system itself, **Figure 26.10**.

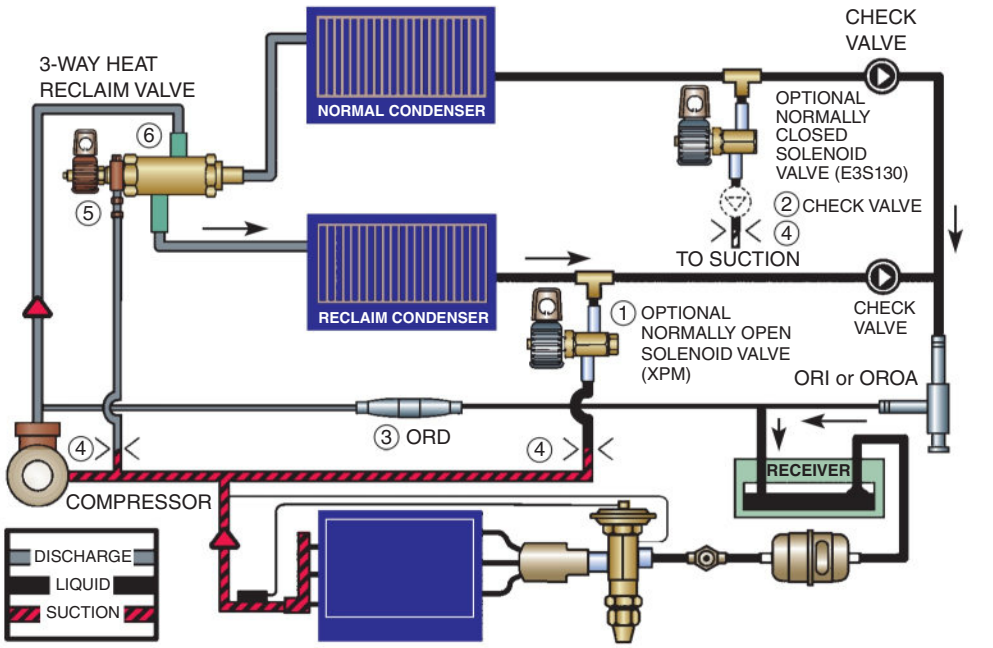
(A)



1. Use optional solenoid valve and piping if pump-out is required and "C" model Heat Reclaim Valve is used; see Note 4. It is optional to omit this solenoid valve and piping on systems using "B" model Heat Reclaim Valve.
2. This check valve is required if lowest operating ambient temperature is lower than evaporator temperature.
3. Not used with OROA (B, C, or D).
4. Restrictor, Part #2449-004, may be required to control pump-out rate on inactive condenser.
5. Pilot suction line must be open to common suction whether or not Heat Reclaim Coil is installed at time of installation and regardless of Heat Reclaim Valve model/type.
6. Proper support of heat reclaim valve is essential. Concentrated stresses resulting from thermal expansion or compressor vibrations can cause fatigue failure of tubing, elbows, and valve fittings. Fatigue failures can also result from vapor-propelled liquid slugging and condensation-induced shock. The use of piping brackets close to each of the 3-way valve fittings is recommended.

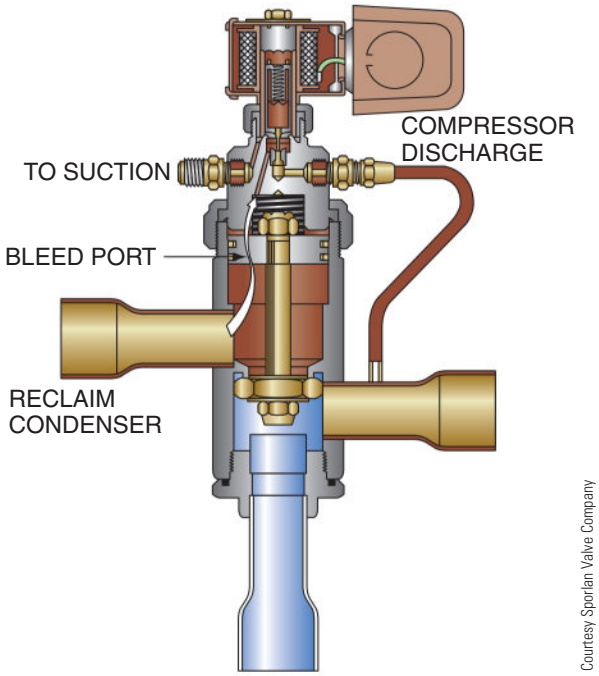
Figure 26.11 A three-way heat reclaim valve showing the bleed port for pumping down the heat reclaim coil when it is not in use.



In a series heat reclaim system, the normal condenser and the heat reclaim condenser are used simultaneously when in the heat reclaim mode. The hot, superheated gas from the compressors enters the heat reclaim condenser first. However, in series with the heat reclaim condenser is the normal condenser, and it also may receive some hot gas. Most of the condensing of the liquid takes place in the normal condenser downstream from the heat reclaim coil. Because of this series arrangement, the heat reclaim coil may not be sized to handle 100% of the heat rejected from the refrigeration system.

In any heat reclaim system, the selection of a parallel or series system and the design of the piping arrangement will depend on the control scheme and the size of the heat reclaim coil being used for the particular application. These installations are designed in two basic ways. One way is to use one compressor for several refrigeration cases. A 30-ton compressor may serve 10 or more cases. This particular application may have cycling problems at times when the load varies unless the compressor has a cylinder unloading design, a method to vary the capacity of a multicylinder compressor by stopping various cylinders from pumping at predetermined pressures. The following are some disadvantages of using one compressor for several cases:

1. The refrigeration load cannot be closely matched even when compressor cylinder unloaders are used.
2. Starting and stopping larger compressors will draw a larger locked-rotor amperage (LRA) and is hard on starting components and compressor windings.
3. Short cycling larger compressors may increase both electrical demand and consumption charges.
4. Even the slightest increase in refrigeration load may call upon a large compressor to cycle on where a smaller compressor would suffice.
5. If the compressor malfunctions, many boxes will be inoperable, as opposed to only one box not working if its individual compressor malfunctions.

Because of the disadvantages of single-compressor systems, parallel compressor systems have become popular.

26.6 PARALLEL COMPRESSOR SYSTEMS

Parallel compressor systems apply two or more compressors to a common suction header, a common discharge header, and a common receiver, **Figures 26.12(A)–(C)**. These systems are often referred to as **rack systems** because they are mounted on a steel rack, **Figure 26.13**. The compressors can be of the reciprocating, scroll, screw, or rotary type.

Advantages of parallel compressor systems are

- load matching,
- diversification,
- flexibility,
- higher efficiencies,
- lower operating costs, and
- less compressor cycling.

Some disadvantages of parallel compressor systems are

- leaks that affect the entire compressor rack,
- compressor burnouts that contaminate compressor oil and will affect the entire compressor rack oiling system.

The primary advantage of parallel compressor systems is their ability to match the refrigeration load nearly exactly, often referred to as **load matching**. As the refrigeration load varies, compressors of varied capacities are turned on or off in response to the ever-changing load. The refrigeration load is sensed by a pressure transducer mounted on the common suction line or manifold, **Figure 26.14(A)**. The pressure transducer is wired to a microprocessor and an input/output control board on the compressor rack. The common suction pressure on the parallel system varies as case thermostats in the store call for cooling or as *evaporator pressure-regulating (EPR)* valves on the individual suction lines, which come into the parallel rack, throttle open and closed, according to the load of each individual line of refrigerated cases, **Figure 26.14(B)**. The pressure transducer senses this pressure increase or decrease and sends a voltage message to a computer or microprocessor-based control board located on the parallel compressor rack, **Figures 26.15(A)** and **(B)**. The pressure transducer changes the pressure signal to a voltage signal so that the microprocessor can process it. The pressure transducer receives its power from the same input/output board that powers the microprocessor, **Figure 26.15(B)**.

Refer to Section 14.7 "Pressure Transducers" in Unit 14, "Automatic Control Components and Applications," for more detailed information on pressure transducers.

As the refrigeration load changes, so does the common suction pressure in the suction manifold, and, thus, the voltage coming from the pressure transducer to the microprocessor. Capacity steps that have been programmed into the microprocessor now control the cycling of the parallel compressor rack. Capacity steps can be changed with programming plugs or computer software and can be monitored on-site or remotely by a personal computer. For example, if the parallel compressor rack had four compressors of unequal sizes, increasing from compressor #1 through compressor #4, 10 capacity steps would be programmed into the microprocessor, **Figure 26.16**. As the pressure transducer on the common suction line sensed the common suction pressure increasing from the increased refrigeration loads, it would send a higher voltage signal to the microprocessor. This would trigger the capacity steps to progress from step 1. Soon the capacity of the compressor rack would

Figure 26.14 (A) A pressure transducer mounted on a common suction header. This transducer transforms a pressure signal to an electrical signal for the controller to process. This cycles the compressors to their next capacity step. (B) Evaporator pressure-regulating (EPR) valves on suction lines of a parallel compressor rack. As the EPR valves open and close according to the load on the cases, the pressure transducer on the common suction line will sense the change in pressure. (C) Modern step-motor-type, electronic evaporator pressure-regulator (EEPR) valves on the common suction line of a parallel compressor system. They react to a thermistor in the refrigerated case's evaporator discharge air.

(C)

match the refrigeration load. This could happen at capacity step 6, where only compressors #2 and #4 were operating. At this time, the common suction pressure would stop rising and the parallel compressor rack would not increase or decrease in capacity steps. The same thing would happen if the load decreased, but the pressure transducer would sense a decrease in pressure. It would now relay a decreased voltage to the microprocessor. This would cause the parallel rack's capacity steps to decrease until the load was matched with the right compressor capacity. This could happen at capacity step 3 with just compressor #3 running. **Figure 26.17** shows line-voltage hardware, which includes circuit breakers and motor starters with current-type relays, used in cycling the parallel compressors.

Parallel compressor racks usually come with compressors of unequal size and are referred to as **uneven parallel systems**. They are used for widely varying loads. Compressors of equal size, referred to as **even parallel systems**, are for refrigeration loads that are relatively constant or have known increases or decreases in capacity, as in an industrial process. Compressor cycling logic for these systems may provide for even run time among all compressors, resulting in even wear on all compressors through the system's life. The parallel compressor system may have a **split suction** line. This enables the same parallel compressor rack to handle two different suction pressures by using two different pressure transducers. A check valve will separate the two suction lines having different saturated suction temperatures. The split suction option enables one parallel compressor rack to handle both low- and medium-temperature applications, thus making it a more diverse refrigeration system.

OIL DISTRIBUTION SYSTEM

A sophisticated oil system was designed to maintain the correct amount of oil in each compressor of the parallel system. This oil system usually consists of four major components:

- Oil separator
- Oil reservoir

- Pressure differential valve
- Oil level regulators

A large oil separator is located in the common discharge line to trap the pumped oil, **Figure 26.12.** Oil is not returned directly from the oil separator to the compressors, as in conventional systems, but is pumped by differential pressure to an oil reservoir. Often, the oil separator and the oil reservoir are combined into one vessel, **Figure 26.18**. From the reservoir, the oil passes to an oil-level regulator float valve, which is mounted on each compressor at its sight glass location, **Figure 26.19**. The oil-level regulator float valve senses crankcase oil levels and opens and closes as necessary to ensure an adequate oil level in each compressor crankcase. A pressure differential valve located on the oil reservoir usually maintains a 5- to 20-psi pressure differential between reservoir pressure and common suction pressure, depending on what pressure differential valve is used, and is vented to the suction line, **Figure 26.12**. This valve ensures that the oil reservoir is pressurized each time an oil regulator opens. The factory pressure setting is system-dependent, which allows the oil-level regulator orifice to be calibrated to a certain pressure difference over suction pressure. This prevents excessive inlet pressures at the oil-level regulator, which may overfill the compressor crankcase with oil before the mechanical float valves can react. The pressure differential valve is shown in **Figure 26.20(B)**, and an oil reservoir is shown in **Figure 26.20(C)**.

Oil-level-regulating float valves can be fixed or adjustable and can be purely mechanical, **Figure 26.20(A)**, or electromechanical. Electromechanical valves can use a liquid-level

Figure 26.18 A combination oil separator and oil reservoir.

Photo by John Tomczyk

switch, a solenoid valve, and a magnetic reed float switch to detect oil levels, **Figure 26.21(A)**. These systems also offer alarm and system shutdown control if oil levels get dangerously high or low. Some electromechanical liquid-level switches detect oil level by sensing light refracting through a glass prism, **Figure 26.21(B)**. Their advantage is that they can be mounted on a system without disturbing the system internally.

SATELLITE OR BOOSTER COMPRESSORS

Often, parallel compressor systems employ a **satellite** *or* **booster compressor**, **Figure 26.12**. *Satellite compressors can be large or small and are often dedicated to the coldest evaporators. This prevents the entire parallel rack from operating at the lower suction pressures inherent to lower-temperature evaporators. This improves the efficiency of the entire parallel compressor rack by letting it run at a lower compression ratio, resulting in higher efficiency.* Satellite compressors can be valved into the parallel rack. This enables the rack of compressors to assist

(B)

the satellite compressor in pulling down. A check valve will then separate the parallel rack from the satellite compressor, allowing the satellite compressor to pull down further.

Satellite compressors often have variable-speed drives called inverters controlling their motor speeds, thus compressor capacity, to save energy, **Figure 26.22**. *The refrigeration load can thus be matched even more closely by varying the frequency of an electronically altered sine wave, which affects the speed of alternating current motors.* As the load decreases, the motor slows down, giving the compressor less capacity. As the load increases, the motor increases in speed, giving the compressor more capacity. Refer to Unit 17, "Types of Electric Motors," for more specific information on inverters. Cylinder unloading is another method of controlling the capacity of satellite compressors and the parallel compressors on the rack.

PRESERVING LIQUID SUBCOOLING

Subcooling can be accomplished in a variety of ways in commercial parallel refrigeration systems. Listed here are the three main methods:

Figure 26.22 Inverters or variable-speed drives that change the alternating current's frequency, thus changing the satellite compressor's speed and capacity for better load matching.

- Liquid/suction-line heat exchangers
- Auxiliary refrigeration systems
- Natural condenser subcooling

Liquid/suction-line heat exchangers bond the liquid line to the suction line. This allows for the transfer of heat from the higher-temperature liquid line to the suction line. Many different types and arrays of commercial liquid/suction heat exchangers can be purchased to fit system needs. The heat exchangers provide for more subcooled liquid, which will increase the net refrigeration effect (NRE) in the evaporator by decreasing the amount of flash gas at the evaporator's entrance. However, the heat exchange between the liquid line and the suction line is not without cost to system capacity. As the suction line experiences more heat from the liquid line, the refrigerant vapors within the suction line will expand and become less dense. This will decrease the mass flow rate of refrigerant through the compressor and have some negative effects on system capacity. The type of subcooling has to be designed and managed carefully for the system to have a net gain in capacity. For more detailed information on liquid/suction heat exchangers, refer to Section 25.37 "Heat Exchangers," in Unit 25, "Special Refrigeration System Components."

Auxiliary refrigeration systems use some of the liquid from the liquid-line header to feed an auxiliary expansion valve and evaporator. This auxiliary expansion valve and evaporator's heat load is the remaining liquid flowing to the liquid header. Often, but not always, this mechanical subcooler is a plate-and-frame or shell-and-tube heat exchanger, and the liquid feeding the expansion valve comes from a different-temperature application parallel refrigeration system in the same equipment room. The suction line coming off the heat exchanger cooling the liquid refrigerant often returns to a different-temperature application parallel refrigeration

system's suction header, **Figure 26.12(B)**. In **Figure 26.12(C)**, the liquid feeding the expansion valve for the mechanical subcooler branches off the same refrigeration system's liquid line. Also, the suction line coming off the shell-and-tube subcooler's heat exchanger returns to an independent compressor's suction line. This type of subcooling is actually using some of its own, or another refrigeration system's capacity and is dedicated to subcool liquid for use in a liquid header feeding multiple expansion devices and evaporators. It does not, however, come completely free and without additional system expenses and costs.

Natural condenser subcooling is free subcooling when the condenser is intentionally designed with extra volume for a liquid subcooling loop at its bottom. The added subcooling loop does not back up liquid in the normal condenser and increase head pressure. The reason is that the additional volume for this extra liquid is intentionally designed into the condenser. Significant increases in system capacity can be realized with this free liquid subcooling in the cooler ambient temperatures, especially when used in conjunction with high-side head pressure controls. However, this free liquid subcooling is only available when the outdoor ambient conditions are cool enough. In summer operations, very little subcooling is possible because of the warmer air flowing across the condenser.

One way to preserve liquid subcooling coming from a condenser and keep it cool before it reaches the liquid header is to avoid allowing the liquid to enter and flow through a conventional **flow-through receiver**. Flow-through receivers can store the cool, subcooled liquid refrigerant for some time before releasing it to the liquid line and liquid header. This can cause a gain in temperature within the liquid and subcooling can be lost. Also, when high-side head pressure controls are used in low-ambient conditions, hot gas bypassed from the compressor's discharge line to the receiver actually helps warm the subcooled liquid coming from the condenser to a higher saturated condition. This allows the receiver to have a higher pressure when feeding metering devices and evaporators. At the same time, the condenser's outlet is being restricted by a head pressure control valve, causing flooding of the condenser. The action of the head pressure control valve will maintain a decent head pressure in low-ambient conditions, while keeping receiver pressure high enough to satisfactorily feed metering devices, **Figure 26.12(C)**. Refer to the section "Head Pressure Controls" in Unit 22, "Condensers," for more detailed information on head pressure control devices.

Figure 26.12(C) shows a piping diagram for a parallel refrigeration system that allows the receiver to be converted from a "flow-through receiver" to a "**surge-type receiver**." This type of arrangement preserves the liquid subcooling formed in the condenser during the cooler ambient months when free subcooling is available. A solenoid-operated diverting valve is opened and the subcooled liquid coming from the condenser's bottom is closed off to the receiver. However, it is allowed to bypass the receiver and flow directly to a mechanical subcooler and then to the liquid header to feed expansion valves and evaporators. This method prevents subcooled refrigerant in the receiver from being warmed and returning to a saturated condition. A thermostat on the drop leg of the outdoor condenser is what controls the receiver-diverting valve in low-ambient conditions. All liquid lines must be insulated to prevent any unnecessary loss of liquid subcooling, especially when the lines pass through a conditioned space.

Another refrigeration system scheme that uses parallel compressors for capacity control and load matching also uses a **system pressure-regulating (SPR) valve** *located between the condenser and the receiver,* **Figure 26.23**. This system has a receiver that is in parallel with the active refrigeration system, instead of a series receiver as in a conventional refrigeration system. The SPR valve has a remote, liquid-filled bulb located in the condenser's inlet air, sensing outdoor ambient temperatures. The sensor is connected to the SPR valve by a small copper tube. A more recent design uses sensors for determining outdoor ambient temperatures, liquid-line temperatures, and other temperatures strategic to the operation of the system. Inputs to an electronic controller operate condenser fans, a vapor relief valve out of the receiver, a liquid bleed line to the receiver, and liquid pressure to the evaporator, **Figure 26.24**. A complex computer program in the electronic controller keeps the system operating at peak performance.

The SPR valve controls the amount of liquid refrigerant used in the active refrigeration system. The active system's refrigerant charge is reduced by taking the receiver out of the active refrigeration circuit and allowing liquid to return directly to the liquid manifold, which feeds the branch refrigeration circuits. With the receiver out of the active refrigeration system, a minimum receiver charge is no longer required as with a conventional system.

The receiver is now simply used as a storage vessel to hold the condenser charge between summer and winter operations. On hot days, the SPR valve will bypass refrigerant to the receiver. This lowers the liquid levels in the condenser and

gives it more internal volume for the hotter weather conditions. On colder days, the SPR valve throttles down, which bypasses less refrigerant to the receiver and keeps more in the condenser. This partially floods the condenser and keeps condensing pressures from dropping too low. The receiver has a bleed circuit that is opened to the suction manifold. This circuit bleeds refrigerant from the receiver back to the system for use, which enables the refrigerant working charge in the system to seek a level of equilibrium relative to the ambient temperature. This means that in some conditions, the receiver is void of refrigerant and at suction pressure.

If the condenser should become damaged, fouled internally or externally, or lose a fan motor, an elevated condensing pressure will occur. This elevated pressure will cause the SPR valve to bypass refrigerant into the receiver because a design temperature difference between the ambient and the condensing temperature has been exceeded. *This will prevent high compression ratios and high discharge temperatures with lower volumetric efficiencies. These occurrences often go unnoticed for long periods of time and stress compressor systems.* Eventually, branch circuit evaporator temperatures will rise, because refrigerant is being bypassed out of the working system. The results will be a starved refrigeration system. Rising evaporator and product temperatures are noticed sooner, and the problem can be remedied immediately. *Refrigerant leaks will also be noticed sooner, which means less refrigerant is lost to the atmosphere.*

26.7 SECONDARY-FLUID REFRIGERATION SYSTEMS

With ozone depletion and global warming legislation raising the cost of refrigerants, some manufacturers are researching, and some are using, a primary (HFC or HCFC) refrigerant to cool a **secondary fluid**. The secondary fluid in this case is also considered a refrigerant. The secondary fluid or refrigerant is usually a low-temperature antifreeze solution, which stays in the liquid state and does not vaporize when it is circulated through the system by centrifugal pumps.

Secondary fluids include **propylene glycol** and **hydrofluoroethers (HFEs)**. Propylene glycol is the most popular secondary fluid used today, but among the newest secondary fluids are HFEs. *They have zero ozone-depletion potential and small global-warming potential, and they are nontoxic.* HFEs are, however, one of the most expensive secondary fluids. Along with other popular secondary fluids, HFEs can be used for all temperature ranges found in supermarket refrigeration, from dairy to frozen-food cases. This secondary fluid, which is the more abundant compound, is circulated instead of the primary (HCFC or HFC) refrigerant by centrifugal pumps to the display cases in supermarkets. A heat exchange then occurs between the primary and secondary fluids.

Figure 26.25(A) illustrates the difference between a secondary-fluid refrigeration system and a direct-expansion refrigeration system. **Figure 26.25(B)** is a photo of chillers and circulating pumps for a secondary-fluid refrigeration system. **Figure 26.25(C)** shows evaporator coils piped for chilled glycol as a secondary fluid. **Figure 26.25(D)** is a photo of a deli case with chilled glycol pans. This system operates in much the same way as a direct-expansion chiller but uses much less HCFC or HFC to accomplish the same task. These systems eliminate the long liquid and suction lines that are usually installed throughout the store, which reduces the overall system refrigerant charge and thousands of joints, which are potential leak points.

Defrost is accomplished by heating the same HFE fluid used in the secondary loop by a controlled process. It is done through a third piping loop with solenoid-controlled valving. The heat for defrost comes from the heat of compression in the discharge gases from the compressor. This heat then is transferred to the same secondary fluid in a third piping loop used for defrost purposes at the case coils.

The advantages of chilled secondary-fluid systems are:

- *large refrigerant reductions,*
- *greatly reduced leak potential,*
- *simpler installations,*
- *less critical piping,*
- *reduced welding and nitrogen use,*
- *minimized vacuum requirements to the equipment room,*
- *few or no oil return concerns,*
- *fewer expansion valve superheat adjustments,*
- *less compressor (total) superheat in the primary refrigerant loop because of shorter suction lines, which adds to the thermodynamic efficiency of the system,*
- *simpler and shorter defrosts,*
- *no requirement for defrost limit thermostats,*
- *faster defrost periods and quicker case pulldown times after defrost, which result in lower energy requirements and improved product temperatures,*
- *better and more stable product temperatures from higher mass flow rates in the secondary fluid,*

(C)

- *more efficient coil surface use, resulting in better and more stable product temperatures,*
- *simpler control strategies,*
- *higher refrigerant coil operating temperatures in secondary loop,*
- *lower maintenance,*
- *lower total equivalent warming impact (TEWI) than conventional refrigeration systems,*
- *the use of PVC piping or K-type copper tubing in the secondary loop for long line runs instead of ACR-type copper tubing used with direct-expansion refrigerants,*
- *need to locate only the low-pressure secondary loop in the store.*

A few system-dependent disadvantages are:

- *higher cost of original equipment,*
- *requiring the use of industrial-grade solenoid valves for case control in the secondary loop,*
- *higher electrical consumption from the extra heat exchange energy penalty—and the added cost of secondary-fluid pumping, which, however, is often offset by the higher refrigerant coil operating temperatures,*

(D)

- *thicker and completely sealed pipe insulation needed in the secondary loop to prevent temperature and system loss, and*
- *higher cost of using the low-viscosity secondary fluid that is required for low-temperature applications.*

26.8 CARBON DIOXIDE (R-744) REFRIGERATION SYSTEMS

Carbon dioxide (CO_2) is not a new refrigerant. Carbon dioxide (R-744) was used in the early days of the refrigeration industry. It was gradually phased out when chlorofluorocarbons (CFCs), often referred to as "synthetic refrigerants," came into existence in the 1920s. Synthetic refrigerants are man-made. Another reason for the gradual phaseout of CO_2 was its very high operating pressures. Finding refrigeration system components that could handle these higher system operating pressures was very difficult back then. However, modern technology has developed refrigeration components that can handle the very high operating pressures of CO_2 in certain applications when required.

Since the 1920s and 1930s, synthetic refrigerants like CFCs and HCFCs have dominated the refrigeration and air-conditioning industry. Synthetic HFC refrigerants were introduced later on. At the time of this writing, the HVAC/R industry still uses HFC refrigerants widely. However, with the ever-growing environmental concerns about ozone depletion and global warming, **natural refrigerants** like CO_2 (R-744), ammonia (R-717), propane (HC-290), butane (HC-600), and isobutane (HC-600a), to name a few, are becoming more popular as refrigerants. These refrigerants occur in nature and can be used effectively as refrigerants. Driven by economics and regulations, some hydrocarbon (HC) refrigerants like propane and butane have become very popular in domestic applications like refrigerators and freezers and some smaller commercial applications in Europe, China, Japan, and India. The Unites States is following close behind in these technologies. The natural refrigerants have a zero ozone depletion potential (ODP), with a very small global warming potential (GWP), if any. The following chart compares the GWPs of two natural refrigerants with those of two synthetic HFC refrigerants.

Global Warming and Ozone Depletion Potentials

Refrigerant	GWP	ODP
(R-744) Carbon Dioxide (CO_2)	1	0
(R-717) Ammonia	0	0
HFC-134a	1300	0
HFC-404A	3260	0

CO_2 occurs naturally in the atmosphere at around 350 ppm and its long-term influence on the environment has been well researched. It is not self-identifying because it does not have a distinctive odor and color. Facilities using CO_2 must be equipped with sensors that trigger when concentrations exceed 5000 ppm. CO_2 is heavier than air so the detecting sensors and ventilators must be located in low areas. CO_2 is a by-product of combustion. Since there are many power plants in the United States, Europe, and throughout the world, it makes sense to capture it from the power industry's combustion processes and use it for refrigeration. CO_2 is very readily available, if not in surplus in the atmosphere, and is also very inexpensive.

Other than its high operating pressures, however, another disadvantage to using CO_2 as a refrigerant is its low **critical point** of 88°F/1067 psia. The critical temperature of a gas is the highest temperature the gas can have and still be condensable by the application of pressure. Above the critical temperature, a gas cannot be saturated regardless of the amount of pressure applied. **Figure 26.26(A)** shows the location of the critical point on the pressure/enthalpy diagram. For CO_2, no liquid refrigerant can be produced above its critical temperature of 88°F. At the critical temperature, the density of the liquid and the vapor states is equal, the distinction between the two phases disappears, and a new phase exists, called the supercritical phase. The supercritical phase exists in the region above the critical point. In this region, the pressure of CO_2 is not solely dependent on its temperature. So, on the condenser side, CO_2 used in refrigeration should be kept well below the critical point (10–20 degrees below) so that condensation of the refrigerant can take place.

CO_2 can exist as all three phases (vapor, liquid, and solid) simultaneously in equilibrium at its **triple point**, −69.9°F/75 psia. So, on the evaporator side, refrigeration applications must be kept well above the triple point to avoid plugging the refrigeration lines with solid CO_2 (dry ice).

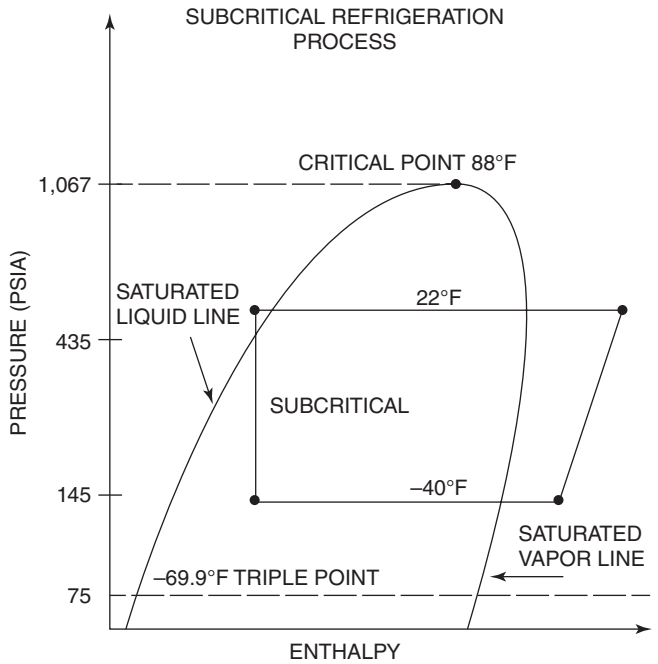
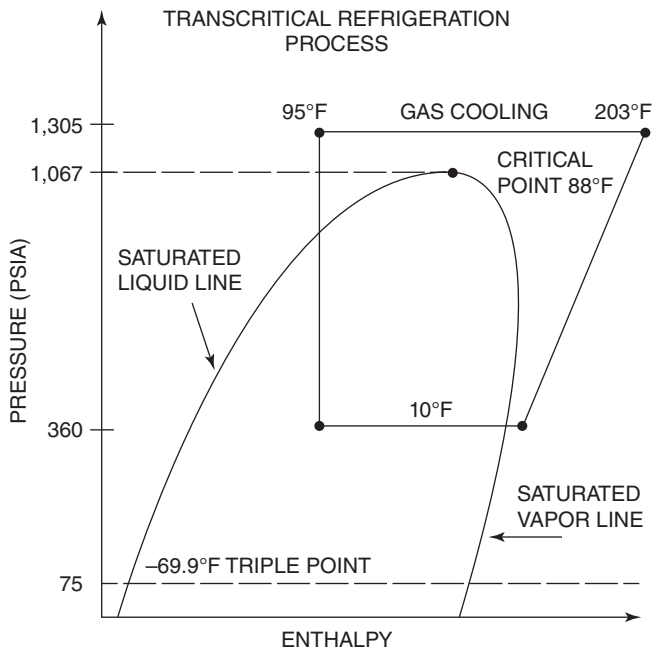
Figure 26.26 (A) Illustration of a subcritical CO_2 refrigeration application in a pressure/enthalpy diagram. This diagram shows the locations of the critical point and triple point. Notice that the cycle takes place below the critical point and above the triple point for CO_2. (B) Illustration of a transcritical CO_2 refrigeration application on a pressure/enthalpy diagram. Notice that evaporation takes place below the critical point and above the triple point for CO_2. However, condensation will not take place because the CO_2 gas has been compressed into the supercritical region. Both its temperature and pressure have been elevated above the critical point.



(A)



(B)

The refrigeration cycles that we are all familiar with so far in this book all take place above the triple point and below the critical point of the refrigerants used.

Refrigeration systems using CO_2 as a refrigerant can be divided into two main processes or cycles. These two processes or cycles are

1. the subcritical cycle and
2. the transcritical (supercritical) cycle.

SUBCRITICAL CO_2 CYCLE

As mentioned, the **subcritical cycle** refers to CO_2 refrigeration cycles that take place above the refrigerant's triple point and below the refrigerant's critical point. **Figure 26.26(A)** illustrates a subcritical CO_2 refrigeration application on a pressure/enthalpy diagram. The subcritical refrigeration cycle for CO_2 is the same as that for any subcritical refrigeration cycle. There are four processes, including

1. compression,
2. condensation with subcooling,
3. expansion, and
4. evaporation with superheat.

Notice in **Figure 26.26(A)** that the critical point is located at the dome of the pressure/enthalpy diagram. Also notice that both the latent heat of condensation and the latent heat of vaporization occur below the critical point and above the triple point for CO_2.

TRANSCRITICAL CO_2 CYCLE

On the other hand, **Figure 26.26(B)** illustrates a transcritical CO_2 refrigeration application on a pressure/enthalpy diagram. ***Transcritical*** simply means that the thermodynamic refrigeration processes span above the subcritical region and into the supercritical region of the pressure/enthalpy diagram. The four processes of the transcritical refrigeration cycle include

1. compression,
2. gas cooling,
3. expansion, and
4. evaporation.

Notice in **Figure 26.26(B)** that evaporation takes place below the critical point and above the triple point for CO_2. However, condensation will not take place because the CO_2 gas has been compressed into the supercritical region. Its temperature and pressure have been elevated above its critical point. **Figure 26.26(B)** shows that superheated CO_2 gas above 88°F cannot be condensed, so it is cooled from 203°F to 95°F in a gas cooler and remains in the supercritical region. This heat of rejection takes place in the supercritical region above the critical point for CO_2 of 88°F/1067 psia. For the

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

transcritical cycle, the heat of rejection is therefore called gas cooling, and the heat exchanger used is referred to as a gas cooler, not a condenser.

Very high pressures can be generated in this region. High-side pressures of 1500 psi can be encountered, with pressures as high as 4000 psi in certain instances. Because of these extremely high pressures, system components have to be designed to handle them. Compressor shells, heat exchangers, pressure relief valves, rings, valves, and microchannel heat exchangers will all be exposed to these higher system pressures. It is because of these extremely high system pressures that designers have favored systems in the subcritical regions. For a review of the applications of pressure/enthalpy diagrams, please refer to Section 3.20, "Plotting the Refrigerant Cycle," in Unit 3, "Refrigeration and Refrigerants."

Following is a comparison of system saturation pressures, when they can be reached, for low- and medium-temperature refrigeration systems employing CO_2, HFC-404A, and HFC-134a.

Saturated Temperatures/Pressures for Low-Temperature Refrigeration

Refrigerant	Saturated Suction Temperature (SST)	Saturated Condensing Temperature (SCT)	Corresponding Saturated Pressures (psig)
CO_2	−25°F	85°F	181/1017
HFC-404A	−25°F	85°F	13/187

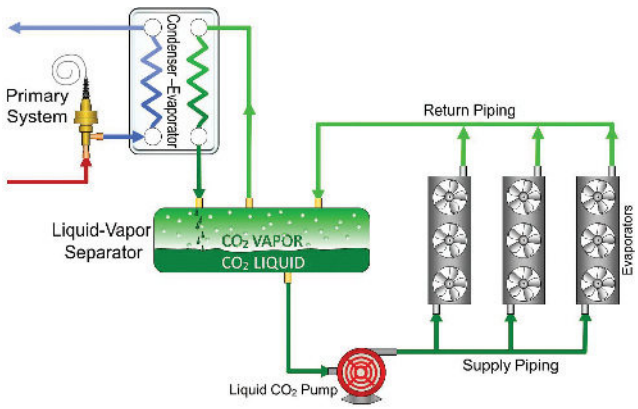
Saturated Temperatures/Pressures for Medium-Temperature Refrigeration

Refrigerant	Saturated Suction Temperature (SST)	Saturated Condensing Temperature (SCT)	Corresponding Saturated Pressures (psig)
CO_2	20°F	85°F	407/1017
HFC-134a	20°F	85°F	18/95

SUBCRITICAL CO_2 REFRIGERATION SYSTEMS

Because CO_2 is environmentally friendly, is readily available, has very low toxicity, is nonflammable, is very inexpensive, and has a high vapor density, it has become more popular in supermarket refrigeration systems. Its safety group classification is A1, meaning CO_2 has very low toxicity and no flame propagation. One popular CO_2 system for supermarket refrigeration is an indirect system that uses CO_2 as a secondary refrigerant. Another popular system uses CO_2 as one of the cascade refrigerants in a cascade refrigeration system. The following paragraphs and diagrams explain these two systems.

Figure 26.27 An indirect refrigeration system where CO_2 is a secondary refrigerant used for freezing applications, with HFC-404A used as the primary refrigerant.



INDIRECT SYSTEMS. The main reasons for using an indirect CO_2 system are its simplicity and the possibility of using other refrigerant system components in the construction of the system. **Figure 26.27** illustrates an indirect refrigeration system that uses CO_2 as a secondary refrigerant for freezing applications and HFC-404A as the primary refrigerant. Chilled liquid CO_2 is pumped by a centrifugal pump through the evaporators and absorbs heat in the refrigerated cases. As the CO_2 absorbs heat in the evaporators, only a portion of its liquid evaporates. The liquid and vapor mixture of CO_2 exits the evaporators and enter a liquid-vapor separator. Once in the separator, CO_2 vapor from the separator's top is pulled into the condenser/evaporator heat exchanger. This is where a primary refrigerant, like HFC-404A, is evaporated and used to cool and condense the CO_2 vapor back to a liquid. The chilled liquid CO_2 falls to the bottom of the separator and is again pumped by a centrifugal pump through the evaporators to absorb heat from the refrigerated cases.

Because CO_2 vapor has the major advantage of a high vapor density, it has a low-volume flow rate, which gives it an important edge compared to brine-based systems. Also, as the CO_2 exits the evaporator, it is about 50% liquid and 50% vapor by design. This will always assure a wet evaporator inner surface, which enhances heat transfer even under changing evaporator heat loads. The centrifugal pump is designed to pump a certain circulation ratio, making the system flexible in the face of changing evaporator heat loads while still maintaining a wet evaporator.

CASCADE SYSTEMS. **Figure 26.28** illustrates a supermarket cascade refrigeration system where CO_2 is being used as the low-stage (primary), low-temperature refrigerant in

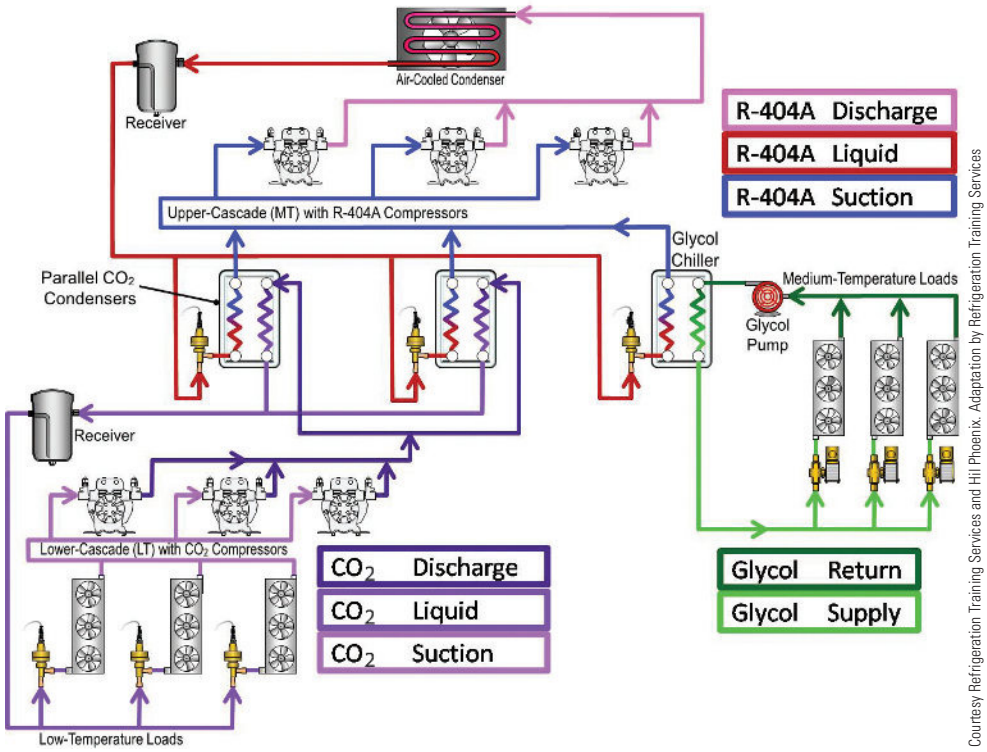
Figure 26.28 A supermarket cascade refrigeration system where CO_2 is being used as the primary (low-stage) low-temperature refrigerant in the lower portion of a cascade system. HFC-404A is used as a secondary (high-stage) refrigerant.



the lower portion of the system. Liquid CO_2 actually flows through expansion valves and is then evaporated in the low-temperature evaporators. CO_2 compressors are used in the lower portion of the cascade system to send hot, superheated vapor to a condenser/evaporator heat exchanger.

HFC-404A is being used as a high-stage (secondary) refrigerant; propane and ammonia have also been used successfully as high-stage refrigerants. The HFC-404A refrigerant system has two cooling functions. One function is to act as a high-stage (secondary) refrigerant in the upper portion of the cascade system to cool the low-stage refrigerant's (CO_2) condensers. Its second function is to chill a glycol solution in the glycol chiller heat exchanger. This glycol solution is then circulated by a centrifugal pump through the evaporators of the medium-temperature case. There is no phase change in the glycol solution. Subcritical cascade CO_2 systems keep the condensing pressure low, so common, off-the-shelf components can be used. **Figure 26.29** shows two subcritical, cascade parallel compressor CO_2 systems for use in supermarket refrigeration. Compressors for subcritical refrigeration applications can be of many different types: reciprocating, scroll, screw, or rotary.

However, the refrigeration cycle would have to run continuously unless some other method of pressure control is used to prevent high pressures from occurring during the off periods. When the CO_2 refrigerant is not being condensed, as when the system is turned off or there is a power failure, it starts to expand as it changes back to a vapor. System pressures would rise (1017 psi at 88°F) to the point where system components or personnel could be endangered or harmed, so relief valves start to open to prevent the failure or bursting of the weakest part of the system. To prevent the system pressures from exceeding the system's design pressures, expansion tanks are often employed on systems with a large enough volume. Larger industrial/commercial CO_2 systems employ a small, sometimes self-powered, refrigeration system that will keep the liquid CO_2 temperatures at levels where the saturation pressures are less than system design pressures. If pressures do elevate in the system and relief valves do blow off CO_2, the valves must be big enough and positioned so as to not let liquid CO_2 pass through or else the triple point might be reached in the blow-off process. Once the triple point is reached (−69.9°F/75 psia), solid CO_2 (dry ice) will form and could plug the relief valves if they are not sized and positioned carefully.

TRANSCRITICAL (SUPERCRITICAL) CO_2 REFRIGERATION SYSTEM

Figure 26.30 illustrates a transcritical CO_2 refrigeration system. The pressure of the superheated CO_2 gas is increased by

(B)

the compressor. Through the desuperheating of the vapors, the heat of rejection of the superheated gas is in the supercritical region. No condensation takes place because the CO_2 gas is above its critical point of 88°F/1067 psia. In fact, the temperature of the CO_2 gas will continually decline in the heat rejection process, but its pressure will remain the same, **Figure 26.26(B)**.

The CO_2 gas is then cooled in the gas cooler and enhancing heat exchanger and then expands by passing through a variable or fixed expansion device where it achieves a lower pressure. The expansion process puts the CO_2 into the subcritical region and over the 100% saturated liquid line, allowing it to enter the evaporator as a mixture of liquid and vapor. The CO_2 mixture now absorbs heat and boils back to a 100% saturated vapor and then superheats. The CO_2 gas is slightly superheated before it enters the compressor, **Figure 26.26(B)**. Because there is no saturation temperature or pressure on the high side of transcritical cycle, the pressure at the compressor's discharge depends on how much CO_2 charge is in the system. Medium-temperature transcritical refrigeration applications usually employ single-stage reciprocating compressors. Two-stage reciprocating compressors are mostly used for low-temperature applications and some medium-temperature applications.

The expansion device at the inlet of the evaporator does not control evaporator superheat as in a conventional subcritical refrigeration system. Its function is to inject refrigerant into the evaporator and control the gas cooler pressure and temperature. The superheat in the evaporator and in the suction line returning to the compressor is determined by the system charge and system balance at the time.

All system components have to be designed and selected to handle the very high pressures of transcritical CO_2 systems. Typical medium-temperature transcritical CO_2 systems may have suction pressures of 350 to 500 psig and discharge pressures in the 1250 to 1500 psig ranges. Because transcritical systems are designed for these higher pressures and the system is critically gas charged, there is no need to compensate for off-cycle gas expansion or provide for triple-point protection as in subcritical systems.

26.9 PRESSURIZED LIQUID SYSTEMS

This technology uses a small centrifugal pump to pressurize the liquid entering the liquid line, **Figure 26.31(B)**. (A normal system is shown in **Figure 26.31(A)** for comparison purposes.) The pressurized amount is equivalent to the pressure loss between the condenser outlet and the TXV inlet on receiverless systems or between the receiver and the TXV inlet on TXV/receiver systems. By increasing the pressure of liquid refrigerant, the saturation temperature is raised but the actual temperature of the liquid remains the same. The liquid becomes subcooled and will not flash if exposed to pressure drops in the liquid line on its way to the metering device. The centrifugal pump can be sized to fit any system design.

Subcooling liquid refrigerant by this method gives the condenser more internal volume for condensing refrigerant. The condenser no longer has to use its bottom passes as a subcooling loop. More condensing volume lowers the condensing temperatures and pressures, which lowers compression ratios and boosts efficiency.

going green

THE GREENCHILL PARTNERSHIP©

At the time of this writing, most refrigerants used in supermarket refrigeration systems have a potentially large environmental impact in terms of ozone depletion and/or global warming when they leak from these large systems. Because of the environmental impacts, the Environmental Protection Agency (EPA), supermarkets, and other supermarket industry participants have formed a partnership to help alleviate the problem. This partnership is "GreenChill©," whose members include

- store architects and designers,
- service technician certification organizations,
- trade organizations,
- component manufacturers,
- service contractors and technicians,
- environmental regulators,
- food retailers,
- chemical manufacturers,
- data system providers, and
- advanced refrigeration technology manufacturers.

The GreenChill© partnership's main mission is to reduce refrigerant emissions from supermarkets and decrease the industry's impact on the ozone layer and climate change by

- transitioning to environmentally friendly refrigerants,
- lowering refrigerant charge sizes and eliminating refrigerant leaks, and
- adopting "green" refrigeration technologies, strategies, and practices.

GreenChill's© partners measure emissions and set annual goals along with facilitating reduction of store refrigerant emissions. The partners also promote the use of advanced refrigeration technologies, strategies, and practices and award certifications to stores for achieving emissions reduction targets. The three award levels are Platinum, Gold, and Silver. Some objective criteria for measuring achievement are:

1. Refrigerant charge
2. Refrigerant leak rate
3. Type of refrigerant used
4. Installation leak tightness (new stores only)

For more information on GreenChill©, go to www.epa.gov/greenchill.

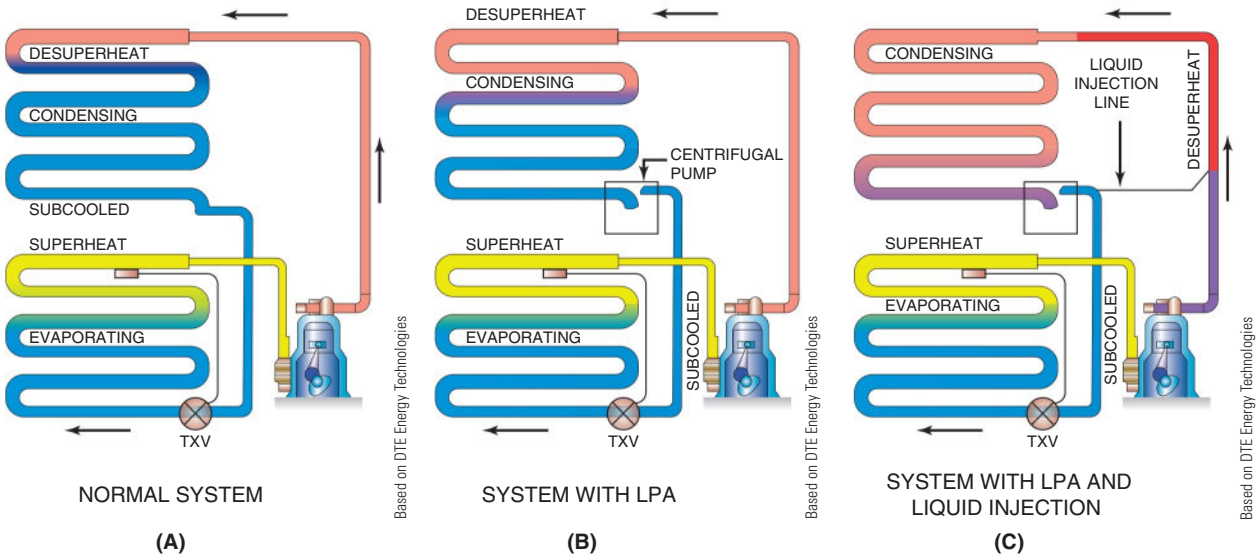
Figure 26.31 (A) A normal refrigeration system. (B) A pressurized liquid system. (C) A pressurized liquid system with liquid injection.



In fact, because the centrifugal pump is doing the liquid subcooling, head pressures are allowed to *float* with the outside ambient temperature. "**Floating**" the head pressure means attaining the lowest possible head pressure by taking advantage of cool ambient temperatures that are used as the condensing medium. Very low condensing pressures can be attained with these systems. TXV valves on the market will handle a 30-psi pressure drop across them and still successfully feed the evaporator if supplied with 100% liquid.

Listed below are four advantages of a pressurized liquid system:

- *They eliminate liquid line flashing by overcoming line pressure losses.*
- *They reduce energy costs because pumping liquid refrigerant is more than 40 times more efficient than using head pressure from the compressor to do the same work.*
- *They increase the evaporator capacity along with the net refrigeration effect.*
- *They lower compression ratios and reduce stress on compressors.*

In conjunction with the pressurized liquid system, liquid refrigerant can be injected into the compressor's discharge line or the condenser inlet. This liquid flashes to a vapor while cooling the superheated discharge gas closer to its condensing temperature. The reduced surface area required for desuperheating makes for a more efficient condenser, which increases the overall performance of the system. The injected liquid comes from the centrifugal pump, which delivers pressurized liquid to the metering device, **Figure 26.31(C)**. Although some efficiency gains are seen at low ambient temperatures, the greatest gains are realized at higher ambient temperatures.

26.10 DISTRIBUTED REFRIGERATION SYSTEMS

Attractive, multiple-compressor, distributed supermarket refrigeration modules that are located very close to the display cases they refrigerate are becoming increasingly popular, **Figure 26.32** and **Figure 26.33**. These modules can be cleverly hidden in the sales display area, mounted on top of display cases, or simply placed behind a wall close to the display cases. Microprocessor-based electronic controllers on each module manage the compressor cycling (load matching) and defrost schedules either on-site or remotely by personal computer. These modules have small, plate-type condensers that are cooled by a closed-loop fluid cooler. Heat reclaim can be performed with these systems for both

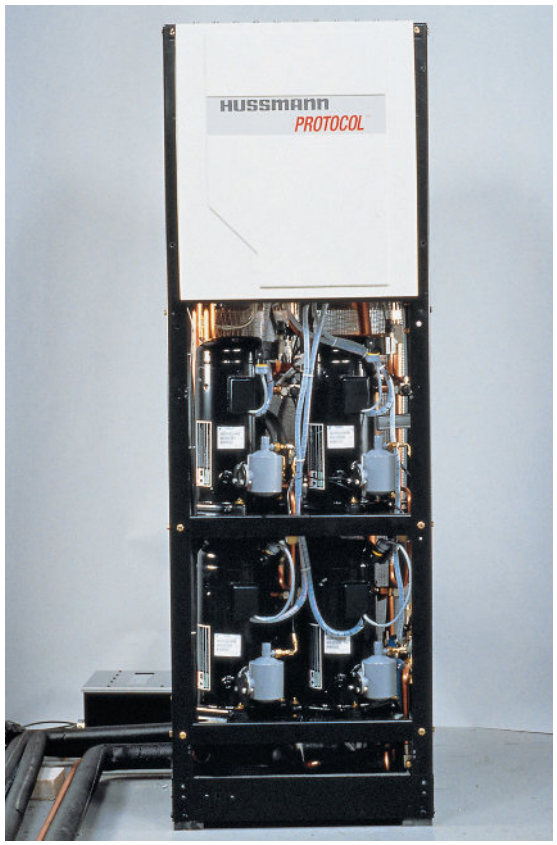
Figure 26.33 An attractive and compact commercial refrigeration module utilizing four hermetic scroll compressors.



Source: Hussman Corporation

store and hot water heating. Modules come in either vertical or horizontal designs and take up very little floor area. A remote mechanical room is not needed.

Other advantages of these modular stand-alone refrigeration systems are that they

- *reduce refrigerant charge by 75% to 80%,*
- *use 75% less piping,*
- *require 75% fewer brazed joints,*
- *reduce the likelihood of refrigerant leaks,*
- *decrease or eliminate the need for EPR valves,*
- *lower installation time, costs, and complexity,*
- *provide load matching with backup capacity protection, and*
- *provide energy savings when compared with conventional back-room systems.*

26.11 EVAPORATOR TEMPERATURE CONTROL

When multiple evaporators are used, they may not all have the same temperature rating. For example, the coldest evaporator may require a suction pressure of 28 psig. EPR valves can be located in each of the higher-temperature evaporators. When the load varies, the compressors can be cycled on and off to maintain a suction pressure of 20 psig. The compressors can be cycled using low-pressure control devices or a pressure transducer located in the common suction line. The pressure transducer transforms a pressure signal to a voltage signal and then relays the signal to a microprocessor-based compressor controller for processing.

26.12 INTERCONNECTING PIPING IN MULTIPLE-EVAPORATOR INSTALLATIONS

When the fixtures are located in the store and the compressors are in a common equipment room, the liquid line must be piped to the fixture and the suction line must be piped back to the compressor area. The suction line should be insulated to prevent it from picking up heat on the way back to the compressor. This can be accomplished by preplanning and by providing a pipe chase in the floor. Preferably, the pipe chase would be accessible in case of a leak, **Figure 26.34**. In some installations, refrigerant lines are routed through individual plastic pipes in the floor, **Figure 26.35(A)** and **(B)**. If a leak occurs, the individual lines may be replaced by pulling the old ones and replacing them with new lines. In modern stores, this may be a more popular method than the trench method because it gives the designer more versatility for locating equipment. It is hard to plan a large trench to every fixture, and long refrigerant lines can cause oil return problems. Individual runs can reduce the line length. Design factors must be carefully considered to ensure correct oil return. Under-floor refrigerant pipes are ventilated to prevent mold and mildew. **Figure 26.35(C)** shows a venting system

Figure 26.34 A pipe chase is an effective method of running piping from the fixture to the equipment room. With a chase like this, the piping can be serviced if needed.

that directs the store's ceiling air to the back of the cases, through the under-floor refrigeration piping system, and through the access pit in the mechanical room.

26.13 FIXTURE TEMPERATURE CONTROL

Remote medium-temperature applications can be controlled without installing interconnecting wiring between the fixture and the equipment room. A power supply for the fixture must be located at the fixture, and planned off-cycle defrost can be accomplished at the equipment room through a time clock and a liquid-line solenoid valve. The clock and solenoid valve can be located at the case, but the equipment room provides a more central location for all controls. The clock can deactivate the solenoid, closing the valve for a predetermined time. The refrigerant will be pumped out of the individual fixture, the evaporator fan will continue to run, and the air in the fixture will defrost the coil. When the proper amount of time has passed, the solenoid-activated valve will open, and the coil will begin to operate normally. The compressor will continue to run during the defrost of the individual cases. The defrost times can be staggered by offsetting them. This is sometimes accomplished with a master time clock with many circuits. Use of electronic timing devices enables many different events to be controlled at the same time.

Low-temperature installations must have a more elaborate method of defrost because heat must be furnished to the coil in the fixture. This can be accomplished at the fixture with a time clock and heating elements when the power supply for the fixture is in the vicinity. It could also be accomplished with hot gas, but a hot gas line must then be run from the compressor to the evaporator, which would mean a third line to be run to each case that must also be insulated to keep the gas hot until it reaches the evaporator. As in the medium-temperature application, the defrost for each case can be staggered by different time clock settings, **Figures 26.36(A)** and **(B)**. This is the most efficient way to defrost because the heat for defrost comes from the other cases; however, electric defrost probably has fewer problems and is easier to troubleshoot. These methods of defrost are typical, but by no means the only, methods. Different manufacturers devise their own methods of defrost to suit their equipment.

26.14 THE EVAPORATOR AND MERCHANDISING

The evaporator is the device that absorbs heat into the refrigeration system. Because the evaporator is located on the outside of the system, it is visible to the store customer. At best, an evaporator is bulky, but it can be built in several ways. Manufacturers and their engineering staff must do a certain amount of planning to provide attractive fixtures that are also functional, **Figure 26.37**. Customer appeal must be considered when choosing equipment, which is why the service technician may not understand the way in which some equipment is installed; customer convenience or merchandising may have played a major part in the decision. Each supermarket chain is trying to stay ahead of the competition in the marketplace, and customer convenience is part of that effort. Display fixtures are available in the following types: (1) chest (open, open with refrigerated shelves, closed) and (2) upright (open with shelves, with doors).

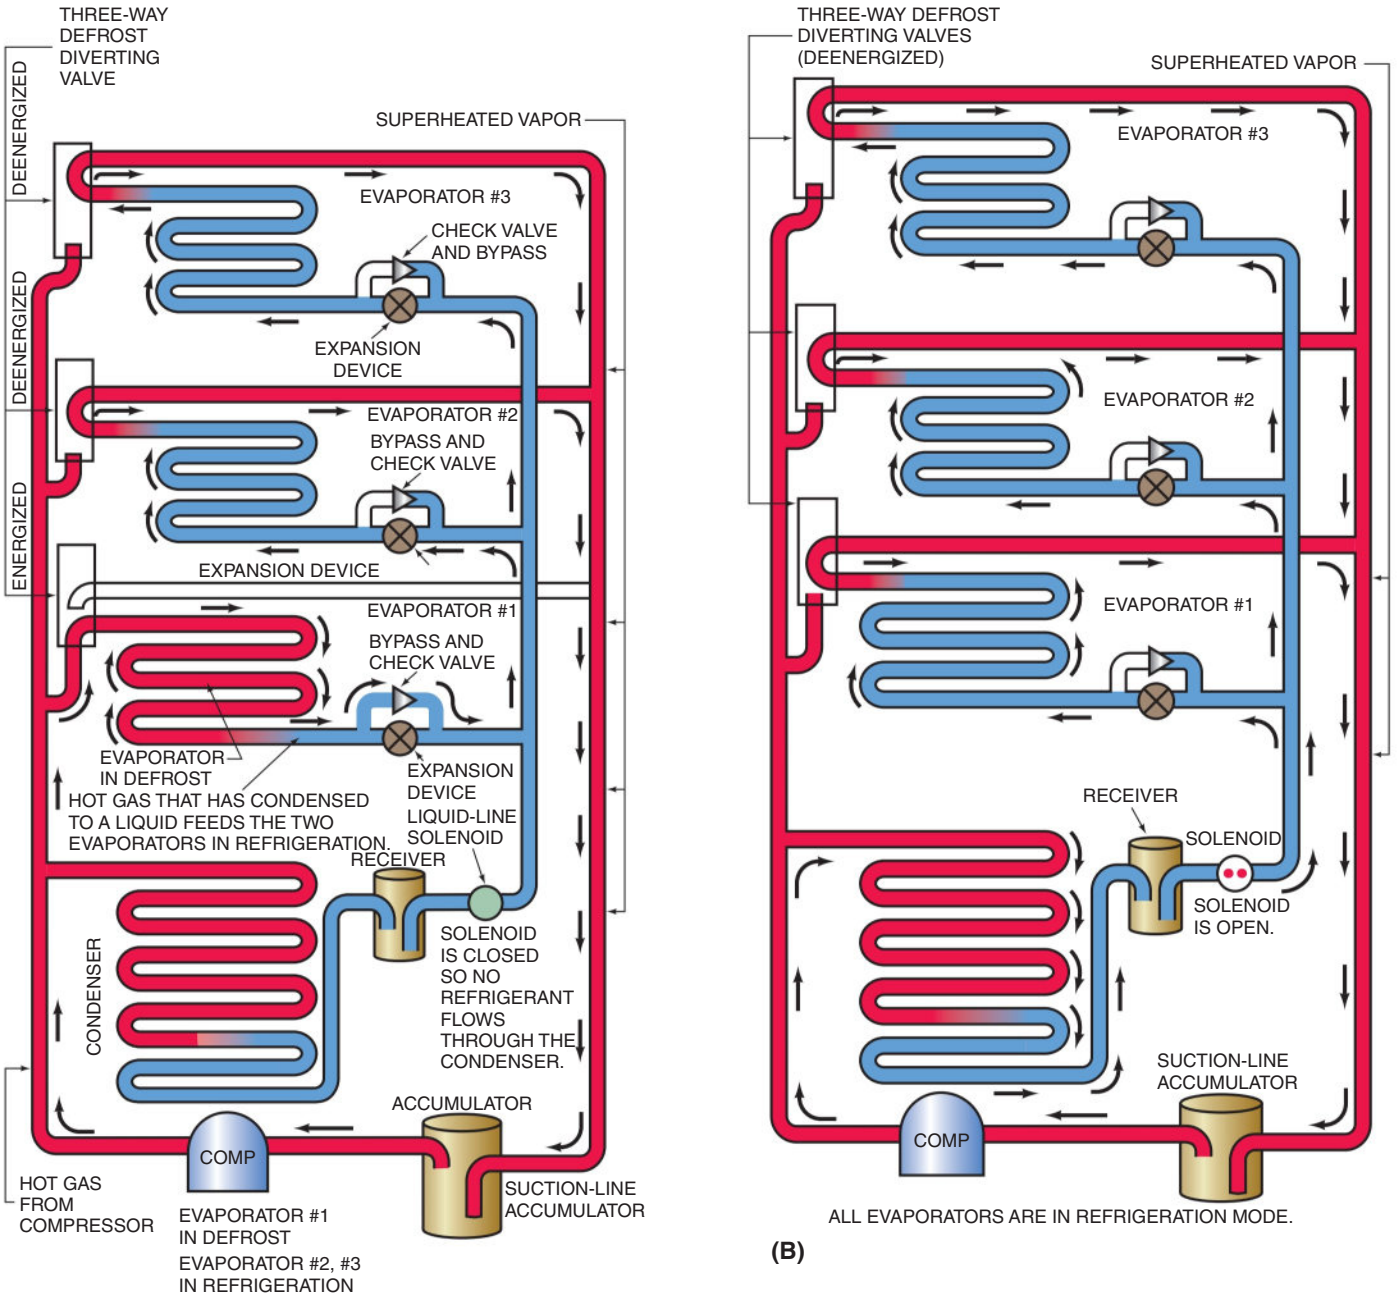
Figure 26.36 (A) Hot gas defrost for multiple cases. The condensed liquid from the evaporator in defrost is returned to the liquid line through the bypass and check valve around the expansion valve. The liquid then feeds the evaporators in the refrigeration mode. Three-way defrost diverting valves control the refrigerant flow in the defrost and refrigeration modes. (B) All three evaporators shown in the refrigeration mode.



26.15 CHEST-TYPE DISPLAY FIXTURES

Chest-type reach-in equipment can be designed with an open top or lids and the fixture may have its own lights so that the customer can better see the product. Vegetables, for example, can easily be displayed in an open chest. The vegetables can be stocked, rotated, and kept damp with an automatic sprinkler system, **Figure 26.38**. Meat that is stored in the open is normally packaged in clear plastic. At night, the product can be covered with plastic lids or film. In this type of fixture the evaporator may be at the bottom of the box. Fans blow the cold air through grills to give good air circulation. Service for the coil components and fan is usually performed through removable panels under the product storage or on the front side of the fixture. The appliance is normally placed against a wall, **Figure 26.39**.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 26.37 A dairy case showing the location of the evaporator.

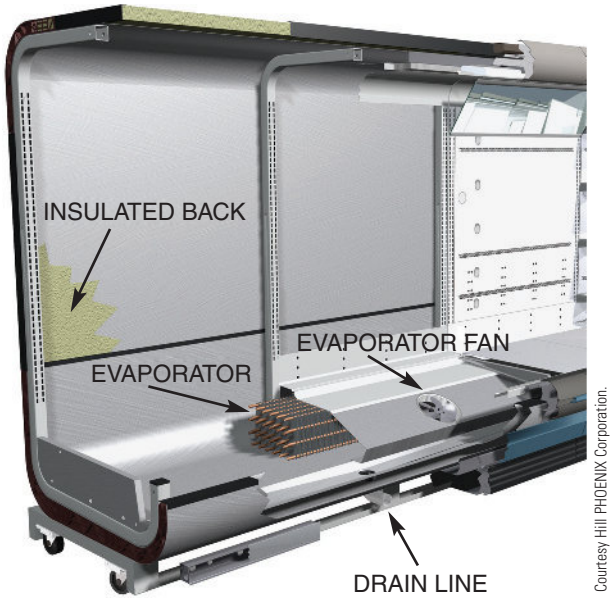


Figure 26.38 An open display case used to store fresh vegetables. The case has a drain, so the vegetables can be moistened by hand or with an automatic sprinkler.

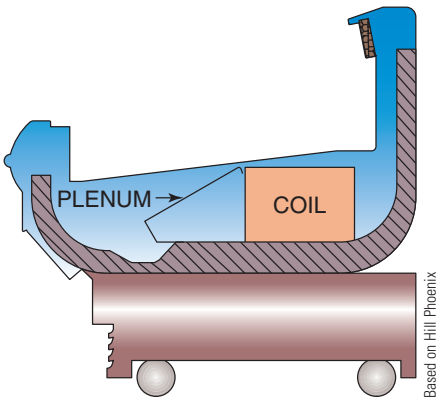
Figure 26.39 The cutaway side view of a chest-type display case. The fans can be serviced from inside the case. The case is normally located with its back to a wall or another fixture.



The chest-type fixture can have a built-in condensing unit or be designed so that the condenser is located remotely, such as in an equipment room. If the condensing unit is furnished with the cabinet, it is usually located underneath the front and can be serviced by removing a front panel. When the condensing unit is furnished with a fixture, it is called self-contained.

26.16 REFRIGERATED SHELVES

In some chest-type fixtures, refrigerated shelves are located at the top. These shelves must have correct airflow around them or they must have plate-type evaporators to maintain the correct food conditions. When evaporators are at the top, they are normally piped in series with the evaporators at the bottom, **Figure 26.40**.

26.17 CLOSED CHEST FIXTURES

The horizontal closed chest is a low-temperature fixture that normally stores ice cream or frozen foods. The lids may be lifted off, raised, or slid from side to side. These boxes are not as popular now as in the past because the lids are a barrier to the customer. The upright closed display has doors through which the customer can look to see the product. This type of cooler may have either a self-contained or remote condensing unit. It can also be piped into a system with one compressor. This display is sometimes used as one side of the wall for a

Figure 26.40 Multiple evaporators in a single case because refrigeration is needed in more than one place.

Courtesy Hill PHOENIX Corporation.

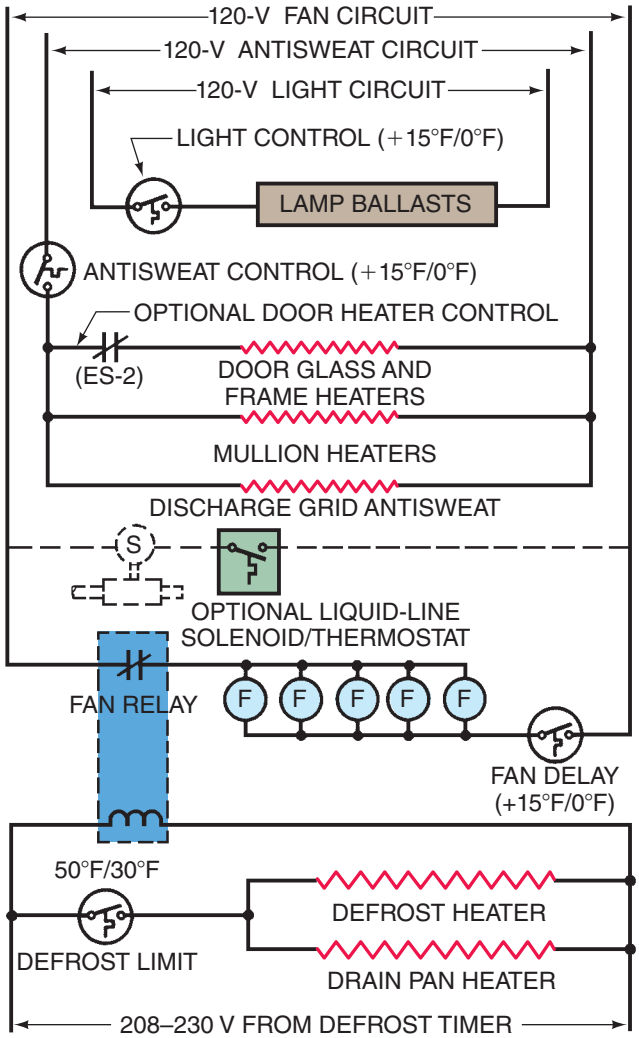
walk-in cooler. The display shelves can then be loaded from inside the walk-in cooler, **Figure 26.41**. These fixtures may be found in many convenience stores.

26.18 CONTROLLING SWEATING ON FIXTURE CABINETS

Cabinet surfaces of display cases that may operate below the dew point temperature of the room (the temperature at which moisture will form) must have some means (usually small heaters) of keeping this moisture from forming. Cabinet heating normally occurs around doors on closed equipment. The colder the refrigerated fixture, the more need there is for the protection. The heaters, of resistance-type wire run just under the surface of the cabinet, are called *mullion* heaters. *Mullion* means "division between panels." In refrigeration equipment, it is the panel between the doors that becomes cold, but any surface that may collect moisture from sweating needs a heater. In some equipment, there can be a large network of heaters, **Figure 26.42**. *Some of them can be thermostatically controlled or controlled by a humidistat based on the humidity in the store.*

More than ever before, air-conditioning (cooling) systems are used for controlling humidity in stores. You may have noticed how cold some supermarkets are. Air-conditioning removes some of the heat and moisture load from the refrigeration equipment, and at a higher level of efficiency. Because the air-conditioning system has a much lower compression ratio than any of the refrigeration systems, it will remove more moisture. Store managers realize that with low humidity in the store, they do not have to use as much mullion heat, and coils operating below freezing do not need as much defrost time.

Figure 26.42 A wiring diagram for mullion heaters on a closed display case. Several circuits can be applied to the heaters. This unit has two power supplies, 120 V and 208 V or 230 V.



26.19 MAINTAINING STORE AMBIENT CONDITIONS

Humidity is taken out of a store in warm weather by the air-conditioning system and the display cases. The more humidity removed by the air-conditioning system, the less the refrigeration fixtures have to remove. This means less defrost time. Some stores maintain a positive air pressure with makeup air that is conditioned through the air-conditioning system. This is different from taking in outside air randomly when the doors are opened by customers. It is a more carefully planned approach to the infiltration of the outside air, **Figure 26.43**. You will notice this system when the front doors are opened and a slight volume of air blows in your face.

In addition, the doors on display cases are usually constructed of double-pane glass and sealed around the edges to

Figure 26.43 Planned infiltration known as ventilation.

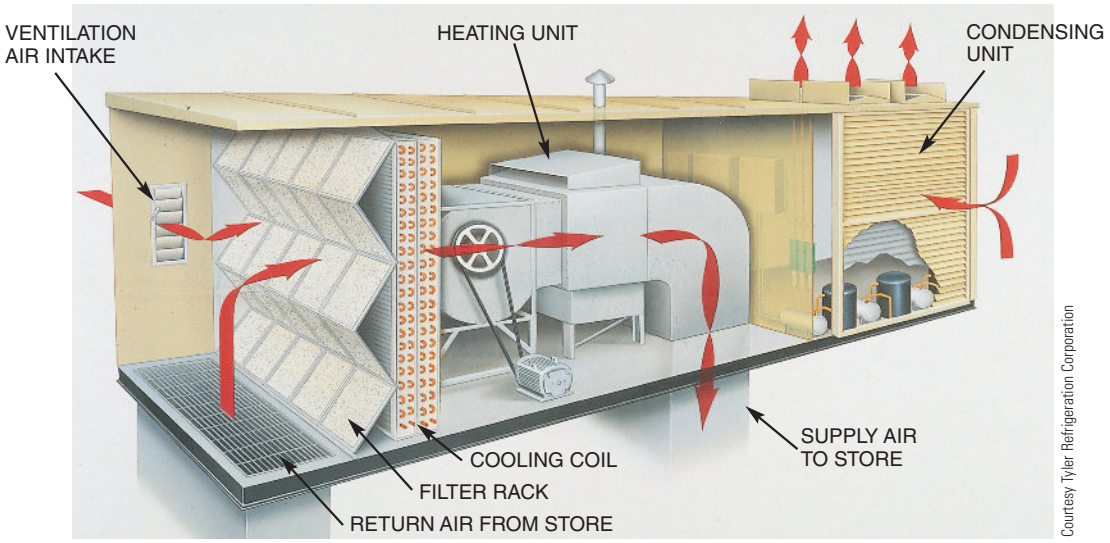

Figure 26.44 These doors are rugged and reliable. They are constructed of double-pane glass sealed on the edges to keep them from sweating between the glass.

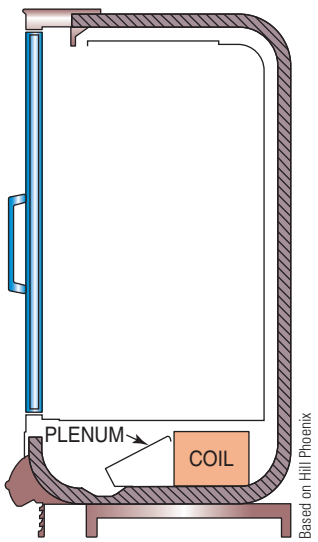

keep moisture from entering between the panes. These doors must be rugged because any fixture that the public uses is subject to abuse, **Figure 26.44**. The cabinets must be made of a strong material—stainless steel, aluminum, porcelain, and vinyl—that is easy to clean. The most expensive cabinets are made of stainless steel, and they are the longest lasting.

26.20 WALK-IN REFRIGERATION

Walk-in refrigeration equipment is either permanent or of the knock-down type. The permanently erected refrigerated boxes cannot be moved. Very large installations are permanent.

26.21 KNOCK-DOWN WALK-IN COOLERS

Knock-down walk-in coolers are constructed of interlocking panels 1 in. to 4 in. thick, depending on the temperature needed inside the cooler. The construction is of a sandwich type, with metal on each side and foam insulation between. The metal in the panels may be galvanized sheet metal or aluminum, and the panels are strong enough that no internal support steel is needed for small coolers. They are shipped disassembled on flats and can be assembled at the job site. This type of cooler can be moved from one location to another and can be reassembled, **Figure 26.45**.

Figure 26.45 A knock-down walk-in cooler that can be assembled on the job. It can be moved at a later time if needed. The panels are foam with metal on each side, creating a structure that needs no internal braces. This prefabricated box is weatherproof and can be located inside or outside.

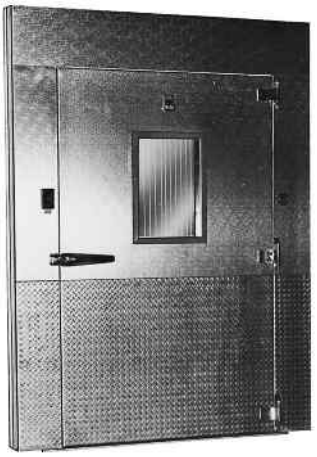
Courtesy Bally Case and Cooler, Inc.

Figure 26.47 Walk-in cooler doors are rugged. They have a safety latch and can be opened from the inside.



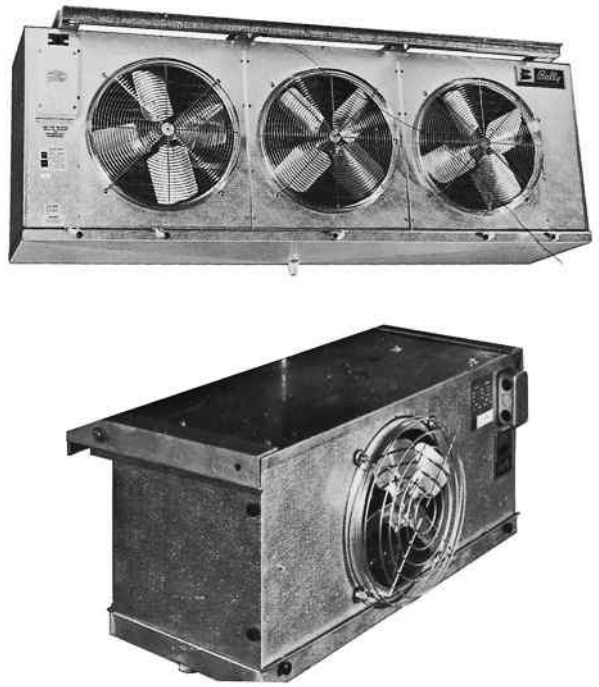
Courtesy Bally Case and Cooler, Inc.

Walk-in coolers come in a variety of sizes and applications. One wall of the cooler can be a display, with the shelves filled from inside the cooler. The coolers are normally waterproof and can be installed outdoors. The outside finish may be aluminum or galvanized sheet metal. When the panels are pulled together with their locking mechanism, they become a prefabricated structure, **Figure 26.46**. **SAFETY PRECAUTION:** *Walk-in cooler doors are very durable and must have a safety latch on the inside to allow anyone trapped on the inside to get out,* **Figure 26.47**. •

26.22 EVAPORATORS IN A WALK-IN COOLER

Refrigerating a walk-in cooler is much like cooling any large space. The methods that are used today take advantage of evaporator fans to improve air circulation and make

Figure 26.48 Fan coil evaporators are used in walk-in coolers.



Source: National Refrigeration and Air Conditioning Products

evaporators compact. Following is a list of the types of systems used to refrigerate walk-in coolers:

1. Evaporators piped to condensers using field-assembled pipe
2. Evaporators with precharged piping
3. Package units, wall-hung or top-mounted, with condensing units built in

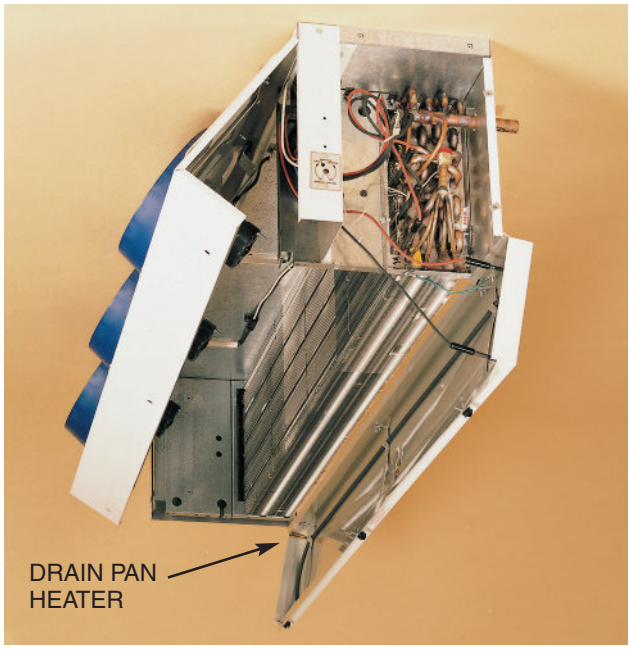
Evaporators should be mounted in such a manner that the air currents blowing out of them do not blow all of the air out the door when the door is opened. They can be located on a side wall or in a corner. These evaporators are normally in aluminum cabinets in which the expansion device and electrical connections are accessed at the end panel or through the bottom of the cabinet, **Figure 26.48**. Some installations have a fan switch that shuts the fan off when the door is opened to prevent cold air from being pushed out of the cooler. This works well if the door is not propped open for long periods of time. When the door is open, the compressor is operating without the fans; this can cause liquid flooding to the compressor. Some coolers deenergize the liquid-line solenoid valve and pump the refrigerant from the evaporator to the condenser and receiver while the fans are off. This works also but is an added step in the control sequence.

26.23 CONDENSATE REMOVAL

The bottom of the evaporator cabinet contains the drain pan for the condensate that must be piped to the outside of the cooler. When the inside is below freezing, heat has to be

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 26.49 Drain pan heaters to keep pans from freezing.



Source: Larkin Coils, Inc.

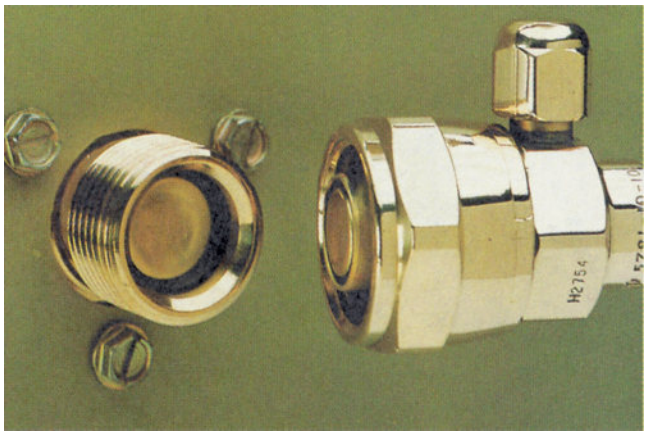
provided to keep the condensate in the line from freezing, **Figure 26.49**. Normally, this heat is provided by an electrical resistance heater that can be installed in the field. The line is piped to a drain and must have a trap to prevent the atmosphere from being pulled into the cooler. The drain lines also should be sloped downward about ¼ in. per foot for proper drainage. The line and trap must be heated if the line is run through below-freezing surroundings. These drain line heaters sometimes have their own thermostats to keep them from using energy during warm weather. Thermostatically controlled heaters are used when the drain line is run outside. The heaters can cycle off when the outside temperature is warm. When the drain line is located inside the box, the heater is energized all of the time. Heat tape is usually used in this case.

26.24 REFRIGERATION PIPING

There are two methods of installing refrigeration piping for walk-in coolers. One method is to pipe the cooler in the conventional manner. The other is to use precharged tubing, called a *line set*. In the conventional method, the installing contractor usually furnishes the copper pipe and fittings as part of the agreement. This piping can have straight runs and factory elbows for the corners. When the piping is completed, the installing contractor has to leak check, evacuate, and charge the system. This requires the service of an experienced technician.

Precharged tubing is furnished by the equipment manufacturer. It is sealed on both ends and has quick-connect

Figure 26.50 Quick-connect fittings providing the customer with a system that is factory sealed and charged.



Courtesy Aeroquip Corporation

fittings. This piping has no fittings for corners and must be handled with care when bends are made. The condenser and the evaporator come with their operating charges already installed, and the tubing has the correct operating charge for the length chosen for the job. This has some advantages because the installation crew does not have to balance the operating charge in the system. The system is factory sealed with field connections, **Figure 26.50**; no soldering or flare connections have to be made. The system can be installed by someone with limited experience.

If, because of miscalculation, the piping is too long for the installation, a new line set can be obtained from the supplier or the existing line set can be cut to fit. If the existing line set is to be altered, refrigerant can be recovered, the line cut, soldered, leak checked, evacuated, and charged to specifications. If the line set is too long, the extra tubing should be coiled and placed in a horizontal position to ensure good oil return. **Figure 26.51** is a step-by-step illustration of how the line set can be altered.

NOTE: *The suction line is charged with vapor. The liquid line has a liquid charge. It contains about as much liquid as may be pulled into it under a deep vacuum. Recover the charge in each tube and cut to the desired length. Fasten together with couplings.*

SAFETY PRECAUTION: *Leak check, evacuate, and charge (1) the suction line with vapor, and (2) the liquid line with liquid. It is now a short line set with the correct charge. See Unit 8, "System Evacuation," and Unit 10, "System Charging."*

26.25 PACKAGE REFRIGERATION FOR WALK-IN COOLERS

Wall-hung or ceiling-mount units are package units, **Figure 26.52**. They can be installed by personnel who do not understand refrigeration, somewhat like installing a window air conditioner. However, proper installation techniques must be followed. Thus, package units are very popular for some applications because costs can be minimized. Care must be used as to where the condenser air is discharged outside. It must have room to discharge without recirculating to the air inlet, or head pressure problems will occur. These units are factory assembled and require no field evacuation or charging. They come in high-, medium-, and low-temperature ranges. Only the electrical connections need to be made in the field.

26.26 REFRIGERATED AIR DRIERS

Many applications use compressed atmospheric air; this must be dehydrated. Compressed air leaves the compressor saturated with moisture. Some of this moisture condenses in the air storage tank and is exhausted through a float, but the air is still very close to saturated as it leaves the storage tank. The air used for special manufacturing processes or air used for controls, called "pneumatic control," must be dry. Air may be dehydrated using refrigeration.

Refrigerated air driers are basically refrigeration systems located in the air supply, after the storage tank. The air may be cooled in a heat exchanger and then moved to the storage tank, where much of the water will separate from the air. The water may be drained using a float that rises and provides for drainage at a predetermined level, **Figure 26.53**. The air then passes through another heat exchanger where its temperature is reduced to below the dew point temperature (the point where water will condense from the air). The heat exchanger consists of an evaporator that normally operates at a temperature just above freezing, **Figure 26.54**.

Figure 26.55 The flow schematic for a refrigerated air drier.

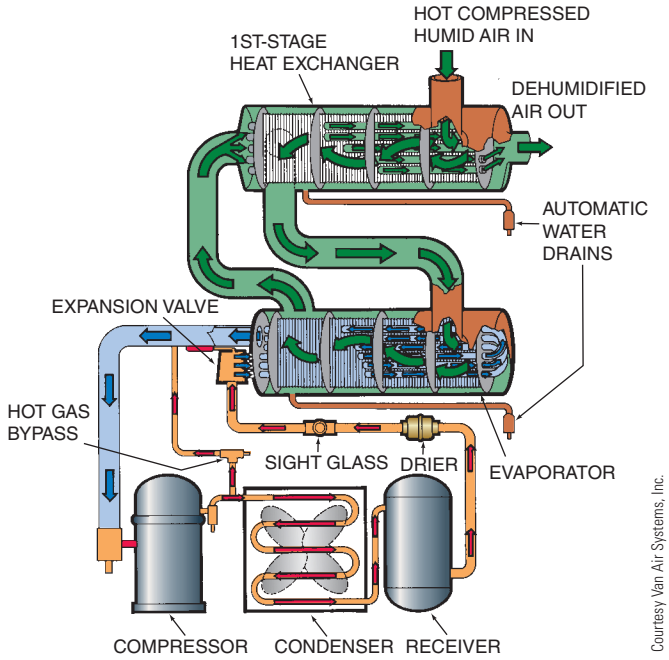

Figure 26.56 Refrigerated air drier with accompanying air compressor, controller, and pressurized air storage tank.

The system typically runs 100% of the time because it does not know when there will be a demand for air flowing through the system. When there is no airflow, there is virtually no load on the refrigeration system. The only time there is a load on the system is when air is passing through that needs to be dried. Because the refrigeration system is running, in case there is a demand, a false load must be placed on the evaporator when there is no load. This is usually accomplished with a special refrigeration valve called a hot gas bypass valve, **Figure 26.55**. This valve is situated between the hot gas line and the inlet to the compressor or the evaporator. It monitors the pressure in the evaporator and allows hot gas to enter the suction line at any time there is no or reduced load on the evaporator by monitoring the suction pressure with a pressure-sensitive valve. The hot gas bypass valve is called a pressure regulator because it does not allow the pressure in the evaporator to drop below the set point. The difference between this pressure regulator and others discussed in this text is that it is located between the high- and low-pressure sides of the system. The set point is usually just above the freezing point of water. For example, for R-22, the set point of the hot gas bypass valve may be 61.5 psig (35°F). The valve will not allow the evaporator pressure to go below 35°F, so the evaporator will not freeze during any no- or reduced-load situations.

Refrigerated air driers are normally self-contained refrigeration systems that may be air- or water-cooled, **Figure 26.56**. The smaller driers can have a hermetic compressor; semihermetic units are used for larger driers. The air line is piped to and through the evaporator of the air drier and then moves on to the system where it is to be used. The water is collected and exhausted to a convenient drain. The evaporator may be one of several types: a pipe within a pipe or a honeycomb type are common.

The service technician should understand the manufacturer's intent for each application. At times, the technician must improvise when replacing components that are not available, which may happen as equipment becomes outdated.

SUMMARY

- Product dehydration can be a factor in the choice of equipment.
- The condensing unit in packaged equipment is normally on top or underneath the fixture.
- All fixtures have condensate that must be drained away or evaporated.
- Fixtures may also be piped to a common equipment room with either individual compressors or multiple-compressor units.
- When a single large compressor is used, capacity control is desirable.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Load matching can be accomplished with parallel compressor systems. These compressors are manifolded together with a common suction and discharge line. They share one receiver.
- A pressure transducer on the common suction line signals the controller on the parallel compressor rack to enact capacity steps.
- A complicated oil system is used on parallel compressor systems to ensure the proper oil level in each compressor's crankcase.
- Parallel compressor systems often use satellite or booster compressors, which are usually used for the coldest cases, but can benefit the entire parallel rack on pull downs.
- Secondary-fluid systems circulate an antifreeze solution to the refrigerated cases and offer many advantages over a conventional refrigeration system.
- Pressurized liquid systems offer a different way to subcool liquid refrigerant.
- Unitary, stand-alone refrigeration modules offer many advantages compared to a conventional supermarket refrigeration system with an equipment room.
- Capacity control is accomplished by cycling compressors on the multiple-compressor racks.
- Several evaporators may be piped together to a common suction line.
- The liquid lines are manifolded together after the liquid leaves the receiver.
- Each fixture has its own expansion valve.
- There must be a defrost cycle on both medium- and low-temperature fixtures.
- Heat must be added to the coil for defrost in low-temperature refrigeration systems.
- Common discharge lines concentrate the heat that was absorbed into the system.
- This heat can be used to heat the space or heat water with heat-recovery devices.
- Heaters are used around the doors of fixtures to keep the cabinet around the doors above the dew point temperature of the room.
- These heaters, called mullion heaters, normally produce electric resistance heat that is sometimes thermostatically controlled.
- Humidity, usually in the summer, leaves a space by two means: the refrigeration equipment and the air-conditioning equipment.
- It is less expensive to remove humidity with the air-conditioning equipment than with the refrigeration equipment defrost cycle.
- Drain heaters normally produce electric resistance heat and may have thermostats to keep them from operating when they are not needed.
- Some coolers have remote condensing units, and some have wall-hung or roof-mount package equipment.
- Some of the remote units are field piped, and some are piped with quick-connect tubing.
- Refrigerated air driers are refrigeration systems that are used to dehydrate air that is compressed with an air compressor.
- Refrigerated air driers typically operate all of the time, whether there is a load or not. They provide cooling to about 35°F.
- The typical refrigerated air drier uses a hermetic compressor and either an air- or water-cooled condenser.
- **SAFETY PRECAUTION:** *There are many applications for refrigeration. There is no substitute for knowing the manufacturer's intent. Do not improvise without this knowledge.* •

REVIEW QUESTIONS

1. The two broad categories of display cases are _____ and _____.
2. How are conditions maintained in open display cases when there are high shelves?
3. What are mullion heaters?
4. The three temperature ranges for refrigeration systems are _____, _____, and _____.
5. The two methods for rejecting heat from refrigerated cases are _____ and _____.
6. When the compressors are located in the equipment room, the piping is routed
   A. in floor chases or in plastic pipes under the floor.
   B. in suspended ceilings.
   C. between the walls.
   D. in back of the walls.
7. When one large compressor is used, what desirable feature should it have?
   A. Discharge muffler
   B. Suction muffler
   C. Cylinder unloaders or variable-speed drive
   D. Hot gas bypass
8. Define a parallel compressor system and list five advantages of these systems.
9. Three disadvantages of parallel compressor systems are _____, _____, and _____.
10. What is the difference between an even and an uneven parallel compressor system?

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. 11. Exactly matching the refrigeration load with the capacity of refrigeration compressors is referred to as
    A. capacity control.
    B. load shedding.
    C. load paralleling.
    D. load matching.
12. What is the function of the pressure transducer in parallel compressor systems?
13. What is the function of the microprocessor-based controller in parallel systems?
14. Explain how the oil separator, oil reservoir, pressure differential valve, and oil-level regulators work together to maintain the correct oil level in parallel compressors.
15. Large or small compressors on parallel compressor racks, which are usually dedicated to the coldest cases, are called
    A. satellite compressors.
    B. remote compressors.
    C. booster compressors.
    D. both A and C.
16. A(n) _____ varies the frequency of an electronically altered sine wave, which affects the speed of alternating current motors.
17. Explain the function and advantages of a secondary-fluid system.
18. Explain the main idea behind pressurized liquid systems, and list their advantages.
19. Three advantages of unitary, stand-alone refrigeration modules in supermarket refrigeration are _____, _____, and _____.
20. How is defrost accomplished when the equipment room is in the back and the medium-temperature fixtures are in the front?
21. True or False: The two types of defrosts used with low-temperature fixtures are hot gas and electric defrost.
22. What special precautions should be taken with drain lines in walk-in coolers?
    A. Freeze protection
    B. Trapping to prevent air from being pulled in
    C. Downward sloping
    D. All of the above
23. What holds up the structure of a walk-in cooler?
24. What special valve is used in a refrigerated air drier?
    A. Four-way valve
    B. Defrost valve
    C. Three-way valve
    D. Hot gas bypass valve
25. Briefly explain what is meant by a surge-type receiver.
26. Briefly explain what is meant by a subcritical refrigeration cycle, and list its four processes.
27. Briefly explain what is meant by a transcritical refrigeration cycle, and list its four processes.
28. What is meant by carbon dioxide having a critical point?
29. What is the critical point of carbon dioxide?
30. What is meant by carbon dioxide having a triple point?
31. What is the triple point of carbon dioxide?
32. Define a synthetic refrigerant.
33. Define a natural refrigerant.

UNIT 27

COMMERCIAL ICE MACHINES

OBJECTIVES

After studying this unit, you should be able to

- describe the basic refrigeration cycle for ice flake machines.
- discuss basic troubleshooting for ice flake machines.
- state the purpose of the water fill system in an ice flake machine.
- explain the purpose of a flush cycle in an ice flake machine.
- state the purpose of a bin control in an ice flake machine.
- read and interpret ice production and performance charts for ice machines.
- describe how crescent-shaped ice is made.
- describe how cell-type ice cubes are made.
- explain the sequence of operation of an ice machine.
- describe the purpose of a harvest cycle in an ice machine.
- state the purpose of microprocessor controls in ice machines.
- explain what is meant by input/output troubleshooting for microprocessors.
- discuss the importance of water and ice quality in ice making.
- discuss the difference between cleaning and sanitizing an ice machine.
- define water filtration and treatment.

SAFETYCHECKLIST

- ☑ Follow manufacturers' instructions when using cleaning and sanitizing chemicals.
- ☑ Wear protective clothing and eyewear when handling cleaning and sanitizing chemicals.
- ☑ Be careful not to get your hands or clothes caught in any moving parts involving ice makers.
- ☑ A wet environment exists around ice machines. When servicing these machines, extra precautions must be taken to protect against electrical shock and slipping.
- ☑ Observe all electrical safety precautions. Be careful at all times and use common sense.

27.1 PACKAGED-TYPE ICE-MAKING EQUIPMENT

Ice making is accomplished in a temperature range that is somewhat different from low-, medium-, or high-temperature refrigeration. The ice is made with evaporator temperatures between medium- and low-temperature ranges of about 10°F with the ice at 32°F. Most refrigeration applications use tube and fin evaporators and a defrost cycle to clear the ice buildup from the evaporator. Ice making is accomplished by accumulating the ice on some type of evaporator surface and then catching and saving it after a defrost cycle, commonly called the harvest cycle.

Large, commercial, block ice makers use cans and freeze the ice in the cans. We will discuss only small ice-making equipment, such as that found in commercial kitchens, motels, and hotels. These ice makers are usually of the package type. The power is supplied by a power cord, or in some cases the machines are wired directly to the electrical circuit (hardwired). Some ice makers may be of the split-system type with the condenser on the outside.

Package ice machines store their own ice at 32°F in a bin below the ice maker. This bin is refrigerated by the melting ice in the bin (which explains the storage temperature of 32°F), so there is some melting; the hotter the day, the more melting. A drain must be provided for the melting ice and any water that may overflow from the ice-making process. Do not confuse an ice-making machine with an ice-holding machine such as those seen on the outside of a convenience store or service station. Ice-holding machines hold ice, usually in bags, at a temperature well below freezing. This ice is made and bagged at one location and then stored and dispensed at the retail location.

Most package ice makers are air-cooled and must be located where the correct airflow across the condenser can be maintained. Some package ice makers are water-cooled and use wastewater systems in which the water is used to cool the condenser and then passes down the drain.

Keep the installation of a package machine simple by following these steps:

1. Set and level the machine, much like a refrigerator.
2. Supply power, plug, or hard wire.
3. Provide a water supply.
4. Provide a drain for the ice bin.

Package ice machines make two types of ice, flake ice and several forms of cube (solid) ice.

27.2 MAKING FLAKE ICE

Flake ice is normally made in a vertical refrigerated cylinder surrounded by the evaporator on the outside. Flake ice is the very thin pieces of ice often seen in restaurants and vending machine cups. Some people prefer flake ice to solid forms

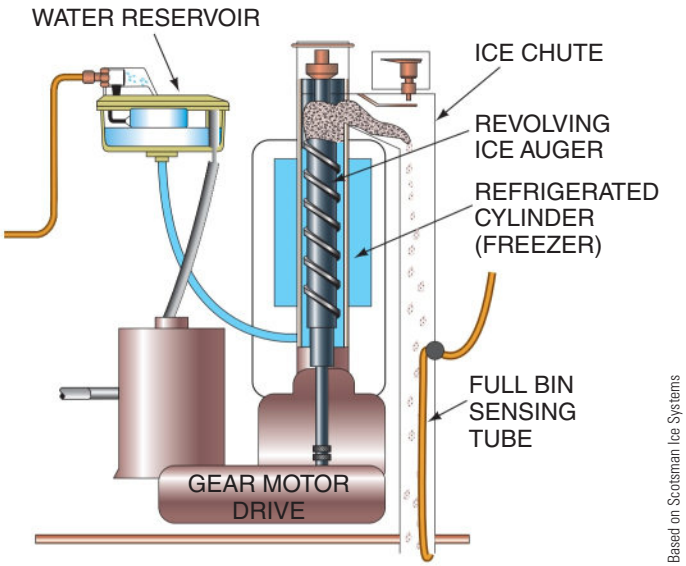
Figure 27.2 A flake ice maker, its evaporator, and its auger. The auger turns and shaves the ice off the evaporator. The tolerances are very close.



Based on Scotsman Ice Systems

Figure 27.3 The auger is on top of the ice maker. The shaft seal prevents oil from seeping into the ice.

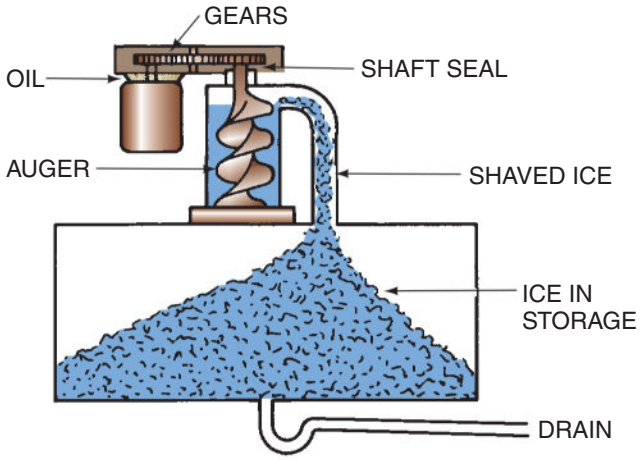


Figure 27.4 The gearbox is on the bottom of the auger. A seal leak would allow water to enter the gearbox.

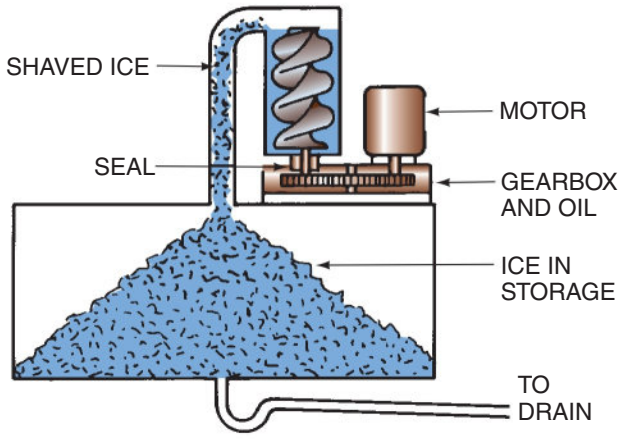

of ice when served in drinks. It melts fast because there is little weight and a lot of surface area. A good bit of air is contained in the flake. Solid forms of ice last longer because there is more weight with less surface area; remember, it takes 144 Btu/lb to make or melt ice. It takes less ice by the pound to fill a cup with flake ice. Solid ice costs more, and some of it is likely to be thrown out.

Flake ice is formed by maintaining a water level inside a cylinder. An auger is constantly turning inside the cylinder and scraping the formed ice off the evaporator surface, **Figure 27.1**. The auger forces the ice upward and out a chute on the side where it moves by gravity to the ice storage bin. The auger's cutting surfaces, called *flights,* cut or shave the ice off the interior of the flooded evaporator cylinder. In some modern ice flake machines, the flights on the auger add pressure to the ice toward the top of the auger. This pressurized ice can then be cut or extruded through small openings near the top of the auger to make many shapes and forms of ice. This type of ice-making machine has a constant harvest cycle, as long as the compressor and auger are operating.

A geared motor is used to turn the auger. The motor may be located on the top or the bottom of the auger. **Figure 27.2** shows a gear motor machine located at the bottom. The auger is in a vertical position and must have a shaft seal where the auger leaves the gearbox. If the gear motor is on top of the auger, the shaft seal prevents gear oil from seeping into the ice, **Figure 27.3**. When the gearbox is on the bottom of the auger, the shaft seal prevents water from entering the gearbox, **Figure 27.4**.

The level of the water in the evaporator is determined by a float chamber located at the top of the evaporator. This float level is critical. If the level is too low, it may impose an extra load on the gear motor. The lower suction pressure

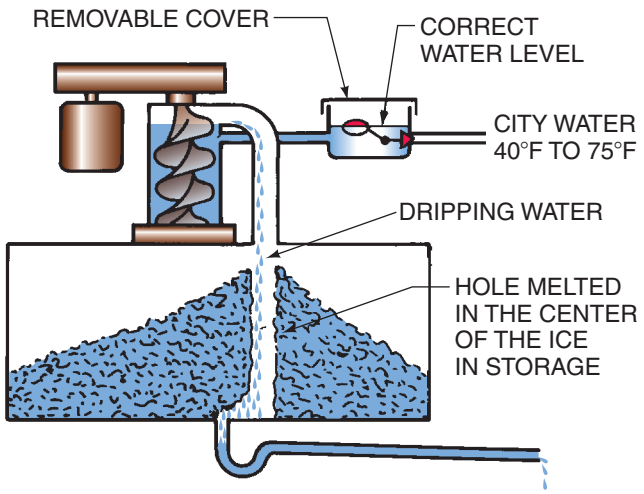
Figure 27.5 When the float level is too high, water will run over and melt ice that has been made. The fresh water must be refrigerated to freezing after start-up.



from too low a water level causes harder ice for the auger to cut. The ice quality may be too hard and the ice maker may not be efficient. In extreme cases, the auger may freeze to the evaporator. In this case, the power of the motor and gears may turn the evaporator out of alignment. If the water level is too high in the evaporator, the auger is doing more work because there is more ice to cut. The motor driving the auger may have a manual reset overload that will shut the motor off and stop the compressor. When the motor reset button must be reset often, suspect that the water level is the problem. Check the seat in the float chamber. A float that will not control the water level may allow water to pour over the top of the chamber during the off cycle. This would impose an extra load on the refrigeration capacity because it must refrigerate this extra water to the freezing point to make ice. Water overflowing the evaporator will drip into the ice bin and melt ice that is already made, causing a loss of ice capacity, **Figure 27.5**.

THE REFRIGERATION CYCLE

The refrigeration cycle for ice flakers is simple and straightforward. A TXV, AXV, or capillary tube can be used as the metering device. However, most modern ice flakers incorporate TXVs for efficiency and capacity reasons. If a TXV is used, low evaporator superheat readings of 3°F to 4°F are common to make sure the ice sheet is full. Often, the evaporator is just a tube coiled around a cylinder, and more than one expansion valve is used in parallel for better refrigerant distribution throughout the evaporator. The tube and cylinder are then both covered with thick, rigid insulation, **Figure 27.1**. Once insulated, the evaporator tubes are not visible. The rest of the refrigeration system is no different from any other refrigeration system containing a suction line, compressor, water- or air-cooled condenser, liquid line, metering device, and evaporator. An EPR valve is sometimes used to prevent a minimum pressure from occurring in the evaporator. An AXV is seen when a constant evaporator pressure is needed.

Ice flake machines are usually critically charged with refrigerant. Weighing in the correct charge will let the ice machine operate to its greatest potential under all conditions. Charging by the frost line, sight glass, or pressure method may create unwanted inefficiencies because an exact critical charge of refrigerant is called for by the manufacturer. A lack of refrigerant charge, usually from a refrigerant leak, mainly shows up as an overheated compressor motor or low ice production capacity. A low-pressure control may open or the mass flow rate of refrigerant may be so low that heat cannot be removed from the evaporator, and low ice production will result.

Often, ice flake machines can be retrofitted to a parallel refrigeration system used in larger supermarkets. In this situation, the compressor and condenser from the parallel refrigeration system are used. Pressurized liquid from the liquid header of the parallel system is routed into the ice flaker. The pressurized liquid then encounters the metering device of the packaged ice flaker. The refrigeration effect takes place in the flooded evaporator freezing cylinder, and ice is cut off the freezing cylinder by the auger. An EPR valve is used on the suction line in this application to prevent too low an evaporator pressure from occurring. Liquid-line solenoid valves are also used to start and stop the liquid flow into the expansion valve. The suction gases exiting the evaporator are routed back to the suction header of the parallel compressor system. Parallel refrigeration systems are covered in detail in Unit 26, "Applications of Refrigeration Systems."

BASIC TROUBLESHOOTING

When water is frozen in the evaporator freezing cylinder, minerals from the water are left behind and often become attached to the interior cylinder walls and other surface areas of the ice flaker. Using an approved ice machine cleaner will dissolve these minerals. Always follow the manufacturer's instructions when using an ice machine cleaner or serious damage can result to the ice machine. When minerals do build up on the interior of the evaporator, they add resistance to the flow of ice that is being cracked, cut, or broken away by the auger and then pushed out of the cylinder. This dirty condition causes the evaporator to run at a lower suction pressure and thus a colder evaporator temperature, which results in the ice being very hard. Often, noises like two pieces of rigid Styrofoam being rubbed together, a crunching sound, or a loud squeal will come from the freezing cylinder when minerals are allowed to build up. A regular clicking sound usually indicates a mechanical problem, which could be in

the drivetrain and is probably a chipped gear. A high-pitched noise is probably a worn auger drive motor. It is a good idea to start troubleshooting by simply observing and listening to the ice flaker. Ask the owner if there have been any strange or unusual noises coming from the ice machine. If the answer is yes, a cleaning may be needed. The auger and freezing cylinder may have to be inspected and removed to look at the interior of the evaporator freezing cylinder or evaporator, **Figures 27.6(A)** and **(B)**. An ice flaker's evaporator cylinder is made of either stainless steel or a more porous material such as brass or copper. If made of copper, the cylinder must be plated as required by the National Sanitation Foundation (NSF). Nickel is typically used as the plating material. Stainless steel is much more durable and resists corrosion better than copper or brass. However, copper is better for heat transfer. Manufacturers who use stainless steel for the ice-making surfaces usually produce some sort of innovative design that enables the heat transfer qualities of the evaporator surface to come close to that of copper.

The auger and evaporator surface must be very clean and free from any score marks or scars. If a bearing failure has occurred, and the auger has touched the evaporator or freezing cylinder's surface, usually either the evaporator or the auger, or sometimes both, must be replaced. Always follow the manufacturer's instructions for disassembly. Drain the freezing cylinder and allow it to dry before inspecting it. A wet piece of equipment may look clean, but once it has had time to dry, mineral buildup will be obvious. Mineral deposits also cause stress to the auger motor, auger bearings, and the gear reducer. It is these components that cause most of the service calls for ice flakers, not the refrigeration system.

Most ice flakers have a gear reduction drive that reduces the auger drive motor's speed from about 1725 rpm to 9 to 16 rpm. These drives are generally maintenance-free; however, if water has been entering the gear case, it should be disassembled and inspected. Often, there is a coupling between the auger and the output shaft of the gear reducer. This coupling may need to be lubricated on a regular basis. All ice flakers have bearings that allow the auger to rotate. The bearings can be either a sleeve bearing or a ball bearing. Bearings are a high-wear item and annual inspection is recommended. Consult the manufacturer's maintenance manual to become familiar with the ice machine before starting this procedure. **Figure 27.7** shows a self-contained ice flake machine with one side cover removed. Notice the water reservoir, the gear drive, the insulated evaporator, and the ice chute that delivers ice to the storage bin. **Figure 27.8** is an exploded view of most of the mechanical parts that make up an ice flaker.

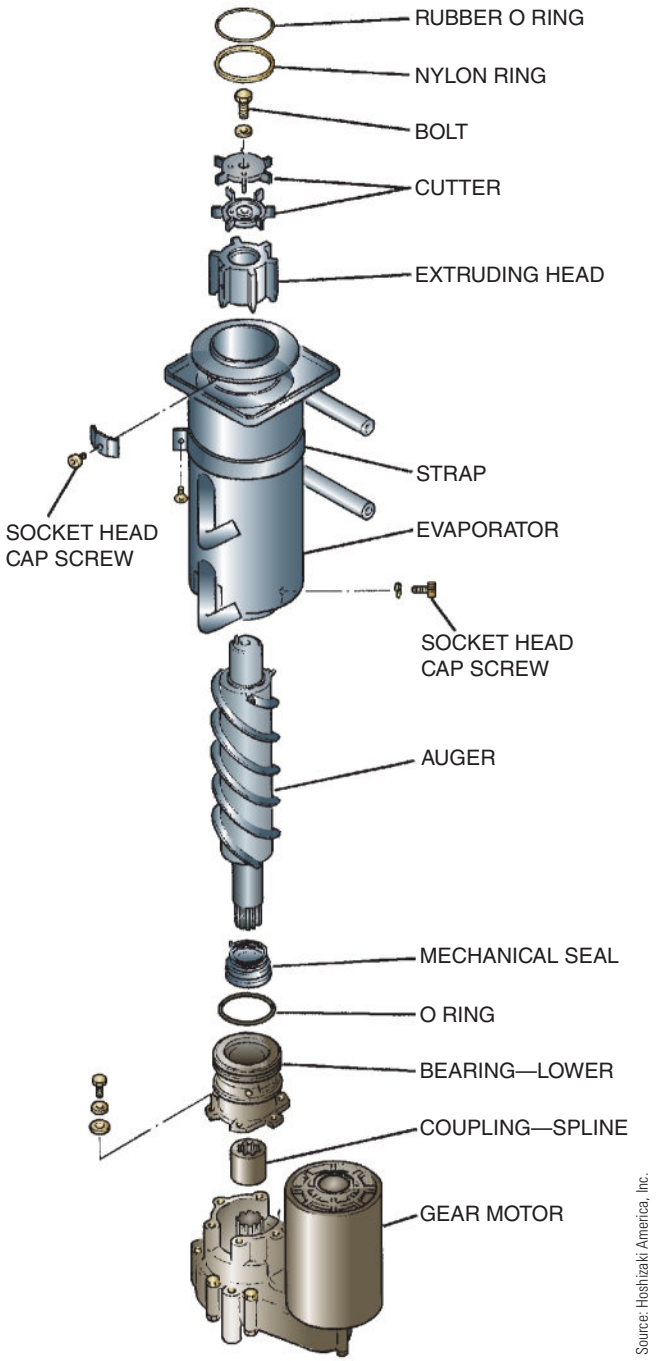
Figure 27.8 An exploded view of most of the mechanical parts of an ice flaker.



The gear motor assembly is more prone to failure than any other part in the ice flaker because of the pressures and stresses put on it. As the auger turns and extrudes the ice, the gear motor senses all of these strains. Because of this, some manufacturers use an open-type gear assembly. This means the gear assembly is open to the atmosphere. Usually, there is a hole in the housing of the gear assembly for hot grease to exit during long run times with extreme stress on the drive motor, which causes high amperage draw and excessive heat. The drawback to the open-type gear drive assembly is that moisture can enter the hole in the drive housing during cool-down periods. This deteriorates the lubricating effect of the grease in the drive housing. Excessive gear wear and a shorter gear life will be the outcome. Some manufacturers use gears made of a fibrous material designed to strip or break when the motor and gearbox are put under heavy loads.

It is important that the auger does not wobble within the freezing cylinder or evaporator. Sleeve-type alignment bearings made from a slippery poly material with a graphite base keep the auger from wobbling on some machines. Others use grease-lubricated steel roller bearings. Grease can leak out, causing overheating of the bearings. This usually causes auger wobble. Auger wobble causes the cutting edges of the auger to scrape the freezing cylinder's wall. Excessive wear on all surfaces, and metal shavings in the ice, will result.

Manufacturers of ice flakers install thermal overload controls in the motor windings or a manual-reset, current-type overload control. In fact, most modern ice machines have solid-state control boards with status indicators that act as self-diagnostic tools. There are usually light-emitting diodes (LEDs) or indicator lights to inform the service technician whether the ice flaker is operating normally, **Figure 27.9**. The lights may indicate the status of the auger drive motor, auger relay, compressor relay, low- or high-pressure control, reservoir level, bin level, starting mode, condenser temperature, discharge

Figure 27.9 A solid-state control board with light-emitting diode (LED) status indicator lights used for self-diagnostics.

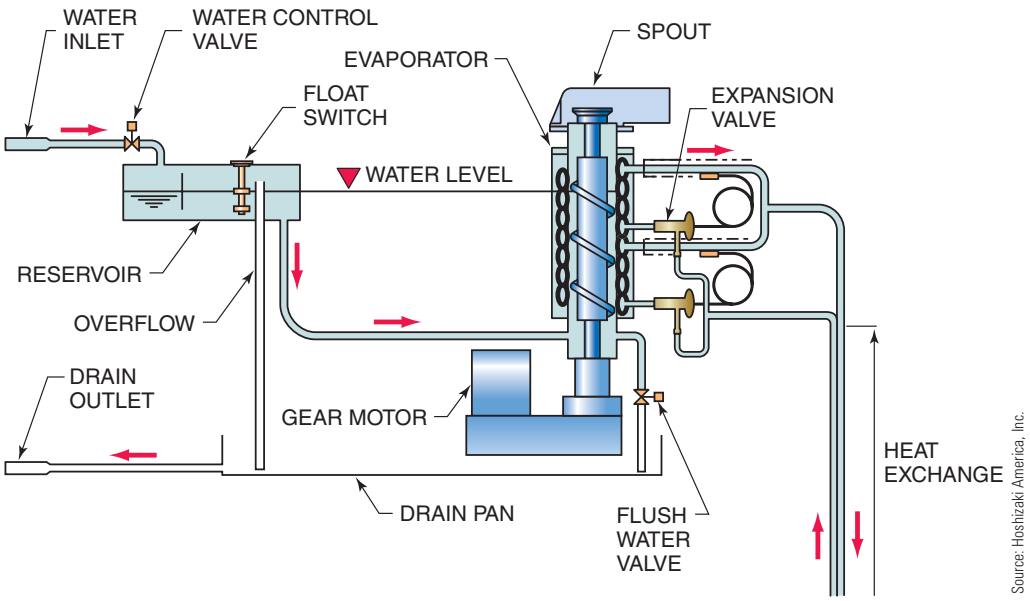
line temperature, and more. The type of control board and its control scheme varies from model to model. When the drive motor is stressed from mineral buildup on the evaporator freezing cylinder or lack of lubrication, the extra motor torque causes higher amperage draws, which create excessive heat. The overload devices will shut the unit down, and a manual reset will often be needed. An annual cleaning with an approved ice machine cleaner along with a bearing inspection will keep the ice flake machine running longer and quieter. Remember, the buildup of mineral scale on the freezing cylinder's surface, caused by poor water quality or lack of a preventive maintenance cleaning schedule, leads to most service problems.

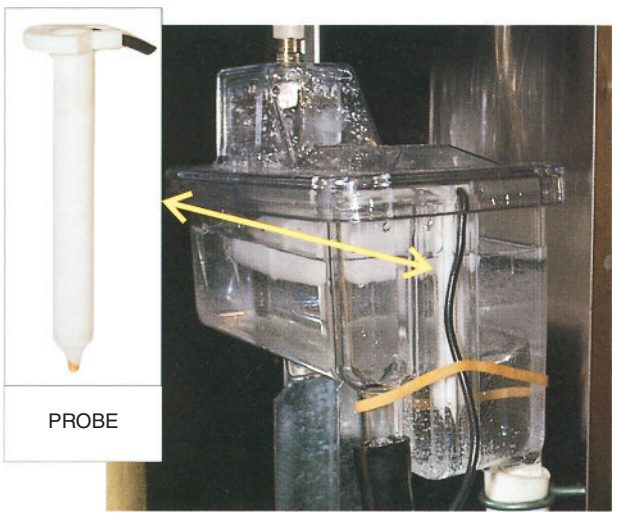
THE WATER FILL SYSTEM

One method of controlling the amount of water coming into an ice flaker's water reservoir is a dual float switch and a water control valve, **Figure 27.10(A)**. Another manufacturer may use

Figure 27.10 (A) The water system diagram of an ice flake machine. (B) A conductivity probe in the water reservoir.



(A)



Water Sensor

- Conductivity probe located in the ice machine's water reservoir.
- Connected to the AutoSentry control board.

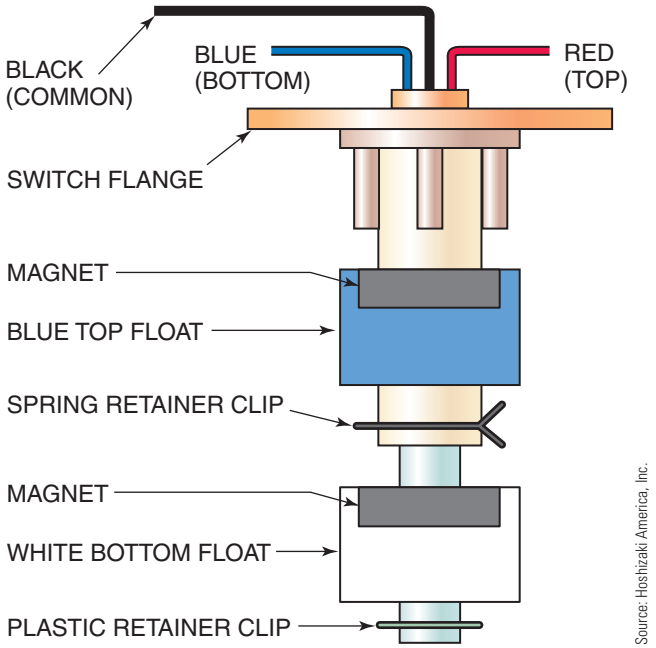
Figure 27.11 A dual float switch that controls reservoir water level and low-water shutdown timing.



a conductivity probe or water sensor located in the ice machine's water reservoir, **Figure 27.10(B)**. This probe senses an electrical path from ground to the tip of the sensor. It is connected to an electronic control board. The sensor eliminates low- or no-water conditions and cannot be affected by adverse water conditions.

With a dual float switch, the water inlet control valve is solenoid-operated and energized through the switch, **Figure 27.11**. The solid-state control board, **Figure 27.9**, monitors both of these components. The reservoir feeds water by gravity to the evaporator freezing cylinder. The dual float switch maintains the proper level of water in the reservoir and also provides for an ice machine shutdown in case of low water level. The dual float switch is usually made of two reed switches and two floats. The reed switches are opened and closed by magnets inside the floats. As ice is made, the reservoir's water level drops, and the top float opens a set of latching relay contacts. Now the bottom float has control of the water control relay and the water inlet control solenoid. As the reservoir's water level continues to drop, another set of contacts opens by the action of the bottom float switch. This action deenergizes the water control relay, which also closes a circuit to the water inlet valve solenoid. At the same time, the control board energizes a low-water shutdown timer. The reservoir is now filled, and the two float switches swap jobs. The bottom switch becomes a latching relay and the top switch reenergizes the water control relay. As the top float rises, the low-water timer is shut off and the water inlet control solenoid valve is deenergized. This type of arrangement keeps a proper amount of water in the reservoir, prevents short cycling of the water inlet solenoid valve, and provides for low-water safety shutdown. **Figure 27.12** illustrates a wiring diagram of a modern ice flake machine and shows the control water valve, water control relay, control timer, and water inlet solenoid valves.

Water levels can also be sensed and controlled by a probe located in the water reservoir. The probe senses water level and relays the message to an electric water valve. The probe should be removed from the reservoir and cleaned at least twice a year.

FLUSH CYCLES

Many manufacturers build in an automatic water flush cycle for ice flakers. When water freezes, minerals are left behind. As mentioned earlier, these minerals can build up in the evaporator freezing cylinder and cause maintenance problems and poor ice quality. A way to get rid of this unwanted buildup of minerals is to flush out the water system on a periodic basis. One manufacturer's control scheme shuts down the refrigeration cycle for 20 min every 12 hours to allow the water system to drain. When to initiate these flushing periods may be adjusted. The control board energizes a solenoid-operated water flush valve, which opens a drain on the bottom of the evaporator freezing cylinder, **Figure 27.10(A)**. This action drains the reservoir, freezing cylinder, and connecting piping of all impurities. The reservoir is then refilled with clean, fresh water. A mechanical or solid-state timer can initiate the flush cycle, which energizes a gravity-flow flush solenoid valve. Manual flushing can also be performed for service purposes. The wiring diagram in **Figure 27.12** shows the flush timer, flush switch, and flush water solenoid valve. A service technician must understand the sequence of events when servicing ice flakers. It is important to remember the flush timer when diagnosing a problem if the unit will not start. Manufacturers often provide a cam wheel, which can be turned manually to advance the flush timer. This allows the unit to start if it had been in a periodic flush mode.

Some models of ice flakers drain the entire water system each time the unit cycles off. This off-cycle draining can be done without the expense of a timer motor. However, when running time is heavy, flushing is not accomplished as often, and trace amounts of minerals may build up in the water system.

BIN CONTROLS

Once the ice-holding bin is full of ice, some sort of automatic control must terminate the operation of the ice flake machine. If this is not done, flaked ice may pile up in the bin and ice chute and overflow. The ice may spill into the ice flake machine's mechanical parts and eventually spill onto the floor. Water from the melting ice may also cause damage to mechanical parts in the ice machine itself or to nearby flooring.

In the past, there have been many ways to control the overflow condition. The following are some of the methods used for bin control:

- Mechanical flapper-type device controlling a microswitch
- Infrared electric eye
- Sonar
- Thermostats
- Liquid-filled bulbs

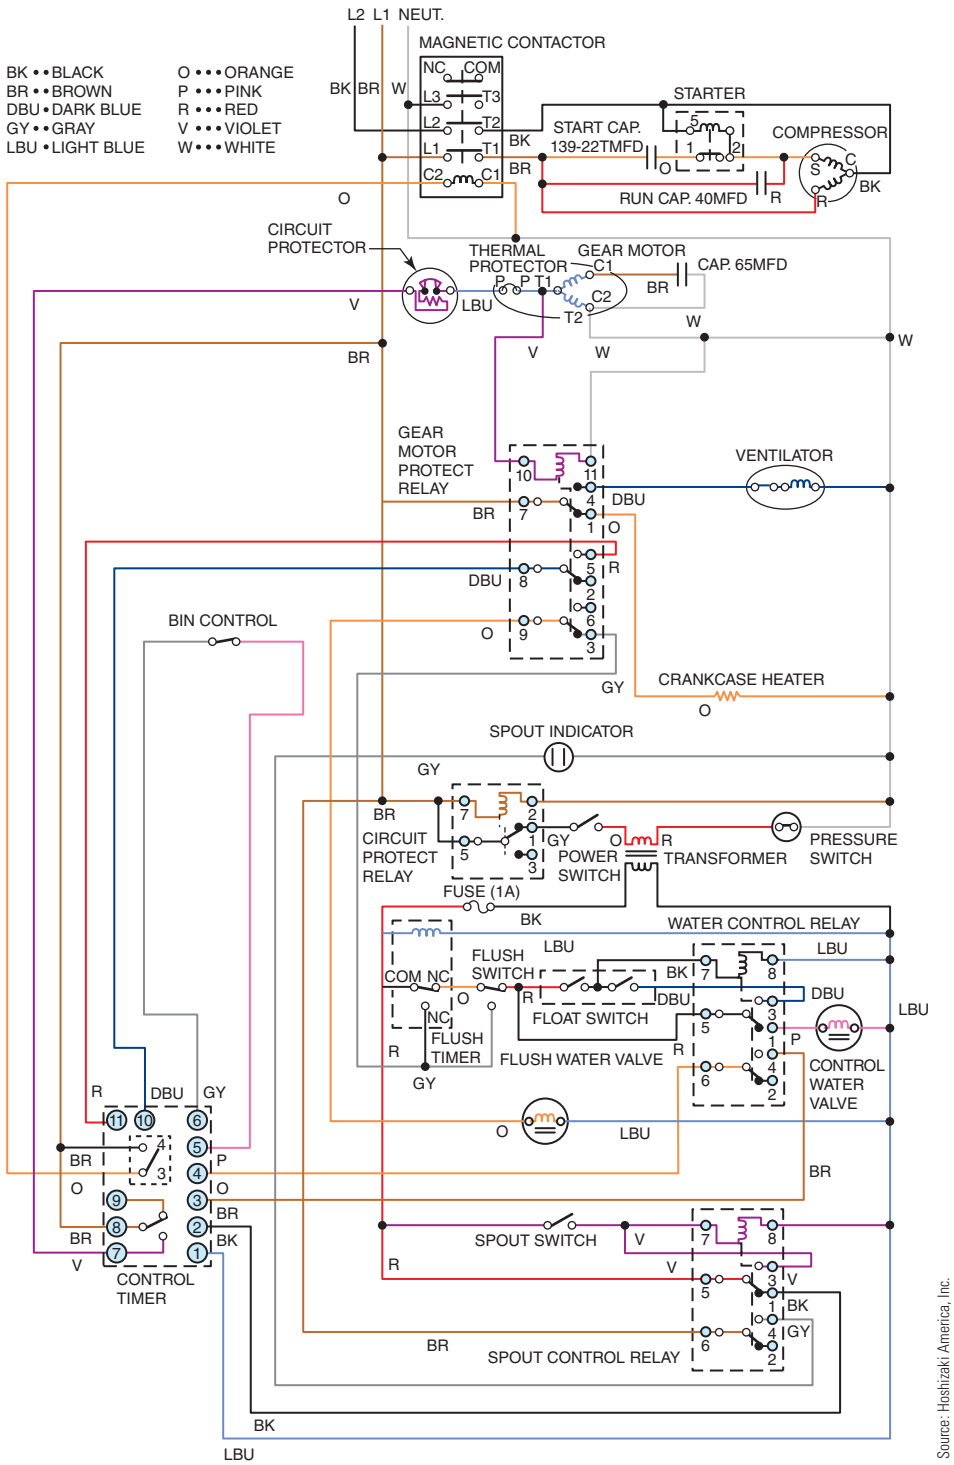
Figure 27.12 The wiring diagram of an ice flake machine.



Mechanical flapper-type devices are usually located in the spout. They simply sense backed-up ice by pressure and activate a microswitch. The microswitch shuts down the operation of the ice flake machine. When in the normal position, they are an electronic control with a known amount of resistance. When the paddle is pushed out of its normal position by ice, the resistance value in the electronic control changes and the unit shuts down in a set amount of time.

Infrared electric eyes sense the buildup of ice by infrared technology. This control allows the ice machine to shut down before the ice chokes the spout opening. Usually, two infrared sensors are mounted on the outside of the ice chute's base, and they are powered and controlled by a solid-state controller. The sensors must be kept clean so that they can see one another. During normal operation, ice passes between two ice-level sensors and interrupts the infrared beam just momentarily,

keeping the machine running. However, if ice builds up and blocks the path between two infrared sensors for 6 sec or longer, the machine shuts down. If the path between the infrared sensors remains clear for more than 10 sec, the ice machine will restart. In most cases, this type of bin control must be removed at least twice a year and cleaned with a soft cloth.

Sonar controls use sonic or sound waves and vibrations, which are reflected back to the control from the ice. One disadvantage of infrared and sonic controls is condensate forming on the lenses, making these controls less accurate.

Thermostats often have liquid-filled sensing bulbs placed somewhere in the ice chute or simply at the top of the ice bin. As the ice touches the sensing bulb of the thermostat, the ice machine terminates its freezing cycle, usually within 10 sec. Most bin thermostats are adjustable and can be checked by placing a handful of ice on the remote bulb and timing the shutdown.

ICE PRODUCTION AND PERFORMANCE DATA

When flake ice machines operate at the proper refrigerant charge, ice production depends on two main factors:

- Inlet water temperature
- Temperature (ambient) surrounding the ice machine

Notice in **Figure 27.13** that the ice production in pounds per 24 hours decreases as the ambient temperature around the ice machine gets warmer. The top row shows four ambient temperatures ranging from 70°F to 100°F. Assuming a constant 50°F entering water temperature, at a 70°F ambient, the ice production is 2010 lb per day. However, as the ambient rises to 100°F, the ice production falls to 1570 lb per day. Italicized figures are in kilograms per day.

Figure 27.13 Ice production and other system performance data for an ice flake machine.

	Ambient Temp. (F)	Water Temp. (F)					
		50		70		90

This loss of ice production with a hotter ambient around the ice machine happens because of more heat gain coming into the ice. For air-cooled machines, a hotter ambient causes a higher head pressure for the refrigeration system. This causes an increase in compression ratios and a loss of efficiency, and thus less ice production. Also notice in **Figure 27.13** that as the water temperature coming into the ice machine increases from 50°F to 90°F, the ice production drops from 2010 to 1895 lb per day. This is assuming a constant 70°F ambient air temperature. This happens because it now takes more energy and refrigeration effect to cool the warmer water down to freezing temperatures. The figure also includes electricity consumption, water consumption, evaporator outlet temperature, head pressure, and suction pressure, as they depend on the surrounding ambient air temperature and inlet water temperature. Notice that head pressure and suction pressure both increase as the ambient temperature around the ice machine increases.

ADJUSTING ICE FLAKE SIZE

Some ice flakers can be adjusted to alter the size or shape of the flake ice to meet the needs of many customers. Flake ice is used in packing produce, fish, and poultry and to fill a salad bar or display case because ice flakes pack tightly and keep the products cool and fresh. One method of adjustment is to rotate an ice cutter at the top of the auger. Since the pressure applied to the ice comes from the last couple of inches of the auger flights on some machines, aligning a small, medium, or large cutter opening with the pressure points on the flights of the auger will change ice size. Small, medium, or large flakes can come from one ice machine. Another method is to change the cutting heads located on the upper side of the auger, **Figure 27.14**. One cutter head will produce fine flakes and another will produce coarse flakes.

The extrusion head can also be changed on some ice flakers, which allows one ice machine to produce both cubelet and flake ice. The size of the cubelets or nuggets can be increased or decreased. Cubelet or nugget ice is about the size of a small marble. The flake ice is extruded through small openings in the extrusion head, squeezing out additional water, which makes the ice more dense and compact. Cubelet or nugget ice lasts much longer than flake ice when submerged in a drink. The health care industry uses cubelets or nuggets because they are much easier to chew than larger cubes, and sick and elderly people are less likely to choke when chewing them.

27.3 MAKING CUBE ICE

Several methods are used to make several types of cube ice in package ice makers. Cube ice should be clear, not cloudy. Clear ice is usually preferred for cooling beverages. Ice with a high mineral content or that is aerated (has minute air bubbles inside) will appear cloudy and is not as desirable to some people because of its appearance. Some of the design features of the cube ice maker result in ice that is very clear. Clear versus cloudy ice will be covered in Section 27.5, "Water and Ice Quality" later in this unit.

CUBE ICE

CRESCENT-SHAPED ICE CUBES. Making a crescent-shaped ice cube involves running water over an evaporator plate in which the copper evaporator tubing is soldered onto the plates at regular intervals. **Figure 27.15** shows two stainless-steel evaporator plates and connected tubing for making crescent-shaped ice cubes. Stainless steel is often used on evaporators because it is durable, very sanitary, and resists corrosion. It is also much less porous than copper, brass, or nickel. The copper serpentine tubes soldered to the evaporator are oval to increase heat transfer; the shape provides more surface area in contact with the stainless plates.

During the freeze cycle, water from the reservoir is circulated to the outside freezing surface; no other water is allowed to enter. Once the water reaches 32°F, ice starts to form on the plates. The coldest point on the evaporator is where the copper serpentine coil contacts the evaporator plate. This is where ice starts to form first and continues to grow outward in a crescent shape. As the ice grows, the reservoir water level

falls because some of the water is freezing into ice. Once the crescent cubes are formed, a float switch in the water sump will open contacts and the harvest cycle begins.

Hot, superheated gas from the discharge of the compressor is circulated through the serpentine coil during defrost. As the heat is transferred to the stainless-steel evaporator, the cubes begin to melt away from the evaporator plate. There will be a film of water between the cube and the plate, which will cause a capillary action and attract the cubes to the plate as they slide down the plate by gravity. As the cubes slide down the plate, they will contact dimples, which break the capillary attraction. This will release the cubes from the plate, and they will fall into the ice bin. Water is allowed to flow during the defrost cycle, but it flows on the opposite evaporator plate. This absorbs heat from the copper coils where hot gas is being circulated and transfers this heat to the freezing surface. This is referred to as water-assisted defrost.

CELL-TYPE ICE CUBES. Cell-type ice cube machines usually have vertical evaporator plates with water flowing over the individual cells, **Figure 27.16**. A plastic water curtain covers the evaporator to prevent splashing **Figure 27.20**, and a serpentine evaporator coil is soldered to the back of the evaporator plate, **Figure 27.17**. The water is distributed over the cells by a water pump through a water distributor tube, shown at the top of **Figure 27.16**, and the tube has evenly spaced holes for even water distribution. The tube is usually removable for cleaning and repair purposes, **Figure 27.18**, and has an adjustable restrictor to let the service technician adjust the water flow rate, **Figure 27.19**. If the water flow is too slow, minerals in the water freeze, causing cloudy ice. Ideally, only water should be allowed to freeze on the evaporator plate. This requires the right water velocity over the plates, which can be adjusted with the restrictor on the water tube. Ice will gradually form on each individual cell until it bridges with the neighboring cells. Ice bridging forms one large ice slab the size of the evaporator itself. Once the ice slab has the proper

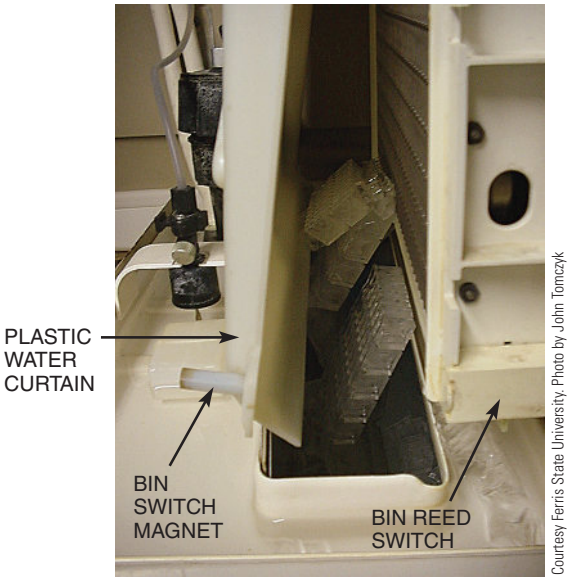
Figure 27.20 An ice slab partially breaking up as it collides with other ice in the storage bin.



bridge thickness, a harvest or defrost cycle is initiated and the ice slab falls into the ice storage bin. Ice harvests are covered in detail later in this unit.

The proper bridge thickness is important for the individual ice cubes to be easily separated when scooped out of the ice storage bin. When a server taps the ice slab in the storage bin with an ice scoop, it should easily break up into individual cell cubes. Most of the time, when the ice slab drops off the evaporator during a harvest period, it partially breaks up as it collides with other ice in the storage bin, **Figure 27.20**. However, as the ice storage bin starts to fill, the distance the ice slab has to fall is reduced. If the bridge thickness is too great, the ice slab will not easily break up into individual cubes. A bridge thickness of 1/8 in. is not uncommon. The ice bridge thickness is adjustable through an ice thickness probe's adjustment screw, **Figures 27.21(A)** and **(B)**. **Figure 27.21(C)** and **(D)** show a different style of ice thickness probe. **Figure 27.16** also shows the ice thickness probe and its location near the cell-type evaporator.

The centrifugal water pump, which gets its water from a water reservoir, is generally a fractional horsepower, alternating current motor, **Figure 27.22(A)**. The water pump may

deliver water to more than one evaporator, **Figure 27.23**. The water reservoir's water level can be controlled by a float mechanism, **Figure 27.24**. The float controls the amount of incoming fresh water to the water reservoir. The float control is adjustable and also controls the level of water in the reservoir. As the water freezes on the evaporator's cells, the water reservoir level starts to drop. Instantly, the float or water level probe senses this drop in water level and slightly opens a valve to let more fresh water into the reservoir. This action keeps just the right level of water in the reservoir for the water pump to use. Too low a water level in the water reservoir allows the water pump to suck a mixture of water and air, which has a detrimental effect on ice quality. The water that does not freeze on the evaporator's cells will trickle into a water trough and eventually make its way into the water reservoir by gravity.

A water level probe, **Figure 27.22(A)**, can also control water levels in the reservoir. It is usually nonadjustable and controls an electric, solenoid-operated water fill valve. One manufacturer uses a water level sensor that provides an electronic controller with two important pieces of information, **Figure 27.22(B)**. As the machine freezes ice, the water level sensor's top photoelectric eye receives infrared light through an open control slot in the float system. When the water falls far enough, the float stem's slot is too low to allow the light to pass, and the stem breaks the top electric eyebeam. This signals the controller to initiate a harvest cycle. Also, when water flows into the reservoir, the float lifts the float stem. When the bottom electric eyebeam is blocked by the solid plastic body of the float stem, the controller knows that the reservoir is full. Water will continue to flow for a predetermined amount of time to overfill and rinse the reservoir.

SEQUENCE OF OPERATION (FREEZE AND HARVEST CYCLE)

Figure 27.25(A) is a refrigeration system diagram of a cell-type ice maker that has two evaporators. **Figures 27.25(B)–(D)** show the water and refrigeration system, freeze cycle, and harvest cycle on one manufacturer's ice maker. **Figure 27.26** is a refrigeration system diagram of a single-evaporator system in the freeze cycle. Every manufacturer seems to have its own control schemes and sequence of operations, so it would be impossible to cover all control schemes in this unit. A typical control scheme with its sequence of operation for a cell-type ice maker is described in the following paragraphs. *The refrigeration compressor comes on for about 30 sec before the water pump turns on. This allows the evaporator to be prechilled. Prechilling makes for a very cold evaporator when it finally experiences water flow and helps prevent slush from forming in the water sump. Slush may interfere with the water flow to the water pump and may also cause an ice dam.* The water pump comes

Figure 27.23 A water pump serving two evaporators.

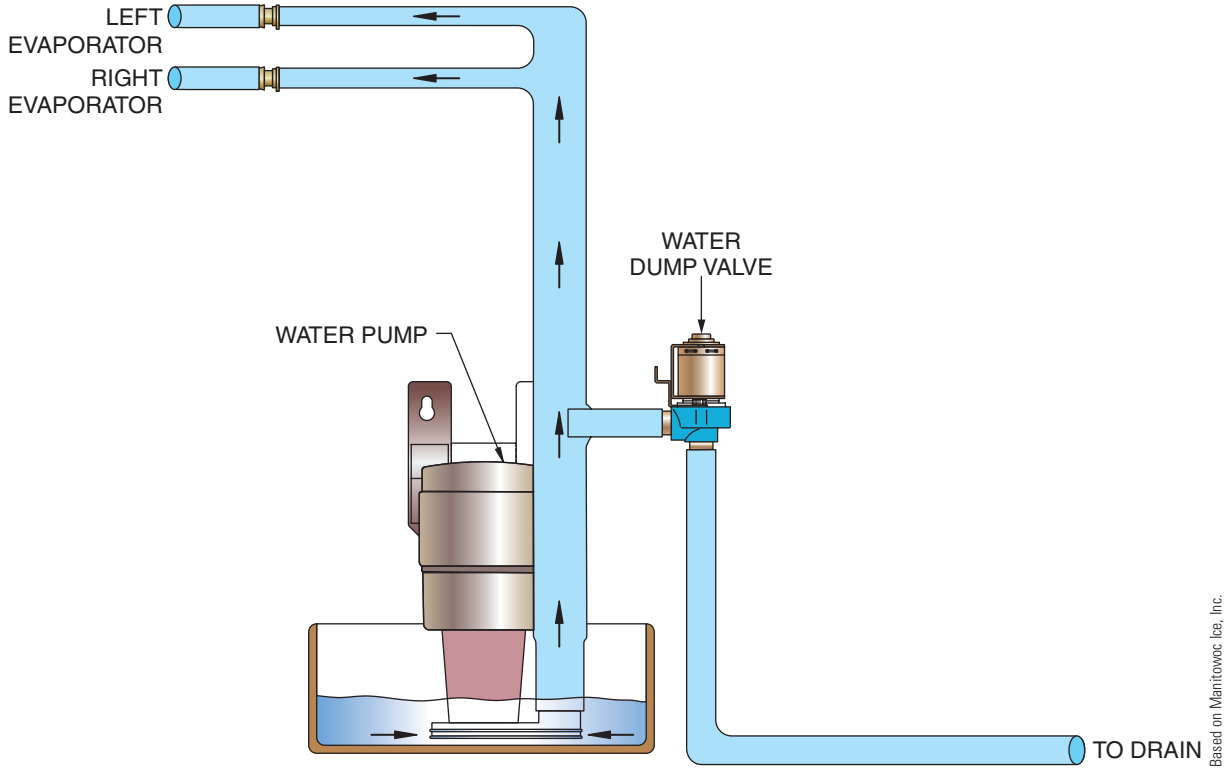

Figure 27.24 A water reservoir, float mechanism, incoming water line, and water pump.

Courtesy Ferris State University. Photo by John Tomczyk

on after about a 30-sec prechill. Water is forced through the water distribution tube and evenly distributed onto the cell-type evaporator where it begins to freeze. Either a float mechanism or an electric, solenoid-operated water fill valve keeps the water in the reservoir at the proper level. Once the right thickness of ice has formed on the evaporator, water flowing over the ice contacts the ice-thickness probe.

Water has to contact the ice-thickness probe for at least 7 sec before an ice harvest is initiated. This keeps the harvest cycle from prematurely initiating due to splashing. Often, ice machines cannot begin harvest until their freeze cycles have been underway for a certain amount of time. A period of 6 to 7 min is not uncommon. This time period is referred to as a freeze-lock time. Freeze lock allows enough ice to form on the evaporator before a harvest is initiated and prevents an evaporator cookout or overheating from a premature harvest. Overheating can cause damage to the metallic plating on some evaporator surfaces.

The diagram in **Figure 27.27** shows a system during the harvest cycle. Once the ice-thickness probe contacts water for more than 7 sec, the hot gas solenoid valve located on the compressor's discharge line is energized, **Figure 27.28(A)**. The compressor continues to pump superheated gas through the evaporator. This hot gas warms the evaporator, causing the sheet of cubes to slide into the storage bin. One manufacturer uses a harvest bypass valve that is open for just a few seconds each harvest period, **Figure 27.28(B)**. The purpose of this valve is to add the correct amount of refrigerant to the harvest circuit to promote a good release of ice.

(B)

At the same time, the water pump continues to run and the electric, solenoid-operated water dump valve, **Figure 27.29**, *is energized for a specified amount of time, usually 45 sec.* **Figure 27.30(A)** *shows sump water being routed down a drain during the harvest cycle when the dump valve is energized. This action purges the water from the sump and gets rid of any residual minerals from the previous freeze cycle, which is very important for clear, hard ice.* The water fill valve will energize for the last 15 sec of the 45-sec water sump purge time. This time may be adjustable on an electronic microprocessor-based unit. If a float mechanism is used, the float valve will automatically fill the water sump to the proper level.

Figure 27.29 An electric, solenoid-operated water dump valve.

As the ice sheet falls off the evaporator, a water curtain swings out and opens a bin switch. This opening and closing of the bin switch ends the harvest cycle and initiates the next freeze cycle. The bin switch is a reed switch that is operated by a magnet. The magnet is attached to the water curtain, and the reed switch is attached to the evaporator mounting bracket, **Figure 27.20**. The bin switch has three functions: to terminate the harvest cycle, to return the ice machine to the freeze cycle, or to cause an automatic shutoff.

If the ice storage bin is full at the end of a harvest cycle, the sheet of ice cubes will not let the water curtain close, **Figure 27.31**. If after a certain time period, usually 7 sec, the bin switch is still open, the ice machine will shut off automatically. It will stay off until the ice in the bin is removed and the water curtain swings back to close the bin switch. A minimum off period of 3 min is generally needed before the ice machine can automatically restart.

On an initial start-up, or after an automatic shutoff, the water pump and the water dump valve are energized for a specific time period, usually 45 sec, **Figure 27.30(A)**. This gets rid of the old, mineral-laden water. One manufacturer uses a purge valve located just above the water reservoir for controlled draining of water from the reservoir, **Figure 27.30(B)**. When it is open and the water pump is on, water flows through this valve to the ice machine's drain. This dilutes the amount of mineral scale in the reservoir. The amount of water purged is adjustable to accommodate local water conditions. *The solenoid-operated hot gas valve is also energized for a specific time period during this start-up. This allows the system refrigerant pressures to equalize between the high and low side for an easier compressor start-up.*

The compressor starts after the 45-sec water purge and remains on during the freeze and harvest cycles. The compressor being on during the harvest cycle ensures quality superheated gas for melting the ice slab from the evaporator. The water fill valve is also energized at the same time the compressor is on. The water level sensor shuts off the water fill valve when the water level is satisfied. The electronic controller will not allow the water fill valve to be on longer than 6 min to prevent flooding. On air-cooled units, the condenser fan motor is energized with the compressor. **Figure 27.32** is an electrical system diagram shown in the freeze cycle.

Many manufacturers supply electrical diagrams with electrical conductor lines in bold print to illustrate which components are energized during a certain part of the electrical

sequence of operation, **Figure 27.33**. This greatly assists the service technician with any systematic troubleshooting problems that may arise with the ice machine. An energized parts chart may also be available from the ice machine manufacturer to assist the service technician in systematic troubleshooting, **Figure 27.34**. The energized parts chart tells which control board relay and contactor is energized, when, and how long. These charts, along with the electrical diagrams, can make the ice machine's sequence of operation easier to understand.

ICE HARVESTS

Most ice makers use a hot gas harvest or defrost to melt an ice sheet off the evaporator. **Figure 27.28** is a system diagram of an ice maker in the hot gas defrost mode. Notice that superheated gas is routed through the evaporator. As the ice sheet absorbs heat from the superheated gas, the gas becomes saturated. As more heat is absorbed from the saturated gas, it can eventually form a saturated liquid that can become a subcooled liquid. This liquid will travel to the suction line and eventually to the compressor. *Some manufacturers install a suction-line accumulator just before the compressor on the suction line in order to accumulate and vaporize this liquid before it reaches the compressor.* However, if the system has no suction-line accumulator, liquid refrigerant can reach the compressor crankcase and dilute the oil in the crankcase. Liquid refrigerant returning to the compressor while the compressor is operating is called **liquid floodback**. Liquid floodback is covered in detail in Unit 25, "Special Refrigeration System Components." Liquid floodback can cause serious compressor problems because of the diluted oil in the crankcase. Bearings and other moving parts in the crankcase can be scored from the inadequate lubrication of diluted oil. The returning liquid refrigerant eventually boils off in the compressor's hot crankcase, which causes oil foaming. A cold and sweating crankcase will result. This foaming of oil and boiling refrigerant can get sucked up into the suction valves of the compressor. Extremely high pressures can result, and valve and valve plate damage can occur. If any liquid refrigerant gets compressed, *wet compression* will result. Wet compression occurs when the compression stroke of the compressor vaporizes any liquid in its cylinder. The vaporizing refrigerant in the cylinder absorbs a lot of the heat of compression, leaving a cool cylinder. The discharge temperature will also be much cooler.

Many manufacturers install a discharge-line thermistor, **Figure 27.35**, to sense the discharge-line temperature. If it falls below a certain temperature—for example, 90°F—during a defrost period, severe liquid floodback is occurring. Since the discharge thermistor is an input to the microprocessor, the ice machine will automatically be taken out of defrost by deenergizing the hot gas solenoid. In the case of dual evaporators, just one evaporator will be taken out of defrost. Once the discharge-line temperature increases, the evaporators will be put back into defrost. This cycling of the hot gas solenoid will repeat until all of the ice has been harvested off the evaporators.

As mentioned earlier, once the ice slab grows to a certain thickness, some means of initiating defrost will put the system into a hot gas defrost. If an ice thickness probe or feeler contacts are used, the water flowing over the ice that contacts the probe must have some electrical conductivity for defrost to start. If the water is too pure because too many minerals have been removed, the conductivity will not be correct and a defrost will not be initiated. A pinch of salt may be added to the circulating water to provide conductivity to initiate a defrost when the evaporator is frozen solid. If a defrost cycle occurs after adding salt, it is an indication that the water is too pure. Special controls can be obtained from the ice maker manufacturer so that the defrost will occur under pure water conditions.

Once hot gas loosens the ice slab from the evaporator by melting some of the ice next to the evaporator surface, a suction or attraction force is formed between the ice slab and the evaporator. Air must be introduced between the ice slab and the evaporator to release this suction force. **Weep holes** between the evaporator cells allow air entering from the edges of the ice to travel along the entire ice slab and relieve the suction force. This releases the ice from the evaporator. The weep holes are shown in **Figure 27.36(A).** One manufacturer uses an air pump to force air between the ice slab and the evaporator, **Figure 27.36(B).**

During an ice harvest, the water pump continues to run and the electric, solenoid-operated water dump valve is energized for a specified amount of time. This action purges the water from the water sump either by gravity or water pump pressure. This removes any residual minerals from the previous freeze cycle, which is very important for clear, hard ice. Some older ice machines do not have water dump valves. When a harvest cycle occurs, the water pump turns off. The excess water from the pumping system that is caught in the piping and water distribution header causes an overflow in the water sump. It also causes a siphon effect in the water sump from the momentum of the overflowing water. This siphon effect is planned so that

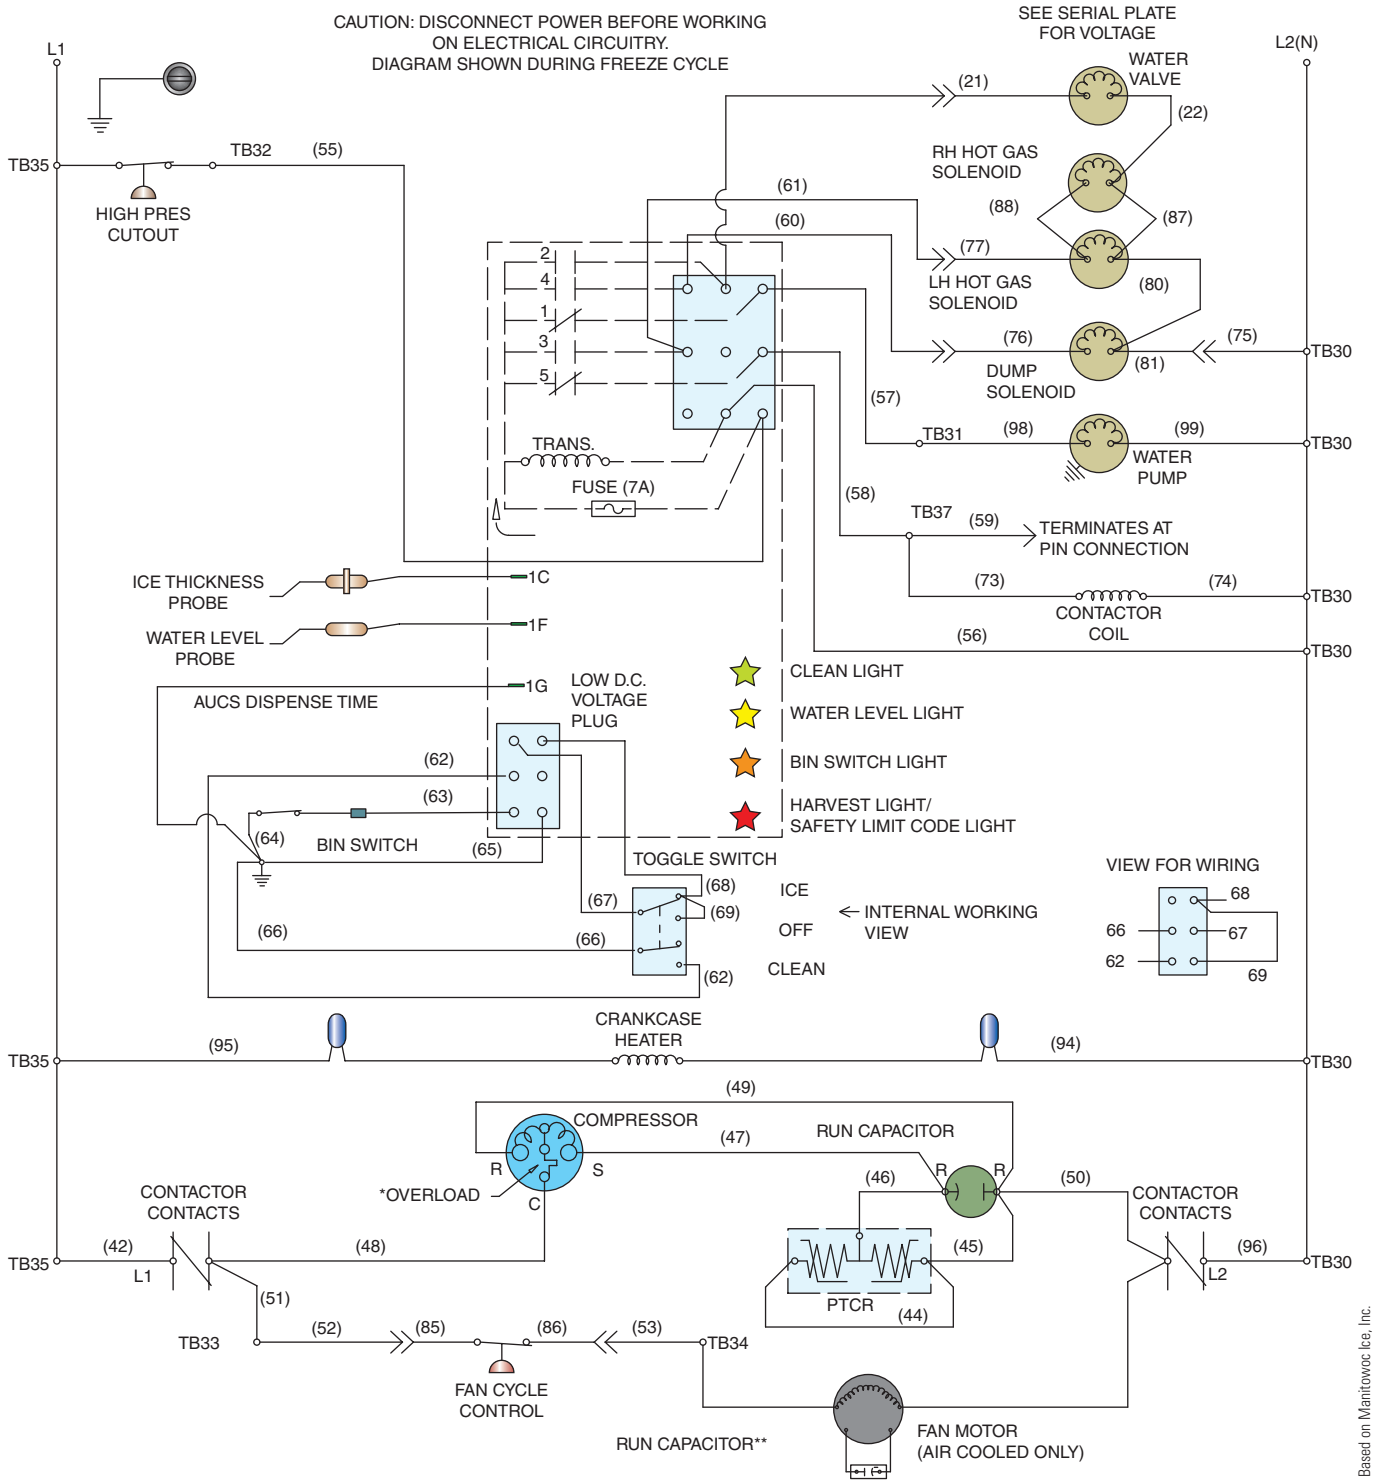
Figure 27.32 An electrical diagram of a cell-type ice maker shown in the freeze cycle.



some of the mineral buildup in the sump water moves down the drain. The siphon effect continues until the water sump is emptied, allowing air to break the siphon. This allows the sump to drain every cycle by gravity and prevents any mineral buildup. The float mechanism then lets fresh water into the water sump. Plumbing the water system to allow the overflow and siphon to occur is very critical on these older machines.

Once the ice falls off the face of the evaporator, something has to sense the falling ice and terminate the harvest cycle. Most of these devices are digital inputs to a controller or microprocessor. **Figure 27.20** shows a magnetic bin

reed switch that is activated by the ice curtain to tell the microprocessor that the ice has fallen from the evaporator. **Figure 27.37** shows an ice curtain switch, and **Figure 27.38** shows a paddle switch activated by a pushrod and ice curtain (the pushrod and ice curtain are not shown in this figure).

Often, a pushrod or probe controlled by a harvest motor, clutch assembly, and cam switch will push the ice off the evaporator during a harvest cycle, **Figure 27.39**. This harvest assist assembly is made up of four major parts:

- Motor
- Clutch assembly
- Probe
- Cam switch

The motor drives the harvest-assist clutch assembly during the harvest cycle. The clutch assembly provides about 6 oz of force against the ice slab. It is a brass cam designed to slip as it pushes against the back of the ice slab during a harvest cycle. The upper half of the clutch slips against the lower half until the ice starts to release off the evaporator plate. The clutch then engages, which allows the probe to push the ice off the evaporator plate into the holding bin.

The probe is a stainless-steel rod, which is driven through a hole in the evaporator by the motor when the clutch engages. To ensure against the probe being frozen into the ice during the freeze cycle, it is recessed about 1/8 in. from the back of the evaporator when not in use. The probe is adjusted by loosening a nut and screwing the probe either in or out. A ball joint between the probe and the clutch allows the probe to pivot while it is being pushed against the ice.

The cam switch rides on the clutch assembly. It is a single-pole–double-throw switch. The switches operate many ice machine components. The normally closed contacts allow the

water pump and water purge valve to operate during the ice-making cycle and sometimes during the first part of the harvest cycle. The normally open contacts of the switch power the harvest-assist motors and hot gas solenoid during a harvest cycle. When the cam's arm starts to ride the lower side of the cam during a harvest, the ice machine starts a freeze cycle again.

CLEAN CYCLE

Most ice machines have an ICE/OFF/CLEAN toggle switch. It is usually a double-pole–double-throw switch that allows the owner or service technician to toggle the

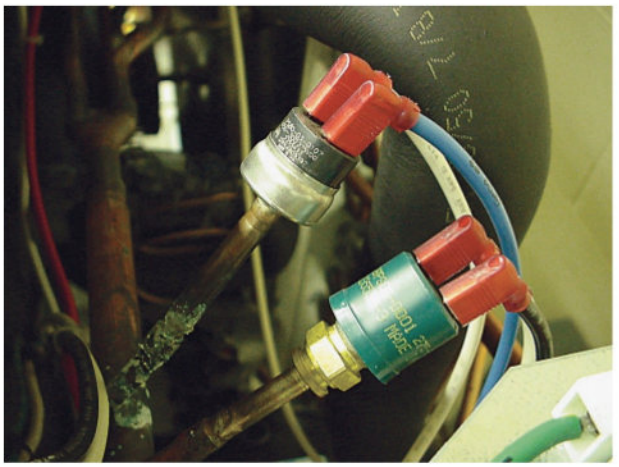
ice machine between either a freeze, off, or clean mode. In most cases, the clean mode energizes the water pump only, allowing the service technician or owner to add the proper chemicals for circulation through the system. Many modern ice makers have a digital switch that simply requires a touch with the fingertips.

ICE MACHINE PRESSURE CONTROLS

Even though the microprocessor controls most of the operations of today's ice machines, there are still some remote safety and cycling controls. **Figure 27.40** shows a modular, nonadjustable, fan-cycling control and high-pressure control. *The fan-cycling control turns the condenser fans on once the ice machine reaches a certain condensing pressure. It also cycles the fan off if the condensing pressure drops below a set point. This ensures the proper pressure drop across the metering device as quickly as possible.* The high-pressure control is a safety control to protect against excessively high pressures. If the high-pressure cut-out switch opens, the machine will stop immediately. It will automatically reset when the pressure falls below its cut-in point. Low-pressure controls also come in this modular style. If the low-pressure control opens, the machine will shut off. It will also automatically reset when the pressure rises above its cut-in point. Both of the control settings are dependent on what refrigerant is being used and the ice machine's

Figure 27.40 Modular, nonadjustable, fan-cycling, and high-pressure controls.



application. **Figure 27.41** shows a manually resettable high-pressure control. If the machine cycles off on high head pressure, it will not continue cycling on high head pressure. A service technician must manually reset the control for the machine to operate.

Some ice machines use a reverse-acting low-pressure control to terminate the freeze cycle. As ice forms on the evaporator, the suction pressure drops from a reduced heat load. A reverse-acting low-pressure control closes its contacts at a set low pressure. This action terminates the freeze cycle and initiates a harvest cycle.

Figure 27.41 A manually reset high-pressure control.

27.4 MICROPROCESSORS

Service technicians in the HVAC/R field will encounter microprocessors in their daily service work, **Figure 27.42(A), (B), (C), and (D). Figure 27.42(D)** is a microprocessor that can be re-programmed using a USB stick. This microprocessor also digitally reads out system pressures and temperatures. In fact, most manufacturers of ice machines and ice flakers incorporate microprocessors into their units. Microprocessors are simply small computers that contain stored programs or algorithms. The sequence of operation is stored in the software of the microprocessor. **Figure 27.43(C)** shows a small microprocessor or controller with an interfacing ice sensor and water-level controller used to control a modern ice cube machine. **Figure 27.43(D)** shows a modern ice cube machine incorporating an electronic controller or microprocessor. The controller operates the ice machine according to instructions, or programs, that reside in its internal memory. Each model made by this manufacturer operates a bit differently. For maximum efficiency, individual ice machine models have different programs called algorithms stored in their **electrical erasable programmable read-only memory (EEPROM)**. These controllers allow the ice machine to optimize efficiency of operations, recall errors that occur during running, have self-diagnostic functions, and customize programs for individual models. Even the water fill, which takes in water in batches, is a controller function. In fact, the amount of time it takes to fill the water reservoir is measured every cycle to determine the fill time needed to maintain the correct amount of water rinse. **Figure 27.43(E)** shows a service controller that can be custom programmed for a particular model of ice machine by rotating a selector switch.

Microprocessors are often referred to as integrated circuit controllers, electronic controllers, or just controllers.

HVAC/R equipment manufacturers are using microprocessors to make their products more reliable, less complicated, and easier to troubleshoot by including self-diagnostics. The microprocessor has cut down on the amount of hard wiring that goes into the control circuit, and it has taken the place of a lot of the hard wiring that used to be inside an ice machine. This type of technology is often referred to as *clean technology*. In fact, many years ago, there were so many wires going in and out of controls that the entire control circuitry looked like a plate of spaghetti. Now, most modern control circuits consist of a microprocessor; a few starting components like a start and run capacitor, a starting relay, and a compressor contactor; and the main loads or power-consuming devices. Most service technicians are not afraid of the main loads or power-consuming devices when troubleshooting, but do fear the microprocessor. However, the microprocessor can be the simplest component to troubleshoot with a little patience, understanding, and practice.

The microprocessor is a small computer that has a sequence of events stored in its memory. It has many sophisticated solid-state devices in its internal circuitry that are needed for its proper operation. However, a service technician does not need to understand how each solid-state device operates in order to tell if the microprocessor is good or bad. What the service technician does have to know is the microprocessor's sequence of operation, its self-diagnostic functions, and how to input/output (I/O) troubleshoot the microprocessor using its external terminals. The microprocessor's external terminals are shown at the right- and left-hand sides of **Figure 27.42(A)** where most of the wires enter and exit the microprocessor. These wires are the inputs and outputs of the microprocessor. Troubleshooting the external terminals of a microprocessor will be covered in detail later in this unit.

MICROPROCESSOR SEQUENCE OF EVENTS AND SELF-DIAGNOSTICS

The sequence of events of a microprocessor is usually found in the service manual. If a service manual cannot be found on-site with the refrigeration equipment, the owner or manager must be contacted to see if it has been filed away in some safe location. If the manual still cannot be located, the equipment manufacturer must be contacted. Usually, a model and serial number of the refrigeration machine is all that is needed for the manufacturer to locate the manual. The Internet is also a very useful tool for finding a service manual or sequence of operations. The service technician simply needs the pages from the manual that include the sequence of events of the microprocessor and how to initiate the self-diagnostics of the machine, if it has any. The technician can ask the manufacturer to fax the pages that include the pertinent information for servicing and troubleshooting. With today's modern technology, this information can be in the hands of the service technician in minutes. **Figures 27.43(A)** and **(B)** show a page from a service manual for an ice maker that includes the sequence of operation and the component test of the microprocessor, respectively. Simply pushing a button or moving a switch initiates the tests that the microprocessor performs. A test button is shown in **Figure 27.42(A)**.

Figure 27.43 (A) A microprocessor sequence of operation.

ICE MAKING PROGRAM					
When the selector switch is turned to the ICE position, in addition to displaying the evaporator and condenser temperatures, the computer will also display the part of the program that the computer is in.					
ICE 1	**ICE 2**	**ICE 3**	**ICE 4**	**ICE 5**	**ICE 0**
ICE 1 is the untimed portion of the freeze cycle. In this part of the program, the computer is waiting for the evaporator temperature to reach 14°F (–10°C) before it starts the timer.	ICE 2 is the timed protion of the freeze cycle. The machine is still in freeze, but the timer in the computer is now running.	ICE 3 occurs during the last 20 seconds (12 seconds on single evaporator units) of the timed portion of the freeze cycle. During this time the purge valve is energized.	Once the amount of time set on the timer has passed, the program enters ICE 4 for 20 seconds. The WATER PUMP is now switched off and the HOT GAS VALVE is energized (open).	During ICE 5 the harvest assist motor(s) are now switched on and remain energized until the cam switch(es) return to the N.O. position, at which time the program returns to ICE 1 or ICE 0.	If the splash curtain(s) are held open when the cam switch(es) opens at the end of ICE 5, the machine will shut off and ICE 0 will display. When the curtain(s) closes the program returns to ICE 1.

Figure 27.43 (*Continued*) (B) A microprocessor component test.

ELECTRONIC CONTROLLER OPERATION
COMPONENT TEST

All high-voltage components are tested in this function. This test allows the technician to distinguish between a defective computer and a defective component or component circuitry. With the machine in the test mode, the component indicated on the display should energize and operate.

To use this test, bring up the display that describes the component to be tested. If the component is indicated on the LED, but the component does not energize, check the output at the high-voltage (left) side of the computer. This is done by checking voltage between the top terminal, marked L1, and the terminal marked with the component description being tested. If the computer output is the same as the supply voltage, the problem is in the component, or the wiring to that component (i.e., a broken wire). If the computer output is different from the supply voltage, the computer is defective and must be replaced.

H2OP	PrG	GAS	FAn	HP-2	HP-1	CnnP
The water pump is switched on. Check voltage across the terminals labeled L1 and WATER PUMP.	The purge solenoid is switched on. Check voltage across the terminals labeled L1 and PURGE.	The hot gas solenoid is switched on. Check voltage across the terminals labeled L1 and HOT GAS.	The condenser fan motor(s) is switched on. Check voltage across the terminals labeled L1 and FAN 1 and L1 and FAN 2.	Harvest probe motor 2 is switched on. Check voltage across the terminals labeled L1 and MOTOR 2.	Harvest probe motor 1 is switched on. Check voltage across the terminals labeled L1 and MOTOR 1.	The compressor is switched on. Check voltage across the terminals labeled L1 and COMP.

Notice that the component test walks the technician through voltmeter checks of the water pump, purge solenoid, hot gas solenoid, condenser fan, harvest probe motors, and compressor. It even instructs the service technician where to place the voltmeter and when to check the component. This gives the technician the knowledge of what the ice machine components are supposed to do at a certain time, temperature, or test mode.

INPUT/OUTPUT TROUBLESHOOTING

Even if the manufacturer of the ice machine does not include a component test mode within the programming of the microprocessor, the service technician can still troubleshoot the microprocessor. Input/output troubleshooting is actually an easy method if the technician uses some common sense. All that is needed is a voltmeter and knowledge of the sequence of events from the service manual. An ohmmeter should not be used directly on a microprocessor because of the ohmmeter's battery voltage. Many times this voltage is too high and may damage the intricate solid-state components or the magnetic memory internal to the microprocessor. However, if certain components (inputs or outputs) to the microprocessor are detached, an ohmmeter can safely be used on these components.

Microprocessors are fed with information from their input devices to their input terminals. Input devices can be analog, as with a thermistor (variable resistor), or digital (on/off), as with a switch. **Figure 27.44** shows a thermistor connected to the midpoint of the condenser. It is acting as an analog input device to the microprocessor for displaying the condensing temperature on a LED.

Figure 27.44 The condenser thermistor is an analog input to a microprocessor.

Courtesy Ferris State University. Photo by John Tomczyk

After processing the data from the inputs, an output signal is sent. The output signal can be read with a meter from the output terminals of the microprocessor. Input and output terminals of a microprocessor can be seen in **Figure 27.45**. Notice that both the input and output terminals are clearly labeled for the service technician to troubleshoot. It is from these terminals that most troubleshooting can be accomplished using a meter. Most of the time, but not always, the input signals are low-voltage (AC or DC) or resistance signals, and the output signals are of higher voltage (usually AC) going to the power-consuming devices. Always refer to the service manual for specifics. Input devices are frequently used for digital readouts of a condensing temperature, an evaporating temperature, or a specific sequence mode. **Figure 27.42(A)** shows a service technician measuring the input voltage from a microprocessor. It is important to use as short a measuring probe as possible to avoid shorts to other terminals of the microprocessor. A direct short could ruin any microprocessor. Taping the voltmeter probes halfway up will help prevent electrical shorts when measuring inputs or outputs from a microprocessor.

MICROPROCESSOR SELF-DIAGNOSTICS AND ERROR CODES

Many microprocessors come with a self-diagnostic mode. The microprocessor continually monitors all functions of the ice maker. If a malfunction should occur, the microprocessor will associate the error or malfunction with an error code in its memory. The error code will then be indicated on the LED display. **Figure 27.46** shows some error code descriptions of one manufacturer's ice machine. The service technician in **Figure 27.47** is using a voltmeter to troubleshoot the hot gas high-voltage circuit. Notice that the error code 12 (EC 12) is displayed on the LED of the microprocessor. By referring to the service manual, **Figure 27.46**, the technician finds that this error code indicates that the evaporator temperature exceeded 150°F.

Error codes are a valuable and time-saving troubleshooting tool. However not all problems can be diagnosed with error codes. Always check to see if the fuse on the microprocessor is good before condemning the processor. Most microprocessors have these fuses.

MICROPROCESSOR HISTORY OR SUMMARY

Some microprocessors can record an ice machine's history. This summary of the ice machine's past operations can be retrieved from memory and reviewed at any time by using

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Figure 27.45 A microprocessor showing components that include the input and output terminals.

switches or buttons on the microprocessor. This history may also be erased once it is recorded by the service technician. Important information that happened over long periods of time, such as the number of harvests, error codes stored, and average cycle times, can be recalled, **Figure 27.48**.

The microprocessor is not as complicated as it may seem. All the service technician really has to know is I/O troubleshooting, the sequence of operation, and how to find and follow an instruction manual.

ICE PRODUCTION AND PERFORMANCE DATA

Ice production, cycle times, and system operating pressures for an air-cooled ice machine mainly depend on two factors:

- Temperature of the air entering the condenser
- Temperature of the water entering the ice machine

Assuming a constant water temperature entering the ice machine, the ice production decreases as the air temperature increases through an air-cooled condenser. Notice in **Figure 27.49** that if the water temperature entering the ice machine stays constant at 50°F, the 24-hour ice production is 1880 lb at the 70°F temperature of the air entering the condenser. However, if the air entering the condenser increases in temperature to 100°F, the 24-hour ice production decreases to 1550 lb. This happens because of the inefficiencies associated with a high compression ratio caused by the increase in condensing temperature with warmer air entering the condenser.

As the air entering the condenser stays constant at 70°F, the 24-hour ice production decreases from 1880 lb to 1640 lb as the water temperature entering the ice machine increases from 50°F to 90°F. This happens because it takes more refrigeration effect, and thus more time, to freeze the warmer 90°F water into ice. Notice that the ice machine has longer freeze times as the water temperature to the ice machine and the air temperature through the air-cooled condenser increase.

For both the freeze and harvest cycles, the discharge and suction pressures increase as the air entering the air-cooled condenser increases. This happens because of higher compression ratios associated with a higher condensing temperature caused by the warmer air passing through the condenser. Knowing what the discharge and suction pressures should be for different air and water temperatures is a valuable tool for the service technician.

27.5 WATER AND ICE QUALITY

An ice machine is an important piece of equipment to any business where it is installed and is vital to a food-service customer. Most of these businesses depend heavily on ice. However, many ignore their ice machine and fail to consider

Figure 27.46 Error code descriptions from a microprocessor.

ERROR CODES

The computer constantly monitors the ice-making cycles to determine if everything is operating correctly. Should the computer detect a malfunction, it will record the associated error code in its memory. If the error code is a "FATAL ERROR," the computer will shut the machine down, light the front panel "SERVICE LIGHT," and indicate the error code on the LED display. NOTE: On machines manufactured after August, 1991, error codes 2, 5, 7, and 12 will automatically make 4 attempts (one attempt every 15 minutes) to reset before the machine is shut down and the service fault light illuminates. The same error code must occur 4 consecutive times before the machine shuts down. All computers incorporating this change can be identified by a version number of 0612 or higher. See version number identification, page H-2. Error codes that do not cause a machine shut-down (EC 1 and EC 3) will ONLY display on the LED when in the "SUMMARY MODE."

Below is a description of each Error code.

EC 1	EC 2
Freeze time is greater than 50 minutes or the temperature of the evaporator is above 40°F at 6 minutes into the freeze cycle.	Cam switch(es) did not cycle closed and open within 45 minutes of initiating the harvest sequence (ICE 5). See note below.

NOTE: On computers with version number 0612 or higher, time of failure for EC 2 has been changed from 45 minutes to 15 minutes.

EC 3	EC 4	EC 5	EC 6	EC 7	EC 8	EC 9
Curtain switch(es) did not close within 5 minutes of initiating the harvest sequence (ICE 5).	The microprocessor chip has a defect. The computer must be replaced.	Condenser thermistor circuit is either open or shorted.	Evaporator thermistor circuit is either open or shorted.	Condenser temperature exceeds 150°F (65°C).	Freeze time is greater than 80 minutes.	Evaporator temperature has reached 14°F (−10°C) in LESS than 90 seconds for FOUR CONSECUTIVE ice-making cycles.

NOTE: On computers with version number 0612 or higher, EC 9 has been eliminated.

EC 12
Evaporator temperature exceeds 150°F (65°C).

Based on Ice-O-Matic

If a machine is shut down on a "FATAL" error code, the machine must be reset following the procedure before it can be returned to the ice making mode. Error codes will remain in the memory even after a power interruption.

that it is a self-contained "mini-ice factory." An ice machine takes a raw material and manufactures a consumable product. This product is then stored and provided to the customer for whatever purpose it is needed.

WATER QUALITY

Ice is considered a food source, and the single component material is water. The quality of the ice product depends on the quality of the water supplied to the unit. Good water quality will produce a crystal-clear, hard cube that provides excellent cooling capacity and lasts a long time. Poor water quality will produce ice that can be soft and cloudy and will result in less Btu cooling capacity, ice bridging in the storage container, or both.

Water can contain many different minerals at various levels, and the quality is constantly changing. In fact, water quality varies throughout the United States and may vary across a town or even across a street. It can be improved through filtration and treatment, which are a science by themselves. Technical experts know about the chemical makeup of water and how to treat specific problems.

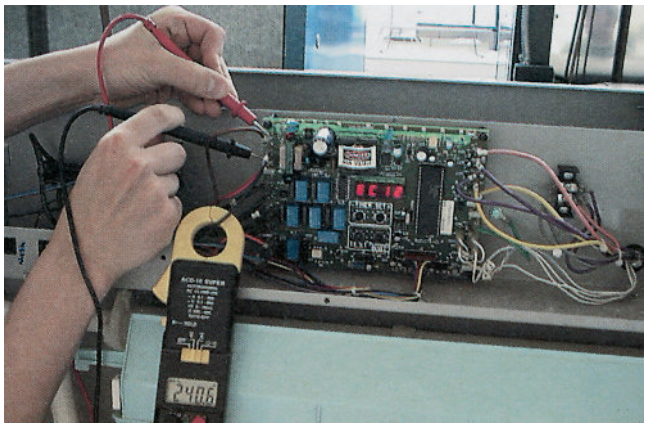
Figure 27.47 A service technician measuring output voltage from a microprocessor.



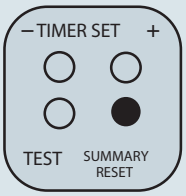
Courtesy Ferris State University. Photo by John Tomczyk

Although few service technicians have this level of expertise when it comes to resolving water-quality issues, it is important to have a basic understanding of water quality in order to service an ice machine. The typical ice machine service technician is called on from time to time to recommend water filtration or treatment for ice-making equipment. Of course, the best source of information concerning filtration and treatment is a water filter manufacturer. These manufacturers will work with you and make recommendations to resolve your water-quality issues. Many interesting websites on the Internet provide educational information on water quality and water filtration and treatment. Although it is impossible to cover every aspect of water quality here, a service technician should have a basic knowledge of key water treatment terminology and

Figure 27.48 A summary or history of the ice machine can be recalled by the microprocessor.

SUMMARY

The machine history is recorded by the computer. This summary of past operation can be recalled and reviewed any time that the selector switch is in the ICE or OFF position. The history may only be erased when the selector switch is in the OFF position, see page H-15. The summary is not affected by power loss.



To recall the history, press the SUMMARY/RESET button momentarily. A summary of past operation will now be displayed.

H254

The drawing to the left gives an example of the first part of the summary, which is the harvest count. The H shown on the display indicates the harvest count in thousands, the number that follows (254) indicates the machine has cycled 254,000 times since last being reset.

The remaining history will be displayed in the order given below.

h	EC	rrrr	r1	15	r2
The number that appears in front of h indicates the number of harvests UP TO ONE THOUSAND since last being reset.	The number that appears in front of EC indicates any error code that has been stored in the memory and not yet erased.	This tells the service tech that the computer is now going to display information or "reviews"of prior ice-making cycles. A review is the average cycle time of a group of 10 ice-making cycles.	The computer is now going to display the first review.	The number displayed after r 1 has been displayed is the average cycle time of the 10 most recent ice-making cycles. The example to the left shows a 15-minute review.	The computer is now going to display the second review. The number displayed after r 2 has been displayed is the next 10 most recent ice-making cycles.

Based on Ice-O-Matic

Note: The maximum number of reviews is 10 (a total history of 100 cycles). If the computer has not operated for a minimum of 10 cycles, there will be no reviews.

NOTE: These characteristics may vary depending on operating conditions.

Based on Manitowoc Ice, Inc.

how it applies to an ice machine. The following terms are used when dealing with water quality in ice machines:

Acidic water: Water containing dissolved carbon dioxide that forms carbonic acid. Acidic water is considered aggressive to most components it comes in contact with and is represented by a low pH reading.

Alkaline water: Water that has a surplus of hydroxyl ions, which results in a pH over 7. It often contains concentrations or a mixture of soluble salts or alkali that are picked up from basic minerals in the earth, such as calcium, magnesium, silica, and so on. These are scale-causing minerals.

Chloramines: Disinfectants used to treat municipal water systems for bacteria. Chloramines are a mixture of chlorine and ammonia. A higher concentration of charcoal is generally needed to reduce the amount of chloramines in the water.

Chlorine: A disinfectant used to treat municipal water systems for bacteria. Chlorine can be corrosive to metals. Charcoal filtration is generally used to reduce the amount of chlorine in the water to improve offensive chlorine taste and odor.

Filtration: A device installed in the water supply inlet of the ice machine to remove contaminants from the water. Coarse filtration removes the "rocks and boulders." Fine filtration removes smaller particles.

Flow rate: The volume of flow through a device measured in gallons per minute (GPM). It is important to size a filter system properly to supply the correct flow rate to the unit per the manufacturer's required specifications.

Hardness: The amount of calcium and magnesium measured in grains per gallon. See the following standards chart from the U.S. Bureau of Standards:

Water Hardness

Description	Grains per Gallon	Parts per Million (TDS)
Soft Water	Less than 1.0	Less than 17.1
Slightly Hard	1.0 to 3.5	17.1 to 60.0
Moderately Hard	3.5 to 7.0	60.0 to 120.0
Hard Water	7.0 to 10.5	120.0 to 180.0
Very Hard	10.5 and over	180.0 and over

Note: 7,000 grains = 1 pound.

Iron: A compound or bacteria found generally in well water. Iron compounds cause a rust-colored scale. Iron bacteria show up as rust-colored slime.

pH: The term used to express the level of acidity or alkalinity in water or solutions. The scale for pH ranges

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

from 0 to 14. A reading of 7 is considered a neutral pH and is the desired condition for ice machine applications. A reading of below 7 is acidic, and above 7 is basic or alkaline.

Reverse osmosis (RO): A device that forces water, under pressure, against a fine membrane to remove minute particles of contaminants.

Scale: A buildup of minerals that forms a flaky coating on the surfaces of the evaporator and water system. Scale buildup restricts water flow and reduces heat transfer in an ice machine. This buildup affects unit efficiency and usually causes service concerns.

Scale inhibitor: A material or element that slows the ability of scale to stick to a surface. Many filter manufacturers use **polyphosphate** to inhibit calcium or lime scale buildup.

Sediment: Larger particles of dirt, trash, sand, minerals, and so on. A sediment filter is generally installed prior to the filter/treatment device to remove larger contaminants. This allows for longer life of the filter/treatment device by reducing rapid plugging of the filter medium.

Total dissolved solids (TDS): The level of dissolved minerals in the water measured in parts per million (ppm). Higher concentrations of TDS can increase mineral buildup.

Treatment: Using a device that adds chemicals or minerals to the water to effect a change in the water quality. Other treatment technologies are also available in the industry. Treatment is generally required to address scale and bacteria concerns.

Turbidity: The degree of water cloudiness generally caused by high mineral saturation or the presence of air bubbles in the water.

Water softener: A device that uses salt to provide an ion exchange that reduces the hardness of water, making it less likely to produce scale.

One last term that is usually understood by the service technician but seldom considered by the customer is **preventive maintenance.** *This refers to the regularly scheduled maintenance performed on a unit, including inspecting, cleaning, sanitizing, and servicing of the ice machine and external water filtration/treatment system. Preventive maintenance pays big benefits. Every equipment manufacturer provides recommendations and instructions that detail the steps necessary to perform preventive maintenance. This process, along with providing proper water filtration and treatment at initial installation, is vital for protecting the customer's investment and maintaining maximum efficiency—as well as ensuring a longer life for the ice machine.* A basic understanding of these terms will help a service technician communicate any water-quality concerns to a filter manufacturer and to the customer. This will definitely help in resolving ice machine water-quality issues.

ICE QUALITY

Ice is a consumable product that serves the specific function of basic refrigeration. Most beverages taste better over ice, especially on a hot summer day. Placing some ice in your cooler keeps your picnic foods and beverages fresh and cool. Whether you crunch it, chew it, or use it as a means of cooling something, ice is an important commodity.

The amount of refrigeration effect that you get from the ice depends on the quality of the ice. Ice quality is measured in percent of hardness. Hardness is a measurement that represents the thermal cooling capacity. The higher the percent of hardness, the more cooling ability the ice possesses. The harder the ice, the denser it is and the longer it will last in a glass or a cooler. Do not confuse ice hardness with hard water. If you have hard water, you will have reduced ice hardness because of the minerals in the ice.

Ice hardness is calculated by conducting a calorimeter test. This is a specific test used by the Air-Conditioning, Heating and Refrigeration Institute (AHRI) to rate ice quality or cooling ability. The American National Standards Institute (ANSI) and the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) have standards for test procedures. ANSI/ASHRAE Standard 29–1988 lists the procedure for conducting this calorimeter test. The test requires an insulated container with a specific amount of water at a specific temperature. The ambient conditions for the test are also controlled. An exact amount of ice is stirred into the container and timed until all the ice melts. The water temperature before and after the ice is added and the actual melting time is listed on a data sheet. This information is then used to calculate the ice hardness.

Water purity definitely has an effect on ice quality. Pure ice will be crystal clear. Cloudy ice usually contains air or minerals, which will limit hardness. Ice is normally made available in blocks, cubes, chunks, flakes, and cubelets or nuggets. Customer preference and use dictate which type of ice is needed. As block ice is frozen, pure water freezes first. Any minerals or trapped air in the cold water push toward the center of the block and finally freeze. This leaves a cloud in the center of the clear block of ice. You may have noticed this if you have ever used ice made in an ice tray in your home refrigerator. This type of ice falls in the 95% to 100% hardness range, depending on the mineral content.

Flaked ice falls in the 70% hardness range. This is due to the freezing process used in the ice flake machine. Water is frozen on a cylinder wall, broken away, and extruded into the storage bin. Generally, all the water that goes into the flaker comes out as ice. Any minerals in the water will be frozen into the ice. Because of the nature of flaked ice, more air is present. This also reduces the overall hardness and cooling effect of flaked ice.

As mentioned earlier, cubelets or nuggets are made of compressed flakes. The flakes of ice are squeezed or extruded through a smaller opening to remove more water. This

extruded ice is then broken into chunks. These chunks fall in the 80% to 90% hardness range. Since cubelets or nuggets of ice are easy to chew, they are preferred by the health care industry.

Cubes fall in the 95% to 100% hardness range, depending on the evaporator style and ice-making process. Commercial ice cube machines circulate water into, across, or over an evaporator plate. As the water circulates and is cooled, pure water freezes first. The minerals tend to "wash out" during this freezing process. The result is a purer and thus harder cube of ice. The ice hardness will vary with the style of evaporator and materials used. Any restrictions to the water path on the evaporator surface can slow down the water flow and allow minerals to freeze into the cube. Such restrictions can occur when the water has to flow over a separator on the evaporator or into the cavity of a grid cell. These cubes may be cloudy and fall in the lower hardness range. **Figure 27.50(A)** shows the difference between hard and soft ice. The ice sheet on the left is cloudy and soft. It contains a lot of minerals. The ice sheet on the right is clearer, denser, and will have a higher hardness percentage with more cooling capacity. **Figure 27.50(B)** shows the water sump full of a fine, white, talcy powder of undissolved minerals. **Figure 27.50(C)** shows a service technician taking a sample of the white, powdered minerals in his fingers.

Regardless of the type of ice or its use, a cleaner ice machine and purer water will produce harder ice. Some ice machine manufacturers provide designs that include built-in flushing or purging capabilities. This helps to eliminate minerals, thus keeping the ice machine cleaner and improving ice quality. Regularly scheduled preventive maintenance checks including cleaning and sanitizing of the ice machine water system are a must. Always use the correct cleaner and follow the manufacturer's recommendations when performing the cleaning and sanitizing procedure.

SANITIZING AND CLEANING

The sanitizing process is becoming more common because it helps to eliminate harmful bacteria that tend to thrive in the cool ice-making environment. Remember that ice is consumed as a food and comes in direct contact with the food or beverage it cools. It is used to cool down beverages and ice down fruits, vegetables, fish, poultry, and meats. Because of these uses, ice is considered a food product. *This is why ice machines must be cleaned and sanitized on a regular basis. Using a sanitizer is an important step in the preventive maintenance process. An acid-based cleaner removes scale. Sanitizing kills harmful bacteria, viruses, and protozoa.*

Bacteria, viruses, and protozoa can also adhere to moist areas on the inside of the evaporator compartment. Some of these bacteria and viruses can make people very sick. These microscopic organisms can be either airborne or waterborne. Municipal water systems are relatively free of harmful waterborne organisms because chlorine has been added as a disinfectant. Water filtration or treatment, which will be covered in detail shortly, can also provide protection against bacterial contamination. However, airborne organisms can still be present. Once an organism sticks to a moist surface,

Figure 27.50 (A) Soft, mineral-laden ice versus clear, hard ice. (B) Water sump with mineral deposits appearing as a white, talcy powder. (C) Service technician taking a sample of the fine, white, talcy mineral powder.

it begins to grow because of the cool, damp conditions inside the evaporator compartment. The result may be a mold, algae, or slime buildup. Slime is the most visible target when sanitizing an ice machine. It is usually a jellylike substance that is made up of algae, mold, and yeast spores. These spores can be either airborne or waterborne.

Lime or calcium buildup, often referred to as scale, is removed from the ice machine by using a commercial-grade ice machine cleaner. Ice machine cleaning solutions are made of a food-grade acid that is approved for use in food applications. They come in different strengths for many different purposes. The weaker solutions are used to protect different metals. Heavy scale deposits may require soaking in the cleaning solution. A stronger cleaner can be used on stainless-steel evaporators; however, a nickel-safe cleaner must be used on plated evaporators to avoid possible flaking or peeling of the plating. Because copper and brass are more porous than stainless steel, if flaking or peeling occurs and the brass or copper is exposed, the evaporator will be more susceptible to bacterial growth. Circulating a dilute solution of acid-based cleaner through the water system will remove scale. However, it does not kill bacteria. A separate procedure called *sanitizing* must be performed to address bacteria.

Sanitizing is accomplished by using a commercial ice machine sanitizer. You cannot remove scale and sanitize with the same solution; two different solutions are needed. In fact, mixing ice machine cleaner and sanitizer together creates a strong chlorine gas that can be dangerous to breathe. The sanitizing solution must be circulated as directed by the ice machine manufacturer. Most manufacturers provide step-by-step cleaning and sanitizing instructions, which point out specific areas that must be disassembled and manually cleaned and sanitized. Sanitizing should be done at least once a month for ice machines used in the food service industry. Many service technicians prepare their own sanitizing solution by mixing 1 oz of household bleach with 2 gal of warm, potable water. The water should be in the temperature range of 95°F to 115°F. This gives the solution about 200 ppm chlorine strength. However, before using any sanitizing solution always consult the manufacturer's directions for sanitizing the ice machine.

WATER FILTRATION AND TREATMENT

As mentioned earlier, water-related problems account for over 75% of service problems in ice makers and ice flakers. However, if cleaning and sanitizing are done on a schedule that is appropriate to local water conditions, the ice machine will have a longer and more productive life dispensing quality ice. Unfortunately, ice machines are often placed out of sight and are seldom cleaned or sanitized until they have to be. This is where water treatment methods come into play. A good water treatment program will extend the cleaning and sanitizing intervals between service calls. But first, it is important to understand the local water conditions.

Water conditions can be broken down into the following three categories:

- Suspended solids
- Dissolved minerals and metals
- Chemicals

Sand and dirt are examples of suspended solids and are probably the easiest to remove. While mechanical filters in the water line can remove both sand and dirt, dissolved minerals and metals are much more expensive to capture. Their removal requires processes like reverse osmosis, distillation, or de-ionization. Reverse osmosis uses water pressure to force water through special membranes that reject most of the dissolved minerals and organics and flush them to waste. Distillation requires water to be heated to its boiling point to create steam. The steam is then recondensed into water, leaving the minerals behind. De-ionization uses columns or beds of special filter media such as plastic beads or mineral granules to remove minerals from the water in exchange for other substances. An example of this is water softening. Water softeners are loaded up or regenerated with sodium ions from ordinary salt. The sodium ions are exchanged for calcium and magnesium, which are often referred to as the *water hardness* ions. Scale-inhibiting chemicals, which have to be food grade, can also successfully control dissolved minerals and metals.

Chemicals, on the other hand, have to be removed by carbon filtration. The most common chemicals in water are chlorine and chloramines, which are common city water disinfectants. Other types of chemicals that make their way into the water system can affect the taste, odor, and color of the water.

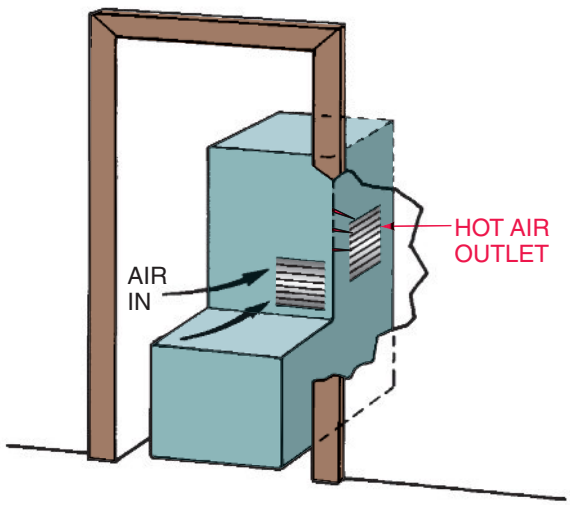
Water filtration and treatment can be applied to a water supply to try to treat these categories of water conditions. *A common treatment for any type of ice machine is a triple-action filter system,* **Figure 27.51**. *These systems can filter out suspended solids, fight scale formation by adding chemicals, and improve the taste, odor, and color of water with carbon filtration.* Because the filters are micron filters, they do

Figure 27.51 A triple-action filter system.

Courtesy Scotsman Ice Systems

plug up and have to be changed on a regular basis. Often, a pressure gauge installed on the filter will indicate a pressure drop when the filter is starting to plug up. Any time the scale inhibitor or carbon is used up is a good time to change all three cartridges. However, water treatment in a specific geographical region is never an exact science. Many times, a trial-and-error method is used because there is never an exact quick fix when it comes to water treatment. Always consult with your local water-quality experts, ice machine distributors, or manufacturers for their professional opinions on the best water treatment for your geographical area. The water filter manufacturer can also assist you in testing the water at your site and recommending the correct water treatment combination to improve the water quality. **SAFETY PRECAUTION:** *These chemicals can be hazardous to humans. Always follow the manufacturer's instructions. The best time to circulate any chemicals is when there is no ice in the bin so they will not contaminate the stored ice. Because it is rare to find an ice maker empty, you may need to remove the ice from the bin and place it in a remote storage area. Then clean and rinse the ice bin according to the manufacturer's directions.* •

Figure 27.52 An ice machine located in an alcove with condenser air recirculating.



27.6 PACKAGE ICE MACHINE LOCATION

Most package ice machines are designed to be located in ambient temperatures of 40°F to 115°F. Follow the manufacturer's recommendations. If the ambient temperature is too cold for the ice maker, freezing may occur and damage the float or other components where water is left standing. If it is too hot, compressor failures and low ice capacities may occur. The ambient conditions under which the ice maker must operate are important.

WINTER OPERATION

A machine located outdoors at a motel may not make ice below about 40°F ambient temperature because the thermostat in the bin is set at about 32°F. With this setting, when ice touches the thermostat sensor, it will shut off the machine. The combination of 40°F outside and some ice in the bin will normally satisfy the thermostat. When the machine is located outside, the water should be shut off when the outside temperature approaches freezing. The water should be drained to prevent freezing and damage to the pump, the evaporator on some units, and the float assembly.

When machines are outside and the ambient temperature is below about 65°F, some method is normally used to prevent the head pressure from becoming so low that the expansion device will not feed enough refrigerant to the evaporator. Low-ambient control causing fan cycling is a common method. Mixing valves or head pressure control valves are also used to maintain both discharge- and liquid-line pressures. These valves mix hot discharge gas with liquid coming from the receiver when the outdoor ambient drops below a certain temperature. At the same time, liquid is backed up in the condenser, causing a flooded condition. This flooding of the condenser will elevate the head pressure. Head pressure control valves are covered in detail in Unit 22, "Condensers."

The correct location of an ice machine indoors is critical because of the airflow across the condenser. Air cannot be allowed to recirculate across the condenser or high head pressures will occur. This will reduce the capacity and may in some cases harm the compressor, **Figure 27.52**.

27.7 TROUBLESHOOTING ICE MAKERS

When an ice maker is not functioning properly, the problem can usually be found in the water circuit, the refrigeration circuit, or the electrical circuit.

WATER CIRCUIT PROBLEMS

Water level is critical in most ice makers. The manufacturer's specifications should be followed. Most manufacturers post the water level on the float chamber or at some location close to the float. Determine what the level should be and set it correctly, **Figure 27.53**.

The float valve has a soft seat, usually made of neoprene. This seat may become worn and a new one may be required. A float seat is inexpensive compared to an ice maker operating

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Figure 27.53 Maintain the correct float level.

inefficiently for any period of time. When a float does not seal the incoming water, water at the supply temperature flows through the system instead of being refrigerated to the freezing temperature. It may also melt ice that has already been made. A temporary repair may be to turn the float seat over if it can be removed from its holder, **Figure 27.54**. The best time to determine whether or not a float is sealing correctly is when the ice maker has no ice. Remember, when there is ice in the bin, it is constantly melting. You cannot tell if the water in the drain is from melting ice or a leaking float. When there is no ice in the bin, the only water in the drain would be coming from a leaking float, **Figure 27.55**.

Water circulation over evaporators that make cube ice is accomplished by a water circulating system that is carefully designed and tested by the manufacturer. You should make every effort to understand what the manufacturer has intended before you modify anything. It is not unusual for a technician to try various methods to obtain the correct water flow over the evaporator when the manufacturer's manual would explain the correct procedure in detail. Do not overlook something as simple as a dirty evaporator. If it must be cleaned, check the manufacturer's suggestions.

Figure 27.54 Sometimes a float seat can be reversed or turned over with the good side out for a temporary repair.

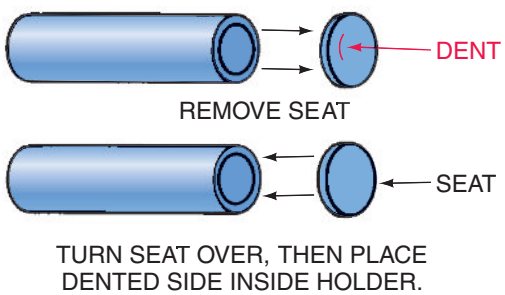

Figure 27.55 The ice machine storage bin is dry. There is no ice, but water is dripping out of the drain. The float valve is leaking.

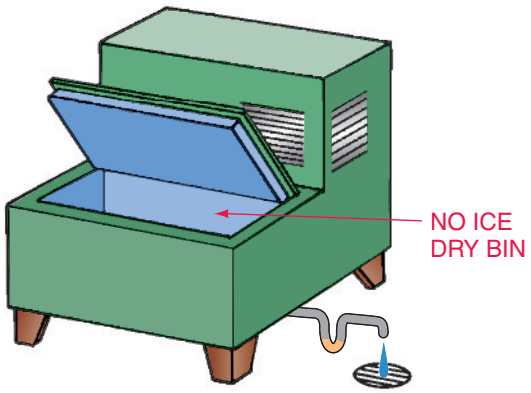


The quality of the water entering the machine must be at least as good as the manufacturer recommends. Check the filter system if the water seems to have too many minerals. A water treatment company may be contacted to help you determine the water condition and the possible correction procedures.

REFRIGERATION CIRCUIT PROBLEMS

Refrigeration circuit problems are either high-side or low-side pressure problems.

HIGH-SIDE PRESSURE PROBLEMS. High-side pressure problems can be caused by

- poor air circulation over the condenser,
- recirculated condenser air,
- a dirty condenser,
- a defective fan motor,
- overcharge of refrigerant, or
- noncondensables in the system.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Another high-side pressure problem is a result of trying to operate a system when the ambient temperature is below the design temperature for the unit. Low head pressure can cause low suction pressure, particularly in systems with capillary tube metering devices. Owners tend to try to place the machines outside and expect them to perform all year. The design conditions the manufacturer recommends should be followed.

LOW-SIDE PRESSURE PROBLEMS. Low-side pressure problems can be caused by

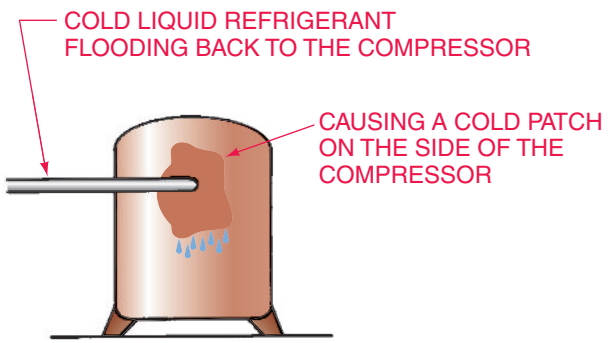
- low refrigerant charge,
- incorrect water flow,
- mineral deposits on the water side of the evaporator,
- a restricted liquid line or drier,
- a defective metering device or thermostatic expansion valve,
- moisture in the refrigerant,
- an inefficient compressor, or
- a blocked metering device.

Low-side problems will show up as a pressure that is too high or too low as indicated on the refrigeration gauges. When the pressure is too low, you should suspect a starved evaporator. When the ice maker makes solid-type ice, a starved evaporator will often cause irregular ice patterns on the evaporator. The ice will become thicker where the evaporator surface is colder. When the pressure is too high, you should suspect an expansion device that is feeding too much refrigerant, a defective TXV, or a compressor that is not pumping to capacity. When the expansion valve is overfeeding, the compressor will normally be cold from the flooding refrigerant, **Figure 27.56**.

A stuck water float can cause excess load if the entering water is warmer than normal, **Figure 27.57**. As mentioned earlier, it is hard to detect a leaking float. Look for the correct level in the float chamber. If adjusting the float does not help, the seat is probably defective.

The troubleshooting checklist from a manufacturer's manual in **Figure 27.58** is a general guide for the ice machine owner or service technician to follow. Similar checklists are available from the manufacturer of the particular ice machine in question. As mentioned earlier, the Internet is an excellent source of quick troubleshooting information that can assist the service technician in systematically troubleshooting an ice machine.

Figure 27.56 The expansion valve is allowing refrigerant to flood back to the compressor.



ELECTRICAL PROBLEMS

A defrost problem may look like a low-pressure problem if the unit fails to defrost at the correct time. Heavy amounts of ice may build up. Remember, defrost is only used on machines that make cube ice. When you find heavy amounts of ice on a machine, determine what the defrost method is. The machine may have a forced defrost cycle that will allow you to clear the evaporator and start again, but some manufacturers may suggest not forcing the machine to defrost or shutting the machine off but waiting for the normal defrost cycle. Waiting for the normal cycle will help determine what type of problem caused the condition. If the evaporator is frozen solid and a defrost is forced, you may not find the problem because it may not recur in the next cycle.

Figure 27.57 A float that does not seal will reduce the usable ice a machine can make.

Figure 27.58 A basic service checklist for an ice machine. (Page numbers do not refer to this text.)

PROBLEM	POSSIBLE CAUSE	TO CORRECT
Ice machine does not operate.	No electrical power to the ice machine.	Replace the fuse/reset the breaker/turn on the main switch.
	High pressure cutout tripping.	Clean dirty air filter and/or condenser coil (See page 4-1).
	ICE/OFF/CLEAN toggle switch set improperly.	Move the toggle switch to the ICE position.
	Water curtain stuck open.	Water curtain must be installed and swinging freely. See page 4-10.
	Remote receiver valve closed.	Open the valve.
Ice machine stops and can be restarted by moving the toggle switch to OFF and back to ICE.	Safety limit feature stopping the ice machine.	Refer to "Safety Limit Feature" on the next page.
Ice machine does not release ice or is slow to harvest.	Ice machine is dirty.	Clean and sanitize the ice machine. See pages 4-3 and 4-4.
	Ice machine is not level.	Level the ice machine. See page 2-6.
	Low air temperature around ice machine (air-cooled models).	Air temperature must be at least 35°F (1.6°C).
	Water regulating valve leaks in harvest mode (water-cooled models).	Refer to "Water-Cooled Condenser" on page 4-2.
Ice machine does not cycle into harvest mode.	The six-minute freeze time lock-in has not expired yet.	Wait for freeze lock-in to expire.
	Ice thickness probe is dirty.	Clean and sanitize the ice machine. See pages 4-3 and 4-4.
	Ice thickness probe wire is disconnected.	Connect the wire.
	Ice thickness probe is out of adjustment.	Adjust the ice thickness probe. See page 3-4.
	Uneven ice fill (thin at top of evaporator).	See "Shallow or Incomplete Cubes" on the next page.
Ice quality is poor (soft or not clear).	Poor incoming water quality.	Contact a qualified service company to test the quality of the incoming water and make appropriate filter recommendations.
	Water filtration is poor.	Replace the filter.
	Ice machine is dirty.	Clean and sanitize the ice machine. See pages 4-3 and 4-4.
	Water dump valve is not working.	Disassemble and clean the water dump valve. See page 4-7.
	Water softener is working improperly (if applicable).	Repair the water softener.
Ice machine produces shallow or incomplete cubes, or the ice fill pattern on the evaporator is incomplete.	Ice thickness probe is out of adjustment.	Adjust the ice thickness probe. See page 3-4.
	Water trough level is too high or too low.	Check the water level probe for damage. See page 3-4.
	Water inlet valve filter screen is dirty.	Remove the water inlet valve and clean the filter screen. See page 4-9.
	Water filtration is poor.	Replace the filter.
	Hot incoming water.	Connect the ice machine to a cold water supply. See page 2-10.
	Water inlet valve is not working.	Remove the water inlet valve and clean it. See page 4-9.
	Incorrect incoming water pressure.	Water pressure must be 20-80 psi (137.9–551.5 kPA).
	Ice machine is not level.	Level the ice machine. See page 2-6.

Figure 27.58 (*Concluded*)

PROBLEM	POSSIBLE CAUSE	TO CORRECT
Low ice capacity.	Water inlet valve filter screen is dirty.	Remove the water inlet valve and clean the filter screen. See page 4-9.
	Incoming water supply is shut off.	Open the water service valve.
	Water inlet valve is stuck open or leaking.	Remove the water inlet valve and clean it. See page 4-9.
	The condenser is dirty.	Clean the condenser. See page 4-1.
	High air temperature around ice machine (air-cooled models).	Air temperature must not exceed 110°F (43.3°C).
	Inadequate clearance around the ice machine.	Provide adequate clearance. See page 2-5.
	Objects stacked on or around ice machine, blocking air flow to condenser (air-cooled models).	Remove items blocking air flow.
	Air baffle is not installed (air-cooled models).	Install air baffle. See page 2-12.

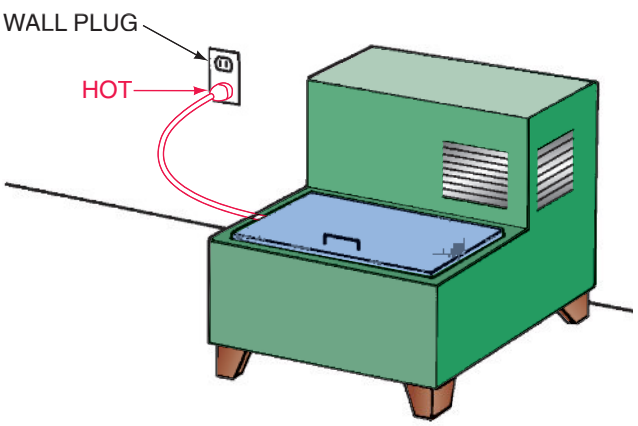
Figure 27.59 This unit has a poor connection at the wall plug.



Line-voltage problems may be detected with a voltmeter. The unit nameplate will tell you what the operating voltage for the machine should be. Make sure the machine is within the correct voltage range. The plug on the end of the power cord may have become damaged or overheated due to a poor connection. Examine it while the machine is running by touching it. If it is hot to the touch, it is not properly conducting power to the machine, **Figure 27.59**. When the power is wired to the junction box in the ice maker, it goes to the control circuit that operates the machine. Larger machines may use relays to energize contactors for starting the compressor.

27.8 SERVICE TECHNICIAN CALLS

The following service calls cover some of the most common problems experienced with ice machines.

SERVICE CALL 1

A service technician is servicing an ice flake machine. After taking the covers off the machine, the technician does not notice anything wrong. The bin is half full of ice and the machine seems to be working properly. The technician then decides to talk to the restaurant manager. The manager says that the ice flake machine makes loud screeching noises intermittently. The technician returns to the machine and does hear some small screeching noises coming from the evaporator and auger assembly. The noises get progressively louder for about 10 min and then quit. Ten minutes later, the noises start again. *The problem is mineral buildup in the evaporator freezing cylinder and auger compartment. This causes the auger to drag on the mineral deposits, making loud screeching noises like two pieces of Styrofoam being rubbed together. Sometimes the mineral deposits break loose and are delivered with the ice.*

The service technician then tells the restaurant manager that the noise he described was occurring again. By doing this, the technician lets the restaurant manager feel that he helped to find the solution to the problem. The service technician examines the ice flakes for quality and finds that they show a lot of cloudiness. This is caused by minerals trapped in the flakes. The technician then decides that the ice flake machine needs a cleaning to rid it of the mineral deposits. The technician also decides to sanitize the machine after the cleaning to rid the machine of any harmful bacteria, viruses, or protozoa. Emptying the ice bin of all ice flakes is the first step the technician takes.

The technician follows the manufacturer's instructions in the service and maintenance manual, acquired from an Internet search, on cleaning and sanitizing the entire ice machine and bin. (Often, instructions for cleaning and sanitizing are located on a label on the ice machine itself.) After restarting the ice flake machine, the technician finds that it runs quietly

and that the ice has a much better quality than before the cleaning and sanitizing procedure.

The service technician stays for about 45 min, cleaning up and talking to the restaurant manager about a preventive maintenance and water treatment program for all the ice machines in the restaurant. The technician then returns to the ice flake machine to check for screeching sounds, but hears none. It appears that the problem has been remedied. Again, the technician explains what the problem was, and then thanks the restaurant manager for his help in solving the problem. The restaurant manager is then given the billing information with a detailed description of the work completed and associated costs. Handshakes are exchanged and the service technician leaves the job site.

SERVICE CALL 2

A service technician is called to service a cell-type ice cube machine that will not harvest the ice from the evaporator. The sheet of ice grows much too thick and actually freezes the ice thickness probe into the ice sheet. *The ice thickness probe's electrodes are scaled with mineral buildup. This prevents them from completing a circuit when the thin water film next to the ice sheet contacts them. (Evaporator damage from too thick an ice sheet can occur. Also, low suction pressure from a reduced evaporator load, which may lead to compressor flooding, can occur if the problem is not fixed.)*

The service technician bypasses the freeze time lock-in feature by moving the ice/clean/off switch to *off* and back to *ice*. The technician waits for water to start running over the evaporator and then clips a jumper wire lead to the ice thickness probe and cabinet ground, **Figure 27.60**. The harvest light on the

Figure 27.60 An ice thickness probe and control board. (A) Before jumper. (B) After jumper.

control board comes on. Eight seconds later, the ice machine goes into a harvest cycle. The technician can hear the hot gas solenoid valves energize and hot gas pass into the evaporators. The ice thickness probe is taken off the evaporator and cleaned with the proper ice machine cleaner to get rid of any mineral deposits. While cleaning up, the technician watches the ice machine through three freeze and harvest cycles and determines that the ice machine is working as designed. After talking with the store owner about preventive maintenance and water treatment, the technician leaves the job.

SERVICE CALL 3

A service technician is called to a restaurant to service an ice machine that makes cube type ice. The restaurant owner is complaining about cloudy ice that melts very fast. Customers are complaining that there is flaky sediment in the bottom of their glasses after the ice melts. Before the service technician enters the restaurant, he makes sure that there is no dirt or grease on his face, clothes, or shoes from a previous job that day. The technician also makes sure his hands are cleaned and sanitized before working on the ice machine, knowing that ice is a food product and can be contaminated very easily. Once introduced to the manager, the technician carefully listens to what he has to say while always maintaining his professionalism. It is important never to be critical of the customer, even in a joking manner, no matter what he has to say about the service call. Always try to be sympathetic, listen carefully, and try to determine why the customer is so upset. Once the customer finishes, the technician is led to the ice machine to begin work. *The problem is a defective water dump solenoid valve* **Figure 27.30(A).** *If the old water from the water reservoir is not dumped or purged every cycle, the same water is being used and the mineral content becomes very high. Excess minerals that are frozen in the ice cause it to become soft, cloudy, and dirty.* **Figure 27.50(A)** *shows the difference between soft, cloudy ice and hard, clear ice.*

The service technician inspects some ice in the ice bin and sees that it is soft, cloudy, and dirty with minerals. After observing the freeze and harvest cycles and determining that there is no purging of water during the harvest cycle, the technician turns off the ice machine and unhooks the purge solenoid from the control board. An ohmmeter is used to check resistance of the purge solenoid's coil. The resistance checks to infinite, indicating an open solenoid coil. A new coil is put in place and is hooked back up to its control board terminals. The ice machine is turned back on and a cycle is again observed. During a harvest cycle, the control board energizes the water purge solenoid and water freely flows down the drain. This action empties the water reservoir of old, mineral-laden water, and fresh water now fills the reservoir. The technician catches the ice before it falls to the bin and observes it. The ice is crystal clear, hard, and clean. The service technician then talks to the restaurant owner about a preventive maintenance and water treatment program, cleans up around the ice machine, gives the customer the billing information and explains each step of the billing in detail, and leaves the job site.

SERVICE CALL 4

A service technician is servicing an ice maker and has determined that the ice machine will not come out of a hot gas defrost mode as quickly as it should. Too long a defrost will cook off the metal coating on the evaporator. Instead of the harvest motor's probe pushing the ice off the coil, which will terminate defrost with a curtain switch, the evaporator gets very hot from the prolonged hot gas defrost. In other words, a "cookout" occurs. The ice slowly falls off the evaporator in chunks by gravity. Sometimes, one of these chunks will trip the curtain switch and bring the machine out of defrost, and other times it will not. *The problem is a defective harvest motor. Ice cannot be forced off the evaporator during harvest with a defective harvest motor.*

The service technician gets out a voltmeter and measures the output terminals of the microprocessor labeled motor 1 and motor 2 while in defrost, **Figure 27.47**. The technician measures 115 V AC at both terminals and determines that this is the correct voltage. This tells the technician that the microprocessor is doing its job and is sending an output signal to the harvest motor, so the microprocessor is not to blame. The problem must lie in the harvest motor or the wires leading to the harvest motor. The service technician then checks voltage at the harvest motor itself and gets 115 V AC. This rules out the problem being in the wiring between the microprocessor and the harvest motor. The problem must lie in the harvest motor itself. (If the correct voltage is going to a power-consuming device and it is not operating, the problem lies within the power-consuming device.)

The service technician retrieves a new harvest motor from the service van and installs it. After watching the ice machine for two complete cycles, the technician determines that everything is working as it should.

SERVICE CALL 5

A service technician servicing an ice maker that has a microprocessor observes that the ice machine will not come out of ICE 1 mode. The technician consults the service manual and finds that the evaporator must reach 14°F before an internal timer will start. The technician wonders if it is the microprocessor's fault or if the problem is in one of the inputs to the microprocessor. *The problem is a defective thermistor on the evaporator. With a defective thermistor, the microprocessor does not know the evaporator's temperature and cannot advance the ice machine to the next mode (ICE 2).*

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The technician reads further in the manual and discovers that the microprocessor is fed an input signal from a thermistor connected to the evaporator. A thermistor is nothing but a resistor that varies its resistance as the temperature changes. This thermistor is what signals the digital LED display what mode the ice maker is in. It also tells the microprocessor when the evaporator has reached 14°F. The manufacturer has supplied a resistance versus temperature relationship table for checking thermistors. The only sure temperature that the technician can simulate accurately is 32°F. This is accomplished by placing some crushed ice in a small amount of water and stirring. The thermistor lug is then taken off the evaporator and is also electrically disconnected from the microprocessor's evaporator input terminal. The thermistor lug is given a chance to stabilize its temperature at 32°F in the ice water bath. A resistance reading taken with an ohmmeter is 5.50 thousand ohms, or 5.50 Kohms. According to the temperature versus resistance chart for the thermistor, the resistance should be 9.842 Kohms. This indicates a defective thermistor and explains why the microprocessor is not going out of ICE 1 mode. A new thermistor is ordered from the manufacturer. The customer is politely informed of the problem and the part ordered. The work site and the technician's hands are then cleaned, and handshakes are exchanged with the customer.

The technician could have measured the signal coming into the microprocessor's input terminal labeled EVAP, but that would require knowing what it was supposed to be. Most of the time these signals are a low AC or DC voltage, but they can be a resistance signal. The service technician must read the manual to find out. The service technician has a service trainee with him and was very careful to explain each step in detail while training. The technician told the trainee never to argue about a service problem in front of a customer, but to wait until they are alone in the service van before voicing a difference in opinion.

SUMMARY

- Most ice flakers are critically charged refrigeration systems that come in a split or a self-contained unit.
- Ice flake machines use an auger turning inside a flooded cylinder to scrape ice off the sides of the cylinder.
- The auger has cutting surfaces called flights that do the ice cutting.
- Ice flake machines can be retrofitted to parallel refrigeration systems in a supermarket.
- When water is frozen in the evaporator or freezing cylinder, minerals from the water are left behind and often become attached to the interior cylinder walls.
- An ice machine cleaner will dissolve many minerals from the freezing section of an ice flake machine.
- Mineral buildup on the freezing cylinder of an operating ice flake machine will cause a sound like two pieces of Styrofoam being rubbed together.
- Ice flake machines usually have a gear reduction drive, which reduces the auger drive's motor speed.
- Mineral buildup on a freezing cylinder of an ice flake machine will cause auger motor and auger bearings to become stressed. Gears will also be stressed.
- The gear motor assembly is more prone to fail than any other part in the ice flake machine because of the pressures and stresses put on it.
- Worn bearings on the auger will cause the auger to wobble and rub against the freezing cylinder walls. This often causes scrape marks on the cylinder walls and metal shavings in the ice.
- A water flush cycle is a way to control unwanted mineral buildup in the water reservoir. A mechanical timer or a microprocessor can initiate these cycles.
- Ice bin controls are designed to terminate the operation of the ice machine when the bin is full of ice.
- Ice production depends on the ice machine's water inlet temperature and the temperature around the ice machine.
- Some ice flake machines provide a means for the service technician or owner to adjust the size or shape of the ice flakes. Rotating the ice cutter or changing the extrusion head are ways to accomplish this.
- During a hot gas harvest, the cubes slide down the evaporator plate by gravity. Dimples in the evaporator plate will break the capillary attraction between the plate and the crescent-shaped cube. Ice then falls in a bin for storage.
- Making cell-type ice cubes involves a vertical evaporator plate with water made to flow over the individual cells by a water pump. A serpentine evaporator coil is soldered to the back of the plate. Ice gradually forms in the cells and soon bridges with the neighboring cells.
- Too slow a water flow will freeze minerals with the ice. A restrictor in the water line regulates the water flow rate.
- Once a certain bridge thickness is reached, the water film on the ice will contact an adjustable ice thickness probe. A hot gas harvest is then initiated.
- A hot gas solenoid is energized in the discharge line. The compressor keeps running and pumps superheated gas through the evaporator.
- A hot gas defrost loosens the cubes from the evaporator plate.
- Weep holes between the cells on the evaporator allow air entering from the edges of the ice sheet to travel along the entire ice slab.
- Ice machine manufacturers provide many different control schemes and controls are used for water sump levels, ice

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

thickness, harvest initiation, defrost termination, and ice storage bin controls.
- During hot gas defrost or harvest, liquid floodback may occur to the compressor.
- Hot gas valves are often cycled by a microprocessor while in harvest in response to the discharge temperature to control liquid floodback.
- Microprocessors are often the main controller on modern ice machines. They have programs or algorithms stored within their memories to control a sequence of events.
- Microprocessors have input and output terminals where they receive and transmit information, respectively. Inputs and outputs can be either digital devices, like switches, or analog devices, like thermistors.
- A service technician should know the microprocessor's sequence of events and how to input/output troubleshoot them. Service manuals and the Internet are often used to gain knowledge of the sequence of events in microprocessors made by different manufacturers.
- Many microprocessors have self-diagnostics to assist the service technician in systematic troubleshooting.
- Microprocessors also have error codes, which can be displayed to assist the service technician in trouble-shooting.
- Many microprocessors can record the ice machine's history or a summary of past operations, which can then be recalled by simply pushing buttons.
- For air-cooled ice machines, ice production depends mainly on entering-water temperature and the temperature of the air entering the condenser.
- Ice quality depends on the quality of the water entering the ice machine. Good water quality will produce a crystal clear, hard cube with good cooling capacity. Poor water quality can produce soft, cloudy ice with less cooling capacity.
- Water can contain many different minerals in various amounts. Water filtration and treatment is a science in itself, but the service technician needs to know the basics of water quality to service ice makers.
- Ice quality is measured in percent of hardness. Hardness is a measurement that represents the thermal cooling capacity of the ice. The higher the percent hardness, the more cooling capacity the ice possesses.
- The cleaner the ice machine and the purer the water, the harder the ice will be.
- Preventive maintenance is regularly scheduled maintenance performed on an ice machine. It includes inspecting, cleaning, sanitizing, and servicing the ice machine and external water filtration/treatment system.
- Cleaning an ice machine with an acid-based cleaner simply removes scale caused by the mineral content in the water.
- A sanitizing fluid that is approved for commercial ice machines kills viruses, bacteria, and protozoa.
- If cleaning and sanitizing are done on a schedule that is appropriate for the local water conditions, the ice machine will have a longer and more productive life dispensing quality ice.
- Water treatment programs are designed to help with certain local water conditions. The water conditions can be broken down into the categories of suspended solids, dissolved minerals, and chemicals.
- A common type of water treatment is a triple-action filter system that can filter out suspended solids, fight against scale formation by adding chemicals, and improve the taste, odor, and color of the water with carbon filters.

REVIEW QUESTIONS

1. Which type of ice maker has a continuous harvest cycle?
2. Which type of ice is made using a gear motor and auger?
   A. Cube ice
   B. Cylinder ice
   C. Flake ice
   D. Block ice
3. What would be the symptoms of a defective float on an ice maker?
4. What are the two functions of the dual float switch in an ice flake machine?
5. Which part of an ice flake machine is most prone to failure?
   A. The gear motor
   B. The float mechanism
   C. The ice chute
   D. The compressor
6. List two causes that may lead to auger wobble.
7. What is the function of a flush cycle for an ice flake machine?
8. Name and explain three types of ice bin controls in ice flake machines.
9. Ice production in an ice flake machine depends mainly on two factors. Name and briefly explain these two factors.
10. Explain the function of weep holes on the evaporator of a cell-type ice maker.
11. True or False: Stainless steel is often used for evaporators because it is durable, very sanitary, and resists corrosion.
12. Explain what is meant by ice bridging in a cell-type ice maker.
13. Explain the function of the centrifugal pump in ice makers.
14. What is the function of the ice thickness probe in an ice maker?
15. Explain the function of the water dump solenoid valve in an ice maker.

16. What is the most common type of defrost during an ice maker harvest cycle?
    A. Electric
    B. Natural
    C. Hot gas
    D. Air
17. Explain how liquid floodback to the compressor may occur during an ice maker hot gas defrost period.
18. Why do ice machines need to be cleaned periodically?
19. Why do ice machines need to be sanitized periodically?
20. True or False: The same solution can be used to clean and sanitize an ice machine.
21. What is a common troubleshooting technique used on microprocessors?
    A. Input/output troubleshooting
    B. Ohmmeter
    C. Ammeter
    D. Guesswork
22. One of the quickest and most thorough ways of obtaining technical service information for an ice machine is through the
    A. manufacturer.
    B. wholesale store.
    C. Internet.
    D. fax machine.
23. Most of the time, the input signals to a microprocessor are
    A. high voltage.
    B. low voltage.
    C. steady.
    D. high frequency.
24. A way in which a microprocessor communicates to a service technician about a certain malfunction in the ice machine is
    A. a summary.
    B. an error code.
    C. a history.
    D. a data link.
25. True or False: Entering-air temperature and water temperature are the main factors determining the amount of ice produced in an air-cooled ice machine.
26. A measurement that represents the thermal cooling capacity of ice and also represents the amount of calcium and magnesium in water is
    A. hardness.
    B. turbidity.
    C. alkalinity.
    D. scale.
27. A buildup of minerals that forms a flaky coating on the surface of the evaporator and water system is called
    A. sediment.
    B. scale.
    C. hardness.
    D. turbidity.
28. A method for killing bacteria, viruses, and protozoa in ice machines is
    A. sanitizing.
    B. cleaning.
    C. rinsing.
    D. brushing.
29. True or False: Cleaning with an approved ice machine cleaner is a method of removing scale from an ice machine.
30. Water conditions can be broken down into three categories. Name these categories.
31. True or False: A common type of water filtration and treatment for ice machines is a triple-action filter system.
32. True or False: Chemicals in the water have to be removed with carbon filtration.
33. Usually, sand and dirt in water are easily removed by
    A. filters.
    B. reverse osmosis.
    C. distillation.
    D. de-ionization.

UNIT 28

SPECIAL REFRIGERATION APPLICATIONS

OBJECTIVES

After studying this unit, you should be able to

- describe methods used for refrigerating trucks.
- discuss phase-change plates used in truck refrigeration.
- describe two methods used to haul refrigerated freight using the railroad.
- discuss the basics of blast cooling for refrigeration.
- describe cascade refrigeration.
- describe basic methods used for ship refrigeration.

SAFETYCHECKLIST

- ☑ Ensure that nitrogen and carbon dioxide systems are off before entering an enclosed area where they have been in use. The area should also be ventilated so that oxygen is available for breathing and has not been replaced by these gases.
- ☑ Liquid nitrogen and liquid carbon dioxide are very cold when released to the atmosphere. Take precautions to avoid getting them on your skin. Wear gloves and goggles if you are working in an area where one of these gases may escape.
- ☑ Ammonia is toxic to humans. Wear protective clothing, goggles, gloves, and breathing apparatus when servicing ammonia refrigeration systems.

28.1 SPECIAL REFRIGERATION APPLICATIONS

There are many special refrigeration applications. Some technicians may never work with them, but others will. Keep in mind the principles of heat and heat transfer covered in Unit 1 as they pertain to refrigeration.

28.2 TRANSPORT REFRIGERATION

Transport refrigeration is the process of refrigerating products while they are being transported from one place to another—by truck, rail, air, or water. For example, vegetables may be harvested in California and shipped to New York City for consumption. These products may need refrigeration along the way. Many products must be shipped in different ways. Some are shipped in the fresh state, such as lettuce and celery, which are shipped at about 34°F. Some are shipped in the frozen state, such as ice cream, which is shipped at about −10°F. Fresh vegetables may be shipped through climates that are very hot, such as through Arizona and New Mexico. They may also be shipped through very cold climates, such as when fresh vegetables are shipped through Minnesota in the winter. Different situations require different types of systems. For example, refrigeration may be needed for a load of lettuce when leaving California, but when it goes to the northern states, the load may need to be heated to prevent it from freezing, **Figure 28.1**. Products that fall into the preceding categories are carried on trucks, trains, airplanes, and ships. The refrigeration system is responsible for getting the load to the destination in good condition.

28.3 TRUCK REFRIGERATION SYSTEMS

Several methods are used to refrigerate trucks. One of the most basic still being used is to merely pack the product in ice that is made at an ice plant. This is successful in a well-insulated truck for short periods of time. However, the melting ice produces water that must be handled. You can usually spot these trucks because of the trail of water left behind, **Figure 28.2**. Packing in ice can hold the load temperature only to above freezing.

Dry ice, which is solidified and compressed carbon dioxide, is also used for some short-haul loads. It is somewhat harder to hold the load temperature at the correct level using dry ice because it is so cold. Dry ice changes state from a solid to a vapor (called sublimation) at −109°F without going through the liquid state. As a result, food products can be reduced to very low temperatures. But dehydration of food products that are not in airtight containers can become a problem when dry ice is used because the very low temperature of −109°F attracts moisture from the food.

Liquid nitrogen or liquid carbon dioxide (CO_2) may also be used to refrigerate products by refrigerating and storing them as a liquid in a cylinder at a low pressure. A relief valve on the cylinder releases some of the vapor to the atmosphere if the pressure in the cylinder rises above the set point of about 25 psig. This boils some of the remaining liquid and drops the cylinder temperature and pressure, **Figure 28.3**. The liquid is piped to a manifold where the refrigerated

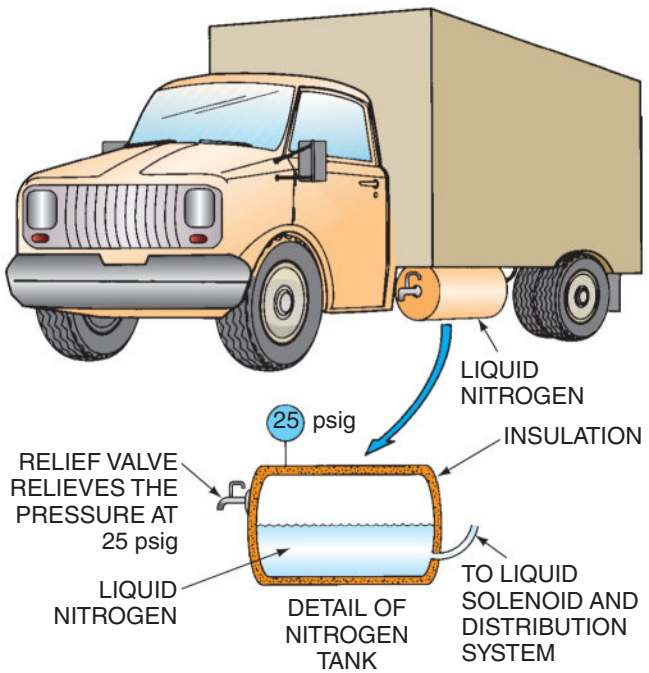
product is located and released to cool the air in the truck and the product. A thermostat located in the food space controls a solenoid valve in the liquid nitrogen line, stopping and starting the flow of liquid, **Figure 28.4**. Fans may be used to disperse the cold vapor evenly over the product.

Air in the atmosphere is 78% nitrogen; it is the source for the nitrogen used in refrigeration. It is not toxic, and it can be released to the atmosphere with confidence that no environmental harm will occur.

SAFETY PRECAUTION: *Nitrogen has no oxygen in it, so it is not suitable for breathing. Special safety interlocks shut the refrigeration off if the door to the refrigerated truck is opened to prevent personnel from being smothered by lack of oxygen. Nitrogen is also very cold; it evaporates at −320°F at atmospheric pressure. Any contact with the skin would cause instant freezing. Never allow liquid nitrogen to get on your skin.*•

Figure 28.3 A nitrogen cylinder maintained at about 25 psig.



Liquid CO_2 can be used in the same manner as liquid nitrogen to refrigerate products. The system works much the same as a liquid nitrogen system, only CO_2 boils at −109°F. Even though liquid nitrogen and CO_2 are both very cold, they can be used to refrigerate medium–temperature loads at 35°F with proper controls. These controls would include a distribution system for the refrigerant that does not impinge on the product and a space-temperature thermostat that accurately senses the refrigerated space temperature.

Figure 28.4 A control for a liquid nitrogen cooling system.

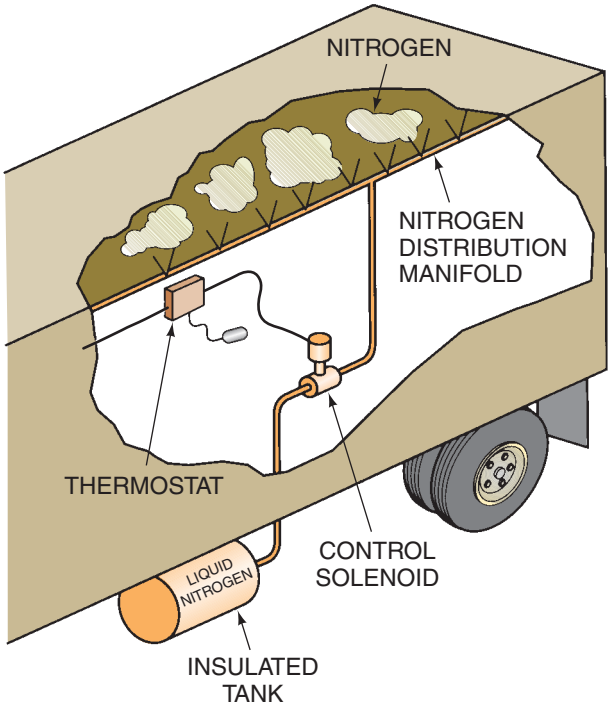

Figure 28.5 Cold plates mounted in a truck body.

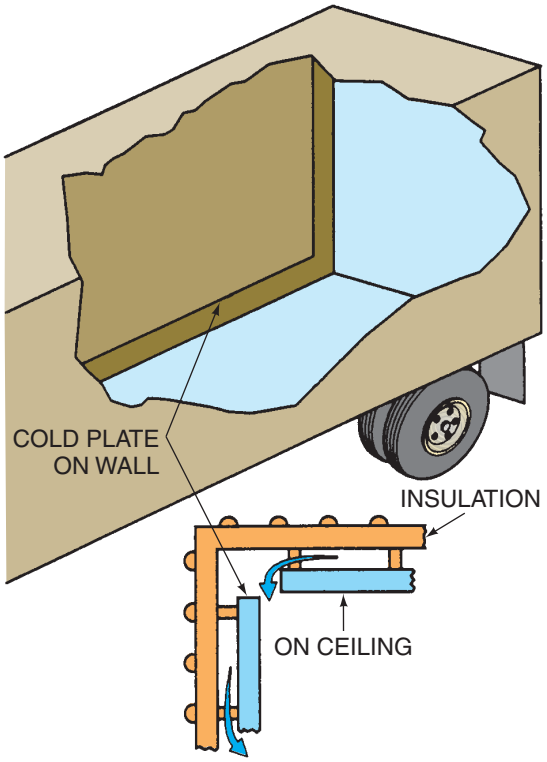

Both of these liquid injection methods have been used for many years to replace mechanical refrigeration for permanent installations and for emergency use. They are probably more expensive in the long run than a permanent installation, but they also have some good points. For example, when used to refrigerate fresh foods, the presence of nitrogen or CO_2 vapor displaces any oxygen and helps preserve the food. The system is simple and easy to control because only a solenoid and a distribution manifold need to be maintained.

Many truck bodies are equipped with refrigerated plates (called cold plates) that contain a phase-change solution called a **eutectic solution**. *Phase change* means a change in the state of matter, much like the change of state from ice to water, except at a different temperature. When the change of state occurs, much more heat is absorbed per pound of material. The eutectic solution has the capability of changing state at many different temperatures, depending on the composition of the solution. The eutectic solution in the cold plate is brine, a form of saltwater made up of either sodium chloride, a form of table salt, or calcium chloride. These brines are very corrosive and must be handled with care. Various strengths of brine solution may be used to achieve the desirable melting temperature below freezing, called the eutectic temperature. Actually, the brine does not freeze solid; salt crystals form, and the remaining solution is liquid. Different strengths of brine will cause the crystals to form at different temperatures.

The brine solution is contained in plates that are from 1 in. to 3 in. thick mounted on the wall or ceiling of a truck in such a manner that air can flow all around them, **Figure 28.5.** The air in the enclosed truck body transfers heat to the plates. The brine solution then changes from a solid to a liquid while absorbing heat. These plates will hold a refrigerated load at the correct temperature (in a medium- or low-temperature application) to allow an all-day delivery route to be run. For example, a truck loaded with ice cream may be loaded at night for delivery the next day. The ice cream must be at its prescribed temperature, and the truck cold plates must be at the design temperature. For ice cream, this may be −10°F or lower. When the truck comes back at night, it may still be −10°F, but most of the brine solution will have changed back to a liquid and need regenerating to the solid crystal state. The heat absorbed during the day is in the brine solution and must be removed. To recharge the plates, they must be cooled to the point that the brine changes state back to solid crystals.

The plates are recharged in several ways. Some systems have a direct expansion coil located in the cold plate. This coil is connected to the refrigeration system at the loading dock, **Figure 28.6.** The refrigeration system may use one of the typical refrigerants—R-134a, R-404A, or R-717, ammonia, or an environmentally friendly alternative refrigerant. When the truck backs up to the loading dock, quick-connect hoses are connected from the central refrigeration plant to the truck. The expansion valve may be located on the loading dock or at the actual coil in the eutectic cold plate. The

Source: Carrier Corporation

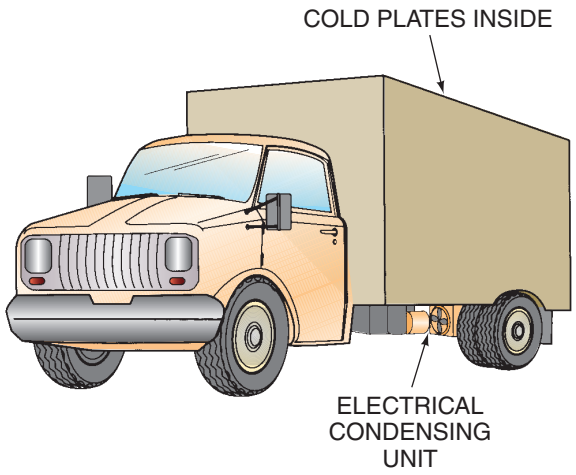
central refrigeration system will reduce the pressure in the evaporator in the cold plate to the point that the brine solution will change back to solid crystals in a few hours. The truck may then be loaded with product.

Another method of recharging the cold plate is to circulate refrigerated brine solution through a coil located in the cold plate. Brine that is refrigerated at a lower temperature than the cold plate will then recharge or freeze the brine in the plate, but the circulating brine must be much colder than the solution in the plate. Connecting this system to the truck also involves quick-connect fittings at the loading dock. There is always the possibility that some brine will be lost during the connecting and disconnecting of the quick-connect fittings. This brine must be cleaned up, or corrosion will occur.

Trucks may also be refrigerated using a refrigeration system mounted on the trucks. Whatever the refrigeration source, it must have a power supply. This power supply may be the truck's power supply, a diesel or gas engine-driven compressor, a land line (electric power from a building), or an electric compressor operated by a motor generator. Van-type delivery trucks often use a refrigeration compressor mounted under the hood that is turned by the truck engine. The refrigeration may be controlled by cycling the compressor using an electric clutch that is thermostatically controlled, **Figure 28.7**. This system works well as long as the truck engine is running. Because the truck is usually moving all day during delivery, refrigeration can easily be maintained. Some of these trucks have an auxiliary electric motor-driven compressor that may be plugged in at the loading dock while the truck engine is not running.

Small condensing units under the truck body are also used to refrigerate the load. These units are often used to recharge cold plates at night when the truck is at the dock or

Figure 28.8 A small refrigeration system on the truck recharges the cold plates while the truck is parked at night.



other power supply; the cold plates hold the load during the day, **Figure 28.8**. The advantage of this system is that it is self-contained and does not require a connection to a central refrigeration system at the loading dock. The condensing units may be powered while on the road by a small motor generator unit mounted under the chassis. In this case, there is no need for cold plates because the generator operates on the road and the compressor is plugged in at night.

Motor generators have either a gas or diesel engine that turns the generator to generate 230-V, 60-cycle current to operate the compressor. Diesel is the preferred fuel because diesel engines will operate longer with less fuel and with less

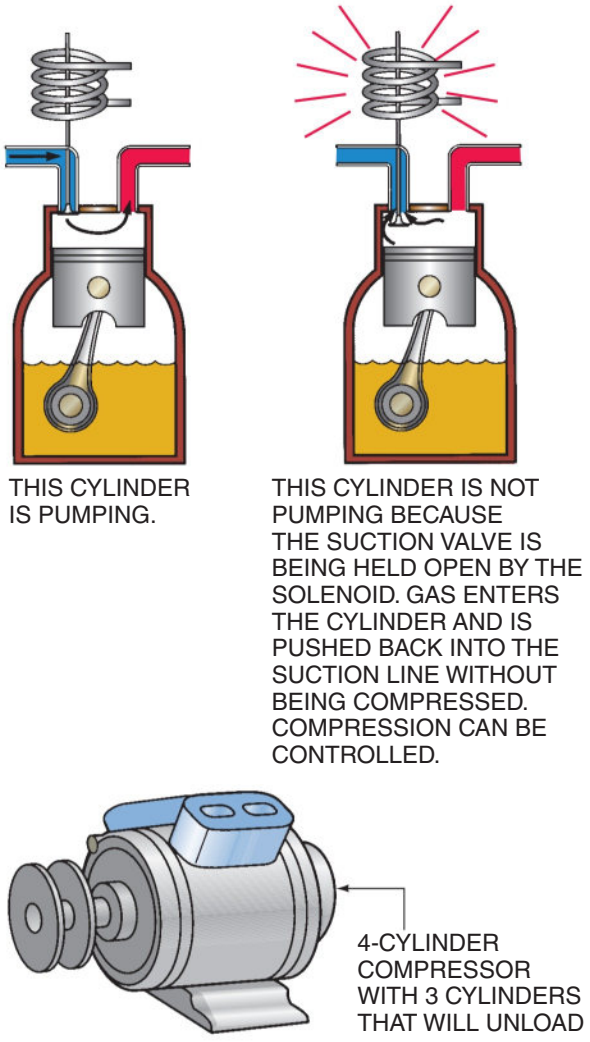
Figure 28.10 A capacity control for a compressor.



maintenance. Diesel engines cost more but seem to be less expensive in the long run. In some cases, a generator producing 230 V from the truck engine has been used. It must have a rather sophisticated control because the truck engine turns at so many different speeds. The stationary generator has only one speed. Different speeds would affect the power supplied to the compressor. As the engine turns faster, the voltage and the cycles per second vary; 60 cps is normal for alternating current electric motors. Electronic circuits may be used to maintain a constant voltage.

Larger trucks use either nose-mount or under-belly units that may be operated by either a diesel-engine-driven compressor or a motor generator driven by a diesel engine, **Figure 28.9**. An engine-driven compressor has a governor to regulate the speed of the compressor, which may have two speeds, high and low. The compressor may be controlled by means of cylinder unloading. For example, a four-cylinder compressor with a capacity of 1 ton per cylinder may be operated from 1 ton to 4 tons by unloading cylinders, **Figure 28.10**. A minimum load of 1 ton must be maintained at all times, or the diesel engine will have to be cycled off and on, so it is most desirable to keep the engine running. However, controls for diesel engines have been developed that will automatically start and stop the engine, **Figure 28.11**.

The evaporator for truck refrigeration units is typically located at the front of the truck and blows air toward the back of the truck, **Figure 28.12**. The fan is usually a type of centrifugal fan that distributes a high volume of air at a high velocity so that the air will reach the back. The air is then returned to the inlet of the air handler over the product load. The fan is driven with belts or gearboxes from the engine that drives the compressor. These components are normally located just inside the access door to the unit, where they can be checked and serviced easily from outside the refrigerated space, **Figure 28.13**. The condenser fan is often driven from the same drive mechanism and is typically a prop-type fan, **Figure 28.14**.

The evaporator and condenser coils are usually made of copper with aluminum fins because truck systems must be designed and built to be both rugged and lightweight given that each truck has a maximum load limit. Any weight added to the refrigeration unit is weight that cannot be hauled as a paying load. Many other components are aluminum, such as the compressor and others that can be successfully manufactured and maintained with this lightweight material.

Truck refrigeration systems must be designed to haul either low- or medium-temperature loads or even carry both low- and medium-temperature loads at the same time. This is accomplished using one refrigeration condensing unit with more than one evaporator. Part of the time, trucks may be hauling fresh vegetables; at other times the load may be frozen foods. The space temperature is controlled with a thermostat that starts out at full load; when it is within approximately 2°F of the set point, the system starts to unload the compressor. If the space temperature continues to drop, the unit will shut down. The air distribution system is designed to hold the load at the specific temperature, not to pull the load temperature down. As mentioned earlier, the food should be at the desired storage temperature before being loaded because the truck does not have much reserve capacity for pulling the load temperature down, especially if the interior is warmed up very much. If the refrigeration system for a medium-temperature load of food has to reduce the load temperature, the air distribution system may overcool some of the highest parts of the load because the truck body is so small that the cold air from the evaporator may impinge directly on the top product, **Figure 28.15**. If the load is frozen food and has warmed, it may be partially thawed. The truck unit may not have the capacity to refreeze the product, and if it does, it may be so slow that product damage may occur. Various alarm methods are used to alert the driver of problems with the load, **Figure 28.16**. The driver should stop and check the refrigeration at the first sign of problems. It may not be easy to locate a technician when the truck is away from metropolitan areas.

Truck bodies are insulated to keep the heat out, usually by foam insulation sprayed onto the walls with wallboard fastened to the foam. This makes a sandwich type of wall that is very strong, **Figure 28.17**. The walls must be rugged to withstand the loading and unloading of product. Aluminum- and

Figure 28.15 Due to air distribution, cold air may overcool food on top of the load.

fiber-reinforced plastic products are often used to cover the walls. The floor must be strong enough to support the weight of the load while traveling on a rough highway, and it must also be able to support a forklift that may be used for loading. The interior of a refrigerated truck must be manufactured in such a manner that it can be kept clean because food is being handled. The doors are normally in the back so that the truck may be loaded with a forklift; however, some trucks have side doors and compartments for different types of product. The doors must have a good gasket seal to prevent infiltration of the outside air. The doors must also have a secure lock to prevent the load from being stolen.

Truck transport refrigeration technicians should be diesel technicians as well as refrigeration technicians. Trained in both fields, they usually do not work on other types of refrigeration systems. Often, they are factory trained to service a particular type of refrigeration system and engine combination. A good knowledge of basic refrigeration would be good preparation for truck transportation systems, and knowledge regarding diesel engines can be added.

28.4 RAILWAY REFRIGERATION

Products shipped and refrigerated by rail are mechanically refrigerated either by a self-contained unit located at one end of the refrigerated car or by an axle-driven unit. The axle unit is an older system and not used to any extent today. The railcar using axle-driven units would have refrigeration only while the train is in motion. The self-contained unit is the most popular. It is generally powered by a diesel-driven motor generator, similar to truck refrigeration, **Figure 28.18**. The compressor is a standard voltage and may be powered with a power cord while the car is in a station or on a rail siding for long periods. The evaporator blower is mounted at the end of the railcar with the motor generator. All of the serviceable components can be accessed from this compartment, **Figure 28.19**.

Two-speed engines are often used when the generator has an output frequency of 60 cps at full speed and 40 cps at reduced load. The compressor electric motor must be able to operate at the different frequencies. The diesel engine speed is adjusted by the space-temperature thermostat and operates at a much lower fuel cost at low speed. When low speed is reached, the

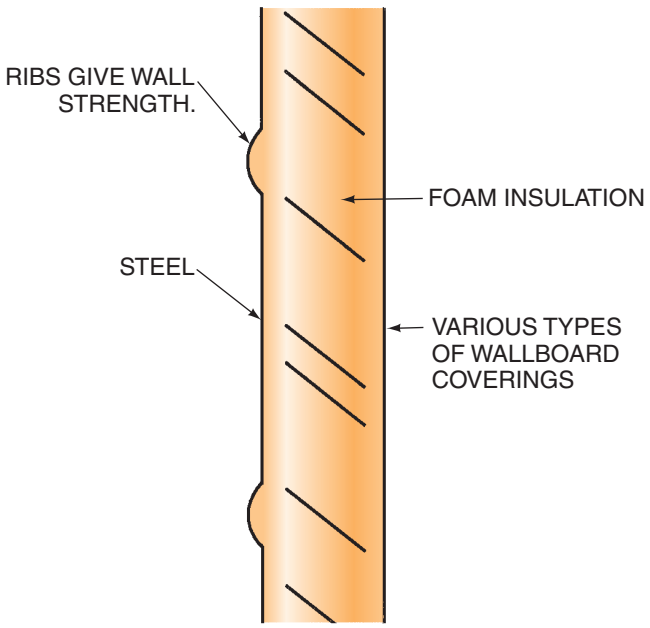
compressor may be unloaded using cylinder unloading. These systems have a rather wide range of capacities to suit the application. Like truck systems, they are capable of reducing the space temperature to 0°F or below for holding frozen foods, or they may be operated at medium temperature for fresh foods. Railcars have an air distribution system much like trucks and are designed to hold the refrigerated load, not reduce the temperature. They do not have much reserve capacity.

Refrigerated railcars are made of steel on the outside and typically have a rigid foam insulation in the walls, **Figure 28.20.**

Figure 28.20 The wall construction of a railcar.



The walls are covered with various types of wallboard that can be easily cleaned. If railroad cars did not have a sophisticated suspension system for en route travel and to protect the load from the rough coupling of cars when the train is assembled, they would ride rough, with metal wheels on metal rails, and have a lot of impact vibration when being connected and disconnected. They have wide doors for forklift access, and the doors must have a very good gasket to prevent air leakage. Typically, the railcar is operated under a positive air pressure and must have good door seals.

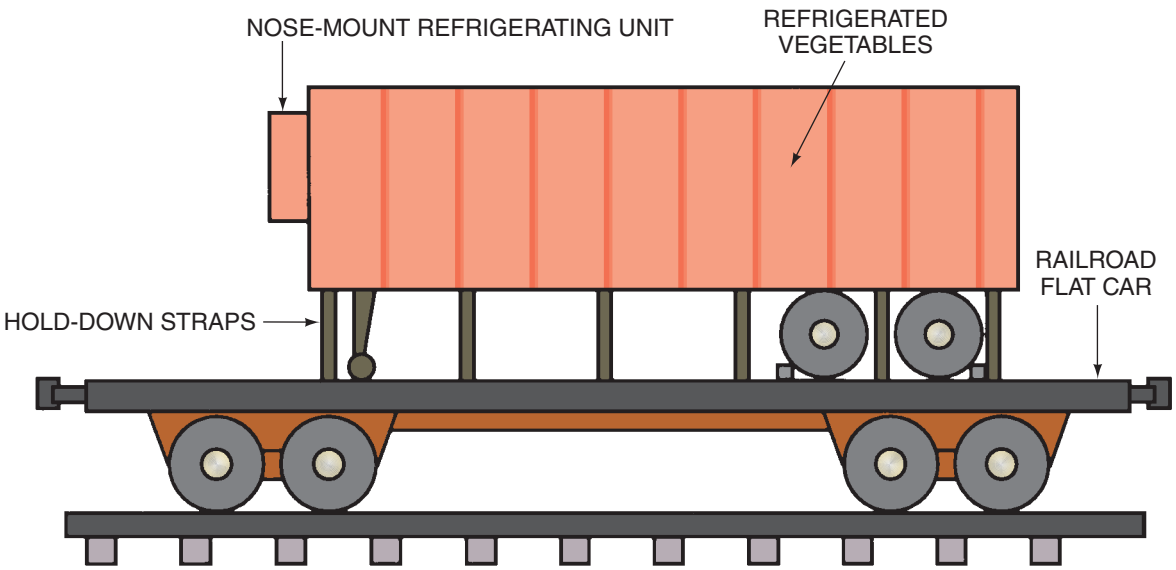
Railroads also ship refrigerated trucks in a system known as "piggyback." The trucks are loaded on the railcars and shipped across country, **Figure 28.21**, a popular system because the refrigerated load often would otherwise have to be off-loaded to a refrigerated truck in the locality where the food is to be consumed or processed. With piggy-back cars, the refrigerated load arrives on the truck for hauling to the final destination.

28.5 EXTRA-LOW-TEMPERATURE REFRIGERATION

This text defines extra-low temperature as below −10°F. Temperatures below that are not used to any great extent for storing food; however, they are used to fast-freeze foods commercially. These temperatures may be in the vicinity of −50°F.

When the product temperature needs to be reduced lower than −50°F, a two-stage system of freezing may be used. At extremely low evaporator temperatures, the compression ratio for the compressor becomes too great for single-stage refrigeration. The two stages of compression are accomplished by using a first-stage compressor (or cylinder) pumping into a second-stage

Figure 28.21 Piggyback railcar refrigeration.



Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

compressor (or cylinder), **Figure 28.22**. The compression ratio is thus divided between two stages of compression. If a single-stage system were operating at a room temperature of −50°F, it would have a boiling refrigerant temperature of about −60°F, using a coil-to-air-temperature difference of 10°F, **Figure 28.23**. This would make the evaporator pressure 6.6 in. Hg (11.48 psia) for R–404A. If the condensing temperature were to be 115°F, the head pressure would be 291 psig (306 psia). The compression ratio would be

CR = Absolute Discharge Pressure ÷ Absolute Suction Pressure
CR = 306 ÷ 11.48
CR = 26.65:1

This is not a usable compression ratio. It can be reduced with a two-stage compressor, **Figure 28.24**. The first stage of compression has a suction pressure of 11.48 psia and a head pressure of 40 psig (55 psia). The compression ratio would be

CR = 55 ÷ 11.48
CR = 4.79:1

The second-stage compressor would have suction pressure of 40 psig (55 psia) and a discharge pressure of 291 psig (306 psia).

CR = 306 ÷ 55
CR = 5.56:1

With a lower compression ratio, the trapped refrigerant gas in the clearance volume at the top of the piston's stroke will go through less reexpansion. This increases the efficiency of the first and second stages of compression. The second-stage compressor then experiences a higher suction pressure, which also will aid in giving it a higher efficiency.

Figure 28.22 Two-stage refrigeration.

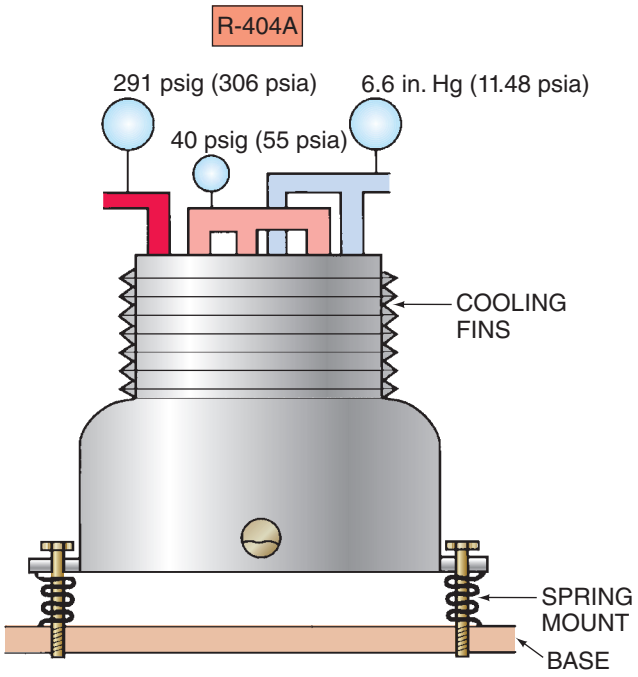
Figure 28.24 The compression ratio and two-stage refrigeration.



COMPRESSION RATIO

USING 1 STAGE OF COMPRESSION

$$CR = \frac{\text{ABSOLUTE DISCHARGE}}{\text{ABSOLUTE SUCTION}}$$

$$= \frac{291 \text{ psig} + 15 \text{ (ATMOSPHERE)}}{11.48 \text{ psia}}$$

$$= \frac{306 \text{ psia}}{11.48 \text{ psia}}$$

$$= 26.65 \text{ TO } 1$$

USING 2 STAGES OF COMPRESSION

$$CR_{(1ST\ STAGE)} = \frac{\text{ABSOLUTE DISCHARGE}}{\text{ABSOLUTE SUCTION}}$$

$$= \frac{55 \text{ (40 psig} + 15 \text{ ATM)}}{11.48}$$

$$= 4.79 : 1$$

$$CR_{(2ND\ STAGE)} = \frac{\text{ABSOLUTE DISCHARGE}}{\text{ABSOLUTE SUCTION}}$$

$$= \frac{306 \text{ psia (291 psig} + 15 \text{ ATM)}}{55 \text{ psia}}$$

$$= 5.56 \text{ TO } 1$$

Manufacturers would always like to have the system operate in a positive pressure. The system just described operates in a vacuum, and if a leak occurs on the low-pressure side, atmosphere would enter the system. This system may not be very practical, but it is very possible. The lower the compression ratio, the better the compressor efficiency. This is particularly true for the first-stage compressor. Designers will pick the best operating conditions for the system, combining several compressors until they find the highest efficiency.

28.6 CASCADE SYSTEMS

Systems with operating temperatures down to about −160°F may use what is called cascade refrigeration. Cascade refrigeration involves two or three stages, depending on how low the lower temperature range needs to be. This is accomplished by the condenser of one stage exchanging heat with the evaporator in another stage. The condenser rejects heat from the system and the evaporator absorbs heat into the system. Cascade refrigeration involves more than one system working at the same time and exchanging heat between them. **Figure 28.25** illustrates a cascade refrigeration system where carbon dioxide is being used as the low-stage, low-temperature refrigerant in the lower portion of the system. HFC-404A is being used as a high-stage or secondary refrigerant. A glycol solution is chilled by the secondary refrigerant. The glycol is then circulated through evaporators by a centrifugal pump to cool medium-temperature applications. Refer to Unit 26, "Applications of Refrigeration Systems" for more detailed information on cascade refrigeration systems.

28.7 QUICK-FREEZING METHODS

Food that is frozen for later use must be frozen in the correct manner or it will deteriorate, the quality will be reduced, or the color may be affected. When the food is frozen, the faster the temperature is lowered, the better the quality of the food. This can be done in several ways using a refrigeration system at very low temperatures. This method is often called "quick freezing."

Generally, the meats that you buy at the grocery store and freeze in your home freezer do not have the same quality as the meats you buy already frozen. The reason for this is the home freezer does not freeze the meat fast enough. When meat is frozen slowly, ice crystals grow in the cells and often puncture them, which is why you often see a puddle of liquid when meat is thawed. This is food value and flavor escaping. When foods are frozen commercially, they are frozen quickly by moving very cold air across the product at a high velocity to remove the heat quickly. When most fresh food is frozen very quickly and thawed, it should still have the quality of fresh food.

Different foods have different requirements for freezing. For example, some poultry must be frozen very quickly to preserve the color. One method of accomplishing this is to seal the meat in an airtight plastic bag and then dip it in a very cold solution of brine, which causes the surface to freeze. The bag is then washed and the poultry removed to another area for freezing the core of the meat at a slower rate.

Foods are often frozen in bulk in packages to be thawed later for processing or cooking. When foods are frozen in this manner, the pieces may stick together, but it makes no difference because they are going to be used in bulk. Many foods are frozen in individual pieces. For example, shrimp may be frozen individually so that they can be sold by the pound while frozen. This may be accomplished by a process called blast freezing, which uses trays in a blast tunnel or on a conveyor system in a blast freezer room, **Figure 28.26**. The blast freeze method is done at very low temperatures and a high air velocity. If the conveyor is placed in a room where the temperature is −40°F or lower and the air is moving fast, by the time small food pieces travel the length of the conveyor they are frozen hard. When the food is placed on the conveyor separated from other pieces, it will be frozen individually, **Figure 28.27**. It may then be packaged and dispensed individually. Larger parcels of food,

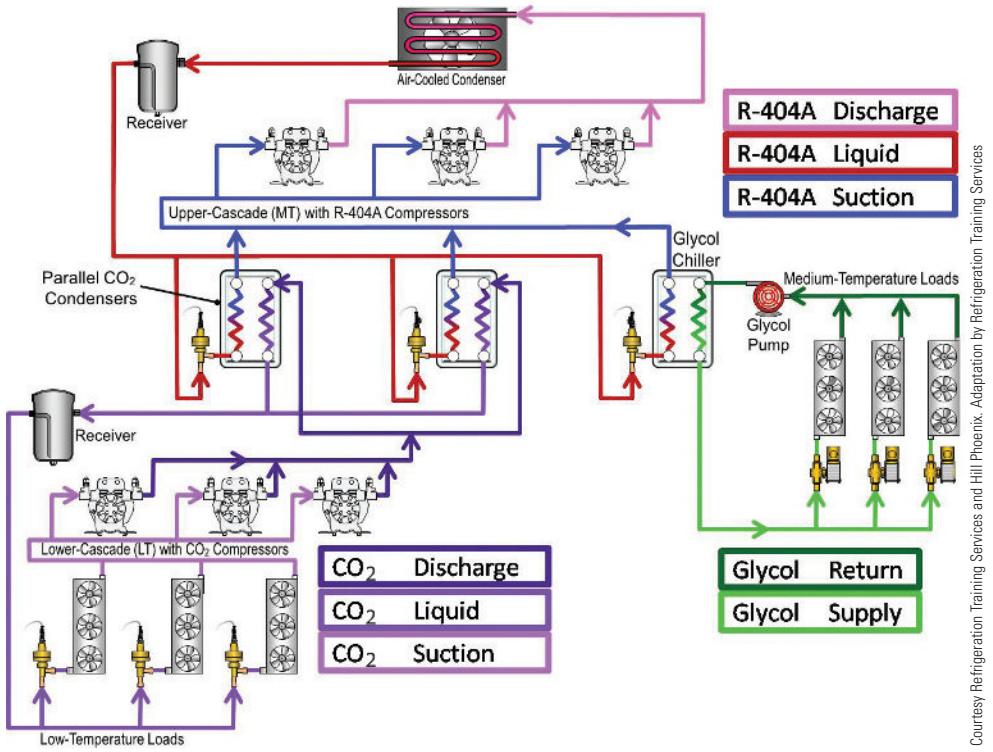
Figure 28.25 A cascade refrigeration system.



such as a carcass of beef, take longer to freeze. These would be precooled to very close to freezing and then moved to the blast freeze room for quick freezing. Different weights of food may be placed on longer or shorter conveyor belts or the belt speed may be adjusted to the correct time for freezing the food.

Food trays and tunnels may also be used for fast-freezing food. Food is placed on trays with plenty of space between the pieces. The trays are then loaded on carts and moved into a tunnel, **Figure 28.28**. When the tunnel is full and a cart is pushed in, a cart is pushed out the other end with frozen food, ready to package. This method requires more labor but is less expensive to build from a first-cost standpoint than a conveyor system, which is more automated. Quick freezing may be accomplished using standard refrigeration equipment. The larger refrigeration systems may use ammonia as the refrigerant and reciprocating compressors. Other systems may use R-22 or newer, environmentally friendly, alternative refrigerants and screw compressors. *The chlorofluorocarbon (CFC)/ozone depletion issue is causing ammonia systems to make a comeback. They are efficient and do not deplete the ozone layer.*

28.8 MARINE REFRIGERATION

Ship refrigeration may be required to transport product in several different ways. For example, a ship may pick up a perishable product requiring medium-temperature refrigeration (34°F) in South America and deliver it to New York City. The ship may then pick up a load of frozen food to be delivered to Spain at −15°F, a low-temperature application. The ship's refrigeration system must be able to operate at either temperature range. Another application for ship refrigeration may be preserving fish caught at sea. If the ship is only out to sea for a few days, it may use ice carried from shore. This would be the case for a shrimp boat operating off the coast. To prevent excess melting, auxiliary refrigeration may also be used to aid the ice in refrigerating the load. If the ship is to be at sea for long periods, the load must be frozen for preservation. It is not unusual for a ship to stay at sea for several months gathering a load of fish. Often, a fleet of small boats catch the fish and deliver it to a large, refrigerated processing ship called a mother ship, **Figure 28.29**. In this case, the refrigeration system may have to be very large, possibly several hundred tons. These ships must have a method for quick freezing fish to preserve the flavor and color.

Another method is to haul refrigerated freight in containerized compartments that are loaded onto the ship. These containers may have their own electric refrigeration system that may be operated at the dock and can be plugged into the ship's electrical system, **Figure 28.30**. These units must be located in such a manner that air can circulate over the condensers or they will have head pressure problems. It is typical for them to be located on the deck of an open ship. The ships that have large refrigeration systems onboard may use any of the refrig-erants listed in this text, including the newer alternative refrigerants and blends, depending on the age and the design of the refrigeration system.

Figure 28.29 The mother ship and a fleet of fishing boats.

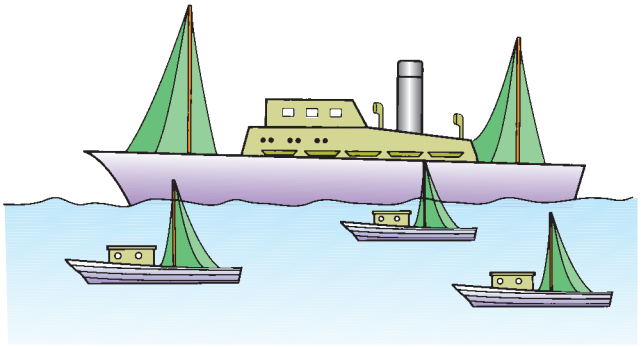

Figure 28.30 Containerized freight for ships.

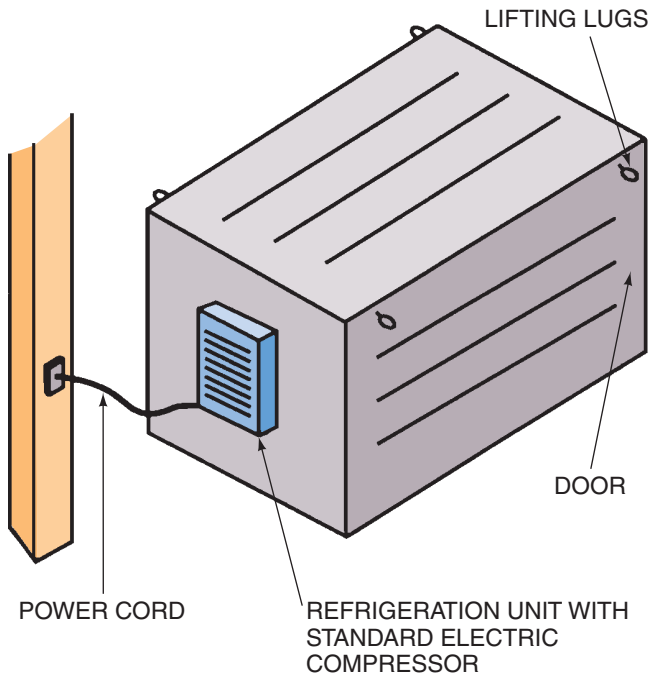

Ammonia refrigeration systems are also used for ships. This refrigerant is not considered dangerous to the environment, so these systems will continue. It is, however, extremely toxic to humans and must be used with care.

SAFETY PRECAUTION: *It is sometimes necessary for technicians to wear breathing apparatus as well as protective clothing, gloves, and goggles when working with ammonia systems.*•

Large-system compressors may be reciprocating, screw, or centrifugal when R-11 is used. R-123 (HCFC-123) is now being used as an interim replacement for R-11 (CFC-11). The compressors may be driven using belts or direct drive by the ship's electrical system if it has a large enough generating plant. A large system may also be driven by steam turbines using the ship's steam system. The evaporators may be large plates in the individual refrigerated rooms or bare pipes, **Figure 28.31.** There

Figure 28.31 Plate evaporators for a ship.

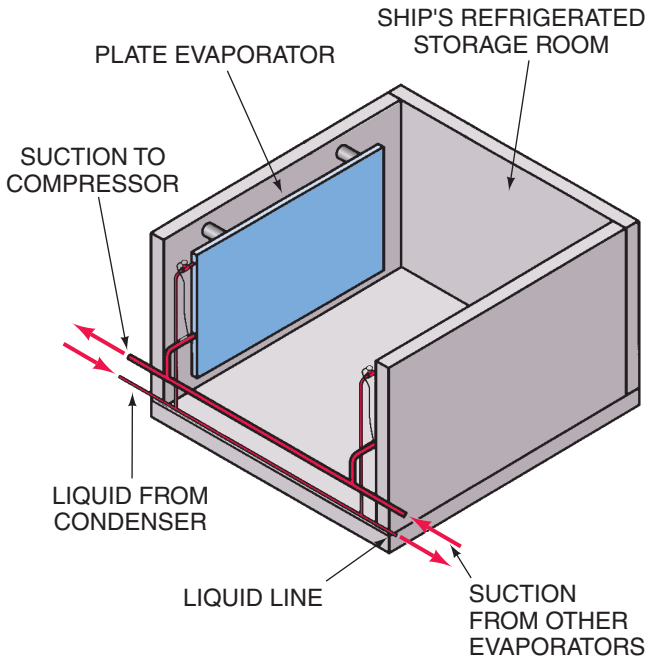

Figure 28.32 Forced-air refrigeration for a ship.

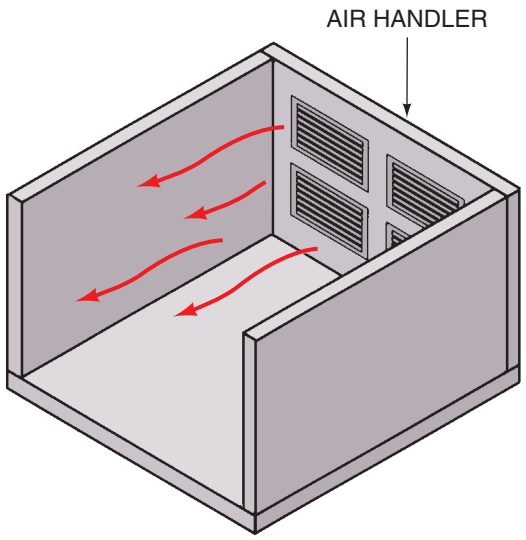

are also systems using forced air, **Figure 28.32.** These systems are direct expansion, using thermostatic expansion valves. The ship may have several refrigerated compartments so that all the refrigeration is not in one large area.

The evaporators must have some means of defrosting because they will normally be operating below freezing at the coils. If the evaporator is close enough to the compressor, this may be accomplished with hot gas. If not, seawater may be used. If the water is too cold, it may be heated and sprayed over the evaporator when the fan is not running on a fan coil

unit and the coil is not refrigerating during defrost time. By stopping the fan and closing the liquid-line solenoid valve during defrost the compressor will pump the refrigerant out of the evaporator during defrost. Defrost can be terminated using coil temperature or time. The refrigerant that is pumped out of the coil will be in the receiver during defrost, and the compressor can continue to run to other refrigerated compartments on the ship. Defrost can be staggered so that all coils will not call for defrost at the same time.

The condensers use seawater, which is readily available everywhere the ship goes. Seawater contains debris and must be filtered with filters that are easy to access and clean, which is commonly done with valves that allow the pumps to reverse the flow through the filters and piping to backwash the system, **Figure 28.33**. The refrigerant condensers for the typical refrigerants—R-11, R-12, R-22, R-502—and the newer alternative refrigerants and blends must be designed and built for easy cleaning because they will become dirty. These condensers have removable water box covers, called marine water boxes, and the tubes can be cleaned using a brush, **Figure 28.34**. The tubes are made of cupronickel (copper and nickel), a tough metal that does not corrode easily. The tube sheet that holds the tubes is typically made of steel, and the water box is made of brass where possible, **Figure 28.35**.

The American Bureau of Shipping recommends reserve capacity refrigeration and a spare parts inventory for making repairs at sea. It also recommends two compressor systems, either one of which should have enough capacity to maintain the load, running continuously while in tropical waters. This provides 100% compressor standby capacity, which is

Figure 28.33 (A)–(B) Flushing the ship's seawater-cooled condensers.

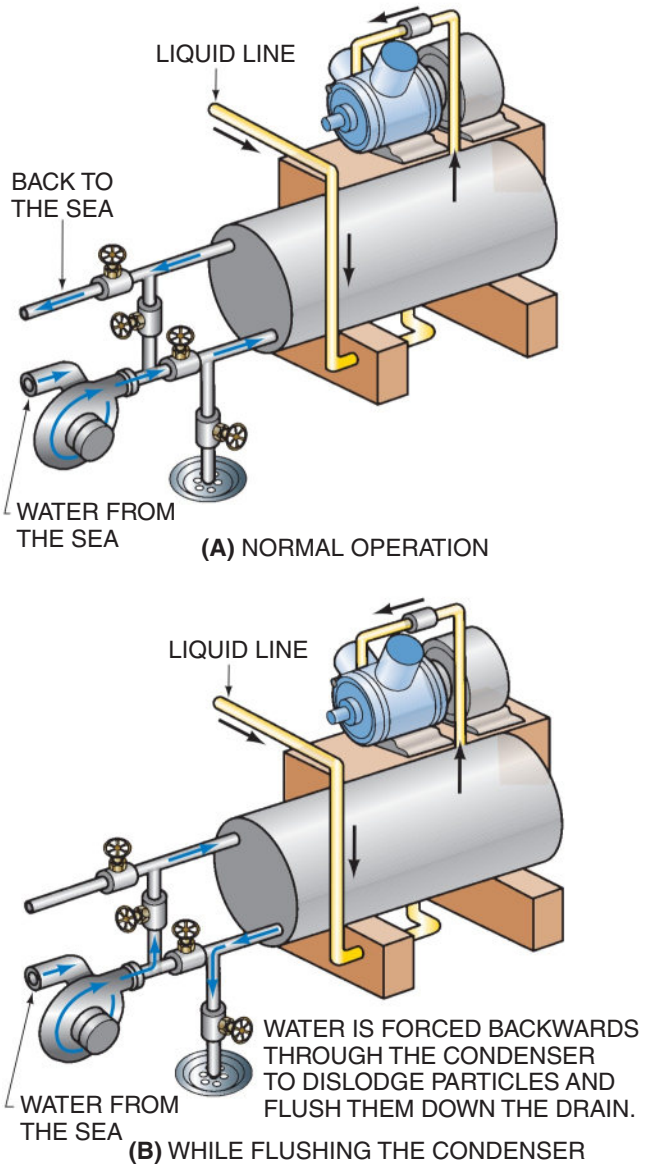

Figure 28.34 (A) Cleaning a condenser using a brush. (B) A cutaway view of a tube showing a rotating brush.

the most likely part of the system to cause a problem. Therefore, marine systems can become quite large. There must be someone aboard with experience who is familiar with the system and can make any necessary repairs. Repairs at sea are not uncommon. It can take days to reach a port with a repair facility.

The individual evaporators can be located at great distances from the ship's condensers and compressors requiring long refrigerant lines to be run. This may lead to problems of returning lubricating oil that leaves the compressor. Oil separators may be used at the compressor to keep most of the oil in the compressor, but some will get into the system and will have to be returned. Circulating brine systems have some advantages over individual evaporators in the refrigerated spaces. The primary refrigeration components and the primary refrigerant can all be contained in the equipment room with a central compressor or compressors. The brine may be chilled and circulated to the various locations for desired applications, **Figure 28.36**.

As with truck refrigeration, cargo ship refrigeration is designed to hold the refrigerated load temperature. It usually does not have much reserve capacity for reducing the load temperature. The ship storage rooms are not designed or built for the type of air circulation necessary to reduce the temperature of the load even if reserve capacity is available. When the ship is loaded, every square foot of storage counts. The ship must be designed to accept the load and store it for the trip even if the seas are rough. The placement of the refrigerated load will have much to do with the successful delivery of that load. Correct circulation of air is important when the load is fresh food, such as fruit or vegetables. These foods give off heat, called heat of respiration, during storage, **Figure 28.37**. This is not at all like storing a load of frozen food that only has to be protected from heat that may enter from the outside, such as with a walk-in cooler. The heat is generated by the load and must be taken into account when calculating the size of the refrigeration equipment.

All ships must have refrigeration for the storage of foods for the crew and passengers. Refrigeration for the ship stores may be drawn from the main refrigeration system as long as it is running when the ship hauls refrigerated cargo. When the ship is not hauling refrigerated cargo, auxiliary systems may be used or the ship may have a separate system for the crew. Many of the same appliances may be used on a ship as in a supermarket. Some of these units may be individual package units with the compressor condenser built into the unit, or central refrigeration rooms may be used.

28.9 AIR CARGO HAULING

Products are often hauled by air to hasten the trip to market. Flowers are frequently shipped by air from places like Hawaii to the rest of the United States. Onboard refrigeration is out of the question because of the weight of the refrigeration systems. When the product needs to be cooled during flight, ice or dry ice is used. Specially designed containers are built to slide into the cargo compartment of the plane, **Figure 28.38**.

SUMMARY

- Transport refrigeration is the process of transporting various refrigerated products by truck, rail, air, or water.
- Some products are shipped at medium temperatures and some at low temperatures in the frozen state.
- Dry ice, made from compressed carbon dioxide (CO_2), may be used to refrigerate loads. It changes state from a solid to a vapor without going through the liquid state, called sublimation, at −109°F. It is particularly good for low-temperature loads.
- Liquid nitrogen or CO_2 may also be used for refrigeration. Nitrogen evaporates at −320°F and CO_2 at −109°F.
- **SAFETY PRECAUTION:** *Nitrogen and CO_2 must be handled with care because they are so cold. They can freeze flesh immediately on contact. Be sure to wear protective clothing, gloves, and goggles when working with either of these systems. Both vapors also displace oxygen, so the system cannot be operating while people are in the refrigerated space. Special controls shut the system off if the door is opened to the refrigerated space.* •
- Trucks are often equipped with refrigerated plates that contain a "eutectic" solution that goes through a phase change when cooled and warmed. The solution is typically a brine solution of either sodium chloride (table salt) or calcium chloride.

- Brine solutions are corrosive to ferrous metals.
- The brine solution does not actually turn solid; it turns to crystals when frozen and the crystals turn to liquid when warmed.
- Trucks may also be refrigerated using mechanical refrigeration located on the truck.
- When at the dock, the compressor may be plugged into a power supply.
- Larger trucks use either nose-mount or under-belly refrigeration units.
- The evaporator and fan are located in the front of the truck on a typical unit.
- Truck systems are not designed to have the capacity to refrigerate a load that is not down to temperature. They are meant to hold the load temperature while in transit.
- Truck bodies are insulated and the doors have gaskets to prevent infiltration.
- Two-speed engines and compressors that unload or have Variable Frequency Drives (VFDs) are used for capacity control.
- Extra-low-temperature refrigerated applications at temperatures below −10°F often make use of the compression cycle by employing either two-stage compressors or cascade refrigeration systems.
- Cascade refrigeration systems use more than one stage of refrigeration to reach very low temperatures.
- Fresh food that is frozen quickly retains its fresh color and taste. The quicker the food is frozen, the better these qualities will be maintained.
- When meats are frozen slowly, ice crystals form slowly and puncture the cell walls of the meat.
- Food may be frozen quickly by dipping it in a cold solution, such as brine (saltwater), or by using blast freezers, which is very cold air blown directly on the food. The cold air and the velocity help to remove heat from the food quickly.
- Conventional refrigeration systems may be used for blast freezing.
- Ship refrigeration may involve keeping the product at medium or low temperatures.
- A fish processing ship must have the capability of quick freezing and holding the fish after they are processed.
- Refrigerated cargo ships may have large refrigerated holds where plate-type or forced-draft evaporators are used to maintain the temperature.
- The condensers for ship refrigeration usually use sea-water and are made of cupronickel.
- Another method for shipping refrigerated cargo is self-contained air-cooled refrigeration on containerized freight.
- Ships must also have refrigeration for the ship's stores.
- Many products are shipped by air to speed them to market (e.g., flowers). They are typically kept cool using ice or dry ice.

REVIEW QUESTIONS

1. List the evaporating temperatures for liquid nitrogen and CO_2: _____ and _____.
2. What is the working pressure of a typical liquid nitrogen storage tank, and how is this pressure maintained?
3. True or False: Solutions used in eutectic plate refrigeration are brine, calcium chloride, and sodium chloride solutions.
4. Describe phase-change refrigeration in the eutectic cold plates.
5. What is the advantage of cold plate refrigeration?
6. What is the method of refrigerating cold plates?
7. Two locations for truck refrigeration systems are _____ and _____.
8. Which are power supplies used for truck refrigeration?
   A. Gas-engine driven compression
   B. Electric compressor operated with a motor generator
   C. Diesel compressor
   D. All of the above
9. What type of reserve capacity does truck refrigeration have?
10. Why is truck refrigeration designed to provide low- and medium-temperature refrigeration?
11. How is the air distributed over the cargo in truck refrigeration?
12. Name two types of engines used for truck refrigeration systems.
13. How are railcars refrigerated?
14. Truck trailers with their own refrigeration systems, which are transported on railway cars, are called
    A. self-contained refrigeration systems.
    B. piggyback refrigeration systems.
    C. double-layer refrigeration systems.
    D. dependent refrigeration systems.
15. Why is two-stage compression popular for extra-low-temperature refrigeration systems?
16. An R-404A system is operating with a −50°F evaporator and the condenser is operating at 115°F. What is the compression ratio of this system?
    A. 16.9 to 1
    B. 17.8 to 1
    C. 19.1 to 1
    D. 21.33 to 1
17. Describe cascade refrigeration and tell why more than one refrigerant is used.
18. Why is a circulating brine system more attractive for ship refrigeration than individual evaporators?
19. Two methods used to power refrigeration compressors on a ship are _____ and _____.

UNIT 29

TROUBLESHOOTING AND TYPICAL OPERATING CONDITIONS FOR COMMERCIAL REFRIGERATION

OBJECTIVES

After studying this unit, you should be able to

- list the typical operating temperatures and pressures for the low-pressure side of a refrigeration system for high, medium, and low temperatures.
- list the typical operating pressures and temperatures for the high-pressure side of a system.
- state how different refrigerants compare on the high-pressure and low-pressure sides of the system.
- diagnose an inefficient evaporator.
- diagnose an inefficient condenser.
- diagnose an inefficient compressor.

SAFETYCHECKLIST

- ✔ Wear goggles and gloves when attaching and removing gauges and when transferring refrigerant or checking pressures.
- ✔ Wear warm clothing when working in a cooler or freezer. A cold technician does not make good decisions.
- ✔ Observe all electrical safety precautions. Be careful at all times and use common sense.
- ✔ Disconnect electrical power whenever possible when working on a system. Lock and tag the panel and keep the key on your person.
- ✔ Wear rubber gloves when using chemicals to clean an evaporator or condenser. Use only approved chemicals. This is particularly important when cleaning an evaporator in a food storage unit.
- ✔ Do not attempt to perform a compressor vacuum or closed-loop test without the close supervision of an instructor or other experienced person.

29.1 ORGANIZED TROUBLESHOOTING

To begin troubleshooting any area of a refrigeration system, you need some idea of what the typical conditions should be. In commercial refrigeration you may be dealing with air temperatures inside a refrigerated box or outside at the condenser. You may need to know the current draw of the compressor or fan motors. The pressures inside the system may be important for troubleshooting and diagnoses. There are many conditions both outside and within the system that are important to know and understand.

When a piece of equipment has been running well for some period of time without noticeable problems, normally only one problem will trigger any sequence of events that may be encountered. For instance, it is common for the technician to think that two or three components of a piece of equipment have failed at one time. The chance of two parts failing at once is remote, unless one part causes the other to fail. These failures can almost always be traced to one original cause.

Knowing how the equipment is supposed to be functioning helps. You should know how it is supposed to sound, where it should be cool or hot, and when a particular fan is supposed to be operating. Knowing the correct operating pressures for a typical system can help you get started. **Before you do anything, look over the whole system for obvious problems.**

Troubleshooting procedures are divided into high-, medium-, and low-temperature ranges and some typical pressures for each. Each system has its own temperature range, depending on what it is supposed to be refrigerating. The table in **Figure 29.1** shows the temperature ranges for some refrigerated storage applications. This is only a partial table from the ASHRAE *Fundamental Guide*; refer to this guide for a complete table for all foods. Notice that for almost every food there is a different temperature requirement under more than one situation. For example, there may be a different temperature requirement for long-term storage than for short-term storage. The temperatures and pressures on the low-pressure side of the system are dependent on the product load. **An evaporator acts the same whether there is a single compressor close to the evaporator or a large compressor in the equipment room.** The examples given relate to evaporators. The function of the compressor is to lower the pressure in the evaporator to the correct boiling point to achieve the desired condition in the evaporator.

The service technician will have to deal with many numbers to address the conditions in various applications. In the

(B)

past, basically one refrigerant was used for medium- and high-temperature applications and one was used for low-temperature applications. On routine service calls, the technician needed to think only of pressures that were common to these two refrigerants for the specific application. Several new refrigerants recently have entered the equation, which adds to the numbers to be considered, but the technician should concentrate only on the temperatures that are suggested for the particular applications. The temperatures can readily be converted to the correct pressures that should be displayed on the gauges. This text makes many references to R-134a and R-404A because many refrigeration systems are using these alternative refrigerants. R-134a is the refrigerant replacement for R-12, and R-404A is the refrigerant replacement for R-502 in many applications. However, R-134a and R-404A are *not* drop-in replacements for any refrigerant. This text does provide some examples involving R-12 and R-502 because older systems still use these refrigerants. Because of global warming concerns, the Environmental Protection Agency's Significant New Alternatives Policy (SNAP) program is the governing body that can make changes, after a public comment period, as to what refrigerants will be acceptable for refrigeration and air conditioning systems. At the time of this writing, there is more and more of a move away from HCFC and HFC refrigerants, and more of a move toward HC, HFO, carbon dioxide, and other natural refrigerants. Many refrigerants and refrigerant blends that have high global warming potentials (GWPs) will no longer be allowed to be used even as retrofit refrigerants. These refrigerants and blends may still be referred to in this book because they exist in HVAC/R equipment from past installations and retrofits. It is important that service technicians understand what these refrigerants and blends consist of for service purposes. It is the service technician's responsibility to keep abreast with the most recent laws and rules concerning refrigerant use and service. Refer to Unit 9, "Refrigerant and Oil Chemistry and Management—Recovery, Recycling, Reclaiming, and Retrofitting" for more detailed information on refrigerants. Always consult with the refrigeration system's manufacturer before retrofitting any system's refrigerant. You may convert to any other refrigerant using a pressure-temperature chart.

29.2 TROUBLESHOOTING HIGH-TEMPERATURE APPLICATIONS

High-temperature refrigerated box temperatures start at about 45°F and go up to about 60°F. Normally, a product temperature will be at one end of the range or the other depending on the product (flowers may be at 60°F and candy at 45°F). The low- and high-temperature and pressure conditions for high-temperature refrigeration systems must be therefore maintained. In these conditions, the coil temperature is normally 10°F to 20°F cooler than the box temperature, a difference referred to as temperature difference (TD). This means that the coil will normally be operating at 22 psig (45°F − 20°F = 25°F coil temperature) at the lowest temperature for an R-134a system. For the highest temperature of a high-temperature application, the pressure would be 57 psig (60°F coil temperature) at the end of the cycle when the compressor is off. **Figure 29.2** is a chart of some typical operating conditions for high-, medium-, and low-temperatures for typical applications in which R-134a and R-404A are used.

Figure 29.2 (A) These charts can be used to determine typical operating temperatures and pressures for refrigerating systems using forced-air evaporators.

This table is intended to show the typical operating pressures for commercial refrigeration systems. Column 1 is with the compressor off and the box temperature just at the cut-in point. Column 2 is just after the compressor comes on. Column 3 is just before the compressor cuts off. This is not intended to be the only operating pressures, but the upper and lower limits as applied to high-, medium-, and low-temperature typical applications. A coil-to-inlet air temperature of 20° F (TD) was used as an average. Many systems will use 10° F or 20° F TD.

R-134a			
	Column 1 Compressor Off	Column 2 Compressor On	Column 3 Compressor On
HIGH–TEMPERATURE			
Box Temperature	60° F	60° F	45° F
Coil Temperature	60° F	40° F	25° F
Temperature Difference	0° F	20° F	20° F
Suction Pressure	57 psig	35.1 psig	22 psig
MED-TEMPERATURE			
Box Temperature	45° F	45° F	30° F
Coil Temperature	45° F	25° F	10° F
Temperature Difference	0° F	20° F	20° F
Suction Pressure	40 psig	22 psig	11.9 psig
LOW-TEMPERATURE			
Box Temperature	5° F	5° F	−20° F
Coil Temperature	5° F	−15° F	−40° F
Temperature Difference	0° F	2° F	20° F
Suction Pressure	9.1 psig	0 psig	14.7 in. Hg

R-404A			
LOW-9TEMPERATURE			
Box Temperature	5° F	5° F	−20° F
Coil Temperature	5° F	−15° F	−40° F
Temperature Difference	0° F	20° F	20° F
Suction Pressure	38 psig	20.5 psig	4.8 psig

R-404A
ICE MAKING Ice begins to form at 20° F coil temperature. Suction pressure 56# End of cycle, ice about to harvest at 5° F coil temperature. Suction pressure 38#

When a service technician installs the gauge manifold, the readings for a typical installation should not exceed or go below these readings. For instance, if the gauges were applied to a medium-temperature vegetable box, the highest suction pressure that should be encountered on a typical box should be 22 psig with the compressor running and a low of 11.9 psig at the end of the cycle. Any readings above or below these will be out of range for a box that has a 20° F temperature difference between the air temperature entering the coil and the coil's refrigerant boiling temperature.

TEMPERATURE AND PRESSURE RANGES FOR THE LOW-PRESSURE SIDE OF THE SYSTEM

← LOW TEMPERATURE

← MEDIUM TEMPERATURE

← HIGH TEMPERATURE

Vacuum—Red Figures
Gauge Pressure—Bold Figures

(B)

For any other refrigerant or application, the temperature and pressure readings may be converted.

When the technician suspects problems, the following pressure gauge readings should be obtained on a 20°F TD high-temperature system using R-134a:

1. With the compressor running just before the cut-out point, a reading below 22 psig would be considered too low.
2. With the compressor running just after start-up with a normal box temperature, 60°F (60°F − 20°F = 40°F coil temperature), a reading above 35.1 psig would be considered too high.
3. When the compressor is off and the box temperature is at the highest point, the coil pressure would correspond to the air temperature in the box.

If a 60°F box is involved, the suction pressure could be 57 psig just before the compressor starts in a normal operation. These pressures are fairly far apart but serve as reference points for most high-temperature applications. The preceding illustration is for a 20°F TD. There will be times when a 10°F TD is normal for a particular application. The best procedure is to consult the chart in **Figure 29.1(A)** for the application and determine what the pressures should be by converting the box temperatures to pressure. This chart shows what the storage temperatures are.

The correct box humidity conditions may also be found by studying **Figure 29.1(B)**. The box humidity conditions will determine the coil-to-air temperature difference for a particular application. For example, you may want to store cucumbers in a cooler. The chart shows that cucumbers should be stored at a temperature of 45°F to 50°F and a humidity of 90% to 95% to prevent dehydration. Examining the second part of the chart indicates that to maintain these conditions the coil-to-air temperature difference should be 8°F to 12°F; probably 10°F should be used.

The pressures from one piece of equipment to another may vary slightly. *Do not forget that any time the compressor is running, the coil will be 10°F to 20°F cooler than the fixture air temperature.*

29.3 TROUBLESHOOTING MEDIUM-TEMPERATURE APPLICATIONS

Medium-temperature refrigerated box temperatures range from about 30°F to 45°F in the refrigerated space. Many products will not freeze when the box temperature is as low as 30°F. Using the same methods as in the high-temperature examples to find the low- and high-pressure readings that would be considered normal, we find the following. The lowest pressures that would normally be encountered would be at the lowest box temperatures of 30°F. If the coil were to be boiling the refrigerant at 20°F below the inlet air temperature, the refrigerant would be boiling at 10°F (30°F − 20°F = 10°F). This corresponds to a pressure for R-134a of 11.9 psig. If the service technician encounters pressures below 11.9 psig for an R-134a medium-temperature system, there is most likely a problem. The highest pressures that would normally be encountered while the system is running would be at the boiling temperature just after the compressor starts at 45°F. This is 45°F − 20°F = 25°F, or a corresponding pressure of 22 psig,

Figure 29.2. The pressure in the low side while the compressor is off would correspond to the air temperature inside the cooler. When 45°F is considered the highest temperature before the compressor comes back on, the pressure would be 40 psig. Consult the chart in **Figure 29.1** for any specific application, because each is different. Use the chart as a guideline for the product type. The equipment operating conditions may vary to some extent from one manufacturer to another.

29.4 TROUBLESHOOTING LOW-TEMPERATURE APPLICATIONS

Low-temperature applications start at freezing and go down in temperature, although not many are designed for just below freezing. The first significant application is for the making of ice, which normally occurs from 20°F evaporator temperature to about 5°F evaporator temperature. Ice making has many different variables, which are associated with the type of ice being made. Flake ice is a continuous process, so the pressures are about the same regardless of the equipment manufacturer, although the manufacturer should be consulted for exact temperatures and pressures for flake ice machines.

For cube ice makers using R-404A, a suction pressure of 36 psig (20°F) at the beginning of the cycle will begin to make ice. The ice will normally be harvested before the suction pressure reaches the pressure corresponding to 5°F, or 38 psig, **Figure 29.2**. If the suction pressure for an R-404A machine does not go below 56 psig, suspect a problem. If it goes below 38 psig, also suspect a problem. These pressures indicate the normal running cycle.

The low temperatures for frozen foods are generally considered to start at 5°F space temperature and go down from there. Different foods require different temperatures to be frozen hard; some are hard at 5°F, others at −10°F. The designer or operator of the equipment will use the most economical design or operation. For instance, ice cream may be frozen hard at −10°F, but it may be maintained at −30°F without harm. The economics of cooling it to a cooler temperature may not be cost-effective. As the temperature goes down, the compressor has less capacity because the suction gas becomes thinner. The compressor may not even cut off at the very low temperatures if the box thermostat is set that low.

Using the same guidelines as for high- and medium-temperature applications, the highest normal refrigerant boiling temperature for low-temperature refrigeration applications are 5°F − 20°F = −15°F for R-134a. The refrigerant boils at 20°F below the space temperature because the compressor is running and creating a suction pressure of 0 psig. The lowest suction pressure may be anything down to the evaporator pressure corresponding to −20°F space temperature. This would be −20°F − 20°F = −40°F, or 14.7 in. Hg vacuum for an R-134a system, **Figure 29.2(B)**. With the compressor off just at the time the thermostat calls for cooling for the highest temperature, the evaporator would be 5°F, the same as the space temperature, or 9.1 psig.

A different refrigerant for low-temperature applications may be used to keep the pressures positive, above atmospheric. Using R-404A would give a new set of figures: 5°F corresponds to 38 psig when the space temperature is 5°F with the compressor off. When the space temperature is 5°F and the compressor is running, the refrigerant will be boiling at about 20°F below the space temperature, or 5°F −20°F = −15°F. This −15°F corresponds to a pressure of 20.3 psig. The lowest temperature normally encountered in low-temperature refrigeration is a space temperature of about −20°F, which makes the suction pressure about −20°F − 20°F = −40°F, or 4.8 psig, **Figure 29.2(B)**. By using R-404A in this application the system is going to operate well above a vacuum. R-404A boils at −50°F at 0 psig, so the cooler would go down to −30°F air temperature before the suction would go down to the atmospheric pressure of 0 psig with a 20°F TD. Temperatures below −20°F for the space or product are obtainable and are used.

The chart in **Figure 29.2(A)** can be used as a guideline for typical low-side operating conditions for the aforementioned systems. Its intent is to illustrate the high and low temperatures and pressures for each application. The machine you may be working on should fall within these limits.

29.5 TYPICAL AIR-COOLED CONDENSER OPERATING CONDITIONS

Air-cooled condensers have an operating temperature range from cold to hot as they are exposed to outside temperatures. The equipment may even be located inside a conditioned building. The condenser has to maintain a pressure that will create enough pressure drop across the expansion device for it to feed correctly. This pressure drop across the expansion device will push enough refrigerant through the device for proper refrigerant levels in the evaporator. However, some modern thermostatic expansion valves (TXVs) can operate with much less pressure drop as long as 100% liquid is supplied to them. The balanced-port TXV is noted for its low-pressure drop performance. Expansion valves for R-134a are normally sized for a 75- to 100-psig pressure drop. For example, when a manufacturer indicates that a valve has a capacity of 1 ton at an evaporator temperature of 20°F, that means it is designed for a pressure drop of 80 psig. The same valve will have less capacity if the pressure drop goes to 60 psig. Refer to Unit 24, "Expansion Devices" for more detailed information on thermostatic expansion devices.

Because any piece of equipment located outside must have head pressure control, the minimum values at which the control is set would be for the minimum expected head pressure. For R-134a, this is normally about 135 psig for air-cooled equipment, **Figure 29.3**; this corresponds to 105°F

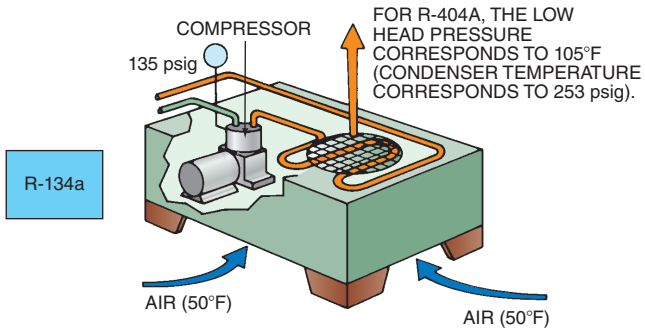
Figure 29.3 A refrigeration system shows the relationship of the air-cooled condenser to the entering air temperature on a cool day. This unit has head pressure control for mild weather. The outside air entering the condenser is 50°F. This would normally create a head pressure of about 85 psig. This unit has a fan cycle device to hold the head pressure up to a minimum of 125 psig.



condensing temperature. R-404A has a head pressure of 253 psig at 105°F. When the discharge pressure is less than 135 psig for an R-134a machine, the condenser is operating at the lowest pressure to maintain an 80 psig drop across the expansion device, and the lower pressure may not be feeding the expansion valve correctly. An exception to this is when the manufacturer *floats* the head pressure with the ambient temperature. Head pressure controls can still be used, but they are usually set at much lower settings to take advantage of the cooler ambient temperatures. Floating head pressures will increase efficiencies by enabling the compressor to run at lower compression ratios. Refer to Unit 22, "Condensers" for more in-depth information on floating the head pressure.

29.6 CALCULATING THE CORRECT HEAD PRESSURE FOR AIR-COOLED EQUIPMENT

The maximum normal high-side pressure would correspond to the maximum ambient temperature in which a condenser is operated. Most air-cooled condensers will condense the refrigerant at a temperature of about 30°F above the ambient temperature when the ambient is above 70°F. **Figure 29.4** presents an example of a refrigeration system operating under low-ambient conditions without head pressure control. When the ambient temperature drops below 70°F, the relationship changes to a lower value. If the condenser is a higher-efficiency condenser or oversized, the condenser may condense at 25°F above the ambient. *For energy-efficiency purposes, many manufacturers of high-efficiency systems are manufacturing condensers with improved heat transfer materials and surfaces. Condenser sizes are also increasing to keep head pressures lower and compression ratios lower for better efficiencies. This will cause some condensing temperatures to be only 10°F to 15°F above the ambient. Refer to Unit 22, "Condensers" for more detailed information on high efficiency condensers.* Using the 30°F figure, if a unit were located outside and the temperature were 95°F, the condensing temperature would be 95°F + 30°F = 125°F. This corresponds to 169 psig for R-12 and 301 psig for R-502, **Figure 29.5**. *Many newer, more environmentally friendly replacement refrigerants are being introduced into the HVAC/R industry. These refrigerants include hydrocarbon (HC), hydrofluoro-olefin (HFO), carbon dioxide, and other natural refrigerants with lower GWP and ODP values. Refer to Unit 9, "Refrigerant and Oil Chemistry and Management-Recovery, Recycling, Reclaiming, and Retrofitting" for more detailed information on newer environmentally friendly refrigerants.*

Figure 29.4 A refrigeration system operating at an ambient temperature that causes the head pressure to be too low for normal operation. The expansion valve is not feeding correctly because there is not enough head pressure to push the liquid refrigerant through the valve.

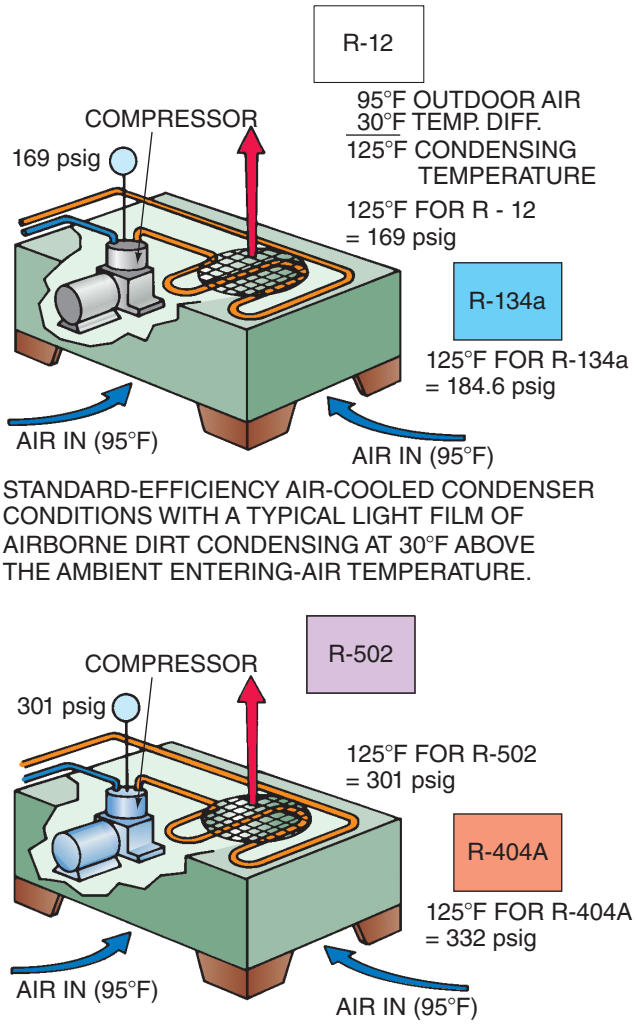
Figure 29.5 An air-cooled refrigeration system with a condenser outside. Typical pressures are shown.



The pressure for R-134a would be 185 psig, for R-404A it would be 332 psig, and for R-22 it would be 278 psig at 125°F condensing temperature.

29.7 TYPICAL OPERATING CONDITIONS FOR WATER-COOLED EQUIPMENT

Water-cooled condensers are used in many systems in two ways. Some use wastewater and some reuse the same water by extracting the heat with a cooling tower. Typically, a water-cooled condenser that uses freshwater, such as city water or well water, uses about 1.5 gal of water per minute per ton, and a system using a cooling tower circulates about 3 gpm/ton. These two applications have different operating conditions and will be discussed separately.

29.8 TYPICAL OPERATING CONDITIONS FOR WASTEWATER CONDENSER SYSTEMS

Wastewater systems use the same condensers as the cooling tower systems, but the water is wasted down the drain. A water-regulating valve is normally used to regulate the water flow for economy and to regulate the head pressure. The condensers are either cleanable or a coil type that cannot be cleaned mechanically. With either type of condenser, it is advantageous to know from the outside how the condenser is performing on the inside.

When a water-regulating valve is used to control the water flow, the flow will be greater if the condenser is not performing correctly. When the head pressure goes up, the water will start to flow faster to compensate. This will take place until the capacity of the valve opening is reached. Then the head pressure will increase with maximum water flow. Sometimes the inlet water is colder, such as in winter. It would not be unusual for the inlet water to be 45°F in the winter. If the water travels through a hot ceiling in the summer, 90°F may be the high value, **Figure 29.6**. Because of the variable flow and variable temperature of water flowing through a wastewater system during different seasons of the year, there is no refrigerant-to-water temperature relationship or rule of thumb for the technician to go by for these systems. The technician must simply rely on the water-regulating valve to throttle more or less water at different temperatures through the condenser to maintain a constant head pressure. For more detailed information on condensers and water-regulating valves, refer to Unit 22, "Condensers."

If the condensing temperature were much above 105°F, suspect a dirty condenser. If the gauges indicated 207 psig (140°F condensing temperature) and the leaving water temperature were to be 95°F, the difference in temperature of the condensing refrigerant is 140°F − 95°F = 45°F. This indicates that the condenser is not removing the heat—the coil is dirty, **Figure 29.7**. It can be cleaned chemically or with brushes if it is a cleanable condenser. Whenever there is a noticeable increase in water flow, a low-temperature differential between water in and out of the condenser, or a high head-pressure situation, a dirty condenser should be suspected.

29.9 TYPICAL OPERATING CONDITIONS FOR RECIRCULATED WATER SYSTEMS

Water-cooled condensers that have a cooling tower to remove the heat from the water usually do not use water-regulating valves to control the water flow. Normally, a constant volume of water is pumped by a pump. The volume is customarily

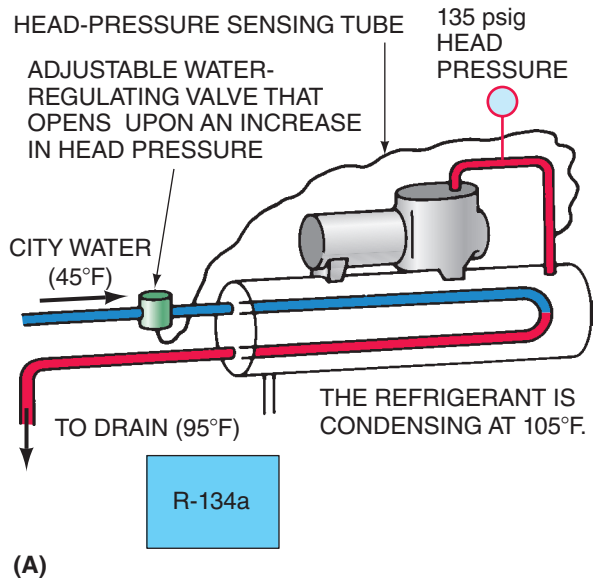
Figure 29.6 (A) A water-cooled wastewater refrigeration system. The water flow is adjusted by the water-regulating valve, which keeps too much water from flowing, maintains a constant head pressure, and shuts the water off at the end of the cycle. (B) Water flow is greater with a 90°F inlet water temperature.



designed into the system in the beginning and can be verified by checking the pressure drop across the water circuit at the condenser inlet to outlet. There has to be some pressure drop for there to be water flow. The original specifications for the system should include the engineer's intent with regard to the water flow, but these may not be obtainable on an old installation.

Most systems reusing the same water by means of a cooling tower have a standard 10°F water temperature rise across the condenser. For example, if the water from the tower were to be 85°F entering the condenser, the water leaving the condenser should be 95°F, **Figure 29.8**. If the difference were to be 15°F or 20°F, the condenser appears to be doing its job of

Figure 29.7 A water-cooled refrigeration system has dirty condenser tubes and the water is not taking the heat out of the system.

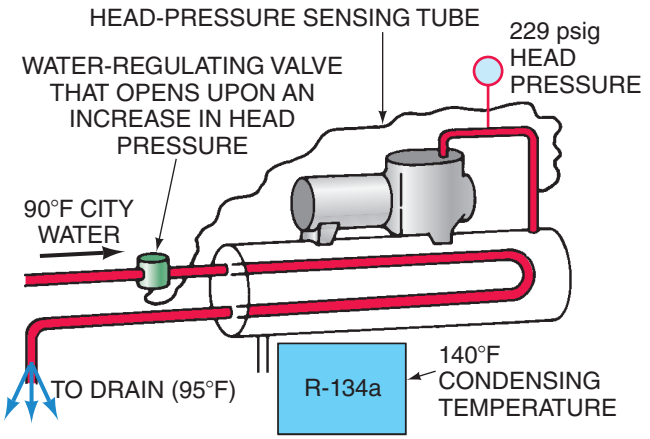


Figure 29.8 A water-cooled refrigeration system reusing the water after the heat is rejected to the atmosphere. There is a constant bleed of water to keep the minerals left behind when the water is evaporated from over-concentrating in the system. The temperature difference between the incoming water and the outgoing water is 10°F. This is the typical temperature rise across a cooling tower system.

removing the heat from the refrigerant, but the water flow is insufficient, **Figure 29.9**. If the water temperature entering the condenser were to be 85°F and the leaving water were to be 90°F, it may be that there is too much water flow. If the head pressure is not high, the condenser is removing the heat and there is too much water flow. If the head pressure is high and there is the right amount of water flow, the condenser is dirty. See **Figure 29.10** for an example of a dirty condenser. **Figure 29.11** shows a 10°F water temperature rise across the condenser and related condensing pressures for a 105°F condensing temperature when R-12, R-502, R-134a, R-22, and R-404A are used as the refrigerants.

In this type of system the condenser is getting its inlet water from the cooling tower. A cooling tower has a heat exchange relationship with the ambient air. Usually, the cooling tower is located outside and may have a natural draft or forced draft (where a fan forces the air through the tower). Either type of tower will be able to supply water temperatures according to the humidity or moisture content in the outside air. The cooling tower can normally cool the water to within 7°F of the wet-bulb temperature of the outside air, **Figure 29.12**. If the outside wet-bulb temperature (taken with a psychrometer) is 78°F, the leaving water will be about 85°F if the tower is performing correctly. Wet-bulb temperature relates to the moisture content in air; it is discussed in more detail in Unit 35, "Comfort and Psychrometrics."

Figure 29.9 This system has too much temperature rise, indicating there is not enough water flow. The water strainers may be stopped up. The condensing temperature is higher than normal, which causes the head pressure to rise. A decrease in water flow may be detected by water pressure drop if what the standard pressure should be is known.

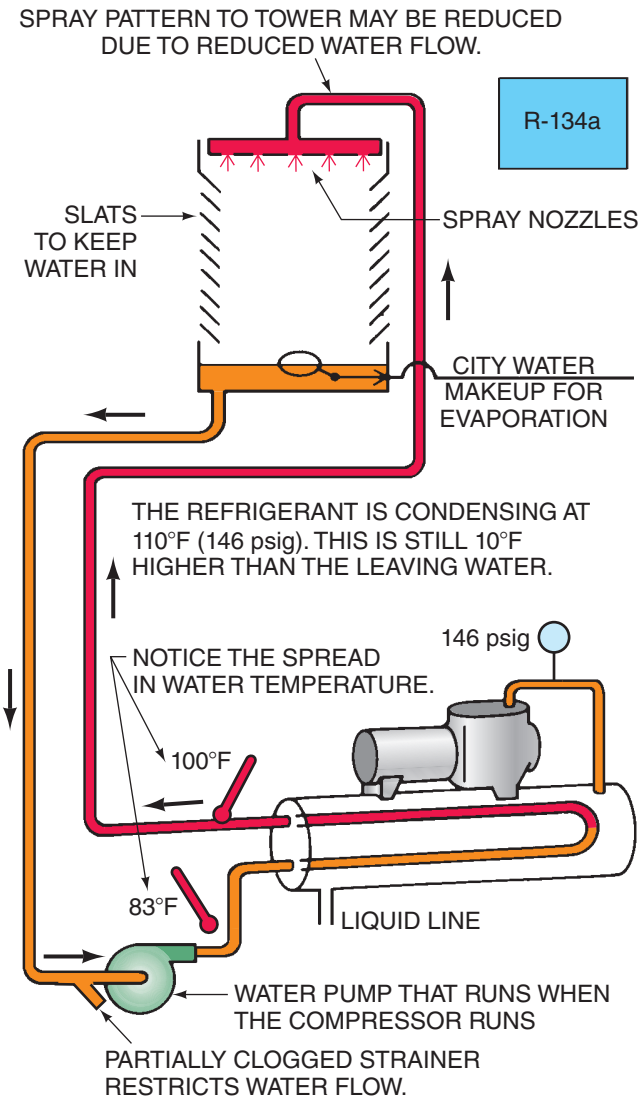

Figure 29.10 This system has dirty condenser tubes.

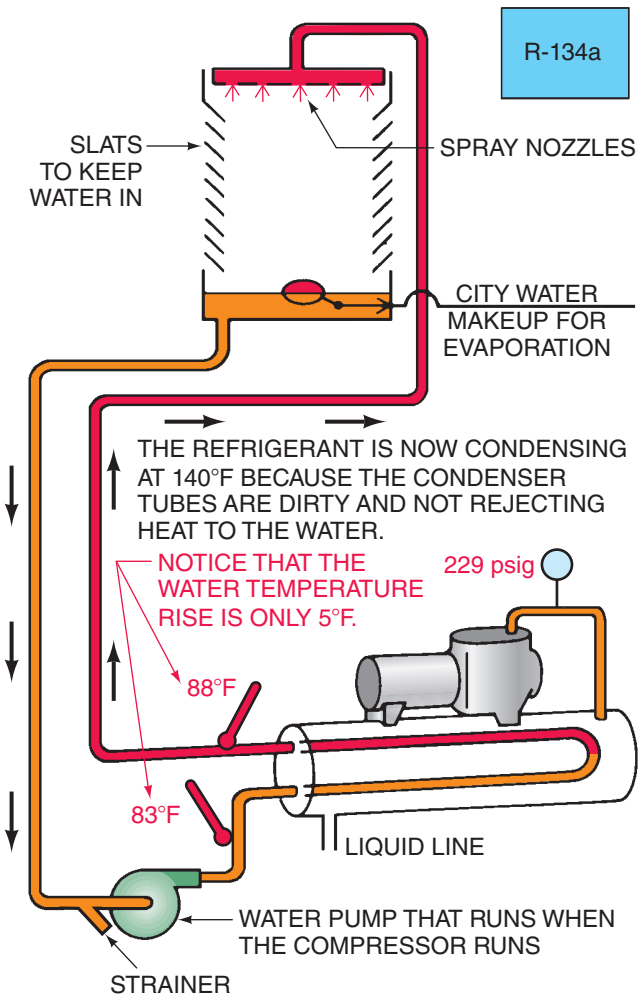

29.10 SIX TYPICAL PROBLEMS

Six typical problems that can be encountered by any refrigeration system are

1. low refrigerant charge,
2. excess refrigerant charge,

Figure 29.11 A cooling tower system showing a 10°F water temperature rise across the condenser and related condensing pressures for a 105°F condensing temperature when R-12, R-502, R-134a, R-22, and R-404A are used as the refrigerants.

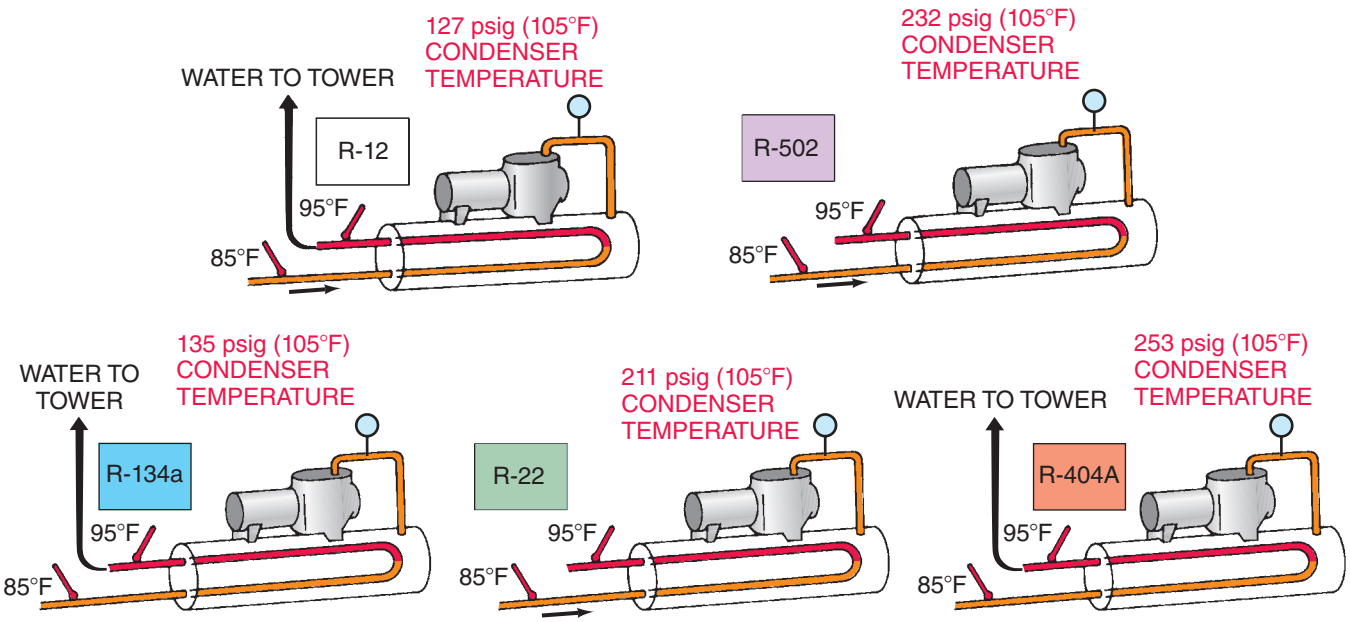

Figure 29.12 This cooling tower has a temperature relationship with the air that is cooling the water. Most cooling towers can cool the water that goes back to the condenser to within 7°F of the wet-bulb temperature of the ambient air. For example, if the wet-bulb temperature is 78°F, the tower should be able to cool the water to 85°F. If it does not, a problem with the tower should be suspected.

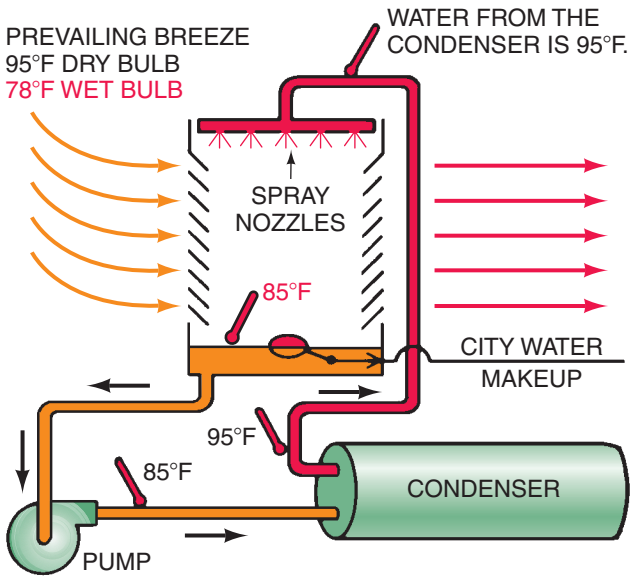
3. inefficient evaporator,
4. inefficient condenser,
5. restriction in the refrigerant circuit, and
6. inefficient compressor.



COOLED WATER IN BASIN OF TOWER IS 85°F. IT CAN NORMALLY BE COOLED TO WITHIN 7°F OF THE OUTDOOR WET-BULB TEMPERATURE DUE TO EVAPORATION.
NOTICE THAT THE FINAL WATER TEMPERATURE IS MUCH COOLER THAN THE OUTDOOR DRY-BULB TEMPERATURE.

29.11 LOW REFRIGERANT CHARGE

A low refrigerant charge affects most systems in about the same way, depending on the correct amount of the refrigerant needed. The normal symptoms of this problem are low capacity. The system has a starved evaporator and cannot absorb the rated amount of Btu or heat. The suction gauge and the discharge gauge will read low. The exception to this is a system with an automatic expansion valve, **Figure 29.13**, which will be discussed later in this unit.

If the system has a sight glass, it will have bubbles in it that look like air but that are actually vapor refrigerant. **Figure 29.14** shows a typical liquid-line sight glass. Remember, vapor or liquid may look the same in a sight glass. If there is only vapor in the glass, a slight film of oil may be present. This is a good indicator of vapor only. A system with a sight glass will generally have a TXV or automatic expansion valve and a receiver. These valves will hiss when a partial vapor–partial liquid mixture goes through the valve. A system with a capillary tube will probably not have a sight glass. The technician needs to know how the system feels to the touch at different points to determine the gas charge level without using gauges.

A low refrigerant charge affects the compressor by not supplying the cool suction vapor that cools the motor. Low

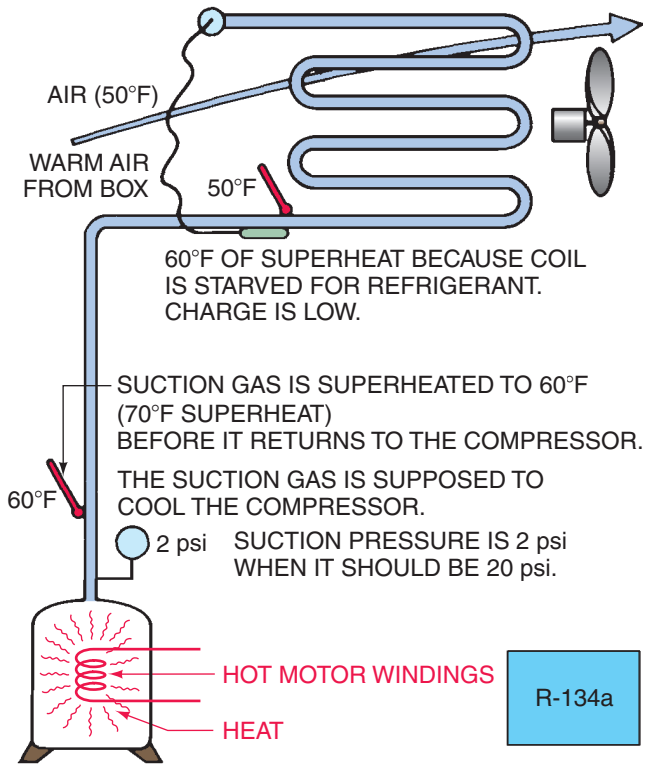
Courtesy Sporlan Division, Parker Hannifin Corporation

charges also cause low suction pressures, which increase the compression ratio. A higher compression ratio causes inefficiencies along with higher discharge temperatures. Most compressors are suction-cooled, so the result is a hot compressor motor. The motor may even have been turned off by the motor-winding thermostat, **Figure 29.15**. If the compressor is air-cooled, the suction line coming back to the compressor

Figure 29.15 A system with a suction-cooled hermetic compressor. The compressor is hot enough to cause it to cut off because of motor temperature. It is hard to cool off a hot hermetic compressor from the outside because the motor is suspended inside a vapor atmosphere.



will not need to be as cool as for a suction-cooled compressor. It may be warm by comparison, **Figure 29.16**.

An undercharge of refrigerant will produce low compressor amperage because the higher superheat coming back to the compressor inlet will cause the inlet vapors to expand, which decreases their density. Low-density vapors entering the compressor will mean low refrigerant flow through the compressor. This will cause low amperage (amp) draw, because the compressor does not have to work as hard compressing the low-density vapors. This low refrigerant flow may also cause refrigerant-cooled compressors to overheat. Due to the low refrigerant flow rate through the compressor and system that occurs with an undercharge of refrigerant, the 100% saturated-vapor point in the condenser will be very low, causing low condenser subcooling. The condenser will not receive enough refrigerant vapors to condense them to a liquid and feed the receiver (if the system has one). Condenser subcooling is a good indication of how much refrigerant charge is in the system. Low condenser subcooling may mean a low charge, whereas high condenser subcooling may mean an overcharge.

Capillary tube systems usually have no receiver so a capillary tube system can run high subcooling simply from a restriction in the capillary tube or liquid line. The excess refrigerant will accumulate in the condenser, causing high subcooling and high head pressures. If the liquid line of a

Figure 29.16 An air-cooled compressor. The compressor motor will not normally get hot as a result of a low refrigerant charge, but the discharge gas leaving the compressor may get too warm because the refrigerant entering the compressor is too warm. Most compressor manufacturers require the suction gas temperature to be not more than 65°F for continuous operation.

Courtesy Tyler Refrigeration Corporation

TXV/receiver system is restricted, some refrigerant will accumulate in the condenser, but most will collect in the receiver. Remember, a receiver is designed to handle the system's entire refrigerant charge and still have a 25% vapor head for safety. This will cause low condenser subcooling and a low head pressure.

In summary, the symptoms of a low refrigerant charge are

- low system capacity,
- starved evaporator (high superheat),
- low suction pressure,
- low discharge pressure,
- high compression ratio,
- bubbles in the sight glass,
- low compressor amperage (amp) draws, and
- low condenser subcooling.

29.12 REFRIGERANT OVERCHARGE

A refrigerant overcharge also acts much the same way from system to system. The discharge pressure is high, and the suction pressure may be high. The automatic expansion valve system will not have a high suction pressure because it maintains a constant suction pressure, **Figure 29.17**. The TXV system may have a slightly higher suction pressure if the head pressure is excessively high because the system capacity may be down, **Figure 29.18**.

The capillary tube system will have a high suction pressure because the amount of refrigerant flowing through it depends on the difference in pressure across it. The more head pressure, the more liquid it will pass. The capillary tube

Figure 29.17 The system has an automatic expansion valve for a metering device. This device maintains a constant suction pressure. The head pressure is higher than normal, but the suction pressure remains the same.

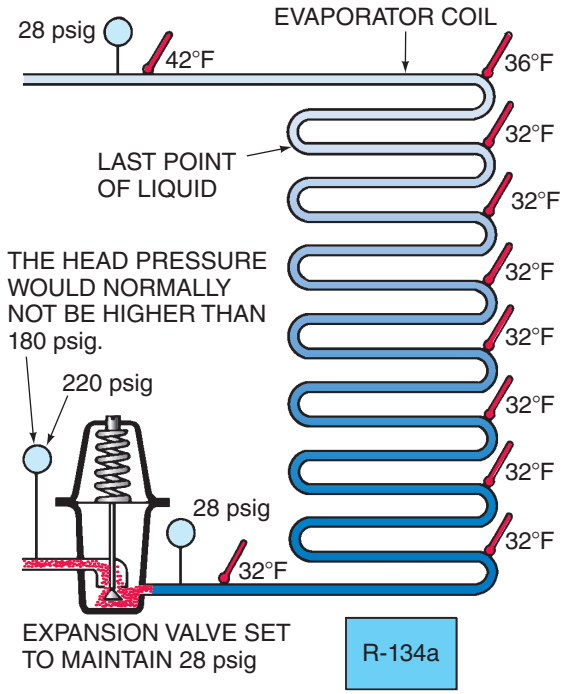

Figure 29.18 A TXV system using R-134a, which has a higher-than-normal head pressure.

will allow enough refrigerant to pass to allow liquid into the compressor. When the compressor is sweating down its side or all over, it is a sign of liquid refrigerant in the compressor, **Figure 29.19** and **Figure 29.20.**

Figure 29.19 The capillary tube system using R-134a has an overcharge of refrigerant, and the head pressure is higher than normal. This has a tendency to push more refrigerant than normal through the metering device.

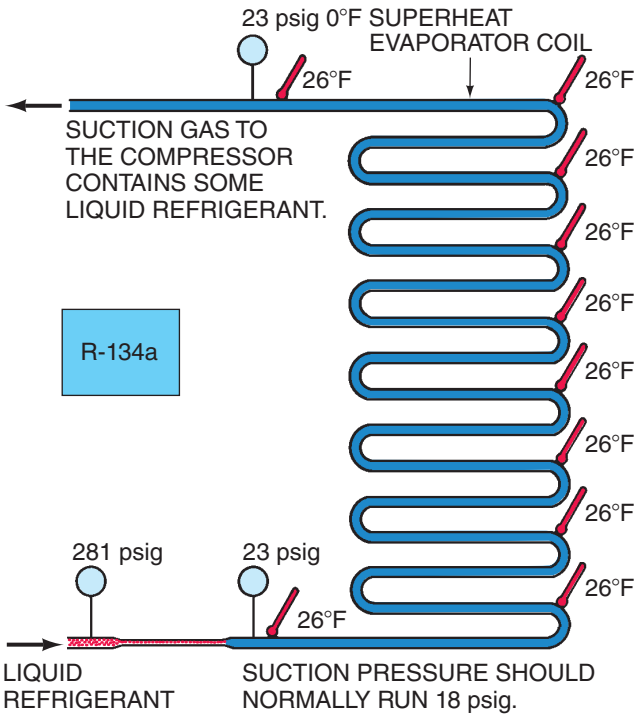

Figure 29.20 When liquid refrigerant gets back to the compressor, the latent heat that is left in the refrigerant will cause the compressor to sweat more than normal. When vapor only gets back to the compressor, the vapor changes in temperature quickly and the compressor does not sweat a lot.

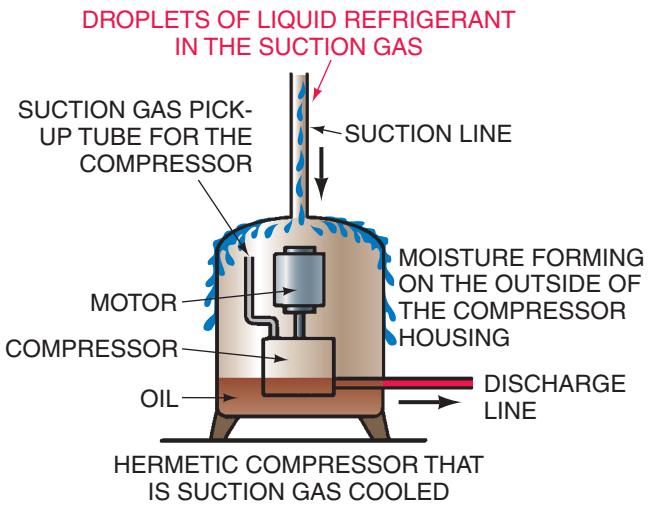

Critically charging a capillary tube system may help reduce the severity of these flooding problems. Often, in high head-pressure situations in which the system is critically charged with refrigerant, there may not be enough refrigerant in the system to adversely affect the compressor when flooding occurs. The manufacturer will determine the amount of critical charge and stamp it on the unit's nameplate. If it is not stamped on the unit, contact the manufacturer to determine the correct charge.

Only vapor should enter the compressor. Vapor will rise in temperature as soon as it touches the compressor shell, but when liquid is present, it will not rise in temperature and will cool the compressor shell. **Liquid refrigerant still has its latent heat absorption capability and will absorb a great amount of heat without changing temperature. A vapor absorbs only sensible heat and will change in temperature quickly, Figure 29.20.** Another reason that liquid may get back to the compressor in a capillary tube system is poor heat exchange in the evaporator. If liquid is getting back to the compressor, the evaporator heat exchange should be checked before removing refrigerant.

As mentioned earlier, when a system is overcharged with refrigerant, the discharge pressure and suction pressure will be higher. The condenser will be flooded with subcooled liquid, causing the discharge pressure to be excessively high. Remember, any liquid in the condenser at temperatures lower than the condensing temperature is considered to be subcooled. Excessive condenser subcooling will cause a high compression ratio, low efficiency, and low refrigerant flow rates and capacities. Forced-air condensers should have at least 6 to 8 degrees of liquid subcooling; however, amounts depend on system piping configurations and liquid-line static and friction pressure drops.

If the system has a TXV as a metering device, the TXV will try to maintain evaporator superheat even with an excessive overcharge. The TXV may overfeed slightly during its opening strokes, but it should stabilize if still in its pressure operating range.

In summary, the symptoms of a refrigerant overcharge are

- high discharge pressures,
- high suction pressures,
- high compression ratios,
- high condenser subcooling, and
- normal evaporator superheats with a TXV; low superheats with a capillary tube.

29.13 INEFFICIENT EVAPORATOR

An inefficient evaporator does not absorb the heat into the system and will have a low suction pressure. The suction line may be sweating or frosting back to the compressor. An inefficient evaporator can be caused by a dirty coil, a fan running too slowly, an expansion valve flooding or starving the coil, recirculated air, ice buildup, or interference from product blocking the airflow, **Figure 29.21.**

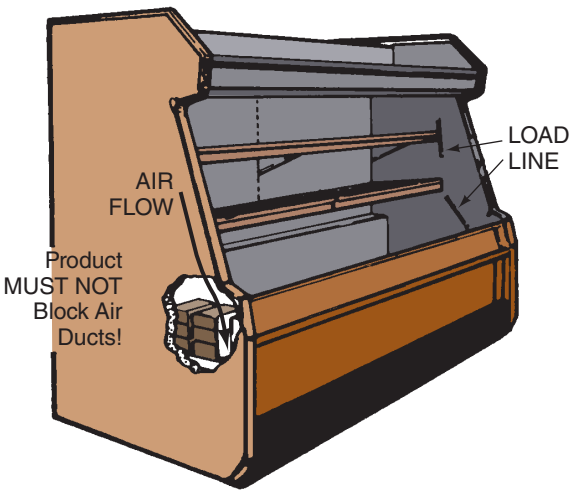
Figure 29.21 An evaporator that cannot absorb the required Btus because of interference from product. There is a load line on the inside where the product is stored.

Canned goods and other nonrefrigerated items are great for presenting imposing piles and eye-catching displays. Don't try the same gimmicks with perishables. The case will fail to refrigerate any of the merchandise when the air ducts are blocked.



Low-temperature multishelf cases are particularly sensitive to air pattern changes as well as extremes of humidity and temperature in the store.

Jumble displays may have some sales benefits, but they really foul up the protective layer of cold air in the case. Observe the LOAD LINE stickers!

Courtesy Tyler Refrigeration Corporation

Whenever there is reduced airflow across the face of the evaporator, there is a reduced heat load on the coil. This reduced airflow and heat load will cause the refrigerant in the evaporator coil to remain a liquid and not vaporize. This causes low suction pressure because there is no vapor pressure being generated from vaporizing refrigerant. This liquid refrigerant will travel past the evaporator coil and eventually reach the compressor and cause compressor damage from flooding and slugging. Often, the system will have no evaporator and compressor superheat. The refrigerant in the suction line is what causes the suction line and compressor to get cold and sweat or frost. If liquid refrigerant enters the crankcase, it will mix with the oil and often vaporize, which will cause a cold and sweaty crankcase. Liquid refrigerant or a dense vapor will enter the suction valves—depending on whether the compressor is air- or refrigerant-cooled. In either case, the amp draw of the compressor will be high.

If a thermostatic expansion valve is starving the evaporator coil, the evaporator will also be very inefficient. This situation will cause low suction pressure with very high superheats. The low suction pressure will cause a low evaporator temperature—causing the suction line and compressor to frost and sweat also. Even though the suction pressure and evaporator temperatures are low, the refrigerant flow rate through the evaporator is also very low. This causes low capacities and a very starved and inefficient evaporator. The reduced heat load on the evaporator causes a reduced heat load on the condenser, and it will have, therefore, less heat to reject. This causes the head pressure to be low.

All of these can be identified with an evaporator performance check. This can be performed by using a superheat check to make sure that the evaporator has the correct amount of refrigerant, **Figure 29.22**. The heat exchange surface should be clean. The fans should be blowing enough air and not recirculating it from the discharge to the inlet of the coil.

The refrigerant boiling temperature should not be more than 20°F colder than the entering air on an air evaporator coil, **Figure 29.2(A)**. A water coil should have no more than a 10°F TD in the boiling refrigerant and the leaving water, **Figure 29.23**. When the boiling refrigerant relationship to the medium being cooled starts increasing, the heat exchange is decreasing. The temperature difference between the evaporating temperature and the leaving-water temperature is referred to as the **approach**. The more efficient the heat exchange between the evaporating refrigerant and the water, the smaller the approach will be.

In summary, the symptoms of an inefficient evaporator are

- low suction pressure,
- sweaty or frosted suction line to the compressor,
- low head pressure,
- low superheat,
- a cold compressor crankcase, and
- high compressor amp draw.

Figure 29.22 Analyzing a coil for efficiency. This requires temperature and pressure checks at the outlet of the evaporator. When a coil has the correct refrigerant level, checked by superheat and the correct air-to-refrigerant heat exchange, the coil will absorb the correct amount of heat. The correct heat exchange is taking place if the refrigerant is boiling at 10°F to 20°F cooler than the entering air. Note that this occurs when the cooler temperature is within the design range, for example, 30°F to 45°F for medium temperature. Every circuit on coils with multiple circuits should be checked for even distribution.

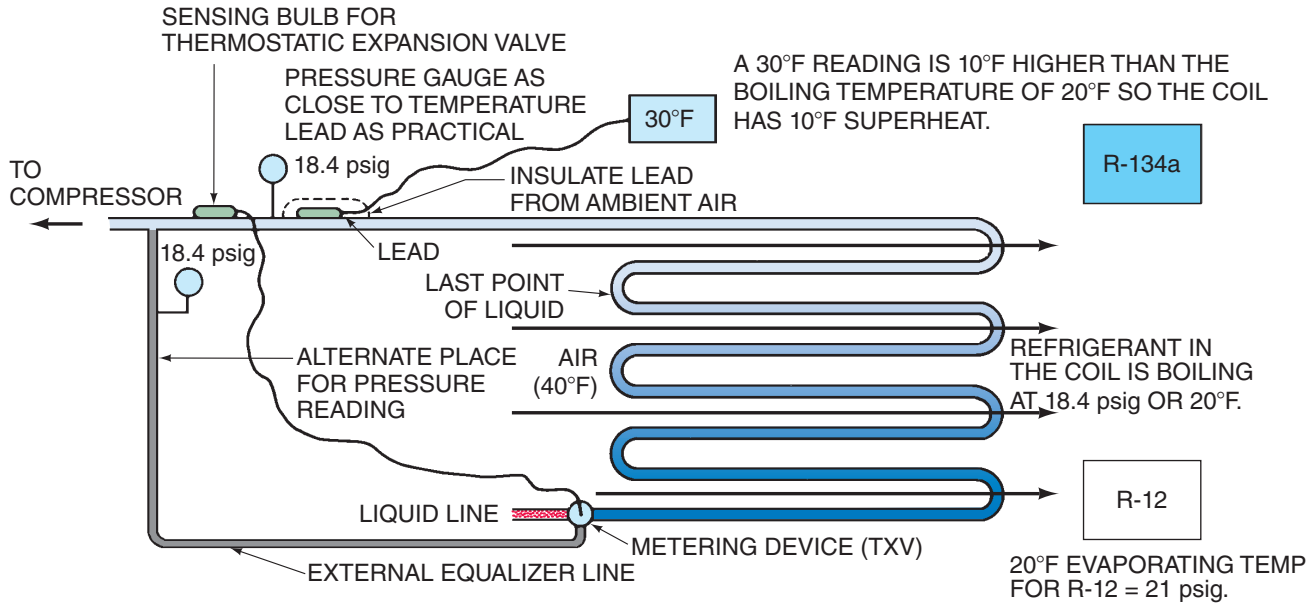

Figure 29.23 Water coils can be analyzed in much the same way as air coils. The refrigerant temperature and pressure at the end of the evaporator will indicate the refrigerant level. The refrigerant boiling temperature should not be more than 10°F cooler than the leaving water.

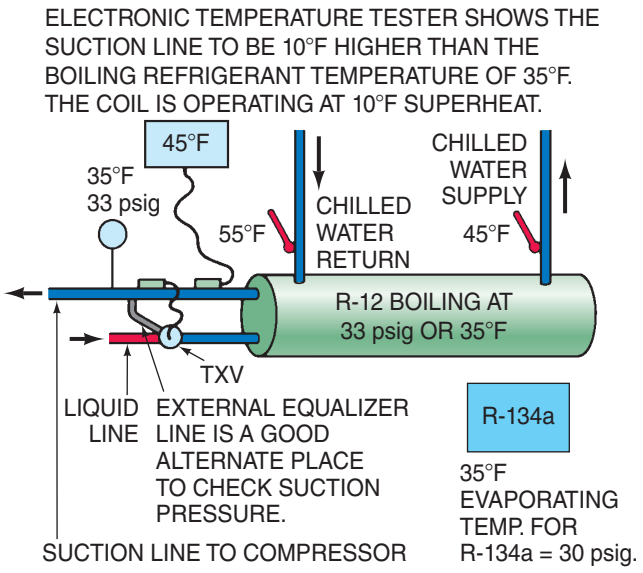

29.14 INEFFICIENT CONDENSER

An inefficient condenser acts the same whether it is water-cooled or air-cooled. If the condenser cannot remove the heat from the refrigerant, the head pressure will go up. The condenser does three things and has to be able to do them correctly, or excessive pressures will occur.

1. Desuperheat the hot gas from the compressor. This gas may be 200°F or hotter on a hot day on an air-cooled system. Desuperheating is accomplished in the beginning of the coil.
2. Condense the refrigerant. This is done in the middle of the coil, the only place that the coil temperature will correspond to the head pressure. You could check the temperature against the head pressure if a correct temperature reading can be taken, but the fins are usually in the way.
3. Subcool the refrigerant before it leaves the coil. This subcooling is cooling the refrigerant to a point below the actual condensing temperature. A subcooling of 5°F to 20°F is typical. The subcooling can be checked just like the superheat, only the temperature is checked at the liquid line and compared with the high-side pressure converted to condensing temperature, **Figure 29.24**.

The condenser must have the correct amount of cooling medium (air or water). This medium must *not* be recirculated (mixed with the incoming medium) without being cooled. Ensure that air-cooled equipment is not located so that the air leaving the condenser circulates back into the inlet. This air is hot and will cause the head pressure to go up in proportion to the amount of recirculation, **Figure 29.25**. An air-cooled condenser should not be located down low, close to the roof, even though the air comes in the side. The temperature is higher at the roof level than it is a few inches higher. A clearance of about 18 in. will give better condenser performance, **Figure 29.26**.

Figure 29.24 Checking the subcooling on a condenser. The condenser does three jobs: (1) It desuperheats the hot gas in the first part of the condenser, (2) it condenses the vapor refrigerant to a liquid in the middle of the condenser, and (3) it subcools the refrigerant at the end of the condenser. The condensing temperature corresponds to the head pressure. Subcooling is the temperature of the liquid line subtracted from the condensing temperature. A typical condenser can subcool the liquid refrigerant to 5°F to 20°F cooler than the condensing temperature.

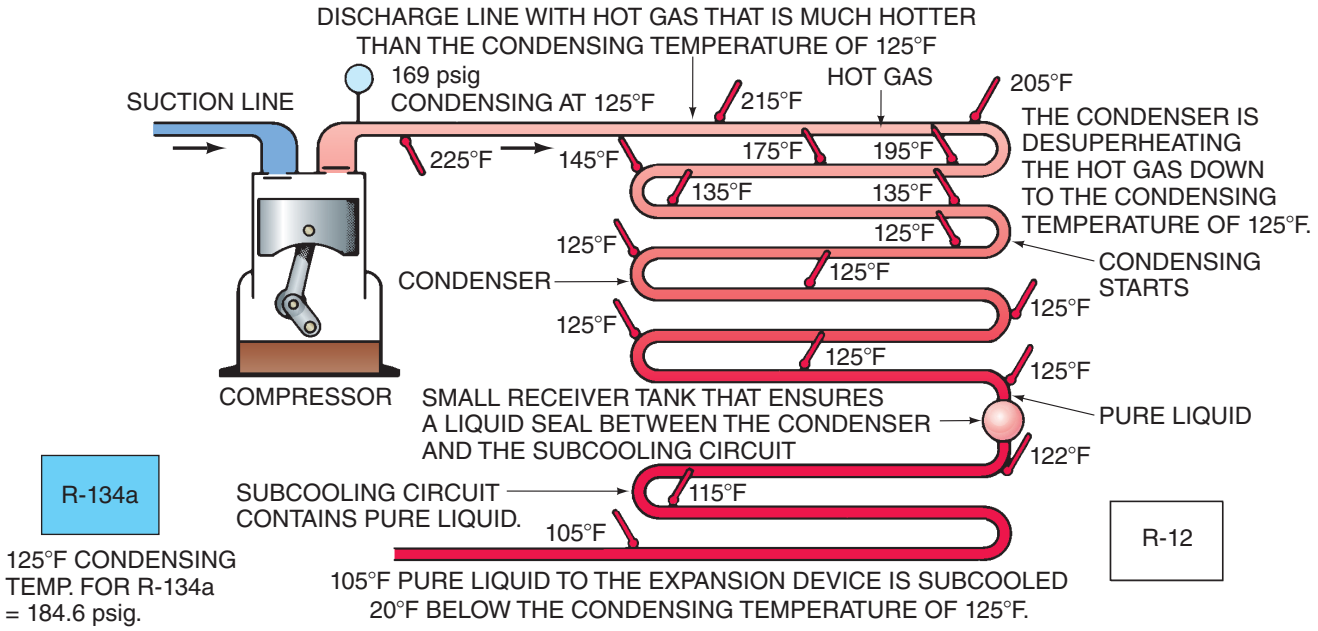

Figure 29.25 The air-cooled condenser is located too close to an obstacle, and the hot air leaving the condenser is recirculated back into the inlet of the coil.

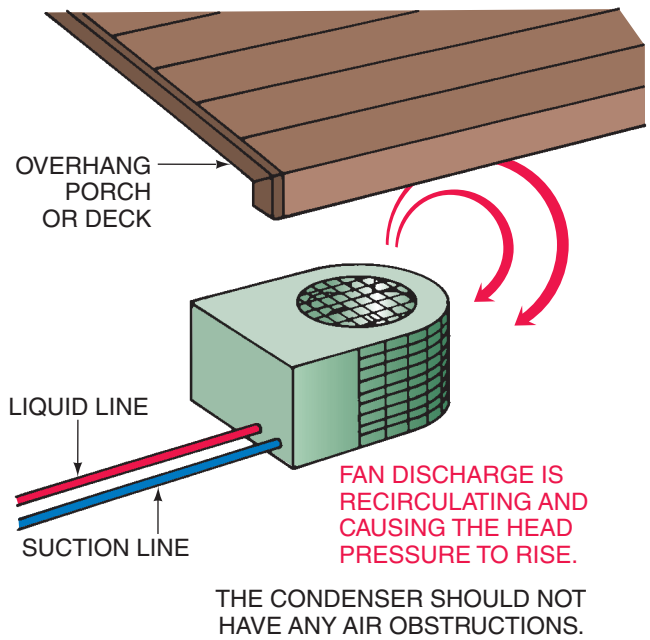

Figure 29.26 An air-cooled condenser should not be located close to a roof. The temperature of the air coming directly off the roof is much warmer than the ambient air because the roof acts like a solar collector.

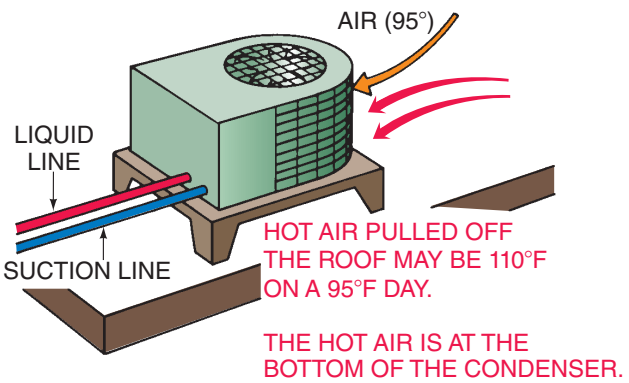

An air-cooled condenser that has a vertical coil may be influenced by prevailing winds. If the fan is trying to discharge its air into a 20-mph wind, it may not move the correct amount of air, and a high head pressure may occur, **Figure 29.27**.

Dirty condenser coils often result in inefficiency. Once the coil gets dirty, the condenser has a hard time rejecting heat. Since heat from the evaporator, suction, compressor motor, and compression is rejected in the condenser, the condenser coil must be kept clean with the proper amount of airflow through it. If the condenser cannot reject heat fast enough, it will accumulate heat until its temperature and pressure are

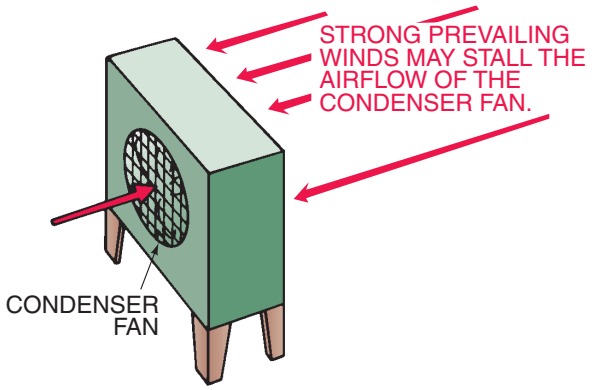
Figure 29.27 A condenser that is located in such a manner that it is discharging its air into a strong prevailing wind may not get enough air across the coil.



high enough to reject the heat to the surrounding ambient. The system is now operating at an elevated condensing temperature and pressure and causing the unwanted inefficiencies that result from high compression ratios.

Now that the system is running at elevated head pressures with unwanted inefficiencies, the suction pressure will be a bit high. Higher-than-normal suction pressures are caused by low refrigerant flow rates, and these are caused by the low volumetric efficiencies resulting from the high condensing pressures. The evaporator may not be able to keep up with the heat load, which creates higher-than-normal suction pressures. High head pressures cause high compression ratios and low volumetric efficiencies. High compression ratios will cause a greater pressure range in which the suction vapors can be compressed, requiring more work for the compressor and increasing the amp draw.

If the head pressure gets too high, the TXV may operate outside of its pressure ranges. The TXV may let too much refrigerant into the evaporator during its opening stroke from the higher head pressures, causing higher-than-normal suction pressures. This action may also cause lower-than-normal evaporator superheats. Otherwise, because the TXV is maintaining superheat and doing its job, there may be normal evaporator pressures, depending on the severity of the condenser's condition.

What liquid subcooling is formed in the condenser will be at an elevated temperature and will reject heat to the ambient faster. Because of this faster heat rejection, the liquid in the condenser will cool faster and have a greater temperature difference as compared with the condensing temperature. Therefore, the condenser subcooling may be a bit high when the condensing temperature is high.

In summary, the symptoms of an inefficient condenser are

- high head pressure,
- normal to slightly high suction pressures,
- normal to slightly low evaporator superheats,
- a high compression ratio,
- high compressor amp draws, and
- normal-to-high condenser subcooling.

29.15 REFRIGERANT FLOW RESTRICTIONS

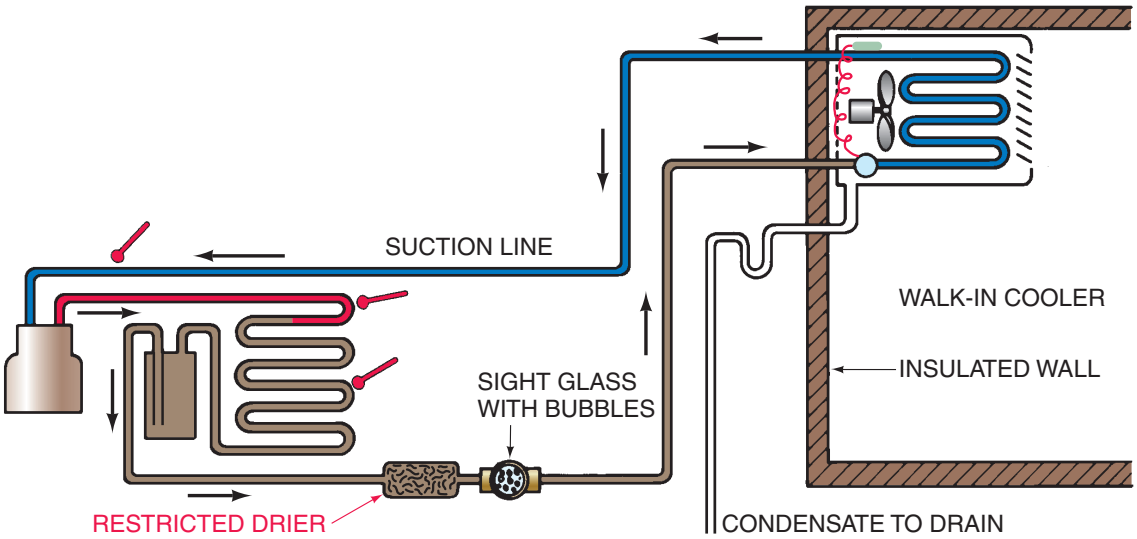
Restrictions that occur in the refrigeration circuit are either partial or full. A partial restriction may be in the vapor or the liquid line. A restriction always causes pressure drop at the point of the restriction. Different conditions will occur, depending on where the restriction is. Pressure drop can always be detected with gauges, but the gauges cannot always indicate the correct location of the restriction. Gauge ports may need to be installed for pressure testing.

If a restriction occurs due to something outside the system, it is usually physical damage, such as flattened or bent tubing. These can be hard to find if they are in hidden places, such as under the insulation or behind a fixture. If a partial restriction occurs in a liquid line, it will be evident because the refrigerant will undergo a pressure drop and will start to act like an expansion device at the point of the restriction. **When there is a pressure drop in a liquid line, there is always a temperature change.** A temperature check on each side of a restriction will locate the place. Sometimes when the drop is across a drier, the temperature difference from one side to the other may not be enough to feel with bare hands, but a thermometer will detect it, **Figure 29.28**. A system that has been running for a long time may have physical damage from a restriction. If the restriction occurs soon after start-up, a

Figure 29.28 Each of the driers has a restriction. One of them is very slight. Where there is pressure drop in a liquid line, there is temperature drop. If the temperature drop is very slight, it can be detected with a thermometer. Sometimes gauges are not easy to install on each side of a drier to check for pressure drop. If possible, use the same gauge when checking the pressure drop through a drier to avoid inaccuracies.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 29.29 The restriction in a system may occur shortly after start-up. This indicates that solid contaminants from installing the system must be in the drier. If the restriction occurs after the system has been running for a long time, the restriction may be physical damage, such as a bent pipe. Normally, loose contamination will make its way through the system to the drier in a matter of hours.



filter or drier may be plugging up. When this occurs in the liquid-line drier, bubbles will appear in the sight glass when the drier is located ahead of the sight glass, **Figure 29.29**.

Another cause of a partial restriction could be valves that do not open all the way. Normally, the TXV either works or it does not. It will function correctly, but if it loses its charge in the thermal bulb, it will close and cause a full restriction, **Figure 29.30**. There is a strainer at the inlet to most expansion devices to trap particles, and it may stop up slowly. If the device is a valve that can be removed, it can be inspected and cleaned if necessary. If it is a capillary tube, it will be soldered into the line and not easy to inspect, **Figure 29.31**.

Water circulating in any system that operates below freezing will freeze at the first cold place it passes through. This would be in the expansion device. One drop of water can stop a refrigeration system. Sometimes a piece of equipment that has just been serviced will show signs of moisture on the first hot day, **Figure 29.32**. This is because the drier in the liquid line will have more capacity to hold moisture when it is cool. On the first hot day, the drier may turn a drop or two of water loose, and it will freeze in the expansion device, **Figure 29.33**. When you suspect this, apply heat to thaw the ice to a liquid. **SAFETY PRECAUTION:** *Care must be used when applying heat. A hot, wet cloth is a good source.* If applying a hot cloth to the metering device causes the system to start functioning properly, the problem is free water in the system. *Recover the refrigerant, change the drier, and evacuate the system. Recharge with recycled or virgin refrigerant.*

Other components that may cause restrictions are automatic valves in the lines, such as the liquid-line solenoid, crankcase pressure regulator, or the evaporator pressure

Figure 29.30 The charge in the bulb of a TXV is the only force that opens the valve, so when it loses its pressure the valve closes. The system can go into a vacuum if there is no low-pressure control to stop the compressor. A partial restriction can occur if the bulb loses part of the charge or if the inlet strainer stops up.

Figure 29.31 A capillary tube metering device with the strainer at the inlet. This strainer is soldered into the line and is not easy to service.

regulator. These valves may easily be checked with gauges applied to both sides where pressure taps are provided, **Figure 29.34**. Restrictions in the liquid line usually occur after the receiver and will cause the evaporator to be starved of refrigerant, resulting in a low suction pressure. High superheats will also be experienced because of the starved evaporator. Because the evaporator is starved of refrigerant, there will not be much heat transferred to it from its surroundings. Because of the highly superheated vapors coming into it, the compressor will also be starved of refrigerant and will run hot and have a low amp draw. Highly superheated vapors mean low-density vapors for the compressor to compress.

Because the evaporator and compressor are starved of refrigerant, the condenser will also be starved. The condenser will not have a lot of heat to reject because the evaporator did not absorb much heat. This will cause a low condensing (head) pressure. If the restriction is ahead of the sight glass, the sight glass may bubble, depending on the severity of the restriction.

In summary, the symptoms of a restricted liquid line after the receiver are

- low suction pressures,
- high superheats,

Figure 29.33 If it is suspected that moisture is frozen in the metering device, mild heat can be added. Heat from a hot, wet cloth will normally thaw the moisture out, and the system will start refrigerating again.

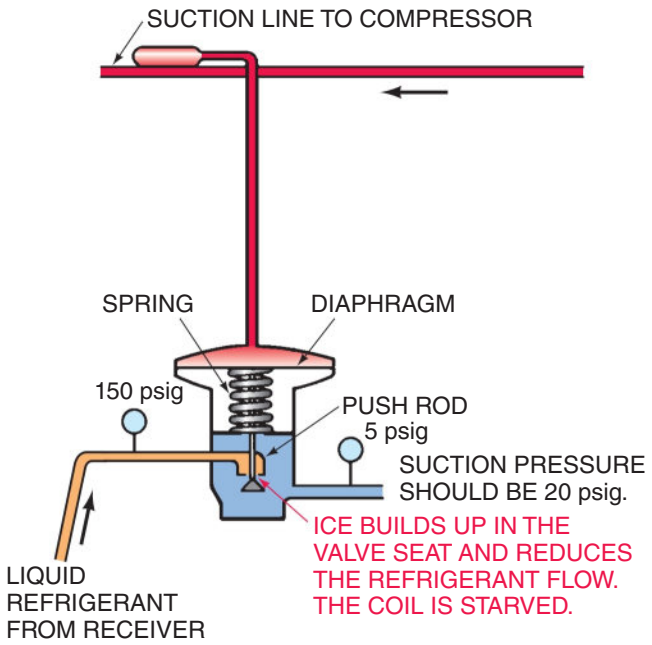

Figure 29.32 This system has had some moisture in it. The drier has all the moisture it can hold at mild temperatures. When the weather gets warm, the drier cannot hold all of the moisture and turns some of it loose. The moisture will freeze at the expansion device where the first refrigeration is experienced if the system operates below freezing.

- a temperature drop in the liquid line across the restriction.

29.16 INEFFICIENT COMPRESSOR

Inefficient compressor operation can be one of the most difficult problems to find. When a compressor will not run, it is evident where the problem is. Motor troubleshooting procedures are covered in Unit 20, "Troubleshooting Electric Motors." When a compressor is pumping at slightly less than capacity, it is hard to determine the problem. It helps at this point to remember that a compressor is a vapor pump. It should be able to create a pressure from the low side of the system to the high side under design conditions.

If a reciprocating compressor is inefficient because its valves are bad, the suction pressure will be high and the head pressure will be low. There is no other situation that will give a system both low head and high suction pressures at the same time, other than worn piston rings causing blow-by of gases around the rings. If a discharge valve is not seating properly, a low head pressure will result. Refrigerant vapor will be forced out of the cylinder and into the discharge line during the upstroke of the compressor. On the downstroke, this same refrigerant that is in the discharge line will be drawn back into the cylinder because the discharge valve is not seating properly. This short cycling of refrigerant will cause high discharge temperatures out of the compressor and low head (condensing) pressures. Refrigerant vapors will be drawn from the suction line into the compressor cylinder during the downstroke of the compressor. However, if the suction valve is not seating properly, this same refrigerant may leak back into the suction line during the upstroke, reducing the refrigerant flow and causing higher-than-normal suction pressures.

Bad valves will cause a low mass flow rate of refrigerant through the system, which will usually cause higher-than-normal superheats on the low side of the system. System capacities will be low—with higher-than-normal box or conditioned space temperatures. Because of the reduced refrigerant flow rates, compressor amp draws will be lower.

In summary, the symptoms of an inefficient compressor due to bad valves are

- low head pressure,
- high suction pressure,
- higher-than-normal superheats, and
- lower-than-normal compressor amp draws.

The following methods are all used by service technicians to diagnose compressor problems.

29.17 COMPRESSOR VACUUM TEST

The compressor vacuum test is usually performed on a test bench with the compressor removed from the system. This test may be performed within the system when the system has service valves. **NOTE:** *Care should be taken not to pull air into the system while in a vacuum. Make sure that there is no residual refrigerant mixed in the oil that will affect the outcome of the test. Do this by running the system for 30 minutes or leaving the crankcase heater on for several hours.* •

All reciprocating compressors should immediately go into a vacuum if the suction line is valved off when the compressor is running. This test proves that the suction valves are seating correctly on at least one cylinder. This test is *not satisfactory* on a multicylinder compressor. If one cylinder pumps correctly, a vacuum will be pulled. A reciprocating compressor should pull 26 in. to 28 in. Hg vacuum with the atmosphere as the discharge pressure, **Figure 29.35**. The compressor should pull about 24 in. Hg vacuum against 100 psig discharge pressure, **Figure 29.36**. When the compressor has pumped a differential pressure and is stopped, the pressures should not equalize. For example, when a compressor that has been operated until the suction pressure is 24 in. Hg vacuum and the head pressure is 100 psig is stopped, it should have the same pressures while it is off. When refrigerant is used for this pumping test, the 100 psig will drop some because of the condensing refrigerant. Nitrogen is a better choice to pump in the test because the pressure will not drop.

Figure 29.35 A compressor pulling a vacuum with the atmosphere as the head pressure. Most reciprocating compressors can pull 26 in. to 28 in. Hg vacuum with the atmosphere as the discharge pressure.

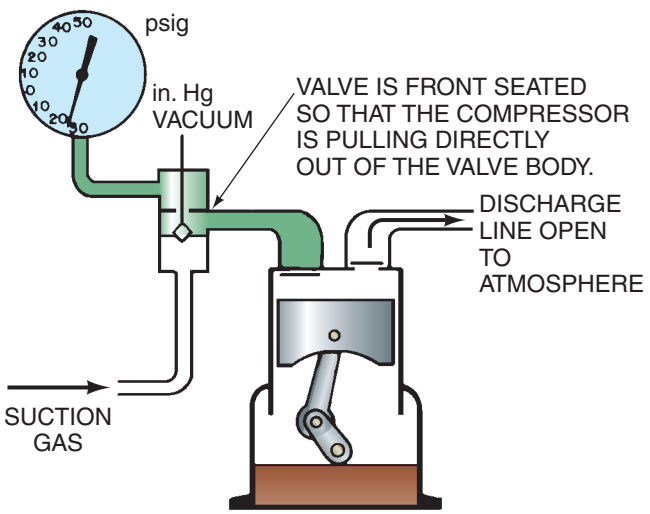

Figure 29.36 Perform a compressor check by pulling a vacuum while pumping against a head pressure. A reciprocating compressor normally can pull 24 in. Hg vacuum against 100 psig head pressure.

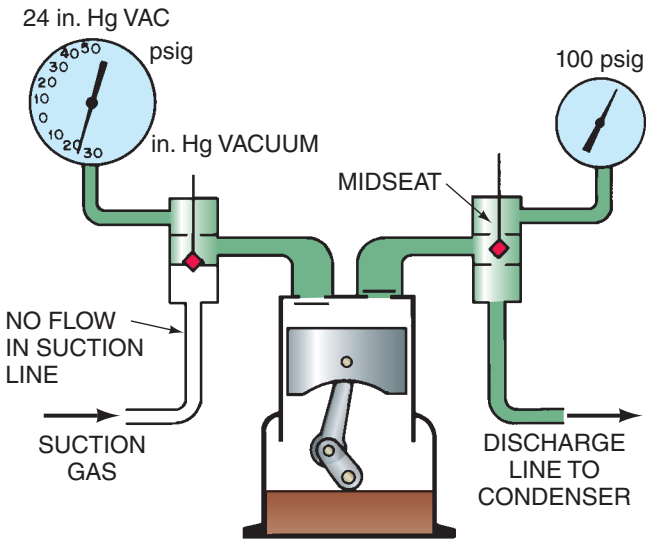


SAFETY PRECAUTION: *Care should be taken when operating a hermetic compressor in a deep vacuum (below 1000 microns) because the motor is subject to damage. This low vacuum cannot be obtained with a reciprocating compressor. Also, most compressor motors are cooled with suction gas and will get hot if operated for any length of time while performing these tests. This vacuum test should not take more than 3 to 5 min. The motor will not overheat in this period of time. The test should be performed only by experienced technicians.* •

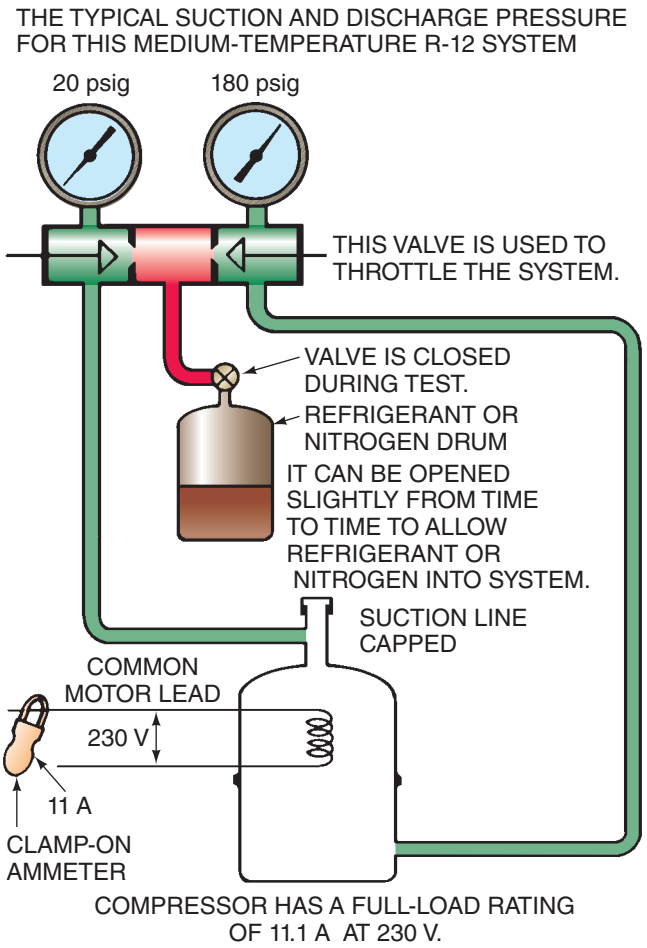
29.18 CLOSED-LOOP COMPESSOR RUNNING BENCH TEST

Doing a running bench test on a compressor can be accomplished by connecting a line from the discharge to the suction of the compressor and operating the compressor in a closed loop. A difference in pressure can be obtained with a valve arrangement or gauge manifold. This will prove the compressor can pump. **NOTE:** *When the compressor is hermetic, it should operate at close to full-load current in the closed loop when design pressures are duplicated.* • Nitrogen or refrigerant can be used as the gas to be compressed. Typical operating pressures will have to be duplicated for the compressor to operate at near the full-load current rating. For example, for a medium-temperature compressor, a suction pressure of 20 psig and a head pressure of 170 psig will duplicate a typical condition for R-12 on a hot day. The compressor should operate near to nameplate full-load current when the design voltage is supplied to the motor.

The following is a step-by-step procedure for performing this test. Use this procedure with the information in **Figure 29.37**.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 29.37 Checking a compressor's pumping capacity by using a closed loop. The test is accomplished by routing the discharge gas back into the suction port with a piping loop. The discharge gauge manifold valve is gradually throttled toward closed (do not entirely close). It can never be closed because tremendous pressure will occur. When the design suction and discharge pressures are reached, the compressor should be pulling close to nameplate full-load amperage. *A suction-cooled compressor cannot be run for long in this manner or the motor will get hot.* The refrigerant that is characteristic to the compressor (or nitrogen) can be used to circulate for pumping. Nitrogen will not produce the correct amperage, but it will be close enough. **SAFETY PRECAUTION:** *This test should only be performed by experienced technicians.*•



SAFETY PRECAUTION: *This test should be performed only under the close supervision of an instructor or by a qualified person and on equipment under 3 hp. Safety goggles must be worn.*•

Steps for performing a closed-loop test with the compressor removed from the system:

1. Use the gauge manifold and fasten the suction line to the low-pressure gauge line in such a manner that the compressor is pumping only from the gauge line.
2. Fasten the discharge gauge line to the discharge valve port in such a manner that the compressor is pumping only into the gauge manifold.
3. Plug the center line of the gauge manifold.
4. **SAFETY PRECAUTION:** *Both gauge manifold valves should be wide open, counterclockwise.*•
5. **SAFETY PRECAUTION:** *Start the compressor; keep your hand on the off switch.*•
6. The compressor should now be pumping out the discharge line and back into the suction line. The discharge gauge manifold valve may be slowly throttled (*do not close entirely*) toward closed until the discharge pressure rises to the design level and the suction pressure drops to the design level.
7. When the desired pressures are reached, the amperage reading on the compressor motor should compare closely to the full-load amperage of the compressor. If the correct pressures cannot be obtained with the amount of gas in the compressor, a small amount of gas may be added to the loop system by attaching the center line to a nitrogen cylinder and slightly opening the cylinder valve.
8. The amperage may vary slightly from full load because of the input voltage. For example, a voltage above the nameplate will cause an amperage below full load, and vice versa.

Figure 29.38 illustrates a situation in which a technician accidentally closed the valve completely.

Figure 29.38 **SAFETY PRECAUTION:** *What happens if a compressor is started up in a closed loop with no place for the discharge gas to go (discharge gauge manifold closed by accident)? One cylinder full of gas could be enough to build tremendous pressures.*•

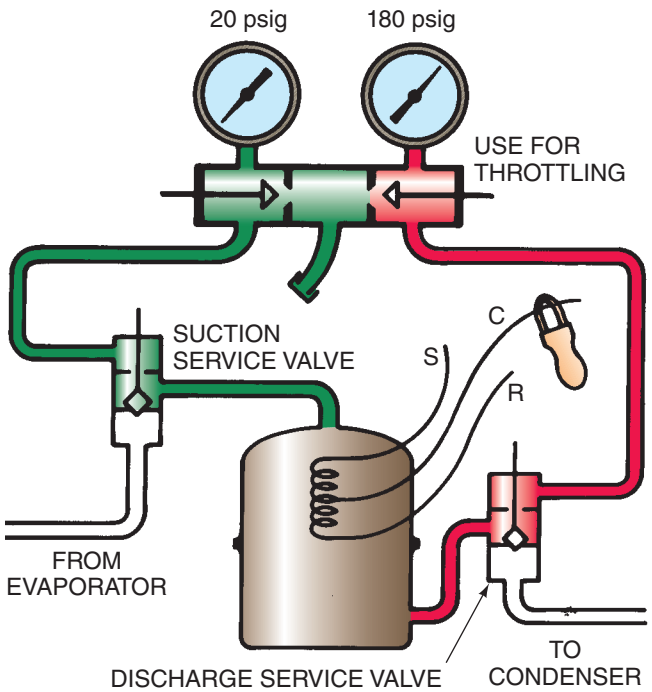
29.19 CLOSED-LOOP COMPRESSOR RUNNING FIELD TEST

When a compressor has suction and discharge service valves, this test can be performed in place in the system using a gauge manifold as the loop, **Figure 29.39**. The compressor is started with the compressor service valves turned all the way to the front seat and the gauge manifold valves open. The center line on the gauge manifold must be plugged. **SAFETY PRECAUTION:** *This can be a dangerous start-up and should be performed only under supervision of an experienced person. The compressor has to have a place to pump the discharge gas because reciprocating compressors are positive displacement pumps. When the compressor cylinder is full of gas, it is going to pump it somewhere or stall. In this test the gas goes around through the gauge manifold and back into the suction. Should the compressor be started before the gauge manifold is open for the escape route, tremendous pressures will result before you can stop the compressor. It takes only one cylinder full of vapor to fill the gauge manifold to more than capacity. This test should only be performed on compressors under 3 hp. Safety goggles must be worn.*•

Figure 29.39 A compressor test being performed in a system using a gauge manifold as a closed loop. Notice that this test can be performed in the system because the compressor has service valves. Do not perform this test without experienced supervision.



THE SUCTION SERVICE VALVE MAY BE CRACKED FROM TIME TO TIME TO ALLOW SMALL AMOUNTS OF REFRIGERANT TO ENTER COMPRESSOR UNTIL TEST PRESSURES ARE REACHED.

NOTE: START THIS TEST WITH GAUGE MANIFOLD VALVES WIDE OPEN. THEN USE THE HIGH-SIDE VALVE FOR THROTTLING.

Steps for performing the closed-loop compressor test with the compressor in the system:

1. Turn the unit OFF and fasten the suction line of the gauge manifold to the suction service valve. Plug the center line of the gauge manifold.
2. Turn the suction service valve stem to the front seat.
3. Fasten the discharge line to the discharge valve and turn the discharge service valve stem to the front seat.
4. **SAFETY PRECAUTION:** *Open both gauge manifold valves all the way, counterclockwise.*•
5. **SAFETY PRECAUTION:** *Start the compressor and keep your hand on the switch.*•
6. The compressor should now be pumping out through the discharge port, through the gauge manifold, and back into the suction port.
7. The discharge gauge manifold valve may be throttled toward the seat to restrict the flow of refrigerant and create a differential in pressure. Throttle (*do not entirely close*) the valve until the design head and suction pressure for the system is attained (the compressor should then be pulling near to full-load amperage). As in the bench test, the amperage may vary slightly because of the line voltage.

29.20 COMPRESSOR RUNNING TEST IN THE SYSTEM

A running test in the system can be performed by creating typical design conditions in the system. Typically, a compressor will operate at a *high suction* and a *low head pressure* when it is not pumping to capacity. This will cause the compressor to operate at a low current. When the technician is called to a job, the conditions are not usually at the design level. The fixture is usually not refrigerating correctly—this is what instigated the call to begin with. The technician may not be able to create design conditions, but the following approach should be tried if the compressor capacity is suspected:

1. Install the high- and low-side gauges.
2. Make sure that the charge is correct (not over or under), using manufacturer's recommendations.
3. Check the compressor current and compare to full load.
4. Block the condenser airflow and build up the head pressure.

If the compressor will not pump the head pressure up to the equivalent of a 95°F day (95°F + 30°F = 125°F condensing temperature, or 170 psig for R-12, 185 psig for R-134a, 278 psig for R-22, 301 psig for R-502, and 332 psig for R-404A) and draw close to the nameplate full-load current, the compressor is not pumping. When the compressor is a sealed hermetic type, it may whistle when it is shut down.

This whistle is evidence of an internal leak from the high side to the low side.

If the compressor has service valves, a closed-loop test can be performed on the compressor using the methods we have explained while it is in the system. **NOTE:** *Make sure no air is drawn into the system while it is in a vacuum.*

SAFETY PRECAUTION: *The compressor temperature should be monitored at any time these tests are being conducted. If the compressor gets too warm, it should be stopped and allowed to cool. If the compressor has internal motor-temperature safety controls, do not operate it when the control is trying to stop the compressor.*

HVAC GOLDEN RULES

When making a service call to a business:

- Never park your truck or van in a space reserved for customers.
- Look professional and be professional.
- Before starting troubleshooting procedures, get all the information you can regarding the problem.
- Be extremely careful not to scratch tile floors or to soil carpeting with your tools or by moving equipment.
- Be sure to practice good sanitary and hygiene habits when working in a food preparation area.
- Keep your tools and equipment out of the customers' and employees' way if the equipment you are servicing is located in a normal traffic pattern.
- Be prepared with the correct tools and ensure that they are in good condition.
- Always clean up after you have finished. Try to provide a little extra service by cleaning filters, oiling motors, or providing some other service that will impress the customer.
- Always discuss the results of your service call with the owner or representative of the company. Try to persuade the owner to call if there are any questions as a result of the service call.

PREVENTIVE MAINTENANCE FOR REFRIGERATION

PACKAGED EQUIPMENT. Packaged equipment is built and designed for minimum maintenance because the owner may be the person that takes care of it until a breakdown occurs. Most of the fan motors are permanently lubricated and will run until they quit, at which time they are replaced with new ones.

The owners should be educated to keep the condensers clean and not to stack inventory so close as to block the condenser airflow. When the unit is a reach-in cooler, the owner should be cautioned to follow the manufacturer's directions in loading the box. The load line on the inside should be observed for proper air distribution.

The owner or manager should examine each refrigerated unit frequently and be aware of any peculiar noises or actions from the box. Each box should have a thermometer that should be monitored each day by management. Any rise in temperature that does not reverse itself should alert the manager that a problem is occurring. This can prevent unnecessary loss of perishable foods.

The electrical service for all package equipment should be visually inspected for frayed wires and overheating. Power cord connections may become loose and start to build up heat. If the end that plugs into the wall receptacle becomes hot, the machine should be shut down until the problem is found and corrected. **SAFETY PRECAUTION:** *If only the plug is replaced, the wall receptacle may still be a problem. The whole connection, the wall receptacle and the cord plug, should be inspected and repaired.*

Ice machines require special attention if they are to be reliable. Management should know what the quality of the ice should be when the machine is operating correctly. When the quality begins to deteriorate, the reason should be found. This can be as simple as looking for the correct water flow on a cube maker or the correct ice-cutting pattern on another type of cube maker. The ice falling into the bin of a flake maker should have the correct quality, neither soft and mushy nor brittle and hard. The level of the ice in the bin the morning after the machine has been left to run all night can reveal if the machine is making enough ice. For example, if it is observed that the bin is full every morning and the bin thermostat is satisfied but then one morning the bin is only half full, trouble can be suspected. Keep a close watch on the machine.

Drains and drain lines for all refrigeration equipment should be maintained and kept clean and free. This can normally be accomplished when the unit is cleaned and sanitized on the inside. When the cleaning water is flushed down the drain, the speed with which the drain moves the water should indicate if the drain is partially plugged or draining freely.

SPLIT-SYSTEM REFRIGERATION EQUIPMENT, EVAPORATOR SECTION, CONDENSER SECTION, AND INTERCONNECTING PIPING. In refrigeration split systems, the evaporator section is located in one place and the condensing unit in another. The interconnecting piping makes the system complete. The evaporator section contains the evaporator, metering device, motor, defrost heaters, drain pan, and drain line. Refrigeration evaporators do not need cleaning often but do need to be inspected and cleaned regularly. The technician cannot always tell when a coil is dirty by looking at the evaporator. Grease or dirt may be in the core of the coil. Routine cleaning of the evaporator once a year will usually keep the coil clean.

PREVENTIVE MAINTENANCE FOR REFRIGERATION (*Continued*)

SAFETY PRECAUTION: *Use only approved cleaning compounds where food is present. Turn off the power before cleaning any system. Cover the fan motors and all electrical connections when cleaning to prevent water and detergent from getting into them.*•

The motors in the evaporator unit are usually sealed and permanently lubricated. If not, they should be lubricated at recommended intervals, which are often marked on the motor. Observe the fan blade for alignment and look for bearing wear. This may be found by lifting the motor shaft. Most small motors have considerable end play. Do not mistake this for bearing wear. You must lift the shaft to discover bearing wear. The fan blade may also gather weight from dirt and become out of balance.

All wiring in the evaporator section should be visually inspected. If it is cracked or frayed, shut off the power and replace it. Do not forget the defrost heaters and any heater tapes that may be used to keep the drain line warm during cold weather.

The entire case should be cleaned and sanitized at regular intervals. You may need to be the judge of these intervals. Do not let the unit become dirty, including the floor and storage racks in walk-in coolers. **SAFETY PRECAUTION:** *Keep all ice off the floor of walk-in coolers, or an accident may occur.*•

The condensing unit may be located inside an equipment room in the store or it may be outside. When the condenser is located inside an equipment room, it must have proper ventilation. Most equipment rooms have automatic exhaust systems that turn fans on when the equipment room reaches a certain temperature. In large equipment rooms, the temperature will stay warm enough for the exhaust fan to run all the time.

Condensers in equipment rooms become dirty just as they do outdoors and must be cleaned. Most system condensers should be cleaned at least once a year to ensure the best efficiency and to prevent problems. The condensers may be cleaned with an approved condenser cleaner and then washed.

SAFETY PRECAUTION: *Turn off the power before cleaning any system. All motors and wiring must be covered to prevent them from getting wet. Watch the equipment room floor. If oil is present and water gets on it, it will become slippery.*•

The technician can identify many future problems by close inspection of the equipment room. Leaks may be found by observing oil spots on piping. Touch testing the various components will often tell the technician that a compressor is operating too hot or too cold. Tape-on temperature indicators may be fastened to discharge lines to indicate the highest temperature the discharge line has ever reached. For example, most manufacturers would consider that oil inside the compressor will begin to break down at discharge temperatures above 250°F. A tape-on temperature indicator will tell if high temperatures are occurring when no one is around, such as a defrost problem in the middle of the night. This can lead to a search for a problem that is not apparent.

The crankcase of a compressor should not be cold to the touch below the oil level. This is a sure sign that liquid refrigerant is in the refrigerant oil on some systems, not necessarily in great amounts, but enough to cause diluted refrigerant oil. Diluted refrigerant oil causes marginal lubrication and bearing wear.

Fan motors may be inspected for bearing wear. Again, do not mistake end play for bearing wear. Some fan motors require lubrication at the correct intervals.

A general cleaning of the equipment room at regular intervals will ensure the technician good working conditions when a failure occurs.

The interconnecting piping should be inspected for loose insulation and oil spots (indicating a leak) and to ensure the pipe is secure. Some piping is in trenches in the floor. A trench that is full of water because of a plugged floor drain will hurt the capacity of the equipment because the insulation value of the suction-line insulation is not as great when wet. A heat exchange between the liquid lines and suction lines or the ground and suction lines will occur. The pipe trenches should be kept as clean as practical.

29.21 DIAGNOSTIC CHART FOR COMMERCIAL REFRIGERATION

Commercial refrigeration equipment that controls the storage temperatures for perishable products must be kept operating properly to prevent spoilage. The technician must restore the system to good working order in the least amount of time. Orderly troubleshooting is the most effective way to arrive at sound conclusions in a minimum of time. Following are some recommendations for troubleshooting commercial refrigeration systems:

1. Listen to the customer's description of the system's symptoms. Most commercial refrigeration equipment customers monitor the system and the temperatures carefully. Question the customer about sounds, cycle times, and temperatures on normal days, and ask what is different now.
2. Observation may be one of the most important steps you can take. Inspect the complete system before making any adjustments or repairs. Check the condenser for dirt, leaves, or trash in the coil or fan. Look for blocked airflow. Inspect the wiring for discoloration of connections. Look for loose or missing insulation on the suction line or kinks or flattened tubing. Check the evaporator for air blockage due to frost, ice, or dirt. Make sure the fan is circulating air.
3. Once the customer has been consulted and the system has been observed, determine what is functioning and what is not functioning. The following chart will help to determine possible causes of the problem.

Problem	Possible Cause	Possible Repair
Compressor will not start or attempt to start; makes no sound	Open disconnect switch	Close disconnect switch.
	Open fuse or breaker	Replace fuse or reset breaker and determine why it opened.
	Tripped overload	Reset and determine why it tripped.
	Pressure control stuck in open position	Reset or replace and determine why it opened.
	Open internal or external overload	Allow to cool down.
	Open coil on motor starter	Check coil and replace if needed.
	Faulty wiring	Repair or replace faulty wiring connectors.
Compressor will not start; hums and trips on overload	Incorrect wiring, **Single Phase**	Check common, run, and start connections.
	High discharge pressure	Overcharge of refrigerant, not enough condenser cooling, closed discharge service valve.
	Incorrect wiring, **Three Phase**	Check all three phases, phase-to-phase.
	Start relay wired wrong or defective, **Single Phase**	Rewire relay if needed or replace if defective.
	Start or run capacitor defective	Replace capacitor.
	Compressor winding open or shorted	Replace compressor.
	Internal compressor problems, stuck or tight	Replace compressor.
Compressor starts but stays in start, **Single Phase**	Wired incorrectly	Check wiring as compared with diagram.
	Low-voltage supply	Correct low voltage.
	Defective start relay	Replace relay.
	Tight or binding compressor	Replace compressor.
Compressor starts and runs for a short time and then shuts off due to overload	Defective overload	Check actual load on overload and replace if it trips below specifications.
	Excess current in overload circuit	Check circuit for added load, such as fans or pumps.
	Low voltage	Determine reason and correct.
	Unbalanced voltage, **Three Phase**	Correct unbalance; possible redistribution of loads.
	Defective run capacitor	Replace.
	Excessive load on compressor	Check and repair defrost control circuit.
	A. HIGH SUCTION PRESSURE: Defrost heater on all the time	Operator education.
	B. Hot food placed in cooler	Move object causing recirculation.
	C. HIGH DISCHARGE PRESSURE: Recirculating condenser air	Remove blockage, make sure all fans are on.
	Reduced airflow	Clean condenser.
	Dirty condenser	Replace compressor.
	Compressor windings shorted	
Compressor starts but short cycles	Overload protector shutting compressor off	See category above.
	Thermostat	Differential too close; thermostat setting; bulb in cold airstream, move location.
	High-pressure condition	Check airflow or water flow.
	Low-pressure condition with pumpdown control	Air blockage or recirculating; correct.
	A. Solenoid valve leaking	Overcharge; remove refrigerant.
	B. Compressor discharge valve leaking during off cycle (will also leak while running)	Air in system; remove.

Problem	Possible Cause	Possible Repair
	With or without pumpdown control	Replace solenoid.
	A. Low refrigerant charge	Repair valve or replace compressor.
	B. Restriction in system such as expansion valve, drier, or crimped pipe	Repair leak and add refrigerant. Repair or replace.
Compressor runs continuously or space temperature is too high	Low refrigerant charge	Repair leak; add refrigerant.
	Operating control (thermostat or low-pressure control) contacts stuck closed	Replace control.
	Excessive load	
	A. Unit undersized	A. Reduce load or replace unit.
	B. Door of cooler open too often	B. Train operator.
	C. Product too hot when placed in cooler	C. Precool food in air-conditioned space.
	D. Poor door gaskets or infiltration	D. Seal air leaks.
	E. Cooler setting in too hot a location	E. Move or reduce heat.
	Evaporator coil not defrosting	Check defrost method and repair.
	Restriction in refrigerant circuit, drier, metering device, crimped pipe	Find and repair.
	Poor condenser performance	Restore airflow.
	A. Restricted airflow	Move objects causing recirculation.
	B. Recirculated air	Clean condenser.
	C. Dirty condenser	

29.22 SERVICE TECHNICIAN CALLS

In addition to the six problems typically encountered in refrigeration systems, many more problems are not so typical. The following service situations will help you understand troubleshooting. Most of these service situations have already been described, although not as actual troubleshooting procedures. Sometimes the symptoms do not describe the problem and a wrong diagnosis is made. Do not draw any conclusion until the whole system has been examined. Become a system doctor. Examine the system and say, "This needs further examination," and then do it. Refrigeration systems often cool large amounts of food so they are slow to respond. The temperature may drop very slowly on a hot or warm pulldown.

SERVICE CALL 1

A customer calls and complains that the compressor for a medium-temperature walk-in cooler with a remote condensing unit is short cycling and not cooling correctly. *The evaporator has two fans, and one is burned. The unit is short cycling on the low-pressure control because there is not enough load on the coil.*

On the way to the job the technician goes over the possible problems. This is where it helps to have some familiarity with the setup. The technician remembers that the unit has a low-pressure control, a high-pressure control, a thermostat, an overload, and an oil safety control. Defrost is accomplished with an off cycle using the air in the refrigerated space with the fans running. By the process of elimination the technician decides that the thermostat and the oil safety control are not at fault. The thermostat has a 10°F differential, and the cooler temperature should not vary 10°F in a short cycle. The oil safety control is a manual reset and will not short cycle. This narrows the possibilities down to the motor protection device and the high- or low-pressure controls.

On arrival, the technician parks so that his service vehicle does not block the driveway and makes sure his uniform is neat, clean, and tucked in. He uses a clean rag to remove some grease smudges from his shoes from a previous job that day.

The service technician then looks over the whole system before doing anything and notices that one evaporator fan is not running and that the coil is iced, so the suction is too low, **Figure 29.40**. This causes the low-pressure control to shut off the compressor. After completing the examination, he replaces the fan motor and puts the system back in operation with the compressor shut off and allows the fans to run

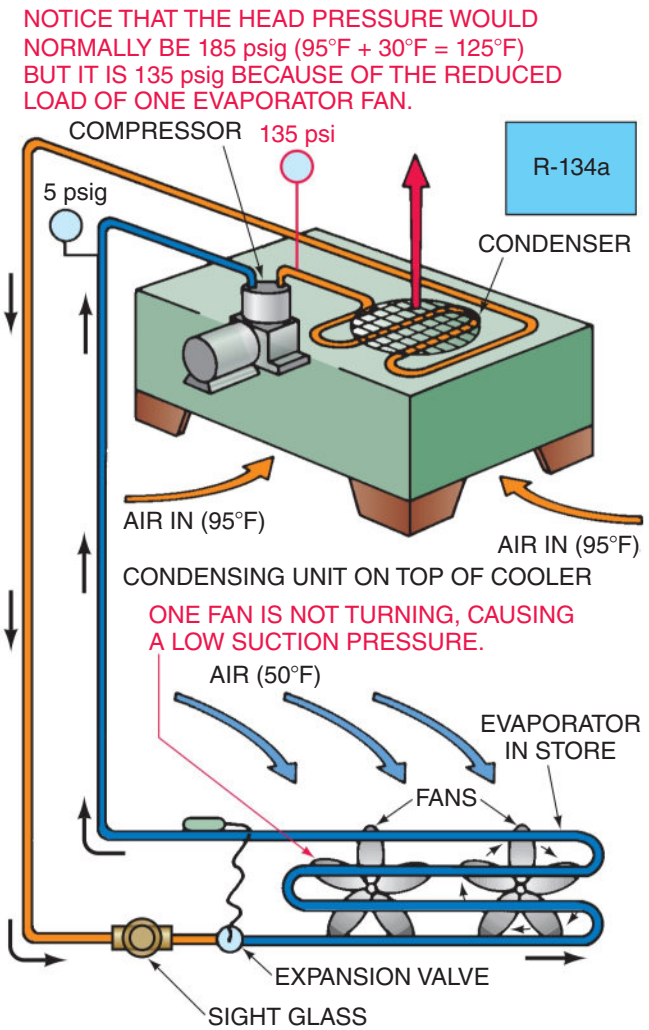
long enough to defrost the coil. The temperature inside the cooler is 50°F; it will take a long while for the cooler to pull down to the cut-out point of 35°F because of the amount of food. The technician cautions the owner to watch the thermometer in the cooler to make sure that the temperature is going down. The technician then politely gives the customer the billing information, work description, and cost of the work performed. A call later in the day will confirm that the unit is working properly.

Figure 29.40 Symptoms of a medium-temperature system with one of the two evaporator fans burned out. This system has a TXV.



SERVICE CALL 2

A medium-temperature reach-in cooler is not cooling, and the compressor is cutting on and off. In this system the condensing unit is on top. *The unit has a TXV and a low charge. Two tubes have rubbed together and created a leak.*

The technician finds the unit is short cycling on the low-pressure control. The sight glass has bubbles in it, indicating a low charge, **Figure 29.41**. The small tube leading to the low-pressure control has rubbed a hole in the suction line, and there is oil around the point of the leak. The system is pumped down by closing the king valve, and the leak is repaired. The system is pressurized with nitrogen and leak checked. The system is then evacuated to the proper micron level. Once evacuation is complete and the vacuum pump has been isolated from the system, the king valve can be opened.

After the repair a leak check is performed, the technician starts the system and charges it to the correct charge. A call later in the day verifies that the system is functioning correctly.

Figure 29.41 Symptoms of a medium-temperature system operating in a low-charge situation. This system has a TXV.

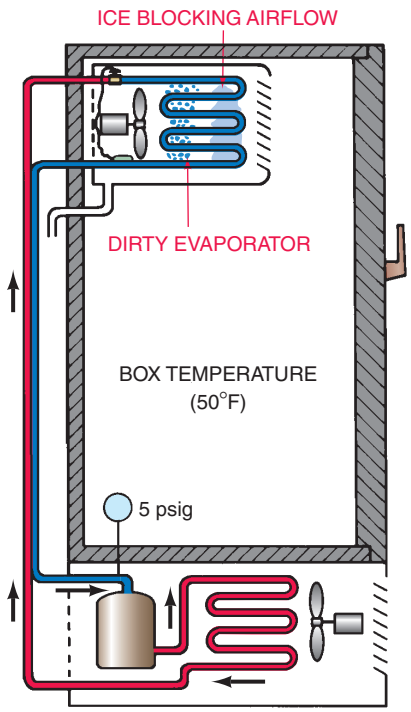
SERVICE CALL 3

A factory cafeteria manager reports that the reach-in cooler in the lunchroom is not cooling and is running all the time. It is a medium-temperature cooler with the condensing unit at the bottom of the fixture that has not had a service call in a long time. *The evaporator is dirty and icing over,* **Figure 29.42**. *The unit has a TXV and there is no off time for defrost because the box does not get cool enough.*

The technician sees that the system is iced. The compressor is sweating down the side, and liquid is slowly coming back to the compressor—not enough to cause a noise from slugging. The TXV should maintain a constant superheat, but it may lose control if the pressure drops too low. The first thing that has to be done is to defrost the evaporator by stopping the compressor and using a heat gun (like a high-powered hair drier). The evaporator has a lot of dirt on it. **SAFETY PRECAUTION:** *The evaporator is cleaned with a coil cleaner that is approved for use in food-handling areas.* After the evaporator is cleaned, the system is started. The unit is now operating with a full sight glass, and the suction line leaving the evaporator is cold. From this point it will take time for the unit to pull the cooler temperature down. While maintaining eye contact with the customer and remembering the customer's name, the technician politely explains how the problem was corrected. After giving the customer billing information, the work site is cleaned and the work double-checked for completeness. The service technician leaves and calls later in the day to confirm that the repair has solved the problem.

Figure 29.42 Symptoms of a medium-temperature cooler with a dirty evaporator coil. This system has a TXV.



SERVICE CALL 4

A convenience store manager reports that the reach-in cooler that stores the dairy products is not cooling properly. *The temperature is 55°F. It had been cooling well until early that morning. There is a leak due to a stress crack (caused by age and vibration) in the suction line near the compressor. The compressor is vibrating because when the customer moved the unit, the condensing unit fell down in the frame. This system has a capillary tube metering device,* **Figure 29.43**.

The technician's examination discloses that the compressor is vibrating because the condensing unit is not setting straight in the frame. While securing the condensing unit, the technician notices an oil spot on the bottom of the suction line and that the compressor shell is hot. When gauges are installed, he discovers that the suction pressure is operating in a vacuum. **NOTE:** *Care must be used when installing gauges if a vacuum is suspected or air may be drawn into the system.* The compressor is stopped and the low-side pressure is allowed to rise. There is not enough pressure in the system to accomplish a good leak test, so refrigerant is added. A leak check in the vicinity of the suction line reveals a leak, which appears to be a stress crack due to the vibration. 4R *The refrigerant is recovered from the system to repair the leak. Air must have been pulled into the system while it was operating in a vacuum, so the refrigerant charge must be recovered.* 4R **This system does not have a low-pressure control**. A short length of pipe is installed where the stress crack was found, and a new liquid-line drier is installed because the old one may not have any capacity left. The system is leak checked, triple evacuated, and charged, using a measured charge that the manufacturer recommends. The technician calls the manager later in the day and learns that the unit is functioning correctly.

SERVICE CALL 5

A restaurant manager calls to indicate that the reach-in freezer used for ice storage is running all the time. A competitor worked on this system in the early spring. A leak was found, the refrigerant was recovered, and the leak was

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Figure 29.43 Symptoms of a medium-temperature system with a low charge. This system has a capillary tube.

repaired. A deep vacuum was then pulled and the unit was recharged. Hot weather is here, and the unit is running all the time. *This system has a capillary tube metering device, and the system has an overcharge of refrigerant. The other service technician did not measure the charge into the system,* **Figure 29.44**.

After parking the service van toward the back of the restaurant and away from the general public, the technician quietly knocks at the back door of the restaurant. Once invited in, the technician politely introduces himself and asks the restaurant manager pertinent questions without dominating the conversation or making the manager feel stupid about any technical topic.

After shaking hands, the technician starts work. Upon examining the fixture, the technician notices that the compressor is sweating down the side. The condenser feels hot for the first few rows and then warm. This appears to be an overcharge of refrigerant. The condenser should be warm near the bottom where the condensing is occurring. The evaporator fan is running and the evaporator looks clean, so the evaporator must be doing its job. Gauges are installed, revealing that the head pressure is 400 psig with an outside temperature of 95°F; the refrigerant is R-502. The head pressure should be no more than 301 psig on a 95°F day (95°F + 30°F = 125°F condensing temperature, or 301 psig). For refrigerant R-404A, a condensing temperature of 125°F would give a pressure of 332 psig. This system calls for a measured charge of 2 lb 8 oz. 4R *There are two possible approaches: (1) Alter the existing charge, or (2) recover the charge and measure a new charge into the unit while the unit is in a deep vacuum. It is a time-consuming process to recover the charge and evacuate the system.* 4R

The technician chooses to alter the existing charge. This is a plain capillary tube system with a heat exchanger (the capillary tube is soldered to the suction line after it leaves the evaporator). A thermometer lead is fastened to the suction line **after the evaporator** but **before the heat exchanger.** The suction pressure is checked for the boiling point of the refrigerant and compared with the suction line temperature. The superheat is 0°F with the existing charge of refrigerant. 4R *Refrigerant is removed to an approved recovery cylinder until the superheat is 5°F at this point.* 4R **NOTE:** *The heat exchanger will allow a lower super-heat than normal.* • When the system charge is balanced, the technician leaves the job and will call the manager later in the day for a report on how the system is functioning.

SERVICE CALL 6

An office manager calls and reports that the reach-in medium-temperature beverage cooler in the employee cafeteria is running all the time. The suction line is covered with frost back to the compressor. *A small liquid-line drier is stopped up with sludge from a compressor changeout after a motor burnout. A suction-line drier should have been installed,* **Figure 29.45**.

After looking the system over closely, the technician sees that the suction line is frosting and that the compressor has a frost patch on it. A first glance indicates that the fan at the evaporator is off and that the coil is dirty. Further examination, however, shows that the liquid line is frosting starting at the outlet of the drier. This means the drier is partially stopped up. The pressure drop across the drier makes the drier act like an expansion device. This effectively means there are two expansion devices in series because the drier is feeding the capillary tube. 4R *The refrigerant charge must be recovered and the drier replaced.* 4R After the refrigerant has been recovered, the drier is sweated into the liquid line. There are no service valves. While the system is open, the technician solders a suction-line drier in the suction line close to the compressor. A deep vacuum is then pulled and the system is recharged.

The reason the unit was frosting instead of sweating is that the evaporator was starved for liquid refrigerant. The suction pressure went down below freezing. The unit's capacity was reduced to the point where it was running constantly and had no defrost. The frost will become more dense, blocking the air through the coil and acting as an insulator. This will cause the coil to get even colder with more frost. This condition will continue with the frost line moving on to the compressor. The ice or frost acts as an insulator and blocks air. Air has to circulate across the coil for the unit to produce at its rated capacity.

SERVICE CALL 7

A restaurant owner calls indicating that the reach-in freezer for ice cream is running but the temperature is rising. *The system has a capillary tube metering device and the evaporator fan is defective. The customer hears the compressor running and thinks the whole unit is running,* **Figure 29.46**.

The technician has never been to this installation and has to examine the system thoroughly. He discovers that the frost on the suction line goes all the way to and down the side of the compressor. The first thought is that the system is

Figure 29.45 Symptoms of a medium-temperature reach-in cooler with a partially stopped-up liquid-line drier.

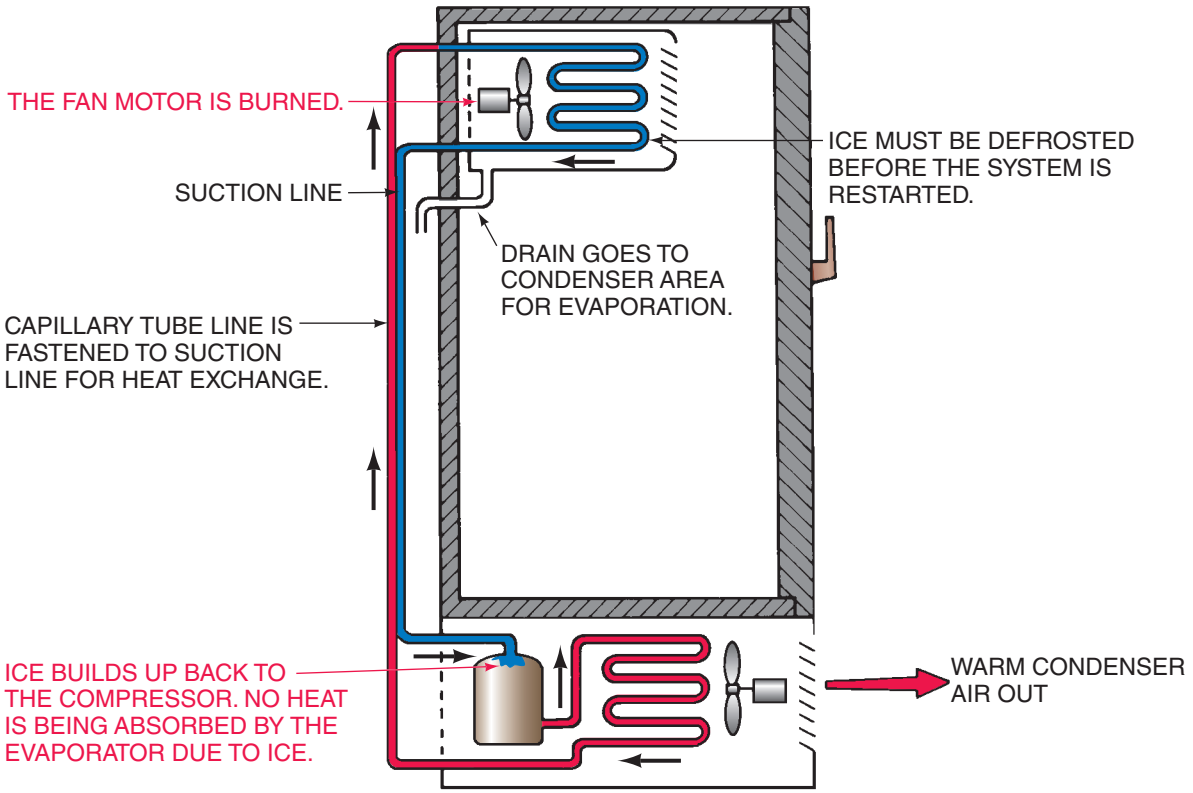
Figure 29.46 Symptoms of a reach-in freezer with a defective evaporator fan motor. This system has a capillary tube.



not going through the proper defrost cycle. The coil is iced and has to be defrosted before anything can be done. The defrost cycle clears the coil of ice, and when defrost is over, the fan does not restart as it should. The technician takes off the panel to the fan compartment and checks the voltage. There is voltage, but the fan will not run. When the motor is checked for continuity through the windings, it is discovered that the fan motor winding is open. The fan motor is changed, and the system is started again. It will take several hours for the fixture to pull back down to the normal running temperature of −10°F.

A call later in the day verifies that the freezer temperature is going down. The service technician then returns to the restaurant and clearly and concisely explains to the customer exactly what was done to remedy the problem. The service technician then gives the manager the billing information with a work description and costs. The technician then shakes the manager's hand and gives him a business card while maintaining eye contact. Before leaving, the technician makes a quick walk-around to make sure the work site has been cleaned and the unit is still pulling down to temperature.

SERVICE CALL 8

A call is received indicating that the customer's reach-in dairy case used for milk storage is running constantly and the temperature is 48°F. This unit has not had a service call in 10 years. *The evaporator is dirty. This unit has an automatic expansion valve. The coils never have had filters, and years of dust have accumulated,* **Figure 29.47**.

An automatic expansion valve maintains a constant pressure. It responds in reverse to a load change. If a load of additional product is added to the cooler, the rise in suction pressure will cause the automatic expansion valve to throttle back and slightly starve the evaporator. If the load is reduced, such as with a dirty coil, the valve will overfeed to keep the refrigerant pressure up.

The technician finds that the suction line is very cold and the compressor is sweating. This is evidence of an overcharge, or that the refrigerant is not boiling to a vapor in the evaporator. A close examination of the evaporator indicates that it is not exchanging heat with the air in the cooler. **SAFETY PRECAUTION:** *The evaporator is cleaned with a special detergent approved for evaporator cleaning and for use in food-handling areas. Areas that have dairy products are particularly difficult because these products absorb odors easily.*•

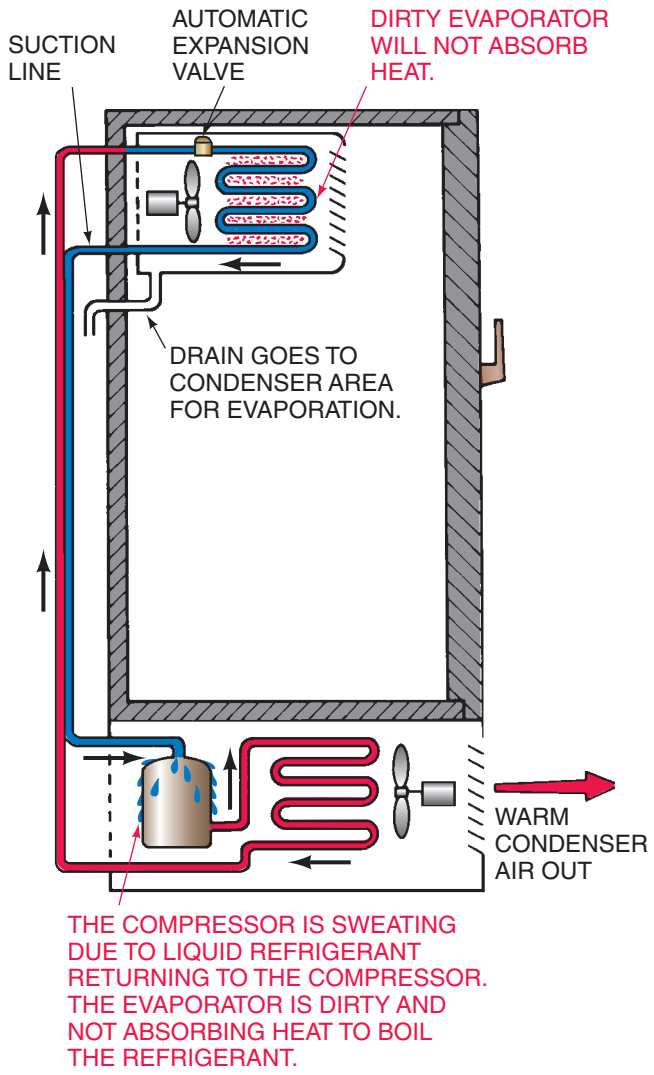
Figure 29.47 Symptoms of a reach-in dairy case with a dirty evaporator coil. This system has an automatic expansion valve.



The system is started, the sweat gradually disappears from the compressor, and the suction line feels normally cool. The technician leaves the job and will call back later to see how the unit is performing.

SERVICE CALL 9

A golf club restaurant manager calls to say that a small beverage cooler is not cooling drinks to the correct temperature. *A small leak at the flare nut on the outlet to the automatic expansion valve has caused a partial loss of refrigerant,* **Figure 29.48**.

Since this is an exclusive golf club and restaurant, the technician makes sure that the appearance of both the service van and himself are clean and presentable. The technician also takes care not to interfere with any golfers or restaurant customers. After ringing the bell at the service entrance and being invited in, the technician makes sure to maintain a comfortable distance between himself and the customer, politely shaking hands and maintaining eye contact while handing out a business card. After formally introducing himself and the company he works for, the technician carefully and politely listens to the customer about the service call and asks pertinent questions.

The technician begins work. He hears the expansion valve hissing, which means the valve is passing vapor along with the liquid it is supposed to pass. The sight glass shows some bubbles. The gauges that are installed indicate that the suction pressure is normal and the head pressure is low. The suction pressure is 17.5 psig; this corresponds to 15°F boiling temperature for R-12; 15°F for R-134a is 15.1 psig. The boiling refrigerant normally is about 20°F cooler than the beverages to be cooled. The liquid beverage in the cooler is 50°F and should be 35°F. The head pressure should be about 126 psig, the pressure corresponding to 105°F; 105°F for R-134a is 135 psig. The ambient is 75°F, and the condensing temperature should be 105°F (75°F + 30°F = 105°F). The head pressure is 100 psig. All of these signs point to an undercharge. The technician turns the cooler off and allows the low-side pressure to rise so that there will be a better chance of detecting a leak. A leak is found at the flare nut leaving the expansion valve. The nut is tightened but that does not stop the refrigerant from leaking. The flare connection must be defective.

4R *The charge is recovered, and the flare nut is removed.* 4R

There is a crack in the tubing at the base of the flare nut. The flare is repaired, and the system is leak checked and evacuated. A new charge of refrigerant is measured into the system from a vacuum. This gives the most accurate operating charge. The system is started. The technician will call back later to ensure that the unit is operating properly.

SERVICE CALL 10

A restaurant manager reports that the compressor in the pie case is cutting off and on and sounds like it is straining while it is running, **Figure 29.49**. This unit was charged after a leak and then shut down and put in storage. It has not been operated in several months. *The unit has an automatic expansion valve and has an overcharge of refrigerant. When the unit was charged it was in the back room in the winter, and it was cold in the room. The unit was charged to a full sight glass with a cold condenser.*

The service technician remembers that the unit was started and charged in a cold ambient and assumes that it may have an overcharge of refrigerant. When the technician arrives, the unit is started in the location where it is going to stay; the ambient is warm. Gauges are installed, and the

Figure 29.48 Symptoms of a reach-in beverage cooler with a low charge. This system has an automatic expansion valve.

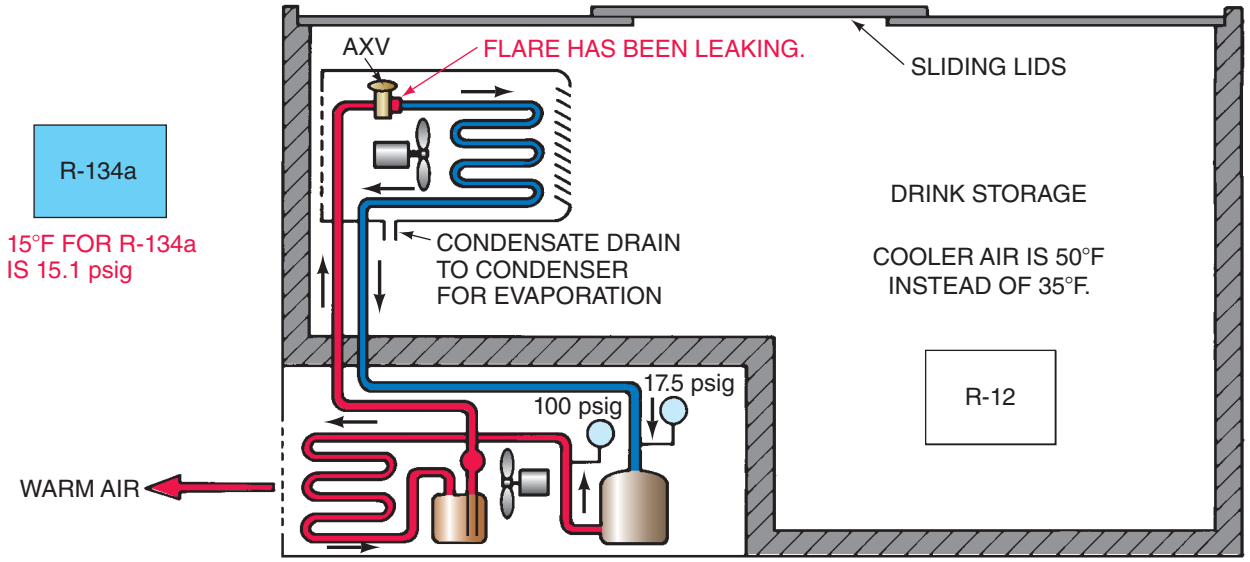


Figure 29.49 Symptoms of a reach-in pie case with an overcharge of refrigerant. This system has an automatic expansion valve.

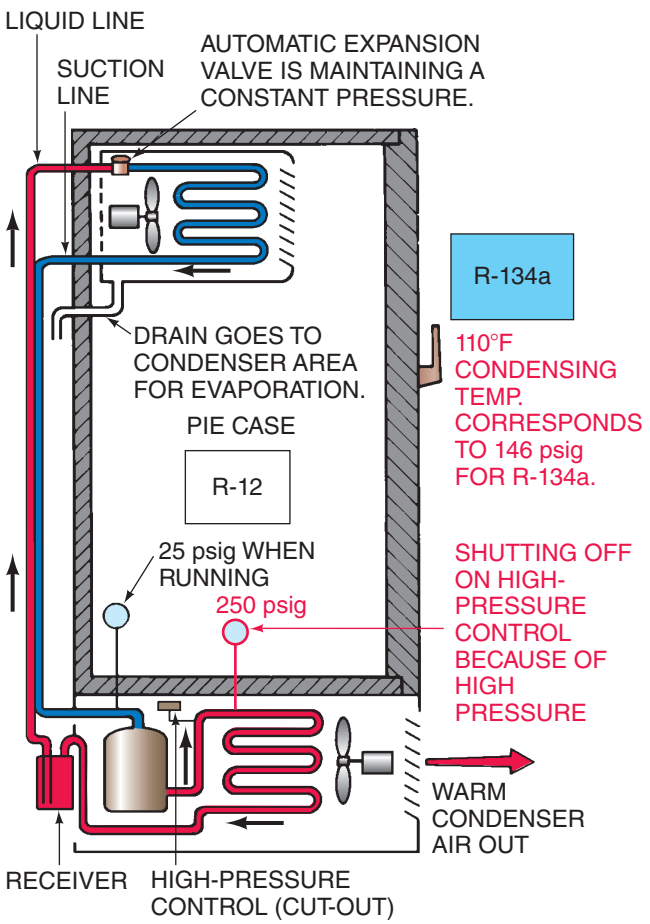

head pressure is 250 psig. The head pressure would be 281 psig for R-134a in the overcharged condition. The pressure should be 136 psig at the highest because the ambient temperature is 80°F. This should create a condensing temperature of no more than 110°F (80°F + 30°F = 110°F), or 136 psig for R-12. The compressor is cutting off because of high pressure at 260 psig. A 110°F condensing temperature for R-134a corresponds to 146 psig. 4R *Refrigerant is removed from the machine to an approved recovery cylinder until the head pressure is down to 136 psig, the correct head pressure for the ambient temperature.* 4R The sight glass is still full. A call back to the owner later in the day verifies that the system is working correctly.

SERVICE CALL 11

A store manager calls to say that a reach-in cooler is rising in temperature and the unit is running all the time. It is a medium-temperature cooler and should be operating between 35°F and 45°F. It has an automatic expansion valve. The unit has not had a service call in 3 years. *The evaporator fan motor is not running. This system has off-cycle defrost,* **Figure 29.50**.

The service technician examines the system. The compressor is on top of the fixture and is sweating down the side. Because this unit has an automatic expansion valve, the sweating is a sign that the evaporator is not boiling the refrigerant to a vapor. The evaporator could be dirty or the fan may not be moving enough air. After removing the fan panel, the technician sees that the evaporator fan

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

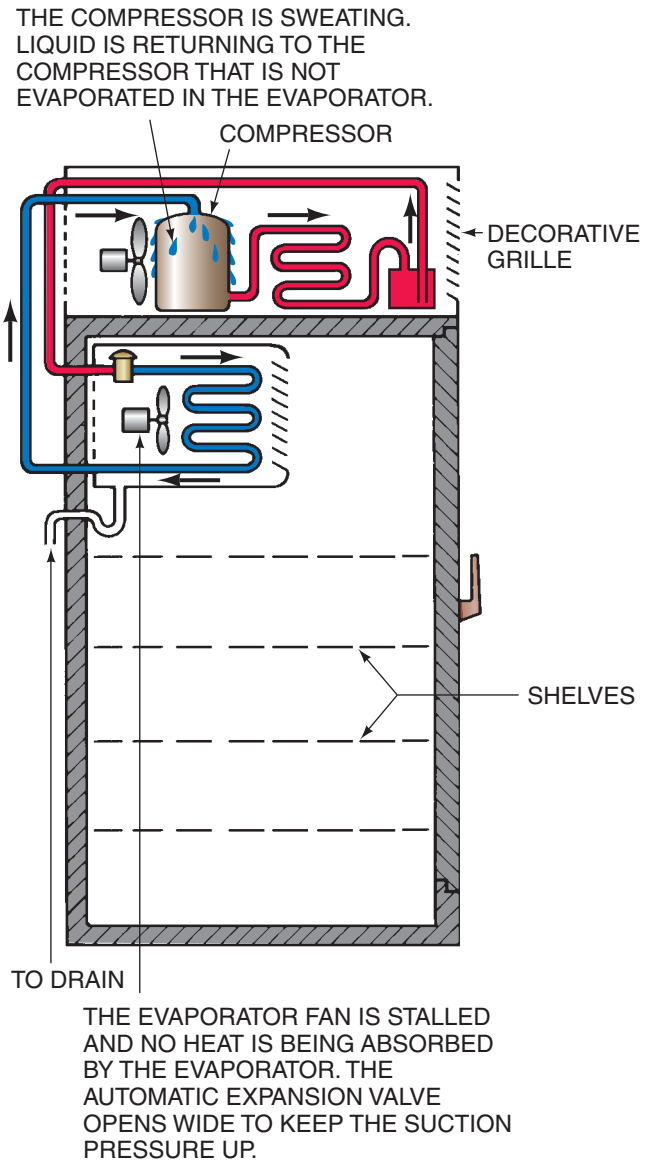
Figure 29.50 Symptoms of a reach-in cooler with a defective fan motor. This system has an automatic expansion valve.



motor is not running. The blades are hard to turn, indicating that bearings are tight. The bearings are lubricated and the fan is started and seems to run like it should. This is a nonstandard motor and cannot be purchased locally. The system is left in running condition until a new fan motor can be obtained.

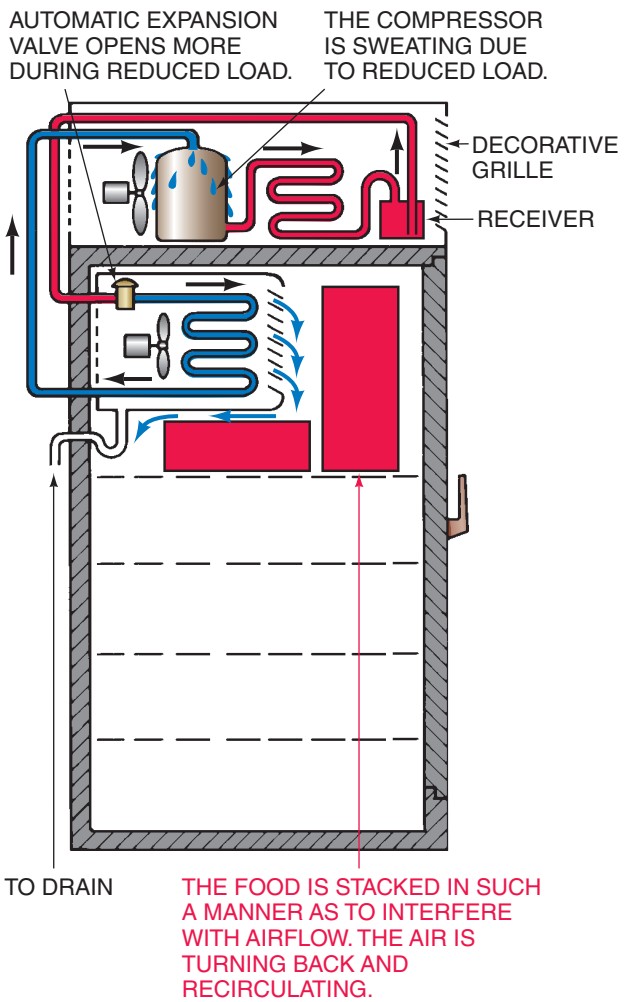
The technician returns in a week with the correct motor and exchanges it for the old one. The system has been working correctly all week. The old motor would fail again because the bearings are scored, which is the reason for exchanging a working motor for a new one.

SERVICE CALL 12

A store assistant manager reports that a reach-in medium-temperature cooler is rising in temperature. *This unit has been performing satisfactorily for several years. A new stock clerk has loaded the product too high, and the product is interfering with the airflow of the evaporator fan. The system has an automatic expansion valve,* **Figure 29.51**.

The technician immediately notices that the product is too high in the product area. The extra product is moved to another cooler. The stock clerk is shown the load level lines in the cooler without making the new stock clerk or the store's assistant manager feel uncomfortable or stupid when telling them what the problem really was. Technicians must always be courteous and show respect for the customer and never brag about their training or skills. A call back later in the day indicates that the cooler is now working correctly.

Figure 29.51 Symptoms of a reach-in medium-temperature cooler where the product is interfering with the air pattern. This system has an automatic expansion valve.



Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Figure 29.52 Symptoms of an air-cooled condenser with the hot discharge air recirculating back into the condenser inlet.

SERVICE CALL 13

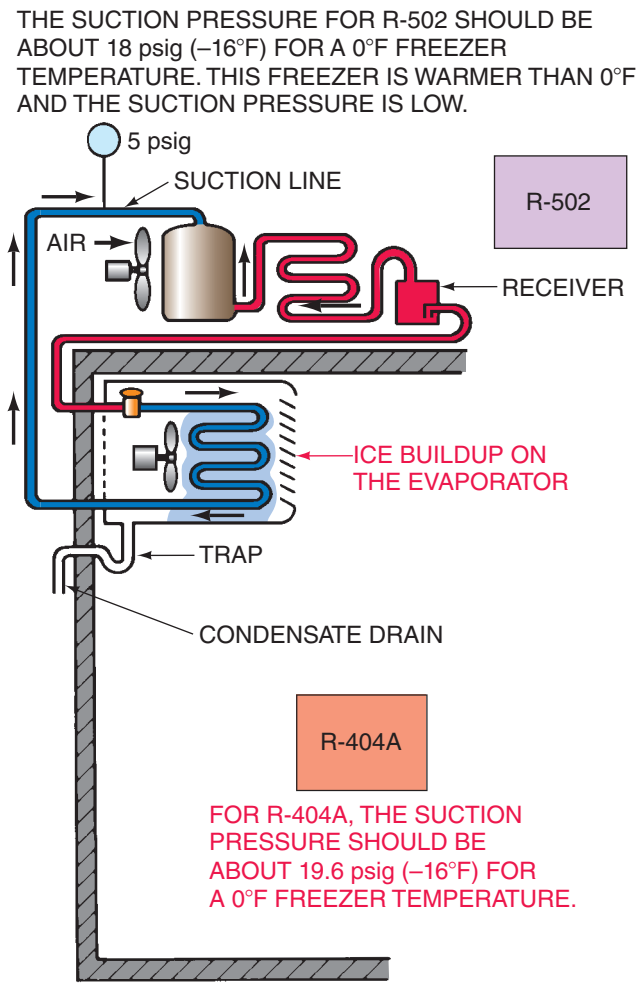
A customer reports that the condensing unit on a medium-temperature walk-in cooler is running all the time and the cooler is rising in temperature. *This is the first hot day of the season, and some boxes have been stacked too close to the condenser outlet. The hot air is leaving the condenser and recirculating back into the fan inlet,* **Figure 29.52**.

The service technician looks over the system. The temperature is 52°F inside the cooler. The liquid-line temperature is hot instead of warm. This is a TXV system, and the sight glass is clear. The unit appears to have a full charge with a high head pressure. Gauges are installed, which reveal that the head pressure is 207 psig. The system is using R-12 as the refrigerant. If the system had R-134a as the refrigerant, the high head pressure would be 229 psig. The head pressure should be no more than 158 psig, which is a condensing temperature of 120°F; it is 90°F (90°F + 30°F = 120°F, or 158 psig). For R-134a, a condensing pressure of 171 psig corresponds to 120°F condensing temperature. Further examination indicates that air is leaving the condenser and recirculating back to the condenser inlet. Several boxes have been stored in front of the condenser. These are moved, and the head pressure drops to 158 psig. The reason there has been no complaint up to now is that the air has been cold enough in the previous mild weather to keep the head pressure down even with the recirculation problem. A call back later in the day verifies that the cooler temperature has returned to normal.

SERVICE CALL 14

A store frozen-food manager calls to say that the temperature is going up in the low-temperature walk-in freezer. *The defrost time clock motor is burned, and the system will not go into defrost,* **Figure 29.53**.

Figure 29.53 Symptoms of a defrost problem with a defective time clock.



Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The service technician examines the system and sees that the evaporator is coated with thick ice. It is evident that it has not been defrosting. The first thing to do is to force a defrost. The technician examines the clock dial on the timer and finds that the indicator says 4:00 AM, but the time is 2:00 PM. Either the power has been off or the timer motor is not advancing the timer. The technician advances the timer by hand until the defrost cycle starts and then marks the time. After the defrost is terminated by the temperature-sensing device, the system goes into normal operation. The technician waits about one-half hour and sees that the clock has not moved. A new time clock is installed.

The customer is cautioned to look out for heavy ice buildup. A call the next day verifies that the system is working correctly. The service technician then stops by the store at the end of the day and politely introduces himself again. After addressing the store manager by his first name (always maintaining eye contact), he gives the billing information to the customer, which includes a work description and cost of the service. He gives the customer a firm handshake and thanks him for the business. The technician then looks around quickly to make sure everything is in good working order and that the work space has been cleaned.

SERVICE CALL 15

A customer states that the defrost seems to be lasting too long in a low-temperature walk-in cooler. It used to defrost, and the fans would start back up in about 10 min. It is now taking 30 min. *The defrost termination switch is not terminating defrost with the temperature setting. This is an electric defrost system. The system is staying in defrost until the time override in the timer takes it out of defrost. This also causes the compressor to operate at too high a current because the fans should not start until the coil cools to below 30°F. With the defrost termination switch stuck in the cold position, the fans will come on when the timer terminates defrost. The compressor will be overloaded by the heat left in the coil from the defrost heaters,* **Figure 29.54**.

The technician examines the system. The coil is free of ice, so defrost has been working. The cooler is cold, −5°F. The technician advances the time clock to the point that defrost starts. The termination setting on the defrost timer is 30 min. This may be a little long unless the cooler is defrosted only once a day. The timer is set to defrost twice a day, at 2:00 PM and 2:00 AM. The coils are defrosted in approximately 5 min, but the defrost continues. The technician allows defrost to continue for 15 min to allow the coil to get to maximum temperature so that the defrost termination switch has a chance

Figure 29.54 Symptoms of a defective defrost termination thermostat (stuck with cold contacts closed) in a low-temperature freezer.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

to close. After 15 min, the system is still in defrost, so the timer is advanced to the end of the timed cycle. When the system goes out of defrost, the fans start. They should not start until the coil gets down to below 30°F.

The defrost termination switch is removed. The wires on its three terminals are marked so that it can easily be replaced with a new control. After a new control is acquired and installed, the system is started. The owner called the next day to report a normal defrost and that the system was acting normally. The old defrost termination switch is checked with an ohmmeter after having been at room temperature for several hours and the cold contacts are still closed. The control is definitely defective.

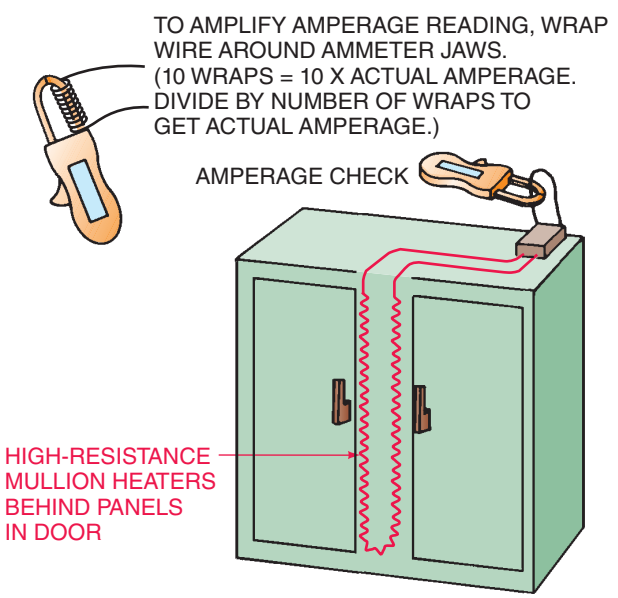
SERVICE CALL 16

The frozen-food manager in a supermarket calls indicating that the walls between the doors on a reach-in freezer are sweating. *This has never happened. The freezer is about 15 years old. The mullion heater in the wall of the cooler that keeps the panel above the dew point temperature of the room is not functioning,* **Figure 29.55**.

The technician first talks to the store manager and carefully listens to what he has to say, without interrupting. The technician then asks the manager a few questions, letting him feel as though he is contributing to the solution of the problem by answering the questions. The technician then starts to work.

The technician examines the fixture to determine the reason the mullion heater is not getting hot. If the heater is burned out, the panel needs to be removed. He traces the circuit to the back of the cooler and finds the wires to the heater. An ohm check proves the heater still has continuity, but a voltage check shows there is no voltage going to the heater. After further tracing, the technician locates a loose connection in a junction box. The wires are properly connected and a current check is performed to prove the heater is working. The service technician then politely explains to the store manager how he found the problem, thanks the customer for the business, and lets him know the store is a valued customer. He explains the billing information and exchanges handshakes.

Figure 29.55 A mullion heater on a low-temperature freezer.



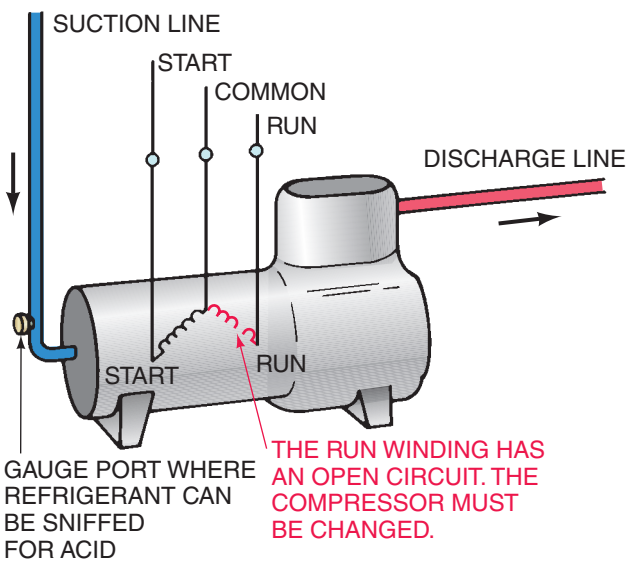
SERVICE CALL 17

A restaurant maintenance person calls to say that the medium-temperature walk-in cooler is off. The breaker was tripped and was reset, but it tripped again. *The compressor motor is burned,* **Figure 29.56**.

The technician examines the system. The food is warming up, and the cooler is up to 55°F. Before resetting the breaker, the technician uses an ohmmeter and finds the compressor has an open circuit through the run winding. Nothing can be done except to change the compressor. A refrigerant line is opened slightly to determine the extent of the burn. The refrigerant has a high acid odor, indicating a bad motor burn. 4R *The technician uses a recovery/recycle unit to capture, clean, and recycle the refrigerant in this cooler.* 4R

It will be several hours before the system can be put back into service, so the food is moved to another cooler. The technician gets the required materials from the supply house, including a suction-line filter drier with high acid-removing qualities. This drier has removable cores for each changeout. The compressor is changed and the suction-line drier is installed.

Figure 29.56 A system with a burned compressor motor.



Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The system is purged with dry nitrogen to push as much of the free contaminants as possible out of the system. The system is leak checked, and a deep vacuum is pulled. The system is then charged and started. After the compressor runs for an hour, the crankcase oil is tested for acid. It shows a slight acid count. The unit is run for another 4 hours, and an acid check shows even less acid. The system is pumped down, and the cores are changed in the suction-line drier. The liquid-line drier is changed, and the system is allowed to operate overnight.

The technician returns the next day and makes another acid check. This check shows no sign of acid. The system is left to run in this condition with the drier cores still in place in case some acid becomes loose at a later date. *The motor burn is attributed to a random motor failure.*

SERVICE CALL 18

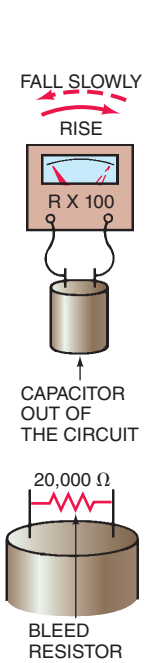
A medium-temperature reach-in cooler is not cooling properly. The temperature is 55°F inside, and it should be no higher than 45°F. The compressor sounds like it is trying to start but then cuts off. *The starting capacitor is defective.*

The technician arrives at the job in time to hear the compressor try to start. Several things can keep the compressor from starting. It is best to give the compressor the benefit of the doubt and assume it is good. Check the starting components first and then check the compressor. The starting capacitor is removed from the circuit for checking, **Figure 29.57**. The example in Figure 29.57 uses an analog ohmmeter for testing the capacitor. However, a modern, digital capacitor tester could be used which will give the service technician instant results whether the capacitor is good or bad. There is discoloration around the capacitor vent at the top, and the vent is pushed upward. These are signs the capacitor is defective. After bleeding the capacitor with a 20,000-Ω, 5-W resistor, an ohm test shows the capacitor open. The capacitor is replaced with a similar capacitor, and the compressor is started. The compressor is allowed to run for several minutes to allow the suction gas to cool the motor; then it is stopped and restarted to make sure that it is operating correctly. A call back the next day indicates that the compressor is still stopping and starting correctly.

SERVICE CALL 19

The compressor in the low-temperature walk-in freezer of a supermarket is not starting. The box temperature is 0°F, and it normally operates at −10°F. *The compressor is locked. This is a multiple-evaporator installation with four evaporators piped into one suction line. An expansion valve on one of the evaporators has been allowing a small amount of liquid refrigerant to get back to the compressor. This has caused marginal lubrication, and the compressor has scored bearings that are bad enough to lock it up.*

Figure 29.57 Symptoms of a system with a defective starting capacitor.



GOOD CAPACITOR

THE CAPACITOR HAS BEEN CHECKED TO SEE THAT IT IS NOT CHARGED BY PLACING A 20,000-OHM 5-WATT RESISTOR FROM TERMINAL TO TERMINAL FOR AT LEAST 5 SECONDS.

1. PLACE THE LEADS OF AN OHMMETER ONTO THE CAPACITOR TERMINALS. NOW, SWITCH EACH OHMMETER LEAD TO THE OPPOSITE TERMINALS OF THE CAPACITOR. REPEAT SEVERAL TIMES. THE NEEDLE SHOULD RISE THEN FALL BACK. THE MAGNITUDE OF NEEDLE RISE WILL DEPEND ON THE MICROFARAD RATING OF THE CAPACITOR. THE HIGHER THE MICROFARAD RATING, THE HIGHER THE NEEDLE RISE BEFORE FALLING BACK.
2. IF THERE IS A RESISTOR BETWEEN THE TERMINALS THE NEEDLE WILL FALL BACK TO THE VALUE OF THE RESISTOR (KNOWN AS A BLEED RESISTOR).
3. TO PERFORM THE TEST AGAIN, THE LEADS MUST BE REVERSED. THE METER'S BATTERY IS DIRECT CURRENT. YOU WILL NOTICE AN EVEN FASTER RISE IN THE NEEDLE THE SECOND TIME BECAUSE THE CAPACITOR HAS THE METER'S BATTERY CHARGE.

DEFECTIVE CAPACITOR

BLEED THE CAPACITOR AS DESCRIBED ABOVE.

1. TOUCH THE METER LEADS TO THE CAPACITOR TERMINALS. IF IT IS DEFECTIVE, IT WILL NOT RISE ANY HIGHER THAN THE VALUE OF THE BLEED RESISTOR. IF THE CAPACITOR DOES NOT HAVE A BLEED RESISTOR, THE NEEDLE WILL NOT RISE AT ALL. THIS SHOWS AN "OPEN" CAPACITOR. ELECTRONIC CAPACITOR TESTERS ARE A QUICK WAY TO TEST FOR AN OPEN OR A WEAK CAPACITOR. SIMPLY PLACE THE LEADS OF THE CAPACITOR TESTER ON THE CAPACITOR BEING TESTED AND PUSH A BUTTON. A MODERN DIGITAL CAPACITOR TESTER WILL INDICATE THE CAPACITANCE OF THE CAPACITOR. IT WILL ALSO TELL IF THE CAPACITOR IS OPEN.

After finishing a previous service call and before arriving at the supermarket, the service technician notices that the service van is very muddy from a rainstorm earlier that morning and decides to run the van through an automatic wash about a mile away. Once the van is clean, the technician spends some time wiping down his shoes from the previous job. He also needs to change his uniform because of grease stains on the pants and shirt sleeves. The technician then washes his hands with waterless hand cleaner and tucks in the new uniform. A quick look in the mirror verifies that the technician's face and hair are presentable.

The service technician examines the system at the supermarket. The compressor is a three-phase compressor and does not have a starting relay or starting capacitor. It is important that the compressor be started within 5 hours, or the food must be moved. The technician turns off the power to the compressor starter then removes the leads from the load side of the starter. The motor is checked for continuity with an ohmmeter, **Figure 29.58(A)**. The motor windings appear to be normal. **NOTE:** *Some compressor manufacturers furnish data that tell what the motor-winding resistances should be.*

The meter is then turned to the voltage selection for a 230-V circuit. The starter is then energized to test its load side to make sure that each of the three phases has the correct power. This is a no-load test. The leads have to be disconnected from the motor terminals and the voltage applied to the leads while the motor is trying to start before the technician knows for sure there is a full 230 V under the starting load, **Figure 29.58(B)**.

When the load is connected, the technician connects up the motor leads and gets two more meters for checking voltage. This allows the voltage to be checked from phase1 to phase 2, phase 1 to phase 3, and phase 2 to phase 3 at the same time the motor is being started. When the power is applied to the motor, there is 230 V from each phase to the other, but the motor will not start, **Figure 29.58(C)**. **This is conclusive—the motor is locked**. The motor can be reversed (by changing any two leads, such as L1 and L2) and it may start, but it is not likely that it will run for long.

The technician now has 4 hours to either change the compressor or move the food products. A call to the local compressor supplier shows that a compressor is in stock in town. The technician calls the shop for help, another technician is dispatched to pick up the new compressor, and a crane is ordered to set the new compressor in and take the old one out. The 30-hp compressor weighs about 800 lb.

When the crane gets to the job, the old compressor is disconnected and ready to set out. This is accomplished by front seating the suction and discharge service valves to isolate the compressor and then recovering the compressor's refrigerant charge. When the new compressor is installed, all that will need to be done after evacuating the compressor is to open the service valves and start it. The original charge is still in the system. By the time the old compressor is removed, the new compressor arrives and is set in place; the service valves are connected. While a vacuum is being pulled, the motor leads are connected. In an hour the new compressor has been evacuated and is ready to start.

When the new compressor is started, the technician notices that the suction line is frosting on the side of the compressor. Liquid is getting back to the compressor. A thermometer lead fastened to each of the evaporators at the evaporator outlet reveals that one of the evaporator suction lines is much colder than the others. The expansion valve bulb is examined and is found to be loose and not sensing the suction-line temperature. Someone has taken the screws out of the mounting strap.

The expansion valve bulb is then secured to the suction line, and the system is allowed to operate. The frost line moves back from the side of the compressor, and the system begins to function normally. After double-checking his work, the technician thoroughly cleans the job site.

The next day the technician stops by the store and determines that the frost line to the compressor is correct, not frosting the compressor. He then presents billing information to the store manager with a complete list of parts required. The technician then spends time with the manager to explain in everyday language how the problems were corrected. Handshakes are exchanged and the technician leaves the job site.

SERVICE CALL 20

A restaurant owner with a cube ice-making machine calls to say that the evaporator is frozen solid and no ice is dropping into the bin. *The problem is that the defrost probes are dirty. These probes sense the ice thickness by creating a circuit through the ice that starts defrost when the ice reaches a predetermined thickness. The probe is monitored by an electronic circuit that measures the conductivity of the ice to determine when the correct thickness has been reached.*

The technician examines the entire system carefully. He has worked on this type of ice maker before and knows that the manufacturer recommends the machine not be shut off at this time until the problem is found. If the technician were to shut the machine off and defrost the evaporator, the condition may not happen again. The technician knows this machine is older and suspects dirty defrost sensor probes. The manufacturer has supplied a special jumper cord with a fixed resistor to measure the value of the resistance through ice. The jumper can be used to jump the ice probes and determine if the sensor is defective. The technician jumps the probe connections and the unit starts a defrost cycle. This is a sure sign that the sensor is dirty where it contacts the ice.

The technician waits until the unit completes the defrost cycle and the ice drops to the storage bin, then shuts the machine off and turns the power off. The probe is removed and cleaned. It is reinstalled, the machine power is restored, and the machine is started. About 25 min later, the machine starts another defrost cycle on its own. The technician leaves the job, telling the owner to watch the machine for the rest of the day for correct operation.

SERVICE CALL 21

The owner of a restaurant calls and states that one of the ice machines is not dropping new ice to the bin. This is a new installation in a new restaurant. *The problem is so many minerals have been removed from the water by filtering that the water does not have enough conductivity to allow the electronic circuit to determine when the ice is touching the probes.*

The technician surveys the situation. The evaporator is frozen solid. This is a new machine, with the best water filtration system. There is a chance the filtration is so effective that the conductivity of the water has been reduced to a point where the defrost sensor probe will not sense the conductivity. The technician remembers the last service school she attended where these symptoms were described and goes to the shelf for a box of salt. A pinch of salt (about 1/10 teaspoon) is placed in the water sump where the pump will pick it up and circulate the slightly salted water over the probes. Within a very few minutes, the machine starts to defrost.

The technician knows the owner cannot put salt in the filtered water every day, so she consults the manual. A resistor is available from the manufacturer that can be placed

across certain terminals on the circuit board to allow the probe and electronic circuit board to sense the conductivity of water that has been filtered. Normal defrost can then be expected.

The technician obtains the resistor from the supplier and installs it across the appropriate terminals. The machine is started; the technician watches it through two defrost cycles and is then satisfied the machine will operate satisfactorily.

SERVICE CALL 22

A restaurant owner calls to request a checkup for the cube-type ice maker in the kitchen. This maker has been in the kitchen for several years and the owner cannot remember when it was last serviced. *There is no particular problem.*

The technician examines the machine thoroughly. The condenser appears to be dirty, and the evaporator section needs cleaning. The machine is full of ice. The technician decides to remove the ice and clean the bin at the same time. Before he gets started on the cleaning, the technician politely explains to the store owner, in plain English, the advantages of cleaning an ice machine on a regular basis—how efficiency will improve and also the health benefits.

The machine is turned off and the power supply is shut off, locked, and tagged. The technician starts transferring the ice to trays to be moved to the walk-in cooler. As the technician gets toward the bottom of the bin, he sees that it is dirty. So cleaning the bin is a good idea.

The panels to the condenser are removed and it is vacuumed to remove lint and light dust. The condenser fan motor and terminal box are covered with a plastic bag to prevent moisture from entering. An approved coil cleaner is applied to the condenser and allowed to set on the coil so it can soak into the dirty surface. While the condenser coil cleaner is working, the bin is cleaned and sanitized. When the coil cleaner has been on the condenser for about 30 min, the technician flushes the cleaner off the condenser with a water hose and down a nearby drain. The restaurant owner is surprised at the amount of dirt washed out of the condenser.

The water that drains off the machine is mopped up from the floor around it. The plastic is removed from the motor and the unit is dried with towels. This unit has a clean cycle for cleaning the evaporator. In the clean cycle only the water pump circulates and chemicals may be circulated with the water for a period of time. The technician pours the recommended amount of chemicals in the sump and starts the pump. The chemicals circulate for the prescribed time; the technician dumps them down the drain and flushes freshwater through the system. The evaporator section is then sanitized using the clean cycle and the water is dumped. A hose is used to wash the bin area one more time to be sure no chemicals are still present and the machine is started. The technician allows the machine to make two harvests of ice and dumps them down the drain. This ensures there are no residual chemicals and that the machine is making ice properly.

The machine is then put back into service. The technician politely thanks the store owner for his business and lets him know he is a valued customer. While giving billing information with a work description and costs to the store owner, the technician calls him by name, makes eye contact, shakes his hand, and quietly leaves the job site.

Solutions for the following service calls are not provided here. Please discuss the solutions with your instructor.

SERVICE CALL 23

A store manager reports that the food is thawing out in the low-temperature walk-in freezer. During the winter, this freezer lost its charge, the leak was repaired, and the unit recharged. The service technician remembers that this unit was serviced by a new technician when the loss-of-charge incident happened. The technician suspects that the unit may be off because of the manual reset high-pressure control. This is the only control on the unit that will keep it off, unless there is a power problem.

After arriving at the job the technician finds that the unit is off because of the high-pressure control. Before resetting the control, the technician installs a gauge manifold so that the pressures can be observed. When the high-pressure control is reset, the compressor starts but the head pressure rises to 375 psig and shuts the compressor off. The system uses R-502. The ambient temperature is 90°F, so the head pressure should not be more than the pressure corresponding to 120°F. This was arrived at by adding 30°F to the ambient temperature: 30°F + 90°F = 120°F. The head pressure corresponding to 120°F is 282 psig. It is obvious the head pressure is too high. The condenser seems clean enough, and air is not recirculating back to the condenser inlet.

What is the likely problem and the recommended solution?

SERVICE CALL 24

A customer calls to indicate that the medium-temperature walk-in cooler unit that was just installed is running all the time and not cooling the box.

The technician looks the job over. This is a new installation of a walk-in medium-temperature cooler that was just started up yesterday. The hermetic compressor is sweating down the side of the housing. The evaporator fan is operating, and the box temperature is not down to the cut-off point, so there is enough load to boil the refrigerant to a vapor.

What is the likely problem and the recommended solution?

SERVICE CALL 25

A customer reports that the low-temperature reach-in cooler that had a burned compressor last week is not cooling properly. The food is beginning to thaw.

Before arriving on the job site, the technician calls the customer on his cell phone and asks for an account of the problem. The technician carefully listens to the details, making sure not to interrupt the customer. Once at the job site, the technician parks his van out of sight of the store's customers and knocks on the service entrance door. Once invited inside, the technician introduces himself and hands the customer his business card. The technician then offers the customer his hand to shake. The customer then shows the technician the same cooler that was serviced last week. The technician examines the whole system. The evaporator seems to be starving for refrigerant. When the technician approaches the condensing unit in the back of the store, he notices that the liquid line is sweating where it leaves the drier. A suction-line drier was not installed at the time of the motor burn.

What is the likely problem and the recommended solution?

SERVICE CALL 26

A customer calls on the first hot day in the spring and says the walk-in freezer is rising in temperature. The food will soon start to thaw if something is not done.

The service technician examines the whole system and notices that the liquid line is hot, not warm. This is a TXV system and has a sight glass. It is full, indicating a full charge of refrigerant. The compressor is cutting off because of high pressure and then restarting periodically. This system uses R-502, and the head of the compressor is painted purple to signify the refrigerant type. Gauges are installed, and the head pressure starts out at 345 psig and rises to the cut-out point, or 400 psig.

What is the likely problem and the recommended solution?

SERVICE CALL 27

A restaurant manager indicates that the compressor on a water-cooled unit is cutting off from time to time *and the walk-in cooler is losing temperature. This is a medium-temperature cooler, using R-12.*

The service technician arrives to find a wastewater condenser (the water is regulated by a water-regulating valve to control the head pressure and then goes down the drain). The water is coming out of the condenser and going down the drain at a rapid rate. The liquid line is hot, not warm. The water is not taking the heat out of the refrigerant as it should. Gauges installed at the compressor indicate the head pressure to be 200 psig. The compressor is cutting off and on because of the high-pressure control. The head pressure should be about 125 psig with a condensing temperature of 105°F.

What is the likely problem and the recommended solution?

SERVICE CALL 28

A customer reports that the temperature is rising in a frozen-food walk-in freezer. Although it tries, the compressor will not start.

Because it is the first service call of the day, the service technician makes sure he takes off his rings before starting the work day. Rings can get caught in mechanical and/or electrical devices and are a serious safety concern. A quick look in the vehicle's mirror tells the technician that his hair needs to be combed before entering the market where the service call is to be made. The technician then notices that his identification badge with his company's name and logo is still on the dash of the service van. He quickly pins the badge on his clean uniform and knocks on the door of the service entrance to the market where his services are needed. Once invited in, the technician introduces himself and carefully listens to the customer. The technician then politely answers the customer's questions, follows the customer to the walk-in freezer, and starts work.

The service technician listens to the compressor try to start and hears the overload cut it off, making a clicking sound. The compressor is hot, too hot to start many more times before it will overheat to the point of being off for a long time. Every start the motor goes through makes it hotter. The technician needs to make sure that it starts and stays on line the next time it starts. This is a single-phase compressor and has a starting relay and starting capacitor. The problem could be in several places: (1) the starting capacitor, (2) the starting relay, or (3) the compressor. The technician uses an ohmmeter to check for continuity in the compressor, from the common terminal to the run terminal, and from the common terminal to the start terminal. The compressor has continuity and should start, provided it is not locked. An ohm check of the starting capacitor shows that it will charge and discharge. (This test is accomplished by first shorting the capacitor terminals with a 20,000-Ω, 5-W resistor and then using the R × 100 scale on the ohmmeter.) The capacitor should cause the meter to rise and then fall. Reversing the leads will cause it to rise and fall again.

NOTE: *This check does not indicate the actual capacity of a capacitor. It indicates that the capacitor will charge and discharge.* •

The starting relay is checked for continuity from terminal 1 to terminal 2. This is the circuit through which the starting capacitor is energized. The circuit shows no resistance; the contacts are good.

What are the likely problems and the recommended solutions?

SERVICE CALL 29

A motel maintenance person calls to report that the ice maker on the second floor of the motel is not making ice. This ice maker is a flake ice machine. It sits outside and the temperature is hot.

The technician arrives and parks his service van out of sight of the motel customers, being especially careful not to block any driveway exits. The technician then puts on shoe covers to protect the motel's carpets from dirt and grease that might be on his shoes from previous job sites. After politely introducing himself to the motel owner and again carefully listening to the service call complaint, the technician asks to be led to the ice machine.

The technician notices right away there is no ice in the bin. The compressor is running and hot air is coming from the condenser. Therefore, it must be refrigerating. The suction line leaving the evaporator is cold. Gauges are fastened to the compressor and reveal that the suction pressure is high, but so is the discharge pressure. The machine uses R-502 and the suction pressure is 55 psig (30°F boiling temperature). No ice can be made under these conditions. The discharge pressure is 341 psig (135°F condensing temperature). It is a hot day, 97°F, but not hot enough to cause a head pressure this high. The technician wonders if the unit is overcharged or if the condenser is dirty. This could cause high head pressure, which would then cause high suction pressure and low or no ice production.

After sitting down and thinking for a minute, the technician thinks of the water circuit, then feels the water line. It is cooler than hand temperature (which is about 90°F). This is not the answer. The technician then looks at the float chamber and discovers that water is running into the chamber.

What is the likely problem and the recommended solution?

SUMMARY

- All evaporators that cool air have a relationship with the air they are cooling. The coil will generally boil the refrigerant between 10°F and 20°F colder than the air entering the evaporator.
- High-temperature evaporators normally operate between liquid-refrigerant boiling temperatures of 25°F and 40°F.
- Medium-temperature evaporators normally operate between liquid-refrigerant boiling temperatures of 10°F and 25°F.
- Low-temperature food-storage systems normally operate between liquid-refrigerant boiling temperatures of −15°F down to about −49°F.
- The automatic expansion valve maintains a constant low-side pressure. For this reason the low-side pressure does not go down during low-charge operation as it does with a capillary tube and a TXV.
- An overcharge of refrigerant always causes an increase in head pressure.
- An increase in head pressure causes an increase in suction pressure when the TXV or the capillary tube is the metering device.
- An increase in head pressure causes more refrigerant to flow through a capillary tube. Liquid refrigerant may flood into the compressor with an overcharge.
- The automatic expansion valve responds in reverse to load changes. When the load is increased, the valve throttles back and will slightly starve the evaporator. When the load is decreased excessively, the valve is likely to overfeed the coil and may allow small amounts of liquid refrigerant to enter the compressor.
- When an inefficient evaporator is encountered, the refrigerant boiling temperature will be too low for the entering-air temperature.
- When an inefficient condenser is encountered, the condensing refrigerant temperature will be too high for the heat rejection medium.
- The best check for inefficiency in an compressor is to see if it will pump to capacity.
- Design load conditions can almost always be duplicated by building the head pressure up and duplicating the design suction pressure.

REVIEW QUESTIONS

1. What is the first thing a technician should know before beginning troubleshooting?
2. What is the coil-to-air temperature relationship for a refrigeration system designed for minimum food dehydration?
   A. 12 to 15°F
   B. 10 to 15°F
   C. 8 to 20°F
   D. 8 to 12°F
3. When food dehydration is not a factor, the coil-to-air temperature relationship is _____ to _____ °F.
4. How is minimum food dehydration accomplished?
5. Why is minimum dehydration not used on every job?
6. What is the coil-to-air temperature relationship for an average coil where dehydration is not a factor?
7. At what evaporator temperature does an ice maker usually begin to make ice?
   A. 35°F
   B. 32°F
   C. 25°F
   D. 20°F
8. What is the evaporator coil-to-air relationship when the compressor is not running?
9. What is meant by the term *approach* when dealing with an evaporator chilling water?
10. How can an evaporator be tested for efficiency?
11. How can a condenser be tested for efficiency?
12. How can a hermetic compressor be tested for efficiency?
13. A TXV system responds to an overcharge of refrigerant by
    A. low suction pressure.
    B. high head pressure.
    C. a flooded compressor.
    D. both A and B
14. An automatic expansion valve system responds to an overcharge of refrigerant by
    A. low suction pressure.
    B. high head pressure.
    C. a flooded compressor.
    D. both B and C
15. A capillary tube system responds to an overcharge of refrigerant by
    A. high suction pressure.
    B. high head pressure.
    C. a flooded compressor.
    D. all of the above

How do the following systems respond to an undercharge?

16. TXV
17. Automatic expansion valve
18. Capillary tube

UNIT 30

ELECTRIC HEAT

OBJECTIVES

After studying this unit, you should be able to

- discuss the efficiency and relative operating costs of electric heat.
- list types of electric heaters and state their uses.
- describe how sequencers operate in electric forced-air furnaces.
- trace the circuitry in a diagram of an electric forced-air furnace.
- perform basic tests in troubleshooting electrical problems in an electric forced-air furnace.
- describe typical preventive maintenance procedures used in electric heating units and systems.

SAFETYCHECKLIST

- ☑ Be careful that nails or other objects driven into or mounted on radiant heating panels do not damage the electrical circuits.
- ☑ Any heater designed to have air forced across the element should not be operated when the blower is not operating.
- ☑ Always observe all electrical safety precautions.

30.1 INTRODUCTION

Electric heat is produced by converting electrical energy into heat energy. This is done by placing a known resistance of a particular material in an electric circuit. The resistance has relatively few free electrons and does not conduct electricity well. The resistance to electron flow produces heat. One type of material commonly used in electric heating is **nichrome**, which is short for nickel chromium. Wire made from nichrome is used in the majority of electric heaters.

Electric heat is very efficient but can be more expensive to operate compared to other sources of heat. It is efficient because very little electrical energy is lost from the meter to the heating element and there are no chimney losses as in the case of fossil-fuel heating systems. It can be expensive because it takes large amounts of electrical energy to produce the heat, and the cost of electrical energy in most areas of the country is expensive when compared to fossil fuels (coal, oil, and gas).

The purchase price of electrical heating systems is usually lower than that of other systems. The installation and maintenance is also usually easier and, therefore, less expensive. This makes electric heating systems attractive to many purchasers, especially those who live in areas where electricity is more reasonably priced. When electric heat is used as the primary heat source, insulation with a high R-value is normally used throughout the structure to lower the amount of heat required.

This unit briefly describes several types of electric heating devices. Emphasis, however, is placed on central forced-air electric heat because in some areas of the country it is frequently serviced by technicians in this industry.

30.2 PORTABLE ELECTRIC HEATING DEVICES

Portable or small space heaters are sold in many retail stores and by many industrial distributors and manufacturers, **Figure 30.1**. Some have glowing coils (due to the resistance of the wire to electron flow). These coils transfer heat by radiation (infrared rays) to the solid objects in front of the heater. The radiant heat travels in a straight line and is absorbed by solid

Courtesy Fostoria Industries, Inc.

objects that warm the space around them. Radiant heat also provides heating comfort to individuals. The heat concentration decreases by the square of the distance and is soon dissipated into the space, **Figure 1.12.** Quartz and glass-panel heaters are also used to heat small spaces by radiation, **Figure 30.2.** Some space heaters use fans or small blowers to move air over the heating elements and into the space. This is called forced-convection heat because the heat-laden air is moved mechanically. The units may be designed to move enough air across the heating elements so that they do not glow.

Radiant spot heating can be effectively used at doorways, warehouses, work areas, and even outdoors. The effect is much like a sunlamp pointing at the heated area. The distance between the heater and the objects being heated has a great bearing on the effectiveness of radiant heating. Refer back to Unit 1 for more information on how distance affects heat transfer by radiation.

30.3 RADIANT HEATING PANELS

Radiant electric heating can be used in residential and light commercial buildings and can be located in either the ceilings or floors of the structure. Panels used for ceiling installation are often made of gypsum board with wire heating circuits running throughout, **Figure 30.3.** When electric

Figure 30.3 A radiant ceiling heating panel.

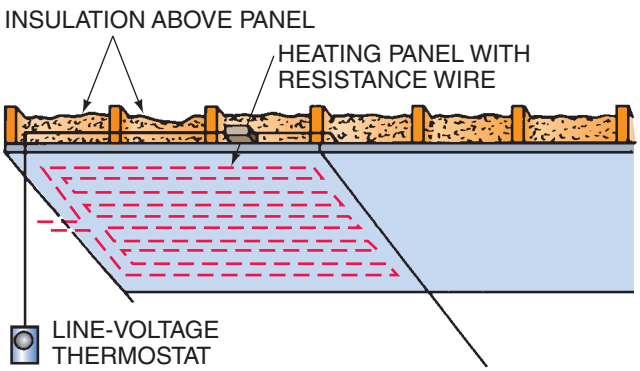

Figure 30.4 A roll of electric radiant heating element.

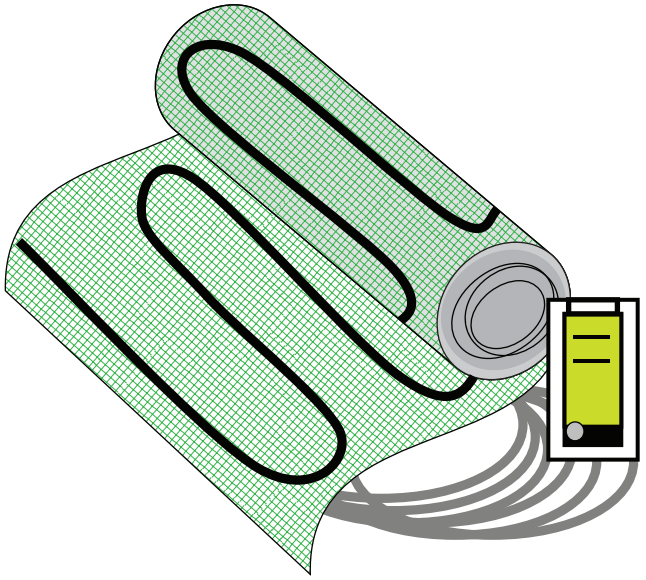

radiant heat is to be installed in floors, it is often supplied in roll form, **Figure 30.4.** This type of product is typically less than 1/8 in thick, so it has little if any effect on finished floor height. It can be installed under the thinset concrete that is typically used for ceramic or porcelain tile installations, **Figure 30.5.** Electric radiant heating elements are often controlled with individual room thermostats, providing individual room or zone control. The heat produced is even, is easy to control, and tends to keep the mass of the room warm by

its radiation. This makes items in the room pleasingly warm to the touch. **SAFETY PRECAUTION:** *Be careful that nails or other objects driven into or mounted on the panels do not damage the electrical circuits. Be particularly careful when installing a cooling system where electric radiant heat is provided if the supply registers or grilles are to penetrate the ceiling or floor where the radiant wires are located.* Electric radiant heaters must have good insulation behind (or above) to keep heat from escaping. When using the floor-heating roll-type material, it is recommended that insulation be placed under the heater to help prevent heat loss.

30.4 ELECTRIC BASEBOARD HEATING

Baseboard heaters are popular convection heaters used for whole-house, spot, or individual room heating, **Figure 30.6.** They are economical to install and can be controlled by individual room thermostats, which are normally line-voltage devices. Unused rooms can be closed off and the heat turned down, which makes baseboard heaters economical in certain applications.

Baseboard units are mounted on the wall just above the floor or carpet, usually on outside walls. The heater is a natural-draft unit. Air enters near the bottom, passes over the electric element, is heated, and rises in the room. As the air cools, it settles, setting up a natural-convection air current. Refer back to Unit 1 for more information on natural convection currents. Baseboard heat is easy to control, safe, quiet, and evenly distributed throughout the house.

30.5 UNIT AND WALL HEATERS

Unit and wall heaters are typically mounted on ceilings or walls and use a fan or blower to force the air across the elements into the space to be heated, **Figure 30.7.** These heaters are controlled with line-voltage thermostats. Some heaters are recessed into the wall and all that protrudes into the occupied space is a decorative cover. Some new-generation wall heaters come with programmable touch controls, **Figure 30.8.**

Figure 30.6 An electric baseboard heater.

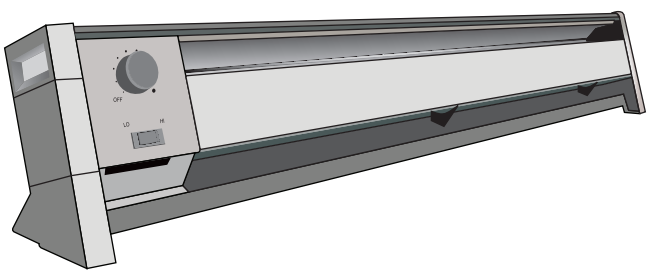

Figure 30.7 (A) Ceiling- and (B) wall-mounted unit heaters.

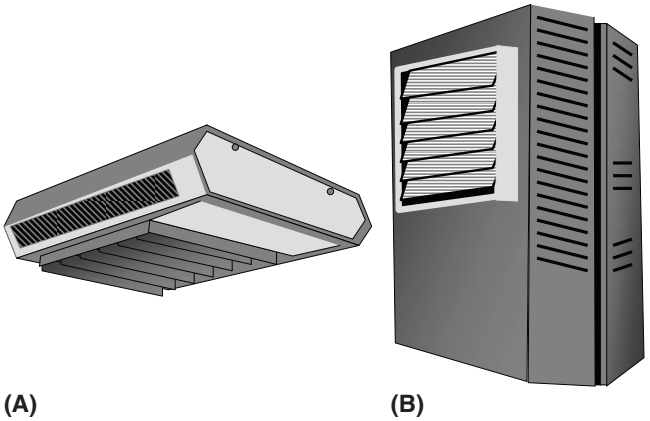

Figure 30.8 Recessed wall heater with programmable touch controls.

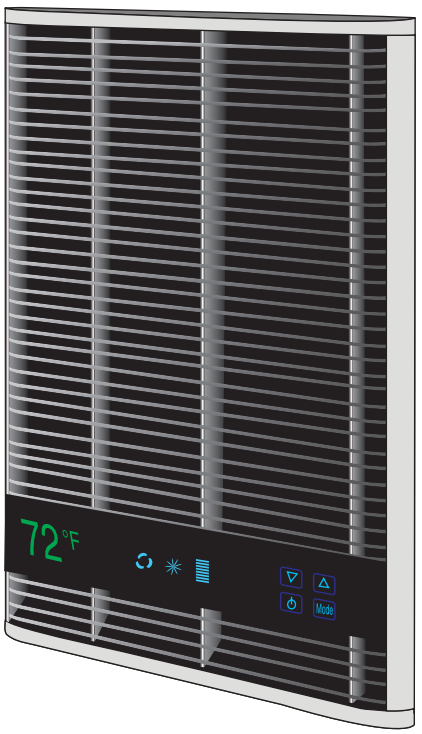

SAFETY PRECAUTION: *Any heater designed to have air forced across the element should not be operated unless airflow is established.*

30.6 ELECTRIC HYDRONIC BOILERS

The electric hydronic (hot water) boiler system is used for some residential and light commercial applications. Except for the control arrangement and safety devices, the boiler is

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Figure 30.9 Electric boiler.

Source: Slant/Fin Corporation

somewhat like an electric domestic water heater. It is also connected to a closed loop of piping and requires a pump to move water through the loop, which consists of the boiler and the terminal heating units, **Figure 30.9.** The electric boiler is small and compact for easy location and installation. It is relatively easy to troubleshoot and repair.

Any boiler handling water is subject to all the problems of a water-circulating system. For instance, if the boiler shuts down and the room temperature drops below freezing, pipes will burst, and the boiler will be damaged; water treatment against scale and corrosion is also required. The boiler itself is efficient because it converts virtually all of its electrical energy input into heat energy and transfers it to the water. When the boiler is located in the conditioned space, any heat loss through the boiler's walls or fittings is not lost from the structure. The system is quiet and reliable, but cooling and humidification systems cannot easily be added.

Electric boilers are often equipped with the following components:

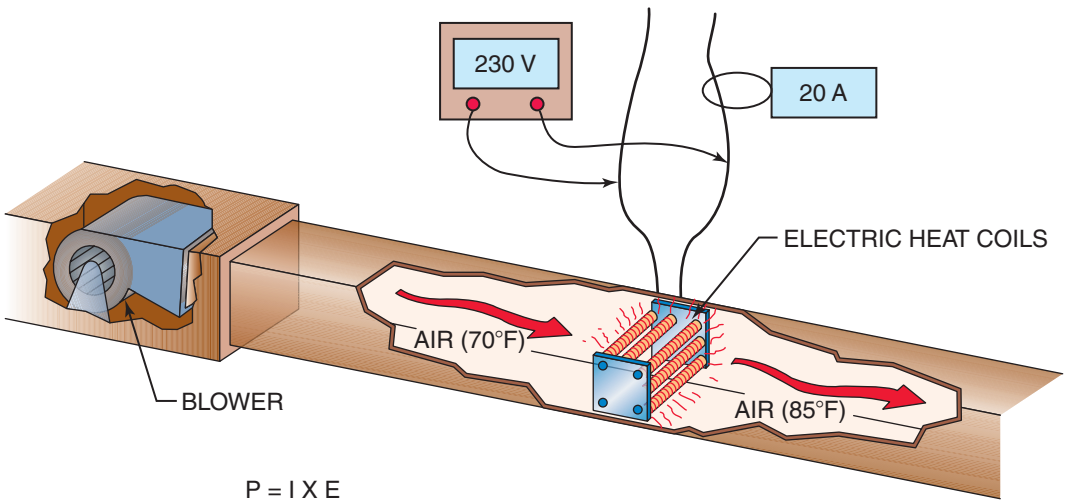
- Contactors to energize and deenergize the heating elements
- Sequencers to ensure that all of the heating elements are not energized at the same time
- Relays to control the operation of the circulator pumps
- A pressure relief valve to prevent system pressure from getting too high
- Aquastats to control and maintain the temperature of the water and prevent the boiler water from getting too hot
- Circuit breaker protection to protect the circuits from an overcurrent condition

When dealing with electric heating equipment, it is important that both operational and safety devices be incorporated into the system to ensure the safety of those in the structure. Quite often, redundant, or backup, controls are used as well in the event one or more of the safeties fail.

30.7 CENTRAL FORCED-AIR ELECTRIC FURNACES

Central forced-air furnaces utilize ductwork to distribute the heated air to remotely located rooms or spaces. The heating elements are factory installed in the furnace along with the blower, or they can be purchased as duct heaters and installed within the ductwork, **Figure 30.10** and **Figure 30.11.** The heating elements are made of nichrome resistance wire

Figure 30.10 This electric duct heater raises the temperature of the air in the duct.



P = I X E
= 20 X 230

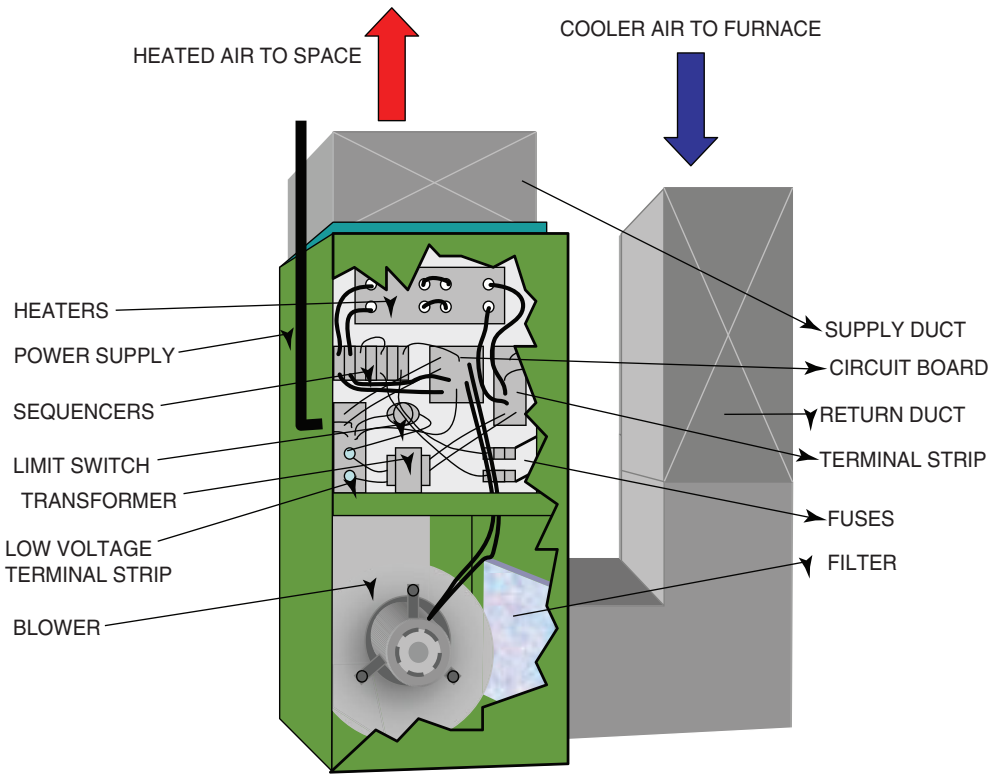
Figure 30.11 A central forced-air electric furnace.



mounted on ceramic or mica insulators. They are enclosed in the ductwork or in the housing of an electric furnace.

Central heaters are usually controlled by a single thermostat, resulting in one control point—there is no individual room or zone control. An advantage of duct heaters is that temperature in individual rooms or zones can be controlled by placing multiple heaters in the ductwork system, **Figure 30.12**. However, an interlock system must be incorporated. The interlock system will not allow power to reach the heating element unless the blower is operating, which keeps the heating elements from overheating and possibly causing a fire. Air conditioning (cooling and humidification) can usually be added to this system because of the air-handling feature.

SAFETY PRECAUTION: *Be careful when servicing these systems because many exposed electrical connections are behind the inspection panels. Electric shock can be fatal.*•

30.8 AUTOMATIC CONTROLS FOR FORCED-AIR ELECTRIC FURNACES

Automatic controls are used to maintain temperature at desired levels in given spaces and to protect the equipment and occupant. Three common controls used in electric heat applications are **thermostats**, **sequencers** (discussed later in this unit), and contactors (or relays). Safety devices commonly found on electric furnaces are the limit switch and the fusible link.

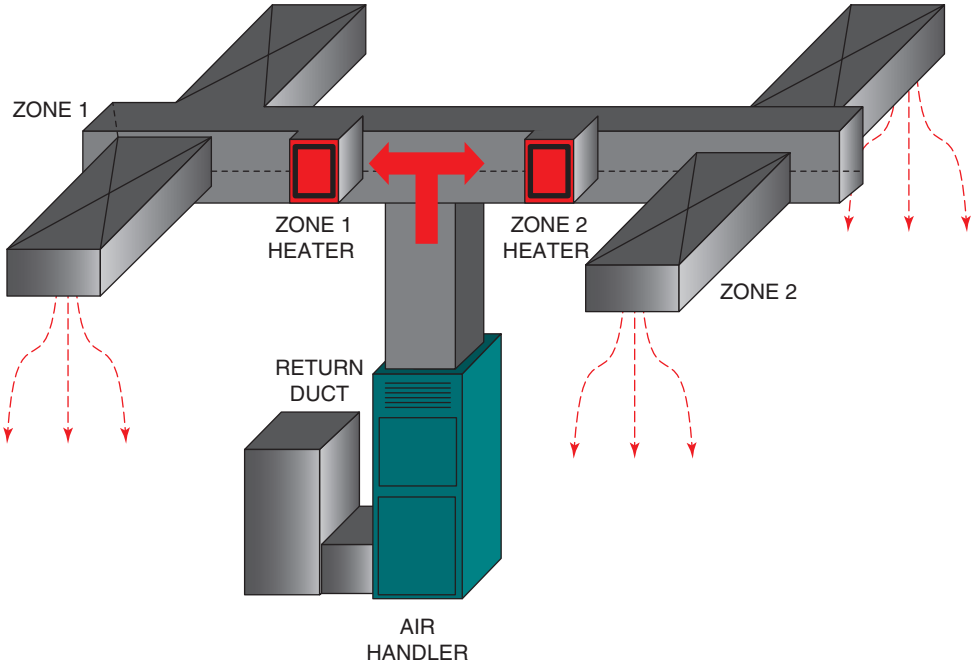
30.9 THE LOW-VOLTAGE THERMOSTAT

The low-voltage thermostat is used to control sequencers and contactors because it is compact, very responsive, safe, and easy to install and troubleshoot. In many localities the low-voltage wiring may be installed without an electrical license. **Figure 30.13** shows a wiring diagram of a low-voltage thermostat typical of those used with electric forced-air furnaces.

The wiring diagram in **Figure 30.13** can be used with a single transformer to control the heating and cooling modes of operation, or can be used with two separate transformers. If two transformers are used, the jumper wire between terminal "R" and terminal "4" is removed. Removal of this jumper creates two isolated control circuits; one for the heating mode and one for the cooling mode. Thermostat subbases that have the capability of isolating the heating and cooling control circuits are referred to as isloating, or isolated, subbases. This isolated subbase may be needed when air-conditioning is added after the furnace is installed. The furnace will have its low-voltage power supply, and the air-conditioning unit may

Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 30.12 An air distribution system with multiple electric heaters to serve different zones.



have its own low-voltage power supply. If one power supply is used for both, the jumper between terminals "R" and "4" will remain in place. The R terminal is the cooling terminal, and the 4 terminal is assigned to heating if the subbase has two power supplies. **NOTE:** *Many thermostat manufacturers identify the power terminals for the heating and cooling circuits as RH and RC. As mentioned, if only one transformer is used, the RH and RC terminals can be jumped together.* •

The heat anticipator used in a thermostat with electric heat must be set at the time of the installation. The setting is determined by the total current draw in the 24-V heating circuit that passes through the thermostat control and heat anticipator. When this current is determined, it is then set with the indicator on the heat anticipator. For example, if the current passing through terminal 4 is 0.75 A, this number is used to set the heat anticipator in the low-voltage thermostat subbase. Digital thermostats have heat anticipator circuitry built into them and automatically adjust themselves, so field setting and adjustments are not needed.

Figure 30.13 A wiring diagram of a low-voltage thermostat. Some manufacturers use different terminal designations.

30.10 CONTROLLING MULTIPLE STAGES

Most electric furnaces have several heating elements that are activated in stages to avoid energizing a high-power load all at once. Some furnaces may have as many as six heaters. The *sequencer*, **Figure 30.14**, is used to bring the heaters into the active electric circuit at the right time to prevent the underheating or overheating of the space. The sequencer uses low-voltage control power to start and stop the electric heaters. A sequencer uses a bimetal strip with a low-voltage wire wrapped around it. When the thermostat calls for heat, the low-voltage wire heats the strip and warps it out of shape in a known direction for a known distance. As it warps or bends, it closes electrical contacts to the electric heat circuit. This bending takes time, and each set of contacts closes in a certain order with a time delay between the closings. When the heat requirement has been met, the thermostat opens the low-voltage circuit, and the steps are reversed.

See **Figure 30.15** for a diagram of a package sequencer. This sequencer can start or stop three stages of strip heat.

Figure 30.14 A multiple-type sequencer.

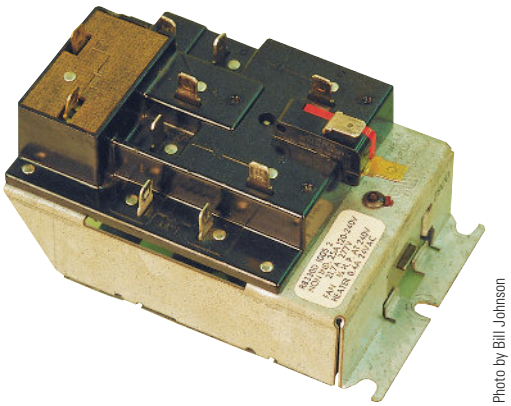

Photo by Bill Johnson

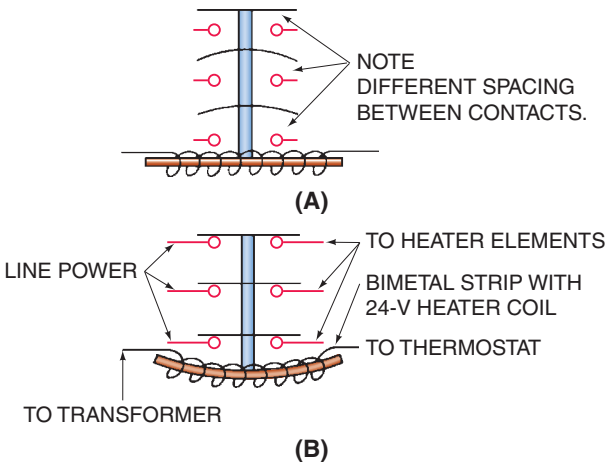
Figure 30.15 A sequencer with three contacts. (A) OFF position. (B) ON position.



Some sequencers have five circuits: three heat circuits, a fan circuit, and a circuit to pass low-voltage power to another sequencer for three more stages of heat.

Another sequencer design, called an *individual sequencer*, has only a single circuit that can be used for starting and stopping an electric heat element, but it could have two other circuits: one to energize another sequencer through a set of low-voltage contacts and one for starting the blower motor. Several stages of electric heat may be controlled with several of these sequencers, one for each heat strip.

30.11 WIRING DIAGRAMS

Individual manufacturers vary in how they illustrate electrical circuits and components. Some use pictorial diagrams, some use schematics, and others use both types of diagrams. The *pictorial* diagram shows the location of each component as it actually appears to the person installing or servicing the equipment. When the panel door is opened, the components inside the control box are in the same location as on the pictorial diagram. The **schematic wiring diagram** (sometimes called the **line wiring diagram** or **ladder diagram**) shows the current path to the components. Schematic diagrams help the technician to understand and follow the intent of the design engineer.

Figure 30.16 contains a legend of electrical symbols for an electric heating circuit. Such a legend is vital in following a wiring diagram. Many symbols are standardized throughout the industry, even throughout the world.

30.12 CONTROL CIRCUITS FOR FORCED-AIR ELECTRIC FURNACES

The low-voltage control circuit safely and effectively controls the heating elements that do the work. The circuit contains devices for safety and for control. For example, the limit switch, a safety device, shuts off the unit if high temperature occurs; the room thermostat, control, or operating device stops and starts the heat based on room temperature.

Safety and operating devices can consume power and do work or pass power to a power-consuming device. For example, the sequencer heater coil that operates the bimetal and a magnetic solenoid that moves the armature in a contactor are power-consuming devices in the low-voltage circuit. The contacts of a contactor or a limit control pass power to the power-consuming devices and are in the line-voltage circuit. **Power-passing devices are wired in series with the power-consuming devices. Power-consuming devices are wired in parallel with each other.**

Figure 30.17 is a diagram of a low-voltage control circuit. By tracing this circuit, you can see that when the thermostat contacts are closed, a circuit is completed. The transformer is the power source. The common leg of power in the diagram

is blue and furnishes power to the top side of the sequencer coil. The red leg furnishes power to the thermostat and on to the bottom of the sequencer coil. When the room is colder than the temperature setting on the thermostat, the thermostat contacts close. This energizes the coil on the sequencer, which causes the contacts on the sequencer to start closing. The closing contacts energize the heating elements in the line-voltage circuit. The line to the G terminal is used for the cooling circuit or when the fan switch on the thermostat is set to the ON position. The heating elements and the fan circuit have been omitted to simplify the circuit.

Control of a single heating element is illustrated in **Figure 30.18.** The electrical current from the L1 fuse block goes directly to the limit switch "A", which is a temperature-actuated switch that opens under excessive heat and provides protection to the furnace. It is usually an automatic reset switch that closes when the temperature drops. It is wired to the heating element, "B", and to a fusible link, "C", that provides additional protection from overheating. Under higher temperatures this fusible link melts and must be replaced. The link is wired to terminal 3 of the sequencer with the circuit completed through L2 when the sequencer contact is closed. **NOTE:** *The fusible link is set to melt at a temperature that is higher than the opening temperature of the high-limit switch. So if the fusible link is found to have melted, the high-limit switch has failed and must be replaced as well.* •

Figure 30.19 presents a diagram of a furnace with two heating elements. **Figure 30.20** is an example of one with three elements. Each of these examples uses the same package sequencer shown in **Figure 30.14.** On this sequencer, contacts

3-4 close first, followed by the closing of contacts 5-6 if there is still a call for heat. After a predetermined time period contacts 7-8 will close if heating is still needed.

30.13 BLOWER MOTOR CIRCUITS

The blower motor, a power-consuming device, forces the air over the electric heat elements and must be started and stopped at the correct time. **Figure 30.21** is an example of the wiring circuit for the blower motor. **NOTE:** *The blower must cycle on before the furnace gets too hot and continue to run until the furnace cools down.* • Note that the L1 terminal is wired directly to the blower motor and that the L2 terminal is wired

directly to terminal 4 on the sequencer and to one side of the normally open (NO) set of contacts on the fan relay. If the coil on the relay is energized, the normally open contacts on the relay will close and the blower will operate at high speed. This will occur when the system is operating in the cooling mode or if the fan switch is moved to the "ON" position.

Power is passed through terminal 4 to terminal 3 when the sequencer is energized long enough for the bimetal to bend and close the contacts. The power then passes to the normally closed (NC) terminal on the fan relay and on to the low-speed winding required for heating. **Figure 30.22** combines **Figure 30.20** and **Figure 30.21** into a line diagram.

Remember that the sequencer contacts and the relay contacts *pass* power and do not consume power. **Figure 30.23** is an example of a legend for terminal designations used on electric forced-air furnaces that use multiple sequencers instead of one package sequencer. **Figure 30.24** is a wiring diagram for a forced-air furnace with individual sequencers. Note the low-voltage circuit wiring sequence:

1. Power is wired directly from the transformer to terminal C and on to the coils of all the sequencers and blower control devices.
2. The other side of the transformer is wired directly to terminal R and then on to the R terminal on the room thermostat. The room thermostat passes power to the respective power-consuming device circuits on a call for HEAT, COOL, or FAN ON.
3. On a call for heat, the thermostat energizes the W terminal and passes power to the timed fan control and the first sequencer. The first sequencer passes power to the next sequencer heater coil and then to the next.

See **Figure 30.24** for the high-voltage sequence:

1. Although there are six fuses, they are labeled either L1 or L2, meaning that there are only two lines supplying power to the unit. The six fuses break the power-consuming heaters and fan motor down into separate circuits, each with an amperage rating that is lower than that of the entire appliance.
2. On a call for heat, the contacts in sequencer 1 close and pass power from L2 to the limit switch and on to heater 1. At the same time, the timed fan control is energized and its contacts close, starting the blower at low speed.

3. When the sequencer contacts close for the high-voltage load, the low-voltage contacts (A1 to A2) also close and pass power in the low-voltage circuit to the next sequencer's operating coil, which sets up the same sequence for the second heater. This continues down the line until all sequencer contacts are closed and all the heaters are energized.

NOTE: *This sequence may take 20 seconds or more per sequencer, and five heat sequencers are involved for the heat to be completely on. When the room thermostat is satisfied, it takes only about 20 seconds to turn off the heat because the power to all sequencers is interrupted by the room thermostat. The temperature-operated fan switch takes command of the blower at this time and keeps the blower on until the heaters cool.* •

The fan circuit is a circuit by itself. The blower will start at low speed if the fan relay is not energized. If the blower is running in low speed and someone turns the fan switch to ON, the blower will switch to high speed. It cannot run in both speeds at the same time due to the relay with NO and NC contacts.

30.14 CONTACTORS FOR CONTROLLING ELECTRIC FURNACES

Using contactors or relays to control electric heat means that all of the heat will be started at one time unless separate time delay relays are used. Contactors are magnetic and make noise. They are normally used on commercial systems where they may not be directly attached to the ductwork. This prevents the noise from traveling through the system, **Figure 30.25**. The contactor magnetic coils are 24 V and 230 V. The 24-V coils are controlled by the room thermostat, and they energize the 230-V coil. There are four contactors and their coils in this diagram for the electric heat and one for the blower. The 24-V coils are energized at the same time and pull in together.

30.15 AIRFLOW IN ELECTRIC FURNACES

The airflow in cubic feet per minute (cfm) may be verified in an electric heating system using the following formula and example. This formula is often called the sensible heat formula and is restated as it is seen in many other text calculations as

$$Q_s = 1.08 \times \text{cfm} \times \text{TD}$$

where: Q_s = Sensible heat in Btu/h
1.08 = A constant
cfm = Cubic feet per minute
TD = Temperature difference across furnace (also often denoted as ΔT)

The formula is restated and solved for cfm:

$$\text{cfm} = \frac{Q_s}{1.08 \times \text{TD}}$$

The total amount of heat energy added to the airstream may be calculated by first calculating the power consumed by the appliance. This is done by taking the total amperage to the electric furnace and multiplying it by the applied voltage. For example, if the amperage draw of a furnace is 85 Amperes and the applied voltage is 208 V, the power in Watts is calculated as:

$$\text{Watts} = \text{Amperes} \times \text{Volts}$$
$$\text{Watts} = 85 \times 208$$
$$\text{Watts} = 17{,}680$$

NOTE: *This calculation includes the blower motor, which is treated like a resistive load. This will give a slight error in the calculation. The motor would actually consume about 200 W less power if measured with a wattmeter. Because this is a fraction of a percent error, it is ignored.* •

To determine the Qs, the wattage must be converted to Btu/h by multiplying it by 3.413. (3.413 Btu/h of heat energy are generated for each watt of electrical power.)

$$\text{Btu/h} = \text{Watts} \times 3.413$$
$$\text{Btu/h} = 17{,}680 \times 3.413$$
$$\text{Btu/h} = 60{,}341.8 \text{ (}\textbf{Figure 30.26}\text{)}$$

If the temperature rise across the furnace is 50°F, we can now use the sensible heat formula to find the cfm:

$$\text{cfm} = \frac{\text{Qs}}{1.08 \times \text{TD}}$$
$$\text{cfm} = \frac{60{,}341.8}{1.08 \times 50}$$
$$\text{cfm} = 1117.4$$

The technician may use the electric heat section of a system to establish the correct cfm for the cooling system. Control the blower speed by setting the fan switch on the thermostat to the ON position. This will ensure that the blower is running at the same speed for cooling. Reduced airflow can cause major problems with cooling systems and is covered later in the book.

HVAC GOLDEN RULES

When making a service call to a residence:

- Arrive at the job on time. If you must be late, be sure to call the customer and let them know beforehand.
- Keep your service truck neat and clean, both inside and out.
- Try to park your vehicle so that you do not block the customer's driveway.
- Look professional and be professional. Clean clothes and shoes must be worn. Wear coveralls for under-the-house work, and remove them before entering the house.
- Ask the customer about the problem. The customer can often help you solve the problem and save you time.
- Check humidifiers where applicable. Annual service is highly recommended for health reasons.

Added Value to the Customer

Here are some simple, inexpensive procedures that may be included with the basic service call:

- Repair or replace all frayed wires.
- Clean or replace dirty air filters.
- Lubricate fan motors when needed.
- Fasten all access panels securely, and replace any missing screws.
- Ask customers if they know how to program the thermostat and offer to help if they do not know how.

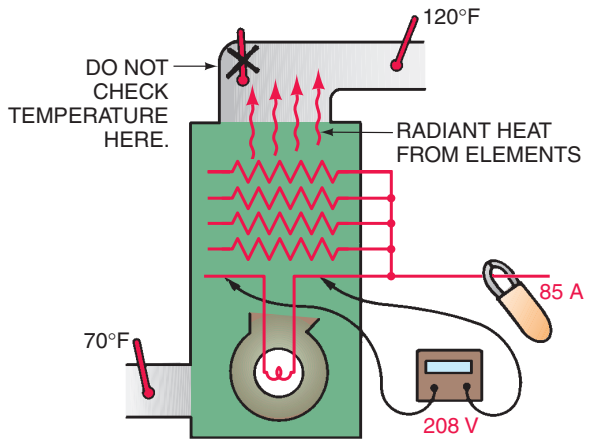
Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 30.26 An electric furnace airflow calculation.



WATTS = AMPERES X VOLTS
= 85 X 208
= 17,680 W

Btu/h = WATTS X 3.413
= 17,680 X 3.413
= 60,341.8 Btu/h

PREVENTIVE MAINTENANCE

Maintenance of electrical heating equipment may involve small appliances or central heating systems. Electric heat appliances, units, or systems all consume large amounts of power. This power is routed to the units by way of wires, wall plugs (appliance heaters), and connectors. These wires, plugs, and connectors carry the load and must be maintained.

ELECTRICAL HEATING APPLIANCES. The power cord at the plug-in connector is usually the first place that trouble may occur on a heating appliance. The heater should be taken out of service at the first sign of excess heat at the wall plug. It may become warm to the touch, but if it becomes too hot to hold comfortably, shut it off and check the plug and the wall receptacle. Fire may start in the vicinity of the plug if the situation is not corrected. The situation that will become worse every time the heater is operated.

An electric appliance heater should be observed at all times to ensure safe operation. Do not locate the heater too close to combustible materials. Only operate the heater in the upright position.

CENTRAL ELECTRICAL HEATING SYSTEMS. Large electrical heating systems may be the panel type, baseboard type, or forced-air system. The panel and baseboard systems do not require much maintenance when properly installed. Baseboard heat has more air circulation over the elements than panel systems, so the units must be kept dust-free. Some areas will have more dust and the baseboards will require cleaning more often. Both panel and baseboard systems use line-voltage thermostats. These thermostats contain the only moving part and will normally be the first to fail. The thermostats will collect some dust and must be cleaned inside at some point. Be sure to turn the power off before servicing.

Central forced-air systems have a blower to move the air and consequently require filter maintenance. Filters should be changed or cleaned on a regular basis, depending on the rate of dust accumulation.

Some motor and blower bearings require lubrication at regular intervals. Shafts with sleeve bearings must be kept in good working order because these bearings will not take much abuse. Lift the motor or fan shaft and look for movement. Do not confuse shaft end-play with bearing wear. Many motors have up to 1/8-in. end-play.

Some systems may have belt drives and require belt tension adjustment or belt changing. Frayed or broken belts must be replaced to ensure safe and trouble-free operation. Belts should be checked at least once a year. It is very dangerous to operate electric heating systems with little or no airflow.

Filters should be checked every 30 days of operation unless it is determined that longer periods may be allowed. Use the filters that fit the holder and be sure to follow the direction arrows on the filter for the correct airflow direction. When the filter system becomes clogged on a forced-air system, the airflow is reduced and causes overheating of the elements. The automatic reset limit switches should be the first to trip and then reset. If the condition continues, these switches may fail, and the fusible link in the heater may open the circuit. When this happens, the link must be replaced by a qualified technician. This requires a service call that could have been prevented. If the fusible link fails, the limit switch should be replaced as well.

The electric heating elements are usually controlled by low-voltage thermostats that open or close the contacts on sequencers or contactors. The contacts in the sequencers or contactors carry large electrical loads, which will probably produce the most stress and be the first component to fail in a properly maintained system. You may visually check the contacts on a contactor, but the contacts on sequencers are concealed. When the contacts on a contactor become pitted, change the contacts on the contactor. The condition will only become worse and could then cause other problems, namely, terminal and wire damage to the circuit.

The only method you can use to check a sequencer is to visually check the wires for discoloration and check the current flow through each circuit with the sequencer energized. If power will not pass through the sequencer circuit, the sequencer may be defective. Do not forget that the heater must have a path through which electrical energy can flow. Many sequencers have been declared defective only to find later that the fuse links in the heater or the heater itself had an open circuit.

Line-voltage electrical connections in the heater junction box should be examined closely. If there is any wire discoloration or connectors that appear to have been hot, these components must be changed. If the wire is discolored, and it is long enough, it may be cut back until the conductor is its normal color.

Fuse holders may lose their tension and not hold the fuses tightly. This is caused by heating and will be apparent because the fuses will blow when no overload exists and for no other apparent reason. These fuses and holders must be changed for the unit to perform safely and correctly.

30.16 DIAGNOSTIC CHART FOR ELECTRIC HEAT

Electric heat may involve either boiler systems or forced-air systems. The discussion in this text has primarily been concerned with forced-air systems as they are the most common. These forced-air systems may be the primary heating system or the secondary heating system when used with heat pumps. The technician should always listen to the customer for symptoms. The customer can often lead you to the cause of the problem with a simple description of how the system is performing.

Problem	Possible Cause	Possible Repair
No heat—thermostat calling for heat	Open disconnect switch	Close disconnect switch.
	Open fuse or breaker	Replace fuse or reset breaker and determine why it opened.
	High-temperature fuse link open circuit	Tighten loose connection at fuse link causing heat.
	Faulty high-voltage wiring or connections	Repair or replace faulty wiring or connections.
	Control-voltage power supply off	Check control-voltage fuses and safety devices.
	Faulty control-voltage wiring or connections	Repair or replace faulty wiring or connections.
	Heating element burned, open circuit	Replace heating element—check airflow.
Insufficient heat	Only some of the heating elements are energized	See possible repair options for a no-heat situation.
	Low voltage	Correct voltage.

30.17 SERVICE TECHNICIAN CALLS

SERVICE CALL 1

A customer with a 20-kW electric furnace calls the service company and informs the dispatcher that she has no heat. The technician arrives at the job, rings the doorbell, and introduces himself. The customer tells the technician that the *blower comes on, but the heat does not. This is a system that has individual sequencers with a fan-starting sequencer. The first-stage sequencer has a burned-out coil and will not close its contacts. The first stage starts the rest of the heat, so there is no heat produced by the furnace.*

The technician is familiar with this system and had started it after the initial installation. The technician realizes that because the fan starts, the 24-V power supply is working. On arriving at the job, the thermostat is set to call for heat. The technician goes under the house with a spare sequencer, a volt-ohmmeter, and an ammeter.

On approaching the electric furnace, the blower can be heard running. Removing the panel covering the electric heat elements and sequencers, the technician uses the ammeter to check whether any of the heaters is energized; none are. **SAFETY PRECAUTION:** *The technician observes electrical safety precautions.*• The voltage is checked at the coils of all sequencers. See **Figure 30.24** for a diagram. 24 V is present at the timed fan control and the first-stage sequencer. The voltage across the normally open contacts is 24 V, indicating that these contacts are in the open position. These contacts should be closed because the sequencer coil is energized. The electrical disconnect is turned off and the wires on the sequencer are marked and removed from the device. The continuity is checked across the first-stage sequencer coil. There is no continuity through the coil, indicating that the coil is open. When the sequencer is changed and power is turned on, the electric heat comes on.

Since this is a relatively new installation and still under warranty, the technician simply replaced the sequencer without getting approval from the customer. Had this been a time-and-material service call, the technician would have informed the customer of the problem, provided information regarding the cost of the repair, and obtained approval to perform the work prior to doing so.

SERVICE CALL 2

A residential customer calls. *There is no heat, but the customer smells smoke. The company dispatcher advises that the customer should turn the system off until the technician arrives. The blower motor has an open circuit and will not run. The smoke smell is coming from the heating unit cycling on the limit control.*

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The technician arrives on the job and notices that the front door is opened slightly. Instead of simply walking in, the technician rings the bell and waits for the homeowner to come to the door. The homeowner invites the technician in, explains the problem, and shows him to the thermostat. At the thermostat, the technician turns the system to heat. This is a system that does not have cooling, or the technician would have turned the thermostat to FAN ON to see whether the blower will start. If it did not start, this would have helped to solve the problem. When the technician goes to the electric furnace in the hall closet, a smoke smell is present. The technician removes the service panel from the front of the furnace and uses an ammeter to check the current at the electric heater. The heater is drawing 40 A, but the blower is not running. **SAFETY PRECAUTION:** *The technician observes electrical safety precautions.*•

The technician looks at the wiring diagram and discovers that the blower should start with the first-stage heat from a set of contacts on the sequencer. The blower motor is getting voltage but is not running. The unit power is turned off, locked, and tagged, and a continuity check of the motor proves that the motor winding is open.

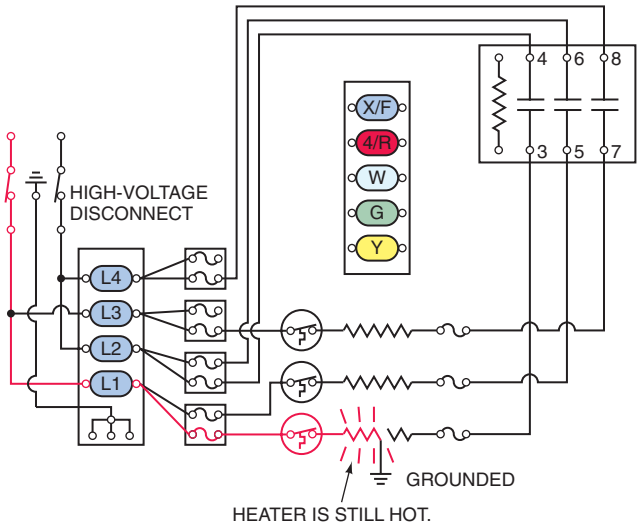
The technician takes down all of the pertinent system and motor information and calls the shop to check on the cost and availability of the motor. Once the technician has the information, he informs the customer about the problem with the system, the cost of the repair, and when the repair can be made. Approval for the repair is given and the motor is replaced early the next morning. Once the motor is replaced, the technician checks the operation of the system to make certain that everything is okay.

SERVICE CALL 3

A customer calls at the end of the heating season and explains that the blower on his electric furnace is starting and stopping from time to time. He has the thermostat set to OFF, so there should be no activity.

The technician arrives at the job, introduces himself to the homeowner, and asks about the problem and the location of the furnace. The owner informs him about the blower problem and leads him to the furnace, which is located in the basement. When the technician touches the cabinet of the furnace, he can feel that it is warm; it shouldn't be—it should be room temperature. He removes the cabinet cover, checks the current at each of the three heating elements with an ammeter, and discovers that one of the elements is drawing 8 A. This heater should not be drawing any current since the system is set to OFF. The technician turns off the power, removes that heating element, and finds that one of the elements has been burned in two and that one of the coils is touching the frame. The element is grounded and drawing current, **Figure 30.27**. (**NOTE:** *The sequencer has no control over this grounded element. The fuse did not open because the current flow was not high enough—but there is enough current flow to create heat and activate the temperature control for the blower. The running blower will cool off the element quickly and turn off, only to turn on again.*) • **SAFETY PRECAUTION:** *It is a good electrical safety practice to check from the frame of any appliance to ground to make sure there is no danger. Do this before touching the appliance! This is particularly important when you are lying on the ground under a house checking equipment.*•

Figure 30.27 One side of this heating element is grounded to the frame of the furnace and is heating all of the time. Technicians should always check an appliance to ground for safety. This furnace is grounded and safe. If the ground were not correct, the technician could be injured.



The technician shows the element to the homeowner, calls the office for the repair cost, and gets approval for the repair. The technician leaves for the supply house to get a replacement element. When the new element is installed, the unit operates correctly.

Solutions for the following service calls are not provided here. Please discuss the solutions with your instructor.

SERVICE CALL 4

The owner of a small business calls. The heating system is not putting out enough heat. This is the first day of very cold weather, and the space temperature is only getting up to 65°F with the thermostat set at 72°F. The system is a package air-conditioning unit with 30 kW (six stages of 5 kW each) of strip heat located on the roof.

The technician arrives, goes to the room thermostat, checks the setting of the thermostat, and finds that the space temperature is 5°F lower than the setting. The technician goes to the roof with a volt-ohmmeter and an ammeter. **SAFETY PRECAUTION:** *After removing the panels on the side of the unit where the strip heat is located, the amperage is carefully checked.*•

Two of the six stages are not pulling any current. It looks like a sequencer problem at first. A voltage check of the individual sequencer coils shows that all of the sequencers should have their contacts closed; there is 24 V at each coil. A voltage check at each heater terminal shows that all stages have voltage but are not drawing any current.

What is the likely problem and the recommended solution?

SUMMARY

- Electric heat is a convenient way to heat individual rooms and small spaces.
- Central electric heating systems are usually less expensive to install and maintain than other types.
- Operational costs may be higher than with other types of fuels.
- The low-voltage thermostat, sequencer, and relays are control mechanisms used in central electric forced-air systems.
- The sequencer is used to activate the heating elements in stages. This avoids putting heavy kilowatt loads in service all at one time. If this were to be done, it could cause fluctuations in power, resulting in voltage drop, flickering lights, and other disturbances.
- Sequencers have bimetal strips with 24-V heaters. These heaters cause the bimetal strip to bend, closing contacts and activating the high-voltage heating elements.
- The blower in a central system must operate while the heating elements are on. The systems must be wired to ensure that this occurs.
- Systems are protected with limit switches and fusible links (temperature controlled).
- Preventive maintenance inspections should be made periodically on electric heating units and systems.

REVIEW QUESTIONS

1. The material often used to manufacture electric strip heater coils is _____.
2. Portable or small space heaters with glowing coils transfer heat by _____.
3. Baseboard heaters transfer heat by _____.
4. A disadvantage of a central forced-air electric furnace is that
   A. there is no zone control for individual rooms.
   B. a thermostat must be installed in each room.
   C. only line-voltage thermostats can be used.
   D. it is difficult to add air-conditioning (cooling).
5. Three common controls used in central electric heat applications are thermostats, contactors (or relays), and
   A. capacitors.
   B. sequencers.
   C. cool anticipators.
6. The low-voltage thermostat is often used to control an electric heating system because it is compact, it is responsive, and
   A. it provides fuse protection.
   B. it acts as a limit switch.
   C. it is safe.
7. The heat anticipator setting is determined by
   A. adding all the current draws in the 24-V circuit that passes through the thermostat control bulb and heat anticipator.
   B. using the amperage of the fan motor.
   C. using the total of the high-voltage amperage in the circuit.
   D. using the voltage at the limit control.
8. The sequencer uses _____ (high or low) voltage control power to start and stop the electric heaters.
9. True or False: A package sequencer can start or stop only one stage of strip heat.
10. Two types of wiring diagrams are the pictorial and _____.
11. The limit switch shuts off the unit if
    A. high temperature occurs.
    B. the furnace is unable to maintain the correct heat.
    C. the heat anticipator does not function properly.
    D. the cool anticipator does not function properly.
12. The _____ wire from the transformer furnishes power to the thermostat.
    A. red
    B. blue
    C. orange
    D. yellow
13. State the formula used for determining the cubic feet per minute (cfm) airflow across the furnace heating elements.
14. Power-consuming devices are wired in _____ (series or parallel).
15. Power-passing devices are wired in _____ (series or parallel).

UNIT 31

GAS HEAT

OBJECTIVES

After studying this unit, you should be able to

- describe each of the major components of a gas furnace.
- list two fuels burned in gas furnaces and describe characteristics of each.
- discuss a multipoise furnace and its safety devices.
- discuss flame rollout switches, auxiliary limit switches, and draft safeguard switches.
- discuss gas pressure measurement in inches of water column and describe how a manometer is used to make this measurement.
- discuss gas combustion.
- describe a solenoid, diaphragm, and heat motor gas valve.
- list the functions of an automatic combination gas valve.
- describe the function of a servo-operated gas pressure regulator.
- discuss the meaning of a redundant gas valve.
- discuss different gas burners and heat exchangers.
- describe the difference between induced-draft and forced-draft systems.
- describe and discuss different ways of controlling the warm-air fan.
- state the function of an off-delay timing device for a warm-air fan control.
- describe the standing pilot, intermittent pilot, direct-spark, and hot surface ignition systems.
- list three flame-proving devices and describe the operation of each.
- discuss reasons and the systems used for the delay in starting and stopping the furnace fan.
- state the purpose of a limit switch.
- describe flue-gas venting systems.
- discuss flame rectification and how it pertains to local and remote flame sensing.
- apply flame rectification troubleshooting and maintenance procedures.
- discuss the components of a high-efficiency gas furnace.
- describe direct-vented, non-direct-vented, and positive pressure systems.
- explain dew point temperature as it applies to a high-efficiency condensing furnace.
- discuss excess air, dilution air, combustion air, primary air, and secondary air.
- describe the condensate disposal system of a high-efficiency condensing gas furnace.
- identify furnace efficiency ratings.
- discuss electronic ignition modules and integrated furnace controllers.
- describe a two-stage furnace, a modulating gas furnace, and a variable-output thermostat.
- explain gas piping as it applies to gas furnaces.
- interpret gas furnace wiring diagrams and troubleshoot flowcharts or guides.
- compare the designs of a high-efficiency gas furnace and a conventional furnace.
- describe procedures for taking flue-gas carbon dioxide and temperature readings.
- describe typical preventive maintenance procedures.

SAFETY CHECKLIST

- ✔ Fuel gases are dangerous in poorly vented areas. They can replace oxygen in the air and cause suffocation. They are also explosive. If a gas fuel leak is suspected, avoid ignition by preventing any open flame or spark. **SAFETY PRECAUTION:** *A spark from a flashlight switch can ignite gas. Vent all enclosed areas adequately before working in them.*
- ✔ Always shut off the gas supply when installing or servicing a gas furnace.
- ✔ A gas furnace that is not functioning properly can produce carbon monoxide, a poisonous gas. It is absolutely necessary that the production of carbon monoxide be avoided.
- ✔ Yellow tips indicate an air-starved flame emitting poisonous carbon monoxide.
- ✔ It is essential that the furnace be vented properly so that all flue gases will be dissipated into the atmosphere.
- ✔ When taking flue-gas samples, do not touch the hot vent pipe.
- ✔ A furnace with a defective heat exchanger (one with a hole or crack) must not be allowed to operate because the flue gases can mix with the air being distributed throughout the building.
- ✔ Wear goggles when using compressed air for cleaning parts.
- ✔ The limit switch must operate correctly to keep the furnace from overheating due to a restriction in the airflow or other furnace malfunction.
- ✔ Proper replacement air must be available in the furnace area.
- ✔ All new gas piping assemblies should be tested for leaks.
- ✔ Gas piping systems should be purged only in well-ventilated areas.
- ✔ Follow all safety procedures when troubleshooting electrical systems. Electric shock can be fatal.
- ✔ Turn off the power before attempting to replace any electrical component. Lock and tag the disconnect panel. There should be only one key. Keep this key on your person while making any repairs.
- ✔ Perform a gas leak check after completing an installation or repair.

31.1 INTRODUCTION TO GAS-FIRED, FORCED-HOT-AIR FURNACES

Gas-fired, forced-hot-air furnaces have a heat-producing system and a heated-air distribution system. The heat-producing system includes the manifold and controls, burners, the heat exchanger, and the venting system. The heated-air distribution system consists of the blower that moves the air throughout the ductwork and the ductwork assembly. See **Figure 31.1** for a photo of a modern, high-efficiency condensing gas furnace.

The manifold and controls meter the gas to the burners where the gas is burned, which creates flue gases in the heat exchanger and heats the air in and surrounding the heat exchanger. The venting system allows the flue gases to be exhausted into the atmosphere. The blower distributes the heated air through ductwork to the areas where the heat is wanted.

Figure 31.1 A modern, high-efficiency condensing gas furnace.

31.2 TYPES OF FURNACES

UPFLOW

The *upflow* furnace stands vertically and needs headroom. It is designed for first-floor installation with the ductwork in the attic or for basement installation with the ductwork between or under the first-floor joists. The furnace takes in cool air from the rear, bottom, or sides near the bottom. It discharges hot air out the top, **Figure 31.2**.

"LOW-BOY"

The *low-boy* furnace is approximately 4 ft high. It is used primarily in basement installations with low headroom where the ductwork is located under the first floor. Air intake and discharge are both at the top, **Figure 31.3**.

DOWNFLOW

The *downflow* furnace, sometimes referred to as a *counterflow* furnace, looks like the upflow furnace. The ductwork may be in a concrete slab floor or in a crawl space under the house. The air intake is at the top, and the discharge is at the bottom, **Figure 31.4**.

HORIZONTAL

The *horizontal* furnace is positioned on its side. It is installed in crawl spaces, in attics, or suspended from floor joists in basements. In these installations it takes no floor space. The air intake is at one end; the discharge is at the other, **Figure 31.5**.

MULTIPOISE OR MULTIPOSITIONAL

A multipoise furnace can be installed in any position. This adds versatility to the furnace, especially for the installation contractor. Multipoise furnaces can be upflow, downflow, horizontal right or horizontal left air discharge, **Figure 31.6**. Many times, these furnaces come from the factory configured for the more

common upflow applications but can be changed in the field with very little modification. Often, the combustion air pipe and exhaust pipe can be attached to either side of the furnace. Condensate drain lines can also be attached to either side of the furnace as long as the one not in use is capped. **Figure 31.7**(A) shows a high-efficiency condensing furnace with two combustion air and condensate drain line connection options. Many multipoise furnaces come with vent and drain extension tubes for ease in retrofitting. Multipoise furnaces look like any other furnace from the outside; however, the inside may have extra condensate drain line connections, more than one combustion air connection and vent pipe or condensate drain line extensions, and plugs for lines not in use during certain position configurations.

Because multipoise furnaces can be placed in four different configurations, multiple safety controls must be designed into the furnace. **Figure 31.7**(**B**) shows multiple bimetallic flame rollout or overtemperature limits very near to one another. This protects the furnace no matter what configuration it is in. Normally closed (NC) flame rollout switches are usually located near the top of the burner box, where the flame is most likely to roll out. When a furnace is installed horizontally, additional rollout switches are wired in series to provide extra flame rollout protection. Control schemes on some furnaces allow for the combustion blower to operate continuously when a rollout switch has opened. Flame rollout switches may have to be manually reset by pushing a button on top of the switch.

Figure 31.7 (A) A multipositional furnace showing two exhaust air location options and two condensate drain location options. (B) A multipoise furnace exhibiting multiple flame rollout switches. (A) and (C) An auxiliary limit switch for horizontal and counterflow furnaces. The switches are located on the warm-air blower housing and monitor return air temperature. SAFETY PRECAUTION: *Never use an automatic reset flame rollout switch to replace a damaged or inoperative manual reset flame rollout switch.*•

Auxiliary limit switches are used for counterflow and horizontal furnaces. They are usually bimetallic, similar to flame rollout switches, but are mounted on the warm-air blower housing, **Figure 31.7(C)**. They monitor room return air temperature and interrupt burner operation when the temperature gets too hot. This protects the furnace's filter from exceeding its maximum allowable temperature. Usually, the combustion blower or warm-air blower will continue to run if any auxiliary limit switch has opened. Most of these controls are automatically reset.

Vent limit or draft safeguard switches are NC switches usually mounted on the draft hood if the furnace is equipped with one. They are typically bimetallic switches similar to flame rollout and auxiliary limit switches. They monitor the draft hood temperature and open when there is any spillage of flue gas, **Figure 31.7(D)**.

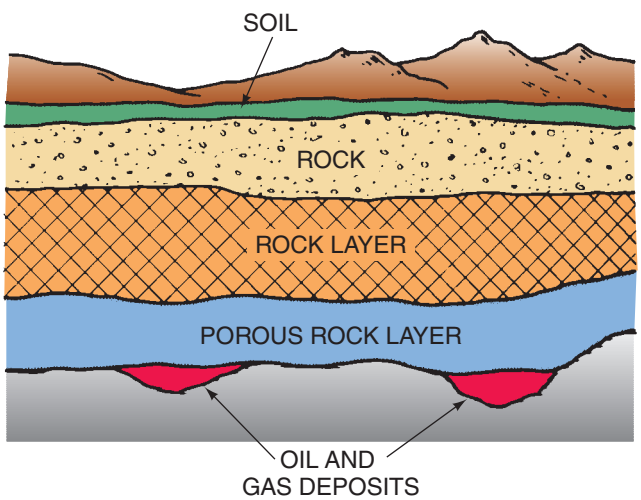
31.3 GAS FUELS

Natural gas, manufactured gas, and liquefied petroleum (LP) are commonly used in gas furnaces.

NATURAL GAS

Natural gas has been forming along with oil from dead plants and animals for millions of years. The accumulated organic material gradually was washed or deposited to great depths in hollow spots in the earth, **Figure 31.8**, causing tremendous pressure and high temperature from its own weight. The pressure and temperature caused a chemical reaction, changing the organic material to oil and gas, which accumulated in pockets and porous rocks deep in the earth.

Figure 31.8 Gas and oil deposits deep in the earth.



Natural gas is composed of 90% to 95% methane and other hydrocarbons, almost all of which are combustible, which makes this gas efficient and clean-burning. Natural gas has an average specific gravity of 0.60 and dry air has a specific gravity of 1.0, so natural gas weighs only 60% as much as dry air. Therefore, natural gas rises when discharged into the air. When burned with air, 1 ft^3 of natural gas will produce about 1050 Btu of heat energy. Gas from these pockets deep in the earth (more generally called wells) may contain moisture and other gases that must be removed before distribution. The characteristics of natural gas will vary somewhat from one location to another. Local utility companies can provide specific characteristics for the gas in their area.

Natural gas by itself has neither odor nor color and is not poisonous. **SAFETY PRECAUTION:** *But it is dangerous because it can displace oxygen in the air, causing suffocation, and when it accumulates, it can explode.*• Sulfur compounds, called *odorants,* which have a garlic smell, are added to the gas to make leak detection easier. No odor is left, however, when the gas has been burned.

LIQUEFIED PETROLEUM

Liquefied petroleum (LP) is liquefied propane, butane, or a combination of propane and butane. When in the vapor state, these gases may be burned as a mixture of one or both of these gases and air. The gas is liquefied by keeping it under pressure until ready for use. A regulator at the tank reduces the pressure as the gas leaves the tank. As the vapor leaves the tank, it is replaced within by means of a slight boiling or vaporizing of the remaining liquid. LP gas is obtained from natural gas or as a by-product of the oil-refining process. The boiling point of propane at atmospheric pressure is −44°F, which makes it feasible to store in tanks for use in low temperatures during northern winters.

Butane in the liquid state, however, has a high boiling point. At any temperature below 31°F a tank of liquid butane would be at a negative pressure, so it must be buried or be supplied with a small heater to keep the fuel pressure high enough to move the gas to the main burner. For these reasons, butane is not very popular. It has a very high heat content but is hard to work with because of the pressures.

LP gas contains more atoms of hydrogen and carbon than natural gas does, which causes the Btu output to be greater. When burned, 1 ft^3 of *propane* produces 2500 Btu of heat. However, it requires 24 ft^3 of air to support this combustion. The specific gravity of propane gas is 1.52, which means that it is 1½ times heavier than air, so it sinks when released in air. **SAFETY PRECAUTION:** *This is dangerous because it will replace oxygen and cause suffocation; it will also collect in low places and create pockets of highly explosive gas.*• *Butane* produces approximately 3200 Btu/ft^3 of gas when burned.

LP gas is used primarily where natural gas is not available. Occasionally, butane and propane are mixed with air

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Figure 31.9 A spud showing the orifice through which the gas enters the burner.

to alter the characteristics of LP gas in order to closely duplicate natural gas. It is then called propane or butane air gas. The mixture is accomplished with blending equipment under pressure. Mixing with air reduces the Btu/ft^3 and the specific gravity and allows the mixture to be substituted and burned in natural gas burners without adjustment for standby purposes.

The specific gravity of a gas is important because it affects the gas flow through the piping and through the orifice of the furnace. The orifice is a small hole in a fitting (called a *spud*) through which the gas must flow to the burners, **Figure 31.9**. The gas flow rate also depends on the pressure and on the size of the orifice. At the same pressure, more light gas than heavy gas will flow through a given orifice. When the proper mixture of LP gas and air is used, it will operate satisfactorily in natural gas furnaces because the mixture will match the orifice size and the burning rate will be the same as for natural gas. **SAFETY PRECAUTION:** *LP gas alone must not be used in a furnace that is set up for natural gas because the orifice will be too large. This results in overfiring and soot buildup.*•

MANIFOLD PRESSURES

The manifold pressure at the furnace should be set according to the manufacturer's specifications because they relate to the characteristics of the gas to be burned. The manifold gas pressure is much lower than 1 psi and is expressed in inches of water column (in. WC). *One inch of water column* pressure is the pressure required to push a column of water up 1 in. One psi of pressure will support a column of water 27.7 in. high, or 1 psi = 27.7 in. WC.

Some Common Manifold Pressures	
Natural gas and propane/air mixture	3 to 3½ in. WC
Manufactured gas (below 800 Btu quality)	2½ in. WC
L2:LP gas	11 in. WC

A **water manometer** is used to measure gas pressure. It is a tube of glass or plastic formed into a U and about half full of plain water, **Figure 31.10**. The standard manometer used in domestic and light commercial installations is graduated in

Figure 31.10 A manometer used for measuring pressure in inches of water column.

in. WC. The pressure is determined by the difference in levels between the two columns. Gas pressure is piped to one side of the tube, and the other side is open to the atmosphere to allow the water to rise, **Figure 31.11**. The instrument often has a sliding scale so it can be adjusted for easier reading. Some common pressure conversions follow:

Pressures Per Square Inch
1 lb/in^2 = 27.71 in. WC
1 oz/in^2 = 1.732 in. WC
2.02 oz/in^2 = 3.5 in. WC (standard pressure for natural gas)
6.35 oz/in^2 = 11 in. WC (standard pressure for LP gas)

A digital manometer is often used to measure gas pressures, **Figure 31.12**, and can measure both positive and negative pressures in inches of water column. One advantage of a digital manometer is that there is no fluid to spill. Another is that the pressure reading does not require the service technician to measure manually the difference in height of the water column. However, the digital manometer does require batteries. **SAFETY PRECAUTION:** *Turn the gas off while connecting any manometer.*•

31.4 GAS COMBUSTION

Heating systems must be installed to operate safely and efficiently. To properly install and service gas heating systems, the heating technician must know the fundamentals of combustion. **Combustion** needs fuel, oxygen, and heat. A reaction between the fuel, oxygen, and heat is known as **rapid oxidation**, or the process of burning. The fuel in this case is the natural gas (methane), propane, or butane; oxygen comes from the

Courtesy Ferris State University. Photo by John Tomczyk

air; and the heat comes from a pilot flame or other type of ignition system. The fuels contain hydrocarbons that unite with the oxygen when heated to the ignition temperature. Air contains approximately 21% oxygen; enough air must be supplied to furnish the proper amount of oxygen for the combustion process. The ignition temperature for natural gas is 1100°F to 1200°F. The pilot flame or other type of ignition must provide this heat, which is the minimum temperature for burning. The chemical formula for the burning process is

$$CH_4 \text{ (methane)} + 2\,O_2 \text{ (oxygen)} \rightarrow CO_2 \text{ (carbon dioxide)} + 2\,H_2O \text{ (water vapor)} + \text{heat}$$

This formula represents perfect combustion. The process produces carbon dioxide, water vapor, and heat. Although perfect combustion seldom occurs, slight variations create no danger. **SAFETY PRECAUTION:** *The technician must see to it that combustion is as close to perfect as possible. By-products of poor combustion are carbon monoxide—a poisonous gas—soot, and minute amounts of other products. It should be obvious that carbon monoxide production must be avoided, as it is a colorless, odorless, poisonous gas.* Soot lowers furnace efficiency because it collects on the heat exchanger and acts as an insulator, so it also must be kept at a minimum.

Some gas furnaces and appliances use an atmospheric burner because the gas and air mixtures are at atmospheric pressure during burning. The gas is metered to the burner through the orifice. The velocity of the gas pulls in the primary air around the orifice, **Figure 31.13(A)**.

Where the gas passes through the burner tube, the diameter is reduced to induce the air. This reduction in burner diameter is called the **venturi**, **Figure 31.13(A)**. The gas-air mixture moves on through the venturi into the mixing tube, where the gas is forced by its own velocity through the burner ports or slots; it is ignited as it leaves the port, **Figure 31.13(B)**. When the gas is ignited at the burner port, secondary air is drawn in around the ports to support combustion. The flame should be a well-defined blue with slightly orange, *not yellow,* tips, **Figure 31.13(C)**. **SAFETY PRECAUTION:** *Yellow tips indicate an air-starved flame emitting poisonous carbon monoxide. Orange streaks in the flame are not to be confused with yellow. Orange streaks are dust particles burning.*

Other than adjusting the gas pressure at the orifice, changes to the primary air supply are the only adjustments that can be made to the flame. Modern furnaces can only be adjusted slightly; this is intentional in order to maintain minimum standards of flame quality. The only thing, aside from gas pressure, that will change the furnace combustion characteristics to any extent is dirt or lint drawn in with the primary air. If the flame begins to burn *yellow,* primary air restriction should be suspected. For a burner to operate efficiently, the gas flow rate must be correct, and the proper quantity of air must be supplied. Modern furnaces use a primary and a secondary air supply, and the gas supply or flow rate is determined by the orifice size and the gas pressure. A normal

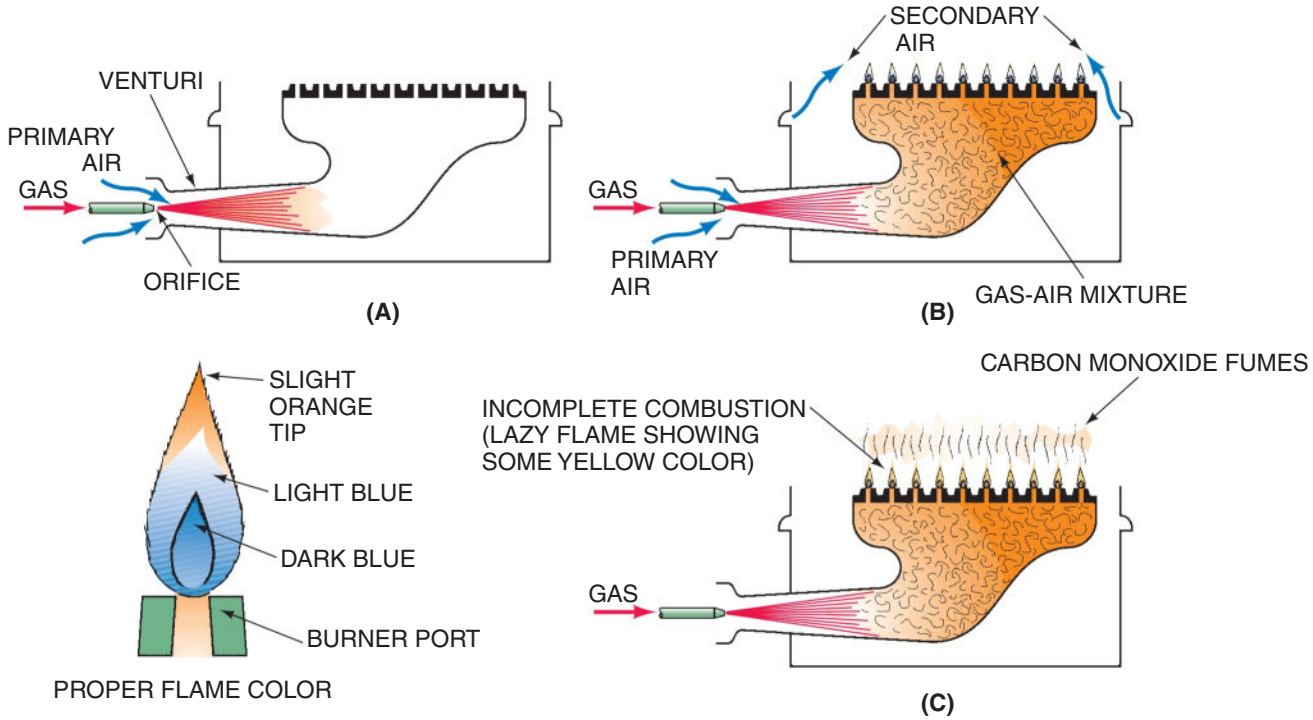
Figure 31.13 (A) Primary air is induced into the air shutter by the velocity of the gas stream from the orifice. (B) Ignition of the gas is on top of the burner. (C) Incomplete combustion yields yellow "lazy" flame. Any orange color indicates dust particles drawn in with the primary air.



pressure at the manifold for natural gas is 3½ in. WC. It is important, however, to use the manufacturer's specifications when adjusting the gas pressure.

A gas-air mixture that is too lean (not enough gas) or too rich (too much gas) will not burn. If the mixture of air and natural gas contains 0% to 4% natural gas, it will not burn. If the mixture contains from 4% to 15% gas, it will burn. **SAFETY PRECAUTION:** *However, if the mixture is allowed to accumulate, it will explode when ignited.•* If the gas in the mixture is 15% to 100%, the mixture will not burn or explode. The burning mixtures are known as the *limits of flammability* and are different for different gases.

The rate at which the flame travels through the gas and air mixture is known as the *ignition* or *flame velocity* and is determined by the type of gas and the air-to-gas ratio. Natural gas (CH_4) has a lower burning rate than butane or propane because it has fewer hydrogen atoms per molecule. Butane (C_4H_{10}) has 10 hydrogen atoms, whereas natural gas has 4. The speed is also increased in higher gas-air mixtures within the limits of flammability; therefore, the burning speed can be changed by adjusting the airflow.

Perfect combustion requires two parts oxygen to one part methane. The atmosphere consists of approximately one-fifth oxygen and four-fifths nitrogen with very small quantities of other gases. Approximately 10 ft^3 of air is necessary to obtain 2 ft^3 of oxygen to mix with 1 ft^3 of methane. This produces 1050 Btu and approximately 11 ft^3 of flue gases, **Figure 31.14.**

The air and gas never mix completely in the mixing tube chamber. Extra primary air is always supplied so that the methane will find enough oxygen to burn completely. This excess air is normally supplied at 50% over what would be needed if the air and gas were mixed thoroughly. This means that to burn 1 ft^3 of methane, 15 ft^3 of air needs to be supplied. Additional air also will be added at the draft hood. This is discussed later. There will be 16 ft^3 of flue gases to be vented from the combustion area, **Figure 31.14.** Flue gases contain approximately 1 ft^3 of oxygen (O_2), 12 ft^3 of nitrogen (N_2), 1 ft^3 of carbon dioxide (CO_2), and 2 ft^3 of water vapor (H_2O). **SAFETY PRECAUTION:** *It is essential that the furnace be vented properly so that these gases will all be dissipated into the atmosphere.•*

A cooler flame results in inefficient combustion. A flame is cooled when it strikes the sides of the combustion chamber (due to burner misalignment), called *flame impingement.* When the flame strikes the cooler metal of the chamber, the temperature of that part of the flame is lowered below the ignition temperature. This results in poor combustion and produces carbon monoxide and soot.

The percentages and quantities indicated here are for the burning of natural gas only. These figures vary considerably when propane, butane, propane-air, or butane-air are used. When making adjustments, always use the manufacturer's specifications for each furnace. **SAFETY PRECAUTION:** *While taking flue-gas samples, be careful not to touch the hot vent pipe.•*

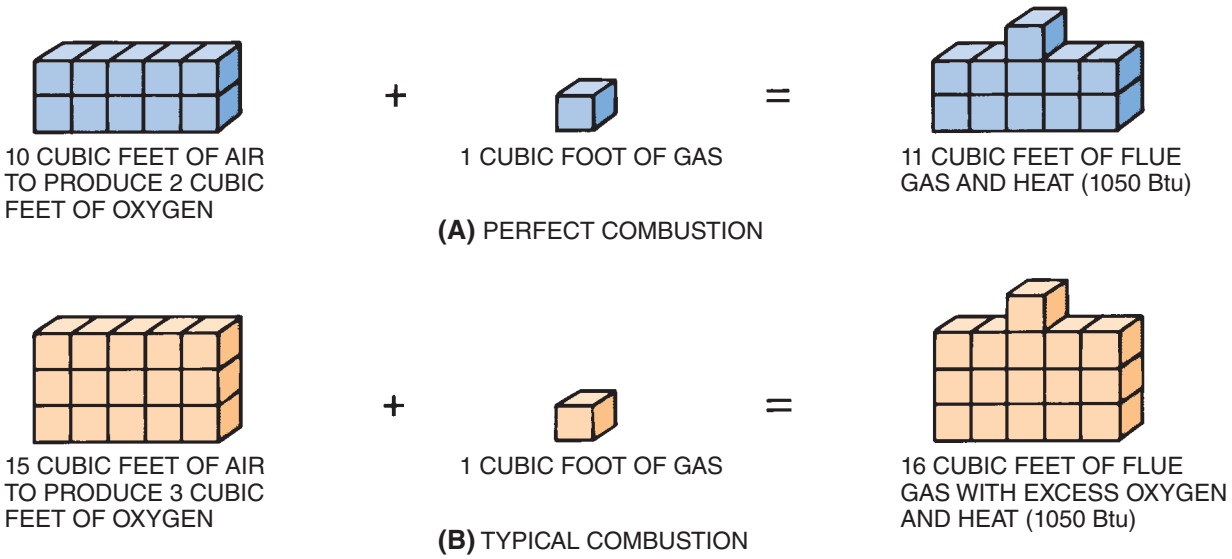
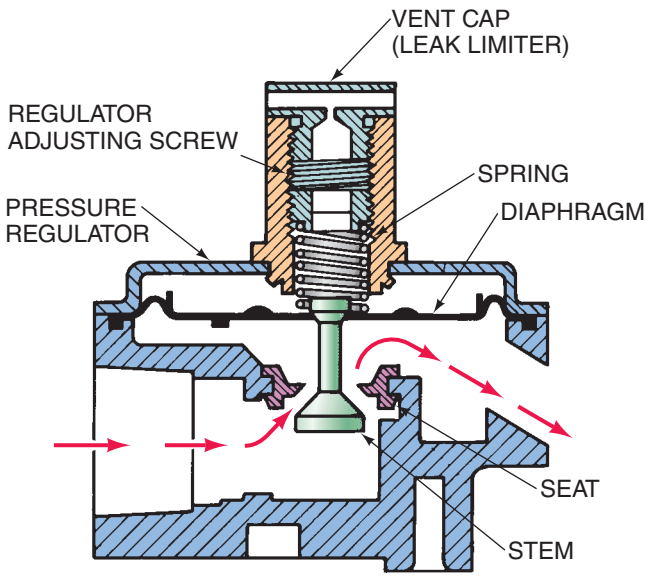
Figure 31.14 The quantity of air for combustion.



31.5 GAS REGULATORS

Natural gas pressure in the supply line does not remain constant and is always at a much higher pressure than required at the manifold. The *gas regulator* drops the pressure to the proper level (in. WC) and maintains this constant pressure at the outlet where the gas is fed to the gas valve. Many regulators can be adjusted over a pressure range of several inches of water column, **Figure 31.15**. The pressure is increased when the adjusting screw is turned clockwise; it is decreased when the screw is turned counterclockwise. Some regulators have limited adjustment capabilities; others have none. Such regulators are either fixed permanently or sealed so that an adjustment cannot be made in the field. The natural gas utility company should be contacted to determine the proper setting of the regulator. In most modern furnaces, the regulator is built into the gas valve, and the manifold pressure is factory set at the most common pressure: 3½ in. WC for natural gas.

Figure 31.15 The diagram of a standard gas pressure regulator.



LP gas regulators are located at the supply tank and are furnished by the gas supplier. Check with the supplier to determine the proper pressure at the outlet from the regulator. The outlet pressure range is normally 10 to 11 in. WC. The distributor usually adjusts this regulator; in some localities the pressure is higher. The installer then provides a regulator at the appliance and sets the water column pressure to the manufacturer's specifications, usually 11 in. WC.

Combination gas valves have built-in regulators in their bodies. LP gas installations normally *do not* use gas valves with built-in regulators. Manufacturers usually will provide some sort of retrofit kit for converting from natural gas to LP gas. Many times, a higher-tension spring will have to be installed in the regulator at the gas valve to hold the valve open all the way. Some valves incorporate a push-pull knob. Pushing the knob down into the regulator will open the regulator all the way, which allows the regulator at the tank or the regulator at the side of the house to take control and regulate at 10½–11 in. WC. The regulators in gas valves sold as LP valves may have already had this done in some fashion. Always consult the manufacturer's specifications when setting regulators for any type of gas.

Converting from natural gas to LP gas involves many steps that may differ from manufacturer to manufacturer

because of design differences in gas valves. For example, converting from natural gas to LP gas will include changing the regulator pressure from 3.5 in. WC by some method, installing smaller main burner orifices, and installing a new pilot orifice. This process also may include changing the ignition/control module to a 100% shutoff module because LP gas is heavier than air. **SAFETY PRECAUTION:** *Only experienced technicians should adjust gas pressures.*•

31.6 GAS VALVE

From the regulator the gas is piped to the **gas valve** at the manifold, **Figure 31.16**. There are several types of gas valves. Many are combined with pilot valves and called *combination* gas valves, **Figure 31.17**. We will first consider the gas valve separately and then in combination. Valves are generally classified as solenoid, diaphragm, and heat motor.

Figure 31.16 Natural gas installation where the gas passes through a separate regulator to the gas valve and then to the manifold.

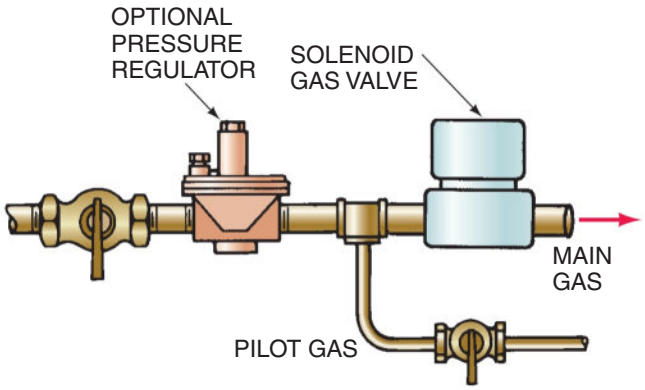

Figure 31.17 (A)–(B) Two gas valves with pressure regulator combined.

31.7 SOLENOID VALVE

The gas *solenoid* valve is an NC valve, **Figure 31.18.** The plunger in the solenoid is attached to the valve or is in the valve. When an electric current is applied to the coil, the plunger is pulled into the coil. This opens the valve. The plunger is spring loaded so that when the current is turned off, the spring forces the plunger to its NC position, shutting off the gas, **Figure 31.19**.

31.8 DIAPHRAGM VALVE

The *diaphragm* valve uses gas pressure on one side of the diaphragm to open the valve. When there is gas pressure above the diaphragm and atmospheric pressure below it, the diaphragm will be pushed down and the main valve port will be closed, **Figure 31.20**. When the gas is removed from above the diaphragm, the pressure from below will push the diaphragm up and open the main valve port, **Figure 31.20**. This is done by a very small valve, called a *pilot-operated* valve because of its small size. It has two ports—one open while the

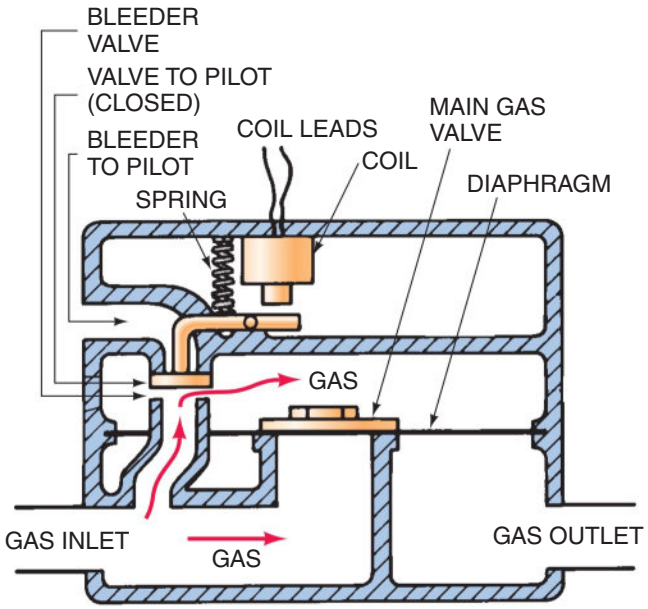
Figure 31.20 An electrically operated magnetic diaphragm valve.



other is closed. When the port to the upper chamber is closed and not allowing gas into the chamber above the diaphragm, the port to the atmosphere is opened. The gas already in this chamber is vented or bled to the pilot, where it is burned. The valve controlling the gas into this upper chamber is operated electrically by a small magnetic coil, **Figure 31.21.**

When the thermostat calls for heat in the thermally operated valve, a bimetal strip is heated and caused to warp by a small heater attached to the strip or a resistance wire wound

Figure 31.21 When an electric current is applied to the coil, the valve to the upper chamber is closed as the lever is attracted to the coil. The gas in the upper chamber bleeds off to the pilot, reducing the pressure in this chamber. The gas pressure from below the diaphragm pushes the valve open.

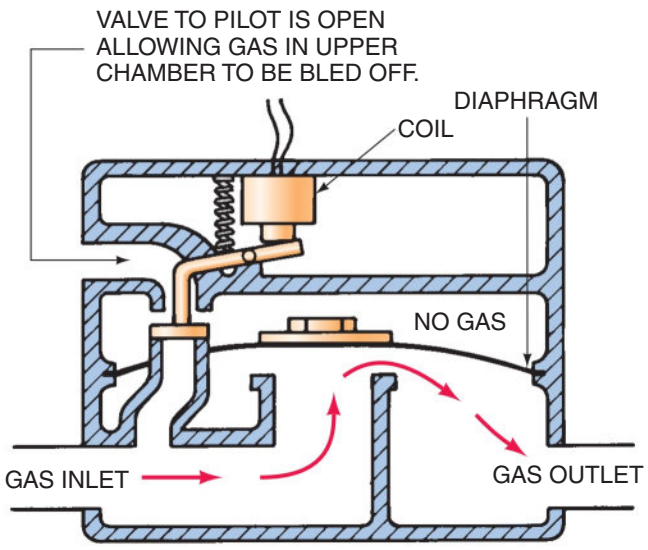


Figure 31.22 The thermally operated diaphragm gas valve.

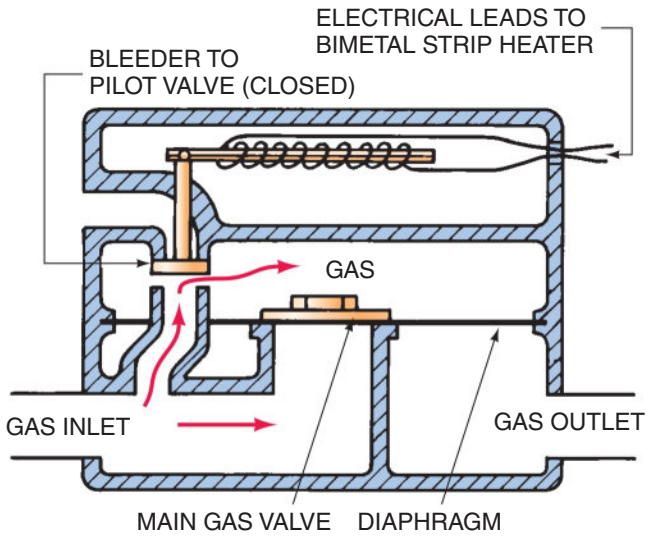

Figure 31.23 When an electric current is applied to the leads of the bimetal strip heater, the bimetal warps, closing the valve to the upper chamber and opening the valve to bleed the gas from the upper chamber. The gas pressure is then greater below the diaphragm, pushing the valve open.

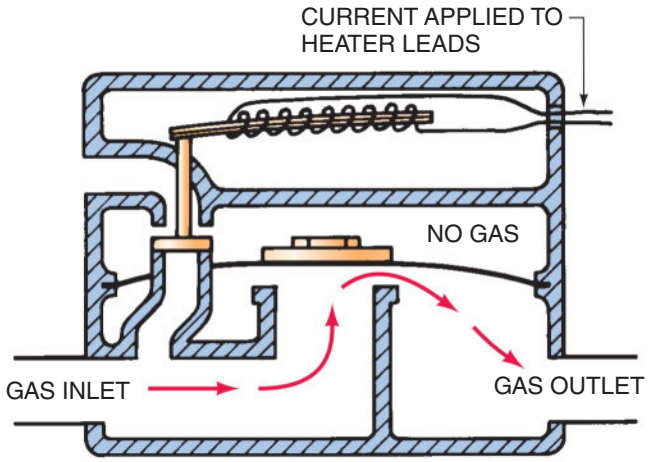

around it, **Figure 31.22.** When the strip warps, it closes the valve to the upper chamber and opens the bleed valve. The gas in the upper chamber is bled to the pilot, where it is burned, reducing the pressure above the diaphragm. The gas pressure below the diaphragm pushes the valve open, **Figure 31.23.**

31.9 HEAT MOTOR–CONTROLLED VALVE

In a heat motor–controlled valve an electric heating element or resistance wire is wound around a rod attached to the valve, **Figure 31.24.** When the thermostat calls for heat, this heating coil or wire is energized and produces heat, which expands, or

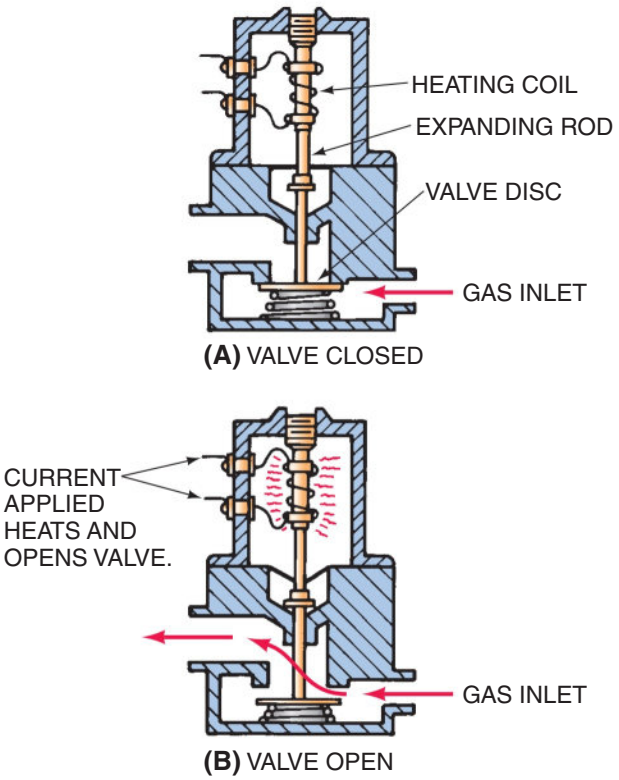

Figure 31.25 An automatic combination gas valve.

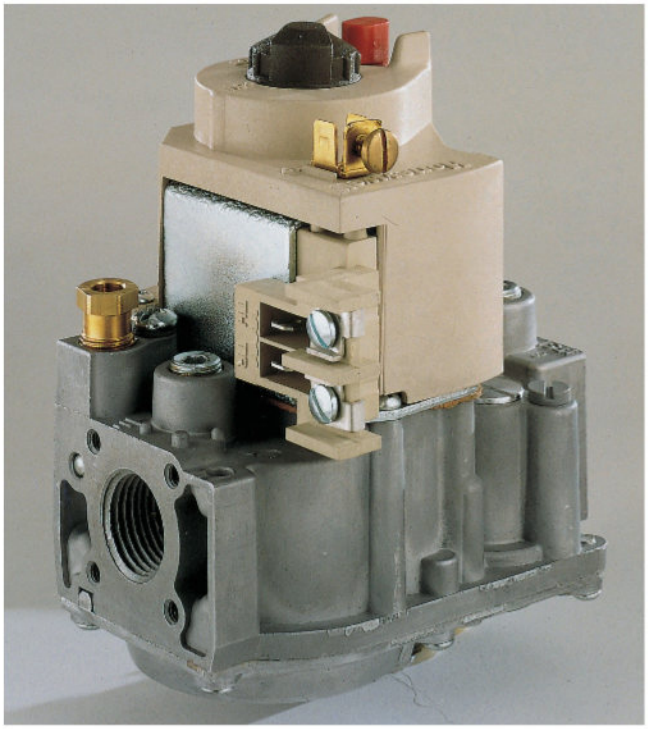

Source: Honeywell, Inc., Residential Division

elongates, the rod. When elongated, the rod opens the valve, allowing the gas to flow. As long as heat is applied to the rod, the valve remains open. When the heating coil is deenergized by the thermostat, the rod contracts. A spring will close the valve. The time it takes time for the rod to elongate and then contract varies with the particular model, but the average is 20 sec to open the valve and 40 sec to close it.

SAFETY PRECAUTION: *Be careful while working with heat motor gas valves because of the time delay. Because there is no audible click, you cannot determine the valve's position. Gas may be escaping without your knowledge.*•

31.10 AUTOMATIC COMBINATION GAS VALVE

Many modern furnaces designed for residential and light commercial installations use an automatic combination gas valve (ACGV), **Figure 31.25**, also called the redundant gas valve. These valves incorporate a manual control, the gas supply for the pilot, the adjustment and safety shutoff features for the pilot, the pressure regulator, and the controls to operate the main gas valve. They often have dual shutoff seats for extra safety protection. These valves also combine the features described earlier relating to the control and safety shutoff of the gas. Modern combination gas valves also may include programmed safe lighting features, servo pressure regulation, choices of different valve operators, and installation aids.

STANDING PILOT AUTOMATIC GAS VALVES

The internals of a typical combination gas valve for a standing pilot system are shown in **Figure 31.26**. A standing pilot system has a pilot burner that is lit all the time. The operation of the valve is described in the following paragraphs.

The power unit consists of a low-resistance coil and an iron core. When the power unit is energized, it has enough power to hold the safety shutoff valve open against its own spring pressure. If the pilot flame is ever lost, the power unit will be deenergized because the thermocouple will quickly stop generating a millivoltage as it cools. This action will stop all gas flow.

The power unit does not have enough power to pull the assembly open once closed because it is simply a holding coil. Once closed, pushing the red reset button on the combination gas valve will manually reset the unit. The red reset button can only be pushed down when it is in the pilot position. **Figure 31.27** shows how a safety shutoff mechanism assembly works, along with its shutoff circuit.

Once the gas passes the safety shutoff valve, it comes to the first automatic valve. The first automatic valve is

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Figure 31.26 A standing pilot combination gas valve with servo pressure regulation. The gas inlet is on the left of the valve. A screen or filter is usually installed at the factory to keep the valve free from dirt and miscellaneous debris. The gas then encounters the safety shutoff valve. Pushing the red reset button can manually open this valve. In fact, this is how the pilot burner is lit. Pushing the red reset button allows gas to flow to the pilot gas outlet. The pilot gas burner is then manually lit. The pilot flame engulfs the thermocouple, which starts generating a direct-current (DC) voltage. The voltage generation of a single standard thermocouple is usually 24 to 30 millivolts DC. A direct current is then generated through the thermocouple and the power unit. Thermocouples will be covered in more detail later in this unit.

NOTE: SECOND AUTOMATIC VALVE OPERATOR AND SERVO PRESSURE REGULATOR SHOWN OUTSIDE GAS CONTROL FOR EASE IN TRACING GAS FLOW.

1 SLOW-OPENING GAS CONTROL HAS A GAS FLOW RESTRICTOR IN THIS PASSAGE.

controlled by the first automatic valve solenoid coil. The closing of the room thermostat energizes its solenoid. The valve is spring loaded and opens against flowing gas pressure. When the solenoid is deenergized, the spring closes the valve. This is one of the valve's built-in safeties.

Once the room thermostat calls for heat, the first automatic valve is opened. The closing of the room thermostat also energizes the second automatic valve solenoid, which raises the second automatic operator valve disc. This in turn controls the position of the second automatic valve diaphragm. The second automatic valve diaphragm is a servo-operated valve, which means that its position is controlled by the pressure of gas coming into a chamber beneath its diaphragm. This modulates the valve diaphragm between the open and closed position. Putting more pressure under the valve diaphragm modulates the valve closed, and less pressure modulates it more to the open position.

The servo pressure regulator, an outlet or working pressure regulator, is an integral part of the second automatic gas valve. During the furnace's running cycle, the servo pressure regulator closely monitors the outlet or working pressure of the gas valve, even when inlet pressures and flow rates

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Figure 31.27 (A) A safety shutoff mechanism. (B) A safety shutoff circuit.

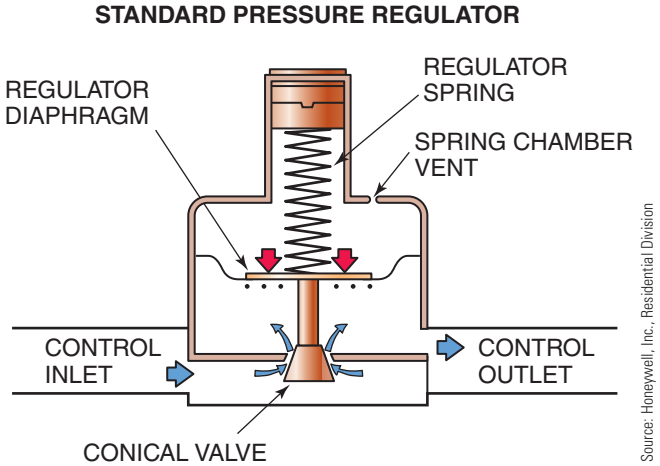
vary widely. This is quite different from a standard gas pressure regulator, which monitors the gas valve's inlet pressure, **Figure 31.28**. Any gas outlet pressure change is instantly sensed and reflected back to the diaphragm in the servo pressure regulator. The servo pressure regulator then repositions its diaphragm and disc to change the flow rate through the servo pressure regulator valve. This changes the pressure under the second automatic valve diaphragm and thus the position of the diaphragm.

If the working pressure or outlet pressure of the gas valve rises, the servo pressure regulator diaphragm moves slightly higher. This allows less gas to bleed out of the servo pressure regulator to the gas valve outlet. However, it increases the pressure under the second automatic valve diaphragm, causing the valve to close. This action reduces gas valve outlet pressure.

If the working pressure or outlet pressure of the gas valve drops, the servo pressure regulator diaphragm moves slightly lower. This allows more gas to bleed out of the servo pressure regulator to the gas valve outlet. This decreases the pressure under the second automatic valve diaphragm, causing the valve to open. This action increases gas valve outlet pressure.

The servo pressure regulation system is a self-balancing system that works off gas valve outlet or working pressure and is independent of flow rate. It can operate over a wide range of gas flow rates. The gas valve's outlet pressure is adjusted at the top of the servo pressure regulator's body. Putting more or less tension on a spring will change the outlet or working gas valve pressure.

Figure 31.28 A standard pressure regulator that monitors gas inlet pressure.



INTERMITTENT PILOT AUTOMATIC GAS VALVES

In an intermittent pilot (IP) automatic gas valve system, the pilot is lit every time there is a call for heat by the thermostat. Once the pilot is lit and proved, it lights the main burner. When the call for heat ends, the pilot is extinguished and does not relight until the next call for heat. In other words, there is automatic and independent control of the gas flow for both the pilot and the main burner.

Figure 31.29 shows the internals of a typical combination gas valve for an IP system. Note that there is no power unit or reset button. In fact, there is no thermocouple circuit either. There are simply two automatic valves. The first valve has an electric solenoid operator, and the second valve is servo operated. The passage for the pilot gas is located between these two main valves.

The first automatic valve solenoid is energized by an electronic module or integrated furnace controller (IFC) when there is a call for heat from the thermostat. This opens the passage for pilot gas to flow. The electronic module or IFC has about 90 sec to light the pilot gas. Four electronic modules and an IFC are shown in **Figure 31.30**. Once the pilot is lit and proved, usually through flame rectification, the ignition module or IFC energizes the second automatic valve solenoid. Flame rectification will be covered in detail later in this unit.

Because the second automatic valve is servo operated, the second main valve will open and the main burner will be lit.

Its servo operator will operate the same way as described earlier for the standing pilot automatic gas valve. The main burner and the pilot burner will remain lit until the room thermostat opens and the call for heat ends. Both automatic valves will close once the call for heat ends. This action will shut off the main burner and pilot burner until the room thermostat initiates another call for heat.

DIRECT BURNER AUTOMATIC GAS VALVES

In a direct burner automatic gas valve system, the electronic module or IFC lights the main burner directly without a pilot flame. A spark, a hot surface igniter, or a glow coil usually accomplishes ignition. These types of ignition will be covered in detail later in this unit. **Figure 31.31** shows the internals of a typical combination gas valve for a direct burner system. Notice that there is no power unit or reset button. There are two automatic valves, and one is servo operated. The servo-operated valve will operate the same way as described for both the standing pilot and intermittent pilot combination gas valves.

In this system, when the room thermostat calls for heat, an electronic module or IFC energizes both the first and second automatic valve solenoids at the same time along with the ignition source. Remember, there is no pilot in a direct burner system. Gas flows to the main burner and must be ignited within a short period of time, usually 4 to 12 sec. The reason for the short time period is safety, because of the large

Figure 31.31 A direct burner combination gas valve with servo pressure regulation.

flow of gas to the main burners compared to the small flow of gas to a pilot burner. Once the main burner is lit and proved, usually through flame rectification, the furnace will run until the room thermostat opens and the call for heat ends. If the main burner flame is not proved, gas flow will be shut off to the main burner through the electronic module or IFC.

Most modern combination gas valves have a built-in slow-opening feature. The second automatic valve opens slowly, letting the flame grow slowly in the main burner. This eliminates noise and concussion in the heat exchanger by giving the main burner a slow and controlled ignition. Slow opening may be accomplished through a restriction in the passage to the second automatic valve operator. This restriction controls and limits the rate at which gas pressure builds in the servo pressure regulator system. The restriction is shown in **Figure 31.26**, **Figure 31.29**, and **Figure 31.31**.

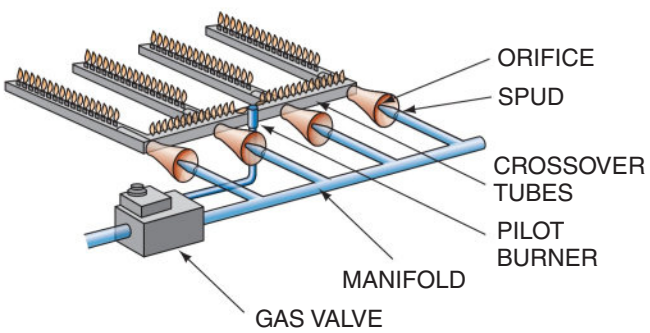
All three types of gas valves—standing pilot, intermittent pilot, and direct burner—are classified as redundant gas valves. A redundant gas valve has two or three valve operators in series physically but wired in parallel with one another. This built-in safety feature allows any operator (pilot or main) to block gas from getting to the main burner. **Figure 31.26, Figure 31.29,** and **Figure 31.31** are all examples of redundant gas valves. Most gas valves manufactured today are redundant gas valves.

SAFETY PRECAUTION: *Most combination gas valves look alike. Their model number may be the only way to differentiate them. The correct combination gas valve must be used in each application or serious injury can occur. Always contact the furnace or gas valve manufacturer if you are unsure of what gas valve to use.*•

31.11 MANIFOLD

The *manifold* in the gas furnace is a pipe through which the gas flows to the burners and on which the burners are mounted. The gas orifices are drilled into a spud, which is threaded into the manifold, and direct the gas into the venturi in the burner. The manifold is attached to the outlet of the gas valve, **Figure 31.32**.

Figure 31.32 The gas valve feeds gas to the manifold.



31.12 ORIFICE

The *orifice* is a precisely sized hole through which the gas flows from the manifold to the burners. The orifice is located in the spud, **Figure 31.9**. The spud is screwed into the manifold. The orifice allows the correct amount of gas into the burner.

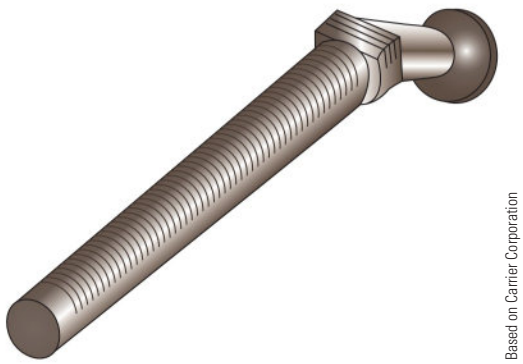
31.13 BURNERS

Gas combustion takes place at the burners. Combustion uses **primary** and **secondary air**. Primary air enters the burner from near the orifice, **Figure 31.13**. The gas leaves the orifice with enough velocity to create a low-pressure area around it. The primary air is forced into this low-pressure area and enters the burner with the gas. The procedure for adjusting the amount of primary air entering the burner is explained later in this unit.

The primary air is not sufficient for proper combustion. Additional air, called secondary air, is available in the combustion area. Secondary air is vented into this area through ventilated panels in the surface. Both primary and secondary air must be available in the correct quantities for proper combustion. The gas is ignited at the burner by the pilot flame.

The drilled-port burner is generally made of cast iron with the ports drilled. The slotted-port burner is similar to the drilled port except that the ports are slots, **Figure 31.33** and **Figure 31.34**. The ribbon burner produces a solid flame down the top of the burner, **Figure 31.35**. The single-port burner is the simplest and has, as the name implies, one port. This is often called the *inshot* or *upshot* burner, **Figure 31.36**. Most inshot burners are made of aluminized steel that has crossover porting for good flame retention, proper flame carryover to each main burner, and excellent flame stability. Inshot burners have no primary or secondary air adjustments. The burners simply slip over the orifice spuds and are screwed in place. **Figure 31.37** shows both inshot and upshot burners. Inshot burners are generally used with induced-draft systems, which pull or suck combustion gases through the heat exchanger.

Figure 31.33 A cast-iron burner with slotted ports.



Based on Carrier Corporation

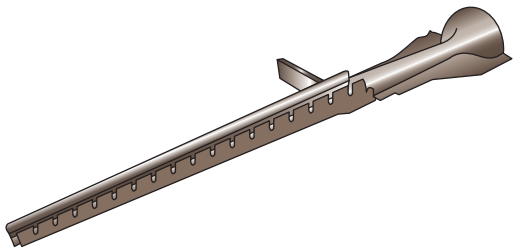
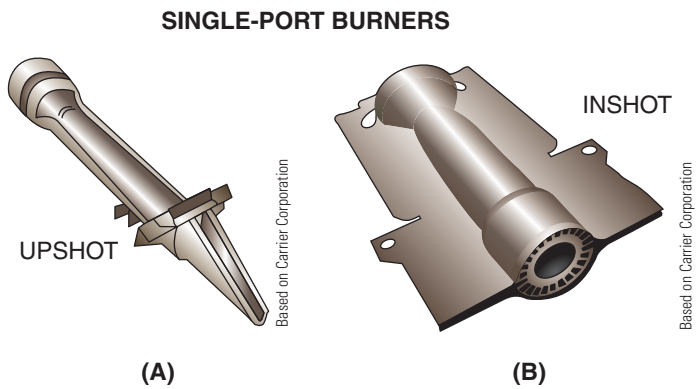
Figure 31.35 A ribbon burner.



Based on Carrier Corporation

Figure 31.36 An (A) upshot and an (B) inshot burner.



All of these burners are known as *atmospheric* burners because the air for the burning process is at atmospheric pressure. Most modern gas furnaces use either induced- or forced-draft systems. Induced-draft systems have a combustion blower motor located on the outlet of the heat exchanger. They pull or suck combustion gases through the heat exchanger, usually causing a slight negative pressure in the heat exchanger itself. Forced-draft systems have the combustion blower motor on the inlet of the heat exchanger. They push or blow combustion gases through the heat exchanger and cause a positive pressure in the heat exchanger. **Figure 31.38** shows a combustion blower motor assembly. Both induced- and forced-draft systems will be covered in detail later in this unit.

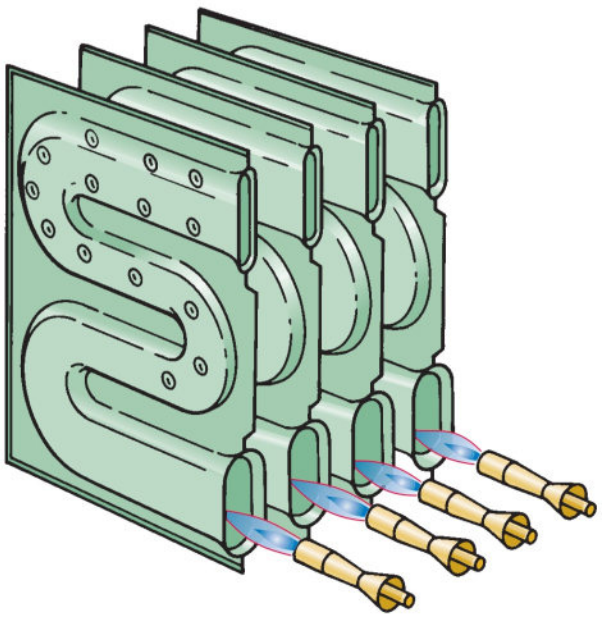
31.14 HEAT EXCHANGERS

Heat exchangers are made of sheet steel or aluminized steel and are designed to provide rapid transfer of heat from the hot combustion products through the steel to the air that will be distributed to the space to be heated. Many burners are located at the bottom of the heat exchanger, **Figure 31.39**. However, modern, high-efficiency gas furnaces have their burners located at the top of the furnace in a sealed combustion chamber, **Figure 31.40(A)**. The combustion gases are pulled or sucked through the heat exchanger. The combustion gases soon reach dew point, and liquid condensate forms and drains by gravity to a condensate sump or drain trap. The burners are located on top to allow the draining of condensate by gravity. High-efficiency furnaces will be covered in detail later in this unit. The *heat exchanger* is divided into sections with a burner in each section.

The airflow across heat exchangers must be correct or problems will occur. If too much air flows across a heat exchanger, the flue gas will become too cool and the products of combustion may condense and run down the flue pipe. These products are slightly acid and will deteriorate the flue system if not properly removed. However, high-efficiency condensing gas furnaces and their venting systems are equipped for the condensation of flue gases. Condensing furnaces will be covered in detail later in this unit.

If there is not enough airflow, the combustion chamber will overheat, and stress will occur. Furnace manufacturers print the recommended air temperature rise for most furnaces on the furnace nameplate. Normally, it is between 40°F and 70°F for a gas furnace. However, you will learn later in this unit that the nameplate's rated temperature rise is dependent on whether the furnace is standard-, mid-, or high-efficiency. The temperature rise of the furnace decreases as the efficiency increases. This can be verified by taking the return air temperature and subtracting it from the leaving-air temperature, **Figure 31.40(B)**. Be sure to use the correct temperature probe locations. Radiant heat can affect the temperature readings.

Figure 31.39 A heat exchanger with four sections.



The following formula may be used to calculate the exact airflow across a gas furnace:

$$\text{cfm} = \frac{Q_x}{1.08 \times \text{TD}}$$

where Q_s = Sensible heat in Btu/h
cfm = Cubic feet of air per minute
1.08 = Constant used to change cfm to pounds of air per minute for the formula
TD = Temperature difference between supply and return air

This requires some additional calculations because gas furnaces are rated by the input. If a gas furnace is 80% efficient during steady-state operation, you may multiply the input times the efficiency to find the output. For example, if a gas furnace has an input rating of 80,000 Btu/h and a temperature rise of 55°F, how much air is moving across the heat exchanger in cfm? The first thing we must do is find out what the actual heat output to the airstream is: 80,000 × 0.80 (80% estimated furnace efficiency) = 64,000 Btu/h. Use this formula:

$$\text{cfm} = \frac{Q_x}{1.08 \times \text{TD}}$$

$$\text{cfm} = \frac{64{,}000}{1.08 \times 55}$$

$$\text{cfm} = 1077.4$$

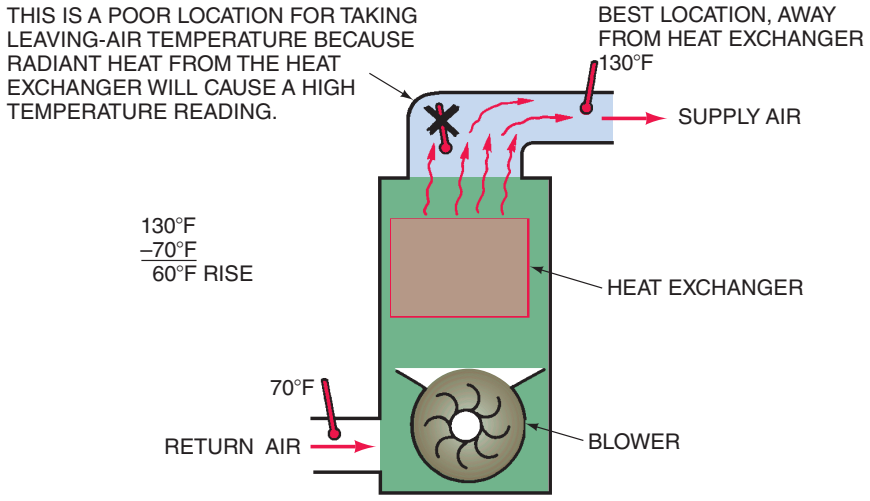
There is some room for error in the calculation unless you take several temperature readings at both the supply and return ducts and average them. The more readings you take, the more accurate your answer. Also, the more accurate your thermometer is, the more accurate the results. Glass stem thermometers graduated in ¼-degree increments are preferred. There is also the heat added by the fan motor to consider. This will be about 300 W for a furnace this size. If you will multiply 300 W × 3.413 Btu/W, you will find that some extra heat is added to the air: 300 × 3.413 = 1023.9 Btu. For an even more accurate reading, you may take a watt reading of the motor or multiply the amperage reading times the applied voltage for a watt reading approximation:

$$\text{Watts} = \text{Amperage} \times \text{Applied Voltage}$$

Poor combustion can corrode the heat exchanger, so good combustion is preferred. The steel in the exchangers may be coated or bonded with aluminum, glass, or ceramic material. These materials are more corrosion resistant, so the unit will last longer. Some exchangers are made of stainless steel, which is more expensive but resists corrosion extremely well.

Figure 31.40 (A) A high-efficiency furnace with burners on top of the heat exchanger. (B) Checking the air temperature rise across a gas furnace.

(A)



(B)

SAFETY PRECAUTION: *The exchanger must not be corroded or pitted enough to leak since one of its functions is to keep combustion gases separated from the air to be heated and circulated throughout the building.*•

Modern heat exchangers come in many sizes, shapes, and materials. **Figure 31.41** shows a heat exchanger with both L-shaped and S-shaped tubes made of aluminized steel. The S tubes are smaller than the L tubes. The combustion gases travel a serpentine path. The L tubes carry the hot combustion gases to a transition box. The S tubes then carry the combustion gases from the transition box to a collection box. The collection box directs the combustion gases to an induced-draft centrifugal fan and then to the furnace's vent. The transition box is usually made of a highly corrosion-resistant stainless steel because it may see some condensation. The tubes are often swaged to the connection and transition boxes. The collection and transition box flanges are crimped for a tight fit.

Condensing furnaces may have three heat exchangers. The third or tertiary heat exchanger is typically made of stainless steel or aluminum to resist corrosion from the slightly acidic condensate, **Figure 31.42**. It may also have extended surfaces or fins for better heat conduction to the heating air. This condensing heat exchanger is designed to intentionally handle condensate and eventually drain it away

Figure 31.41 (A) A modern heat exchanger showing L and S tubes, a transition box, and a collection box. (B) A close-up of S tubes, a transition box, and a collection box.

Source: Bryant Heating and Cooling Systems

from the furnace. One side of the heat exchanger has a plastic condensate drain header. Some high-efficiency condensing furnaces have only two heat exchangers. If this is the case, the second heat exchanger is the condensing heat exchanger. **Figure 31.43** shows a high-efficiency condensing gas furnace with only two heat exchangers. The polypropylene plastic laminate coating of the second heat exchanger resists corrosion from the slightly acidic condensate.

Because of the serpentine path of combustion gases in most modern heat exchangers, they do not lend themselves well to the ribbon and slotted types of burners found in most traditional standard- and mid-efficiency furnaces, **Figure 31.34** and **Figure 31.35**. One of the main reasons for this is the height of the flame in the ribbon and slotted-port burners. Flame impingement would occur in the tubelike passages of these modern heat exchanger surfaces if ribbon or slotted-port burners were used. Also, if ribbon or slotted burners were used with modern, tube-style heat exchangers, the secondary combustion air would flow at right angles to the burner flame. This would cause the flame to be pulled off the ribbon or slotted-port burner. It is for these reasons that the inshot burner is used with tube-style heat exchangers. The inshot burner, sometimes called a *jet burner*, fires a flame straight out its end, making it ideal for modern, tube-style serpentine heat exchangers, **Figure 31.37(B)**.

31.15 FAN SWITCH

The fan switch automatically turns the blower on and off. The blower circulates the heated air to the conditioned space. The switch can be temperature controlled or on a time delay. In either instance, the heat exchanger is given a chance to heat up before the fan is turned on. This delay keeps cold air from being circulated through the duct system at the beginning of the cycle before the heat exchanger gets hot. The heat exchanger must be hot in a conventional furnace because the heat provides a good draft for properly venting the combustion gases. There is also a delay in shutting off the fan. This allows the heat exchanger time to cool off and dissipate the furnace heat at the end of the cycle.

The temperature-sensing element of the switch, usually a bimetal helix, is located in the airstream near the heat exchanger, **Figure 31.44**. When the furnace comes on, the air is heated, which expands the bimetal and closes the contacts, thus activating the blower motor. This is called a *temperature on–temperature off* fan switch.

The fan switch could activate the blower with a time delay and shut it off with a temperature-sensing device. When the thermostat calls for heat and the furnace starts, a small resistance heating device is activated. This heats a bimetal strip that, when heated, will close electrical contacts

(C)

to the blower. This provides a time delay and allows the furnace to heat the air before the blower comes on. The bimetal helix in the airstream keeps the contacts closed even after the room thermostat is satisfied and the burner flame goes out. When the furnace shuts down, the bimetal cools at the same time as the heat exchanger and turns off the blower. This fan switch provides a positive starting of the fan and stops it by temperature and is called a *time on–temperature off* switch.

A third type of switch, called a *time on–time off* switch, uses a small heating device, such as the one used in the time on–temperature off switch. The difference is that this switch is not mounted in such a way that the heat exchanger heat will influence it. The time delay is designed into the switch and is not adjustable. Most models of the other two types of switches are adjustable.

Many modern gas furnaces use electronic modules or IFCs to control the fan or blower's off–delay timing. **Figure 31.45(A)** shows an electronic module that uses dual in-line pair (DIP) switches to control the fan's off–delay time. The on–delay timing is set at 30 sec and is nonadjustable. The service technician cannot control when the fan will come on once the burners light, which for the heating cycle will always be within 30 sec. However, the technician can adjust

the fan or blower's off–delay timing when the fan shuts off once the burners shut off. The four configurations for the DIP switches in **Figure 31.45(B)** let the fan have a 60-, 100-, 140-, or 180-sec on–time period after the burners shut off to cool down the heat exchanger. This electronic module also controls the self-diagnostic functions of the gas furnace. IFCs often have nonadjustable fixed timing periods for blower on and off delays, which are programmed into their software, **Figure 31.30(A)**. Because there are many manufacturers of gas furnaces, the service technician must understand the furnace's sequence of operation, including the blower's on and off times and delays.

31.16 LIMIT SWITCH

The *limit switch* is a safety device. If the fan does not come on or if there is another problem causing the heat exchanger to overheat, the limit switch will open its contacts, which closes the gas valve. **SAFETY PRECAUTION:** *Almost any circumstance causing a restriction in the airflow to the conditioned space can make the furnace overheat, for example, dirty filters, a blocked duct, closed dampers, fan malfunctions, or a loose or broken fan belt. The furnace may also be overfired due to an improper setting or malfunctioning of the gas valve. It is extremely important that the limit switch operate as it is designed to do.*•

The limit switch has a heat-sensing element. When the furnace overheats, this element opens contacts, thus directly or indirectly closing the main gas valve. This switch can be combined with a fan switch, **Figure 31.46(A)**. Different state codes have different high-limit cut-out requirements, often around 200°F to 250°F. The combination fan and high-limit control in **Figure 31.46(B)** can be a high-voltage, low-voltage, or combination high- and low-voltage control. The actions of both the fan and the high-limit contacts are controlled by the same helical bimetal positioned next to the heat exchanger, **Figure 31.44(C)**. The combination control can be easily retrofitted for different voltages in the field. If the furnace's circuit calls for both the high-limit and fan control contacts to be high voltage, a jumper tab must remain in place in the fan/limit switch control, **Figure 31.46(B)**. However, if the furnace's circuit calls for a high-voltage fan control and a low-voltage limit control, the jumper tab must be removed to separate the different voltages. This makes the control more versatile for circuit wiring purposes. **SAFETY PRECAUTION:** *Always read the manufacturer's literature for the contact's voltage rating before wiring or retrofitting any furnace control. Failure to do so may lead to a fire or explosion.*•

Many modern gas furnaces use snap-action, bimetallic, high-limit controls located in close proximity to the heat exchanger, **Figure 31.47**. These disks are set to snap open at a certain temperature dictated by the furnace manufacturer. Most high-limit controls will automatically reset back to the closed position when cooled to a certain temperature. However, some must be manually reset. Bimetallic, snap-action disks are also used as flame rollout safety controls, but they usually have to be manually reset. An example is shown in **Figure 31.48**. Notice that it is wired in series with the high-limit control. If either of these controls overheats and opens its contacts, the circuit to the main gas valve will be interrupted. The stem coming out of the disk must be pushed in once the control has cooled down.

This resets the control. Manual reset requires a service call by a technician to troubleshoot why the furnace has flame rollout problems.

31.17 PILOTS

Pilot flames are used to ignite the gas at the burner on most conventional gas furnaces. Pilot burners can be aerated or nonaerated. In the aerated pilot, the air is mixed with the gas before it enters the pilot burner, **Figure 31.49**. However, the air openings often clog and require periodic cleaning if there is dust or lint in the air. Nonaerated pilots use only secondary air at the point where combustion occurs. They need little maintenance, so most furnaces are equipped with nonaerated pilots, **Figure 31.50**.

(B)

The pilot is actually a small burner, **Figure 31.51**. It has an orifice, similar to the main burner, through which the gas passes. If the pilot goes out or does not perform properly, a safety device will stop the gas flow. *Standing* pilots burn continuously; other pilots are ignited by an electric spark or other ignition device when the thermostat calls for heat. In furnaces without pilots, the ignition system ignites the gas at the burner. In furnaces with pilots, the pilot must be ignited and proved to be burning before the gas valve to the main burner will open. The pilot burner must direct the flame so that there will be ignition at the main burners, **Figure 31.52**. The pilot flame also provides heat for the safety device that shuts off the gas flow if the pilot flame goes out.

31.18 SAFETY DEVICES AT THE STANDING PILOT

Three main types of safety devices, called *flame-proving* devices, keep the gas from flowing through the main valve if the pilot flame goes out: the thermocouple or thermopile, the bimetallic strip, and the liquid-filled remote bulb.

THERMOCOUPLES AND THERMOPILES

The *thermocouple* consists of two dissimilar metals welded together at one end, **Figure 31.53**, called the "hot junction." When this junction is heated, it generates a small voltage (approximately 15 mV with load; 30 mV without load) across the two wires or metals at the other end, called the "cold junction." The thermocouple is connected to a shut-off valve, **Figure 31.54**. As long as the electrical current in the thermocouple energizes a coil, the gas can flow. If the flame goes out, the thermocouple will cool off in about 30 to 120 sec, and no current will flow and the gas valve will close.

A *thermopile* consists of several thermocouples wired in series to increase the voltage. A thermopile performs the same function as the thermocouple, **Figure 31.55**.

BIMETALLIC SAFETY DEVICE

In the *bimetallic* safety device the pilot heats the bimetal strip, which closes electrical contacts wired to the gas safety valve, **Figure 31.56(A)**. As long as the pilot flame heats the bimetal, the gas safety valve remains energized and gas will flow when called for. When the pilot goes out, the bimetal strip cools within about 30 sec and straightens, opening contacts and causing the valve to close, **Figure 31.56(B)**.

LIQUID-FILLED REMOTE BULB

The *liquid-filled remote bulb* includes a diaphragm, a tube, and a bulb, all filled with a liquid, usually mercury. The remote bulb is positioned so as to be heated by the pilot flame, **Figure 31.57**. The pilot flame heats the liquid and the liquid expands, causing the diaphragm to expand, which closes contacts wired to the gas safety valve. As long as the pilot flame is on, the liquid is heated and the valve is open, allowing gas to flow. If the pilot flame goes out, the liquid cools in about 30 sec and contracts, opening the electrical contacts and closing the gas safety valve.

31.19 IGNITION SYSTEMS

Ignition systems can ignite either a pilot or the main burner. They can be divided into three categories:

- Intermittent pilot (IP)
- Direct-spark ignition (DSI)
- Hot surface ignition (HSI)

Figure 31.56 (A) When the pilot is lit, the bimetal warps, causing the contacts to close. The coil is energized, pulling the plunger into the coil, opening the valve, and allowing the gas to flow to the main gas valve. (B) When the pilot is out, the bimetal straightens, opening the contacts. The safety valve closes. No gas flows to the furnace burners. (C) A bimetallic safety device assembly.

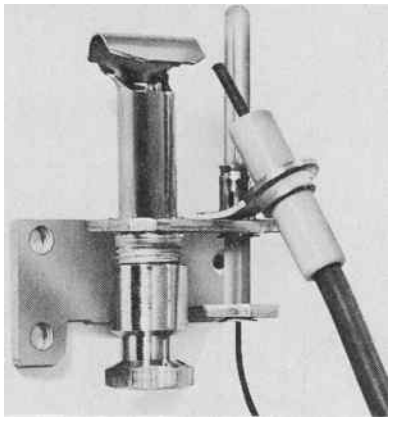
(B)

INTERMITTENT PILOT (IP) IGNITION

In the intermittent pilot or spark-to-pilot gas ignition systems, a spark from the electronic module ignites the pilot, which ignites the main gas burners, **Figure 31.58**. The pilot burns only when the thermostat calls for heat. This system is popular because fuel is not wasted by the pilot burning when not needed. Two types of control schemes are used with this system. One, used a lot with natural gas, is not considered a 100% shutoff system. If the pilot does not ignite, the pilot valve will remain open, the spark will continue, and the main gas valve will not open until the pilot is lit and proved. The other type of system is used with LP gas and some natural gas applications and is a 100% shutoff system. If there is no pilot ignition, the pilot gas valve will close and may go into safety lockout after approximately 90 sec, and the spark will stop. Safety lockout systems will be covered in detail later in this unit. This system must be manually reset, usually at the thermostat or power switch.

Figure 31.58 A spark-to-pilot ignition system.



Courtesy Robertshaw Controls Company

The 100% shutoff control system is necessary for any gas fuel heavier than air, because the fuel will accumulate in low places. Even the small amount of gas from a pilot light could be dangerous over time. Natural gas rises up through the flue system and is not dangerous in small quantities, such as the volume from a pilot light. Even though natural gas is lighter than air, some codes do call for 100% shutoff control. All technicians who service fuel gas products should be totally aware of the local codes. Both 100% shutoff and less than 100% shutoff systems will be covered in detail later in this unit.

When there is a call for heat in a natural gas system, contacts will close in the thermostat, providing 24 V to the ignition module, which will send power to the pilot igniter and to the pilot valve coil. The coil opens the pilot valve, and the spark ignites the pilot. Once the pilot flame is lit, it must be proved. Flame rectification is the fastest, safest, and most reliable method for proving a flame.

In the *flame rectification* system, the pilot flame changes the normal alternating current to direct current. The electronic components in the system will energize and open the main gas valve only with a direct current, measured in microamps. It is important that the pilot flame quality be correct to ensure proper operation. Consequently, the main gas valve will open only when pilot flame is present. Flame rectification will be covered in detail later in this unit.

The spark is intermittent and arcs approximately 100 times per minute. It must be a high-quality arc, or the pilot will not ignite. The arc comes from the control module and is very high voltage. The voltage can reach 10,000 V in some systems but is usually very low amperage. A direct path to earth ground must be provided because the arc actually arcs to ground. A ground strap near the pilot assembly or the pilot hood often acts as ground, **Figure 31.59**.

DIRECT-SPARK IGNITION (DSI)

Many modern furnaces are designed with a spark ignition direct to the main burner or a ground strap, **Figure 31.59**.

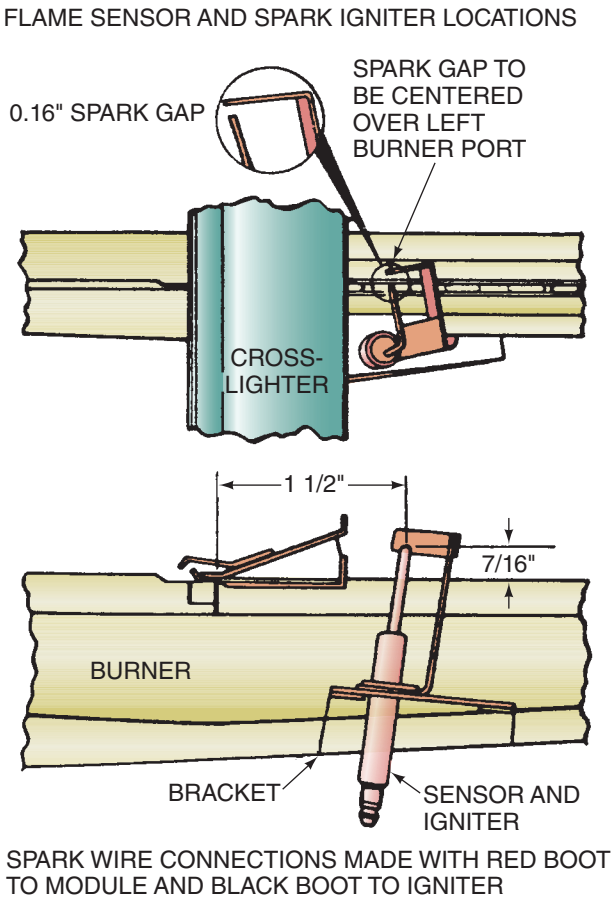
Figure 31.60 The spark gap and igniter position for a DSI system.



No pilot is used in this system. System components are the igniter/sensor assembly and the DSI module. The sensor rod verifies that the furnace has fired and sends a microamp signal through flame rectification to the DSI module confirming this. The furnace will then continue to operate. This system goes into a "safety lockout" if the flame is not established within the "trial for ignition" period (approximately 4 to 11 sec). Gas is being furnished to the main burner, so there cannot be as much time delay as there is in the 90-sec ignition trial for IP systems. The system can then only be reset by turning the power off to the system control and waiting 1 min before reapplying the power. This is a "typical" system. The technician should follow the wiring diagram and manufacturer's instructions for the specific furnace being installed or serviced.

Most ignition problems are caused from improperly adjusted spark gap, igniter positioning, and bad grounding, **Figure 31.60**. The igniter is centered over the left port. Most manufacturers also provide specific troubleshooting instructions. Once the main burner flame is proved by the flame rectification system, the sparking will stop. If the sparking does not stop once the main burner is lit, the electronic DSI module could be defective. The continual sparking may not be harmful to the system, but it is noisy and often can be heard in the living or working area. Read and follow the manufacturer's instructions to repair the system.

HOT SURFACE IGNITION (HSI)

The hot surface ignition (HSI) system uses a special product called silicon carbide that offers a high resistance to electrical current flow but is very tough and will not burn up, like a glow coil. This substance is placed in the gas stream and is allowed to get very hot before the gas is allowed to impinge on the glowing hot surface. Immediate ignition should occur when the gas valve opens.

The hot surface igniter is usually operated off of 120 V, the line voltage to the furnace, and draws considerable current when energized. It is energized for only a short period of time during start-up of the furnace, so this current is not present for more than a very few minutes per day. **Figures 31.61(A)**, **(B)**, and **(C)** shows the hot surface igniter. Some HSI systems operate on 24 V. These systems are usually hot surface to pilot, meaning that the 24-V hot surface igniter lights a pilot flame, **Figure 31.61(D)** and **Figure 31.61(E)**. For many decades the pilot flame has been the most reliable ignition source for lighting the main burner. Also, a low-voltage hot surface igniter lowers the chance of a high-voltage electrical shock.

Even though the HSI system has been used successfully for many years, some problems do occur. The igniter is very brittle and breaks easily. If you bump it with a screwdriver, it will break. Newer hot surface igniters are made of a different material that does not break as easily as older ones. However, care should still be taken when working around hot surface igniters because of their fragile nature. If repeated failures occur with an HSI system, look for the following:

- Higher-than-normal applied voltage. Voltage that is in excess of 125 V can shorten the igniter's life.

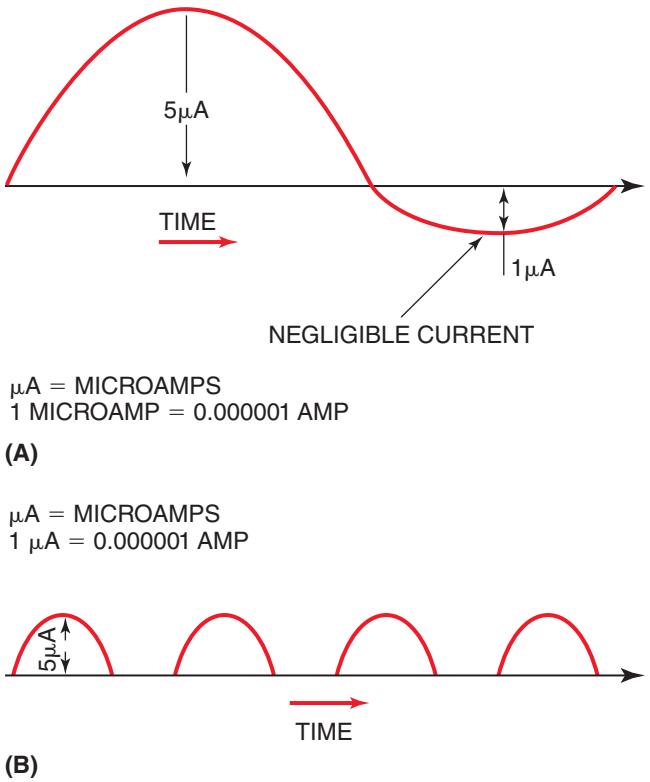
- Accumulation of drywall dust, fiberglass insulation, or sealant residue.
- Stress caused by the small explosion due to delayed ignition.
- Overfiring condition.
- Furnace short cycling as with a dirty filter, which may cause the furnace to cycle on high limit.

The hot surface igniter may be used for lighting the pilot or for direct ignition of the main furnace burner. When it is used as the direct igniter for the burner, it will have very little time, usually 4 to 11 sec, to ignite the burner; then a safety lockout will occur to prevent too much gas from escaping.

31.20 FLAME RECTIFICATION

In the flame rectification system, the pilot flame, or main flame, can conduct electricity because it contains ionized combustion gases, which are made up of positively and negatively charged particles. The flame is located between two electrodes of different sizes. The electrodes are fed with an alternating-current (AC) signal from the furnace's electronic module. Due to the different size of the electrodes, current will flow better in one direction than in the other, **Figure 31.62(A)**. The flame actually acts as a switch. If there is no flame, the switch is open and electricity will not flow. When the flame is present, the switch is closed and will conduct electricity.

Figure 31.62 (A) The different sizes of the electrodes cause current to flow better in one direction than the other. (B) A pulsating direct-current (DC) signal that can be measured in microamps with a microammeter in series with one of the electrodes.



The two electrodes in a spark-to-pilot (intermittent pilot) ignition system are the pilot hood (earth ground) and a flame rod or flame sensor, **Figure 31.63**. In a DSI system, the two electrodes can be the main burners (earth ground) and a flame rod or sensor. These types of systems are often referred to as dual-rod, or remote, sensing systems; one rod senses the flame and the other is used for ignition. However, the flame rod or sensor can also be part of the ignition system and is referred to as a combination sensor and igniter, **Figure 31.60**. This type of system is referred to as a single-rod, or local, sensing system because it has a combination sensor and igniter in one rod.

As alternating current switches the polarity of the electrodes 60 times each second, the positive ions and negative electrons move at various speeds to the different-size electrodes. This produces a rectified AC signal, which looks much like a pulsating DC signal, because the positively charged particles (ions) are relatively larger, heavier, and slower than the negatively charged particles (electrons), **Figure 31.62(B)**. In fact, the electrons are about 100,000 times lighter than the ions. This DC signal is the only signal the electronics of the furnace recognize. It is proof that a flame exists, rather than a short resulting from humidity or direct contact between the electrodes. The DC signal can be measured with a microammeter in series with one of the electrode leads. It usually ranges between 1 and 25 microamps. The magnitude of the microamp signal may depend on the quality, size, and stability of the flame and on the electronic module and electrode design. Always consult with the furnace manufacturer for specific information on flame rectification measurements.

Humidity or direct contact between the electrodes would cause an AC current to flow, which would not be recognized by the furnace's electronic module. An AC signal thus prevents the main gas valve from opening in a spark-to-pilot system. It shuts down the main gas in a DSI system once the time period for ignition has elapsed and may put the furnace in a lockout mode.

Single-rod, or local, sensing consists of an igniter and a sensor all in one rod, often referred to as a one-rod pilot. Single-rod flame rectification systems accomplish both ignition and sensing. There is only one wire, which is the large ignition wire, running from the pilot assembly to the ignition module, **Figure 31.64**. This high-voltage lead does both the sparking and the sensing. The ignition pulse occurs during one half cycle and the sensing pulse current occurs on the other half cycle, **Figure 31.65**. Signal analyzers within the electronic module can differentiate between the two signals.

Dual-rod, or remote, sensing uses separate igniter and flame-sensing rods or electrodes, **Figure 31.66**. The sparking is accomplished with one rod and the sensing is done with the other rod. There are two wires running from the pilot assembly to the module. The spark electrode wire goes to the spark

Figure 31.63 An intermittent pilot dual-rod system showing the pilot hood and the flame sensor rod as the two electrodes for flame rectification. Dual-rod systems are often referred to as remote sensing systems.

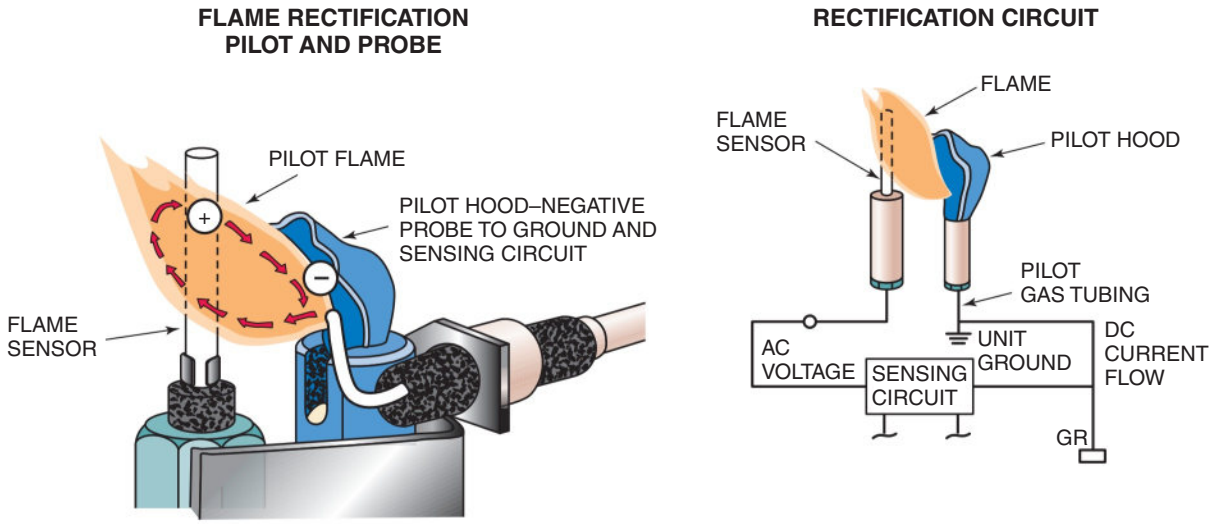

Figure 31.64 A single-rod, or local, sensing system connected to a furnace electronic module.

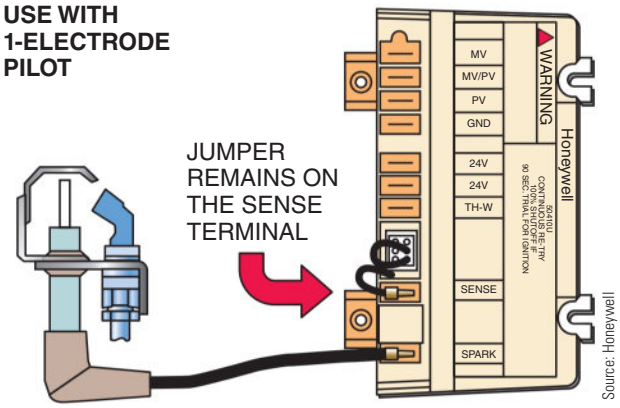

Figure 31.65 Single-rod, or local, flame rectification sensing system senses flame current during one half cycle and the ignition pulse during the other half cycle.

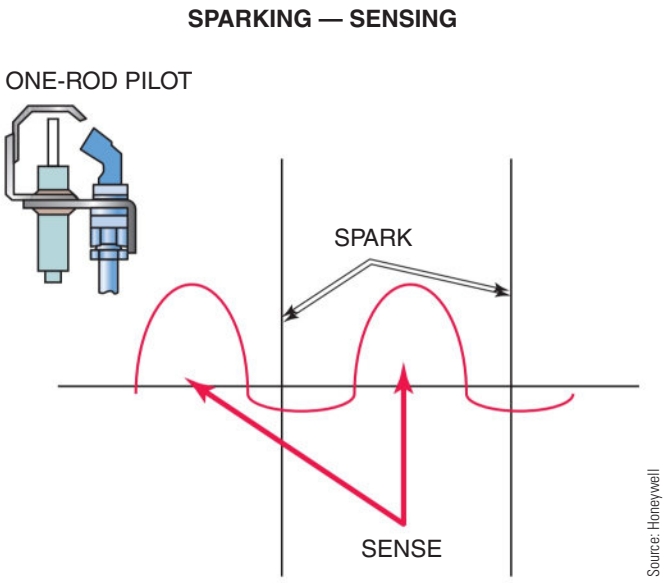

terminal on the module. The flame rod or sensing wire goes to the sensing terminal. A jumper wire will have to be cut off on some models, **Figure 31.67**. The flame sensor works with the grounded burner hood and the ground strap to achieve flame rectification.

The preceding examples describe only a few of the furnace modules seen in the field today. Many newer furnaces have much more sophisticated IFCs. However, the principles of flame rectification still hold true.

TROUBLESHOOTING FLAME RECTIFICATION SYSTEMS

Troubleshooting a flame rectification system must be handled in steps. If the pilot flame or main flame does not light during a normal call for heat, the problem is not in the flame rectification system. It would be in the ignition system, because there must be a flame for there to be a problem in the flame rectification system. If a flame is present but goes out because the system shuts off the gas valve, there could be one of several problems with the flame-sensing system:

- The flame electrodes could be dirty or corroded.
- A wire may be disconnected.
- The flame rod may not be engulfed by the flame.
- The flame signal amplifier (module or IFC) may have failed.
- There may be a poor ground wire connection.

Figure 31.66 A dual-rod, or remote, flame rectification sensing system showing a separate igniter spark electrode and a flame sensing rod.

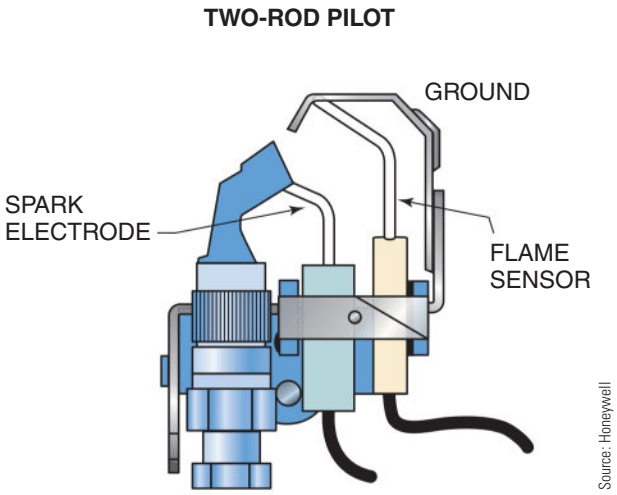

Figure 31.67 A dual-rod, or remote, flame rectification sensing system showing two separate wires going to the electronic furnace module.

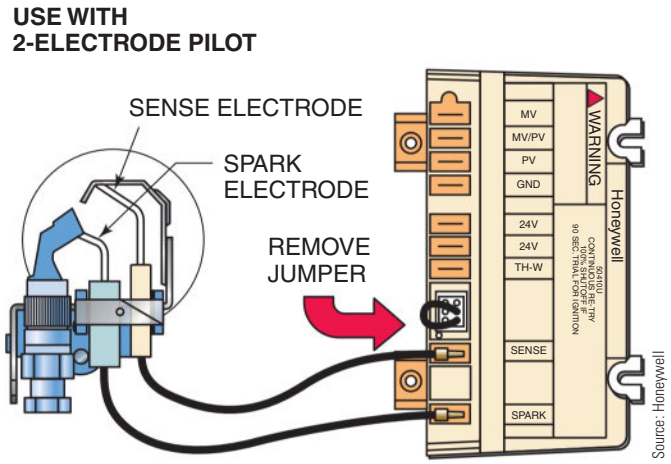

The service technician must understand the ignition control sequence to determine whether the ignition source is working. The system may have either a spark or hot surface ignition element, so it is of utmost importance to know the sequence of events of the particular ignition module or IFC. If the ignition sequence seems to be fine but the pilot or main burner does not ignite, the problem is not flame rectification. It could be one of the following:

- Misadjusted pilot burner
- Out-of-place ignition source
- Low or no gas pressure
- Lack of power to the system
- Insufficient spark or insufficient power to the hot surface element
- Broken or disconnected wires or cables
- Broken electrode or HSI element

FLAME RECTIFICATION MAINTENANCE

Several factors can affect the very small flame current. Remember that this current is measured in DC microamps; 1 microamp equals 0.000001 amp. The following are some factors to consider in basic maintenance:

- Wires should be replaced every 3 to 5 years.
- Wiring between the flame electrodes and the ignition module or IFC should be as short as possible.
- Electrodes must be replaced if there are signs of bending, warping, or deterioration.
- Burner gas pressure must be correct. Poor flame contact with the metal burner components can cause failure.
- Over time, silicon contamination from the outgassing of the ignition cable or ordinary room dust, which is typically high in silicon, can cause an insulating material to build up on the sensing electrode or ground terminal.
- Aluminum oxides can also build up on the surface of the sensing electrode. The source of the aluminum can be the sensing electrode itself. Most flame rods are made of a Kanthol element, which contains aluminum and gives the rod the ability to withstand high temperatures.

MEASURING FLAME CURRENT

A microammeter placed in series with the flame rod or system ground can measure the small current produced by the flame. It is usually easier to place the meter in series with the wire coming from the burner ground terminal to the module or IFC, **Figure 31.68**.

Figure 31.68 A microammeter placed in series with the flame rod or system ground will measure DC microamps of flame rectification.

31.21 HIGH-EFFICIENCY GAS FURNACES

In addition to their efficiency, the lack of sidewall venting material for mid-efficiency furnaces has made high-efficiency gas furnaces popular. Stack temperatures are the limiting factor for sidewall venting. Sidewall venting in high-efficiency furnaces involves inexpensive materials like polyvinyl chloride (PVC). In addition, high-efficiency furnaces are quiet and energy-efficient due to their sealed combustion chamber, shown in **Figure 31.69**. These furnaces also lower gas bills. Because the sealed combustion chamber uses outside air and never receives conditioned room air, there is less outdoor air infiltration into the indoor heated space. The heated, conditioned room air is not pulled into a slight vacuum—that is, depressurized—by being used as combustion air, which would allow cold outdoor air to infiltrate the heated space.

HIGH-EFFICIENCY GAS FURNACE ANATOMY

High-efficiency gas furnaces have some unique characteristics compared to conventional and mid-efficiency gas furnaces:

- A "recuperative" or "secondary" (and sometimes "tertiary") heat exchanger with connecting piping for flue-gas passages from the primary heat exchanger
- A flue-gas condensate disposal system, which includes drain, taps, drain lines, and drain traps, **Figure 31.70(A)**
- A venting system that is drafted by either induced or forced power, **Figure 31.70(B)**

A direct-vented, high-efficiency gas furnace has a sealed combustion chamber. This means that the combustion air is brought in from the outside through an air pipe, which is usually made of PVC plastic, **Figure 31.71**. *The combustion chamber never sees conditioned room air. Since conditioned room air is not used for combustion, it prevents the conditioned room from being depressurized or pulled into a slight vacuum. This cuts down on the amount of infiltration entering the room, and less cold, infiltrated air has to be reheated.*

Figure 31.69 A sealed combustion chamber on a high-efficiency furnace.

Courtesy Ferris State University, Photo by John Tomczyk

Direct venting also minimizes the interaction of the furnace with other combustion sources. Depressurization of a building or home may lead to products of combustion entering the building through the vent systems of water heaters and clothes driers. (*Depressurization* is the term for rooms that have lost pressure and are in a slight vacuum.) Even toxic fumes and particulates from a connecting or attached garage or building can infiltrate a conditioned space when it is depressurized. A high-efficiency furnace that is not direct-vented uses indoor conditioned air for combustion. A room can become depressurized using such a system. These are reasons why the direct venting of a furnace is an added safety feature. Both direct-vented and non-direct-vented systems can be positive pressure systems and vented vertically or through the sidewall. The flue pipe in a positive pressure system has positive pressure its entire distance to its terminal end. However, not all direct-vented systems are positive pressure systems.

Some direct-vented designs need stronger flue fans or combustion blowers to overcome the additional pressure drop created by the sealed combustion chamber of the high-efficiency furnace and the additional combustion air pipe. In fact, the combustion blower must overcome three system pressure drops:

- Pressure drops from the heat exchanger system
- The pressure drop from the vent system (vent and combustion air pipe)
- Vent termination wind resistance pressure

Combustion blower motors use an air-proving switch or pressure switch to prove that the mechanical draft has been established before allowing the main burner to light, **Figure 31.70(B)**. The pressure switches are connected to the combustion blower housing or heat exchanger (burner box) by rubber tubing. These pressure switches have diaphragms that are sensitive to pressure differentials. Some furnaces use a single-port pressure switch that senses the negative pressure inside the heat exchanger caused by an induced-draft combustion blower. Others use a dual-port, or differential, pressure switch that senses the difference in pressure between the combustion blower and the burner box, **Figure 31.70(C)** and **Figure 31.70(D)**.

When the venting system is operating properly, sufficient negative pressure is created by the combustion blower to keep the pressure switch closed and the furnace operating. However, if the heat exchanger has a leak or the furnace vent pipe is blocked, the pressure switch will open from insufficient negative pressure. This will interrupt the operation of the main burners.

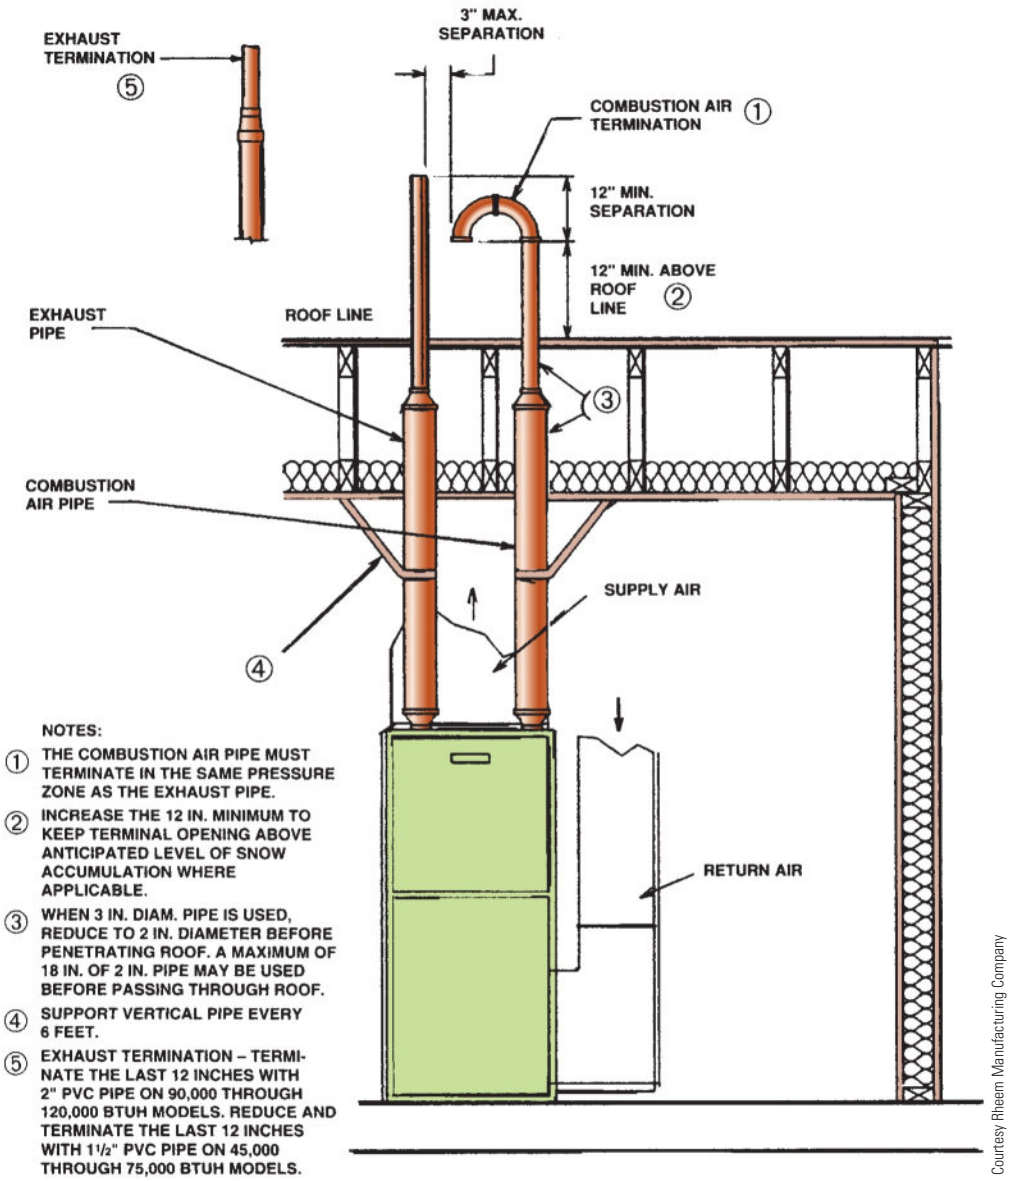
Figure 31.71 A direct-vented, high-efficiency gas furnace.



Different furnace manufacturers use different settings for their pressure switches. The settings are usually measured in inches of water column and are sometimes indicated on the pressure switch housing. Pressures can be measured using a digital or liquid-filled manometer.

SAFETY PRECAUTION: *Never replace a pressure switch with another switch without knowing its operating pressures. Always consult with the furnace manufacturer or use a factory-authorized substitute pressure switch.*•

DEW POINT TEMPERATURE

Water vapor is a combustion by-product when natural gas is burned. More than 2 lb of water vapor is produced for every 1 lb of natural gas burned. This water vapor contains heat. If it can be condensed, it will give off latent heat. The dew point temperature (DPT) is the temperature at which the condensation process begins. In flue gas, the DPT varies depending on the composition of the gas and the amount of excess air (combustion air and dilution air).

For every 1 lb of water vapor that is condensed into liquid, about 970 Btu are given off. This is the latent heat of condensation of water vapor at atmospheric pressure. The latent heat adds significantly to the efficiency of the condensing furnace. The condensate can be somewhat acidic and corrosive, however. The flue gas is carried away with PVC piping, and the liquid condensate can be piped down an appropriate drain, **Figure 31.70(A)**.

EXCESS AIR

Excess air consists of combustion air and dilution air. Combustion air is primary and/or secondary air. Primary air enters the chamber before combustion takes place. It mixes with raw gas in the burner before a flame has been established. Secondary air is air present after combustion and supports combustion. Dilution air is excess air after combustion and usually enters at the end of the heat exchanger. It is brought in by the draft hood of the furnace, **Figure 31.72**.

As excess air decreases, the DPT increases. The DPT for undiluted flue gas is around 140°F; in diluted flue gas, the temperature may drop to about 105°F. This is the main reason high-efficiency condensing furnaces require very little excess air for combustion. High-efficiency condensing furnaces operate below the DPT of the combustion gases to allow condensation to happen. The flue gas is intentionally cooled below the DPT to promote condensation.

Gas furnaces with high efficiency ratings are being installed in many homes and businesses. The U.S. Federal Trade Commission requires furnace manufacturers to provide an annual fuel utilization efficiency rating (AFUE). This rating allows the consumer to compare furnace performances before buying. These annual efficiency ratings have increased in some instances from 65% to 97% or higher, partly by keeping excessive heat from being vented to the atmosphere. In conventional furnaces, stack temperatures are kept high to provide a good draft for proper venting. This also prevents condensation and therefore corrosion in the vent.

Figure 31.72 A standard-efficiency furnace showing dilution air entering a draft hood.

FURNACE EFFICIENCY RATINGS

All forced-air gas furnaces have efficiency ratings. The ratings are determined by the amount of heat that is transferred to the heated medium, which is usually water or air. The following factors determine the efficiency of a furnace:

- Type of draft (natural atmospheric injection, induced, or forced)
- Amount of excess air used in the combustion chamber
- Delta-T, or temperature difference, of the air or water entering versus leaving the heating medium side of the heat exchanger
- Flue stack temperature

The following are furnace classifications and approximate AFUE ratings:

Conventional, or Standard-Efficiency, Furnace (78% to 80% AFUE), Figure 31.73

- Atmospheric injection or draft hood
- 40% to 50% excess air usage
- Delta-T of 70°–100°F (lowest cfm airflow of furnaces)
- Stack temperatures of 350°–450°F
- Noncondensing
- One heat exchanger

Mid-Efficiency Furnace (78% to 83% AFUE), Figure 31.74

- Usually induced or forced draft
- No draft hoods
- 20% to 30% excess air
- Delta-T of 45°–75°F (more cfm airflow than conventional units)

Figure 31.73 A conventional, or standard-efficiency, furnace.

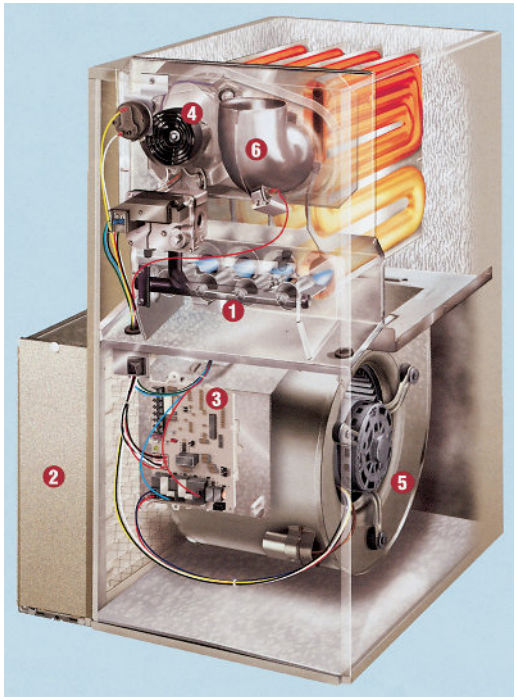
Figure 31.74 A mid-efficiency furnace.

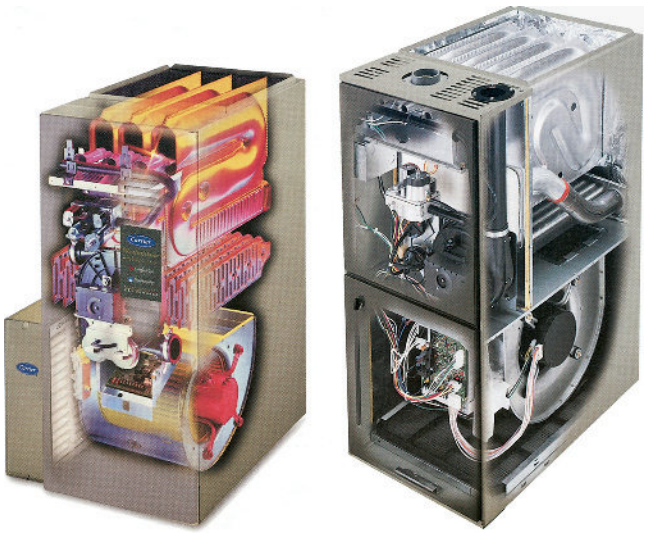


- Stack temperatures of 275°–300°F
- Noncondensing
- One heat exchanger

High-Efficiency Furnace (87% to 97% AFUE), Figure 31.75

- Usually induced or forced draft
- No draft hoods
- 10% excess air
- Delta-T of 35°–65°F (highest cfm of all furnaces)

Figure 31.75 Two high-efficiency gas furnaces.



- Stack temperatures of 110°–120°F
- Two or three heat exchangers
- Condensing furnace (reclaims the latent heat of condensation by condensing flue-gas water vapors to liquid water)
- Uses PVC pipe to avoid corrosion

As mentioned earlier, as excess air decreases, the DPT increases. This is the main reason high-efficiency condensing gas furnaces require very little excess air in the combustion process. High-efficiency condensing furnaces operate below the DPT of the combustion gases to allow condensation to happen. High-efficiency furnaces have a low delta-T due to the increased amount of air (cfm) they receive through their heat exchangers, which keeps the air in contact with the heat exchanger for a shorter period of time.

Annual Fuel Utilization Efficiency (AFUE) is calculated by the manufacturer of fuel burning combustion equipment. The higher the AFUE, the more efficient the combustion equipment is at converting fuel to useful heat energy. An 85% AFUE value means that for every BTU of fuel burned, 85% of the fuel is used for useful energy within the building and 15% is wasted. The AFUE compares the amount of (seasonal) energy used in BTUs to the (seasonal) output of BTUs and expresses the ratio as a percentage.

Another efficiency rating is the **Heating Seasonal Performance Factor (HSPF)**. This efficiency factor is applied to heat pumps in the heating mode and takes into consideration the energy used during the entire heating season. It is very similar to the Seasonal Energy Efficiency Ratio (SEER) of heat pumps, but it is only applied to heat pump systems in the heating mode. SEER applies to cooling equipment and heat pumps only in the cooling mode. The HSPF efficiency rates both the compressor and the electric strip heaters. HSPF is a ratio of the seasonal heat output in BTUs to the seasonal watt-hours used. The higher the HSPF, the more efficient the unit is in moving BTUs of heat energy per BTU of energy consumed.

Seasonal Energy Efficiency Ratio (SEER) is calculated on the basis on the total amount of cooling (in Btu) the system will provide over the entire season, divided by the total number of watt-hours it will consume. Higher SEERs reflect a more efficient cooling system. At the time of this writing, every central split-cooling system manufactured in the United States today must have a SEER of at least 13. This energy requirement was mandated by federal law as of January 23, 2006.

31.22 ELECTRONIC IGNITION MODULES AND INTEGRATED FURNACE CONTROLLERS

Electronic ignition modules and IFCs control the ignition and sequence of operation of most modern gas furnaces. **Figure 31.76** shows examples of electronic ignition modules

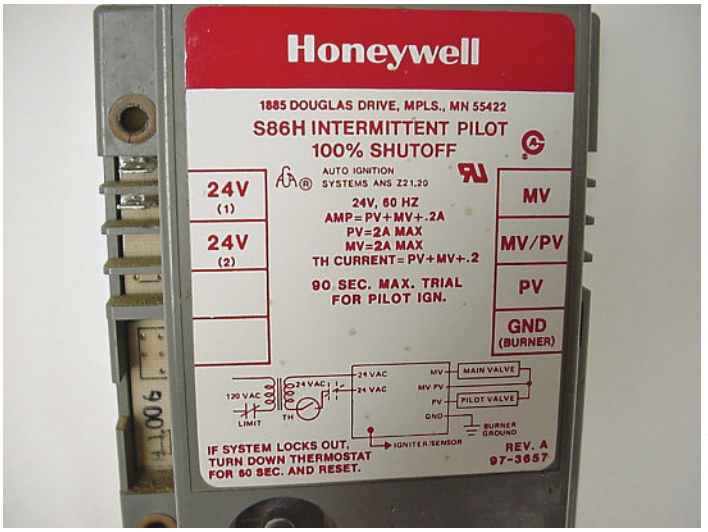
and an IFC. Electronic modules usually indicate on their faceplate what basic sequence of events or operations they include within their electronics. Some of their most common control sequences and control definitions follow.

Figure 31.77 A 100% shutoff electronic ignition module.



Courtesy Ferris State University. Photo by John Tomczyk

100% SHUTOFF SYSTEM

A system is 100% shut off when there is a failure in the flame-proving device system and both the pilot valve and main gas valve are shut down (closed). In the past, these systems had to be used on liquid petroleum gas systems since LP gas is heavier than air and will not vent naturally up the flue. It was thought that letting the pilot gas bleed could create a dangerous situation. This is no longer true. Today, LP gas systems use non-100% shutoff systems in a safe manner by employing short shutdown or soft lockout times between ignition retries to let any residual gas dissipate. Lockout timing will be covered later. A 100% shutoff module is shown in **Figure 31.77**. Notice that it is designed for an IP system and usually has a 90-sec maximum trial for pilot ignition before going into a shutoff.

NON-100% SHUTOFF SYSTEM

A system is considered non-100% shutoff when the pilot valve continues to bleed gas after a failure in the flame-proving device system and the main gas valve shuts down. These systems are used where there is a need to continually try to relight the pilot to avoid nuisance shutdowns. Many commercial rooftop heating units are non-100% shutdown, which prevents nuisance shutdowns on windy days. Many newer ignition control modules have ignition retry sequences for both natural and LP gas. Many modules have soft shutdown periods of 5 min or more to allow any accumulation of fuels to dissipate. The system must have a pilot mechanism to be classified as either 100% or non-100% shutoff. A non-100% shutoff module is shown in **Figure 31.78**.

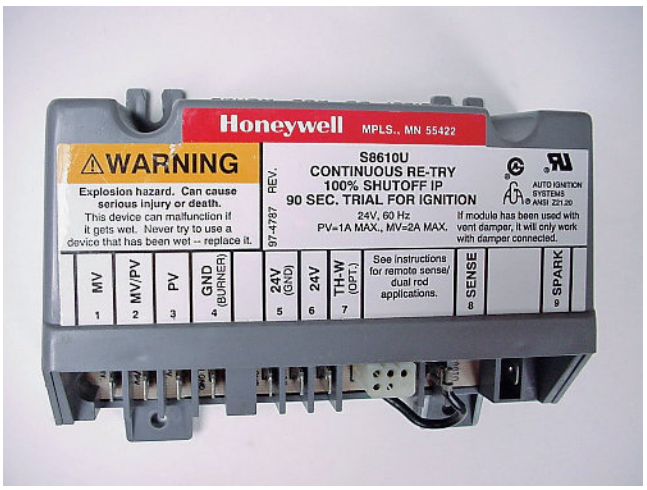
CONTINUOUS RETRY WITH 100% SHUTOFF

A module with a continuous retry control scheme is shown in **Figure 31.79**. It has 100% shutoff with a 90-sec trial for ignition. However, it will continuously try to relight the pilot after the shutoff period. Once in the shutoff period, there will be no bleeding of pilot gas.

LOCKOUT

A lockout is a time period built into the module that allows a specific amount of time for lighting or relighting the pilot or main burner. If this time period is exceeded, the module will go into either a soft lockout or a hard lockout.

Figure 31.79 A continuous retry 100% shutoff electronic ignition module.



Courtesy Ferris State University. Photo by John Tomczyk

SOFT LOCKOUT. A soft lockout allows a certain time for the lighting or relighting of the pilot or main burner. If this time is exceeded, the module will go into a semishutdown for a certain period but will eventually keep trying to relight the system. This system may go into a hard lockout once several soft lockouts have been attempted and still no flame has been established. Soft lockouts can range from 5 min to 1 hour and so allow time to pass with the hope that a change in the local ambient or outside environment will allow the unit to light normally. They also allow for any power interrupts to clear themselves without going into a hard lockout.

HARD LOCKOUT. A hard lockout allows a specific time for the lighting or relighting of the pilot or main burner. If this time period is exceeded, the module will go into a hard lockout or shutdown. To reset the module after this shutdown, power has to be interrupted to the module and then turned back on. This usually takes a service call and costs the building owner money.

PURGING

PREPURGE. Shown in **Figure 31.80** is a 100% shutoff module for an IP system. There is a 90-sec lockout (LO) with a 30-sec prepurge (PP). Before each heating cycle, the PP control scheme allows the combustion blower motor to run for 30 sec to clear, or PP, the heat exchanger of any unwanted flue gases, household fumes, or dust that may have accumulated during the last heating cycle.

INTERPURGE. Interpurge allows the combustion blower to operate for a certain time period between ignition tries. Interpurge is generally used when the furnace does not light or does not sense a flame. The heat exchanger must be purged of residual unburned gas or combustion by-products from the previous unsuccessful ignition attempt.

Figure 31.80 A 100% shutoff module with a 90-sec lockout and a 30-sec prepurge.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

POSTPURGE. A postpurge allows the combustion blower motor to operate for a certain time period after each heating cycle. This control strategy, along with a PP, is double insurance that the heating cycle will start with only air in the heat exchanger, allowing a quick and safe light-off. Both PP and postpurge control strategies can be used alone or with one another.

The IFC provides all of the ignition, safety, and sequence of operation or control schemes for the furnace. Many furnace manufacturers use these controllers because of their safe, reliable operation and versatility. The controller carefully monitors all thermostat, temperature, resistance, and current inputs to ensure stable and safe operation of the combustion blower, gas valve, ignition, flame rectification system, and warm-air blower. They often have many DIP switches that allow the controller to be programmed for different timing functions and control scheme changes. **Figure 31.81(A)** shows a section of an IFC with DIP switches and status lights.

Figure 31.81 (A) An integrated furnace controller showing DIP switches and status lights. (B) DIP switches for setting the warm-air blower off–delay timing.

BLOWER OFF TIMES (SECONDS)				
LOW FIRE	HIGH FIRE	COOLING	SWITCH 1	SWITCH 2
90	60	30	OFF	ON
120	90	45	OFF	OFF
160	130	60	ON	OFF
180	150	90	ON	ON

Courtesy Rheem Manufacturing Company

(B)

DIP switches 1 and 2 are for setting the warm-air blower's off–delay timing in seconds, **Figure 31.81(B)**. DIP switch 3 is for furnace twinning applications. DIP switch 4 is not used in this application.

Twinning involves the side-by-side operation of two furnaces connected by a common ducting system. High-voltage power is supplied from a common source. Transformer-supplied low-voltage power is controlled by one common thermostat for both furnaces. Status lights will usually blink a certain number of times to tell the service technician that the furnace is in the twinning mode. Twinning is used when a heating capacity greater than that of the largest-capacity furnace manufactured is needed. Twinning is also used when the airflow of one furnace, for air-conditioning purposes, is greater than a single furnace can provide.

The status lights monitor incoming power, furnace setup modes, diagnostic status for troubleshooting, and the flame rectification signal. The furnace status check can be a self-diagnostic flashing light with a code to help the service technician systematically troubleshoot the furnace. **Figure 31.82** shows a furnace controller with a self-diagnostic light and flashing codes for some common furnace faults. The diagnostic light is located on the bottom left corner of the controller.

Care must be taken when troubleshooting an IFC because static electricity can damage the sensitive hardware and software. Always make sure you are touching a well-grounded surface before attempting to troubleshoot an IFC board. The small voltage of an ohmmeter can also damage an IFC board. Never put an ohmmeter on an IFC board unless instructed to do so by the furnace manufacturer's troubleshooting procedures. Always disconnect the wires of a power-consuming device or sensor from the IFC before using an ohmmeter in troubleshooting these devices.

Following is a sequence of operation or control scheme for a residential direct-ignition, natural gas furnace employing an IFC and a single-stage thermostat. With the proper settings, either a single- or dual-stage thermostat can be used on this system. This is a two-stage furnace, meaning the gas valve has two heat stages, accomplished by gas pressure regulation and solenoid valves. The combustion blower also has two speeds. The sequence includes a PP, interpurge, and postpurge with a soft lockout. The control board or IFC used on this furnace is shown in **Figure 31.76(B)**.

1. The W terminal on the thermostat is connected to the W2 terminal on the IFC board.
2. When there is a call for heat, the R and W2 contacts close and the IFC runs a self-check routine to verify that the draft-proving pressure switch contacts are open. The limit switch contacts are constantly monitored.
3. The induced-draft motor starts on high for a few seconds, to ensure that the low-pressure switch contacts close, and then changes to low speed. After a 30-sec prepurge, the spark indicator is energized and the low stage of the gas valve opens, lighting the burners.
4. After the gas valve opens, the remote flame sensor must prove ignition for 1 sec using the process of flame rectification. If the burners do not light, the system goes through another ignition sequence. It does this up to four times (two tries on low fire and two tries on high fire).
5. The main blower starts on low speed 30 sec after the burners light. The furnace will operate on low fire for 12 min. Then, if the thermostat is not satisfied, it will shift to high fire, causing the draft inducer to go to heat speed. (If a two-stage thermostat is used, the second stage of the thermostat, W2, will initiate high fire.) The draft inducer will continue running for a 5-sec (low-speed) or 10-sec (high-speed) postpurge.

The main blower will run for 90 sec on high speed or 120 sec on low speed. (This timing is field adjustable for 60, 90, 120, or 150 sec.)

The following is the sequence if the system does not light or does not sense flame:

1. If a flame is not sensed within 8 sec after the gas valve opens, the valve closes and the igniter is deenergized. The induced-draft motor will run for 60 sec on low, stop momentarily, and then restart. The ignition process will go through one more try on low fire. If this fails, there will be two tries on high fire with a 30-sec interpurge between trials. If there is no ignition after the second trial on high fire, the furnace will go into soft lockout for 1 hour.
2. The sequence will repeat after a 1-hour delay and continue repeating until ignition is successful or the call for heat is terminated.
3. To reset the lockout, make and break power either at the thermostat or at the unit disconnect switch for 5 to 10 sec. The furnace will then go through another set of trials for ignition.

ELECTRONIC IGNITION MODULE WIRING AND TERMINAL NAMING

Most terminals in electronic modules are marked with abbreviations, **Figure 31.76(A)**. Some electronic modules include a wiring diagram on their faceplate, **Figure 31.77** and **Figure 31.78**. This can be helpful to the service technician in wiring and troubleshooting the furnace's electrical and mechanical systems. The following are important terminal abbreviations and names:

MV	Main valve (gas valve)
PV	Pilot valve
MV/PV	Common terminal for main and pilot valves
GND	Burner ground
24V	24-V source out of the transformer
24V(GND)	Common or ground out of the 24-V transformer
TH-W	Thermostat lead to the module
IGNITER/SENSOR	High-voltage igniter and flame rectification rod or sensor for local sensing (single-rod systems)
SENSE	Flame rectification rod or sensor for remote sensing (dual-rod systems)
SPARK	High-voltage igniter

SMART VALVE

The smart valve is a gas valve and an electronic control module enclosed in one package, **Figure 31.83**. It combines the features of an IP system and an HSI system in one. The smart valve is a continuous pilot trial system and is designed for both natural and LP gas furnaces. The pilot flame is probably one of the most reliable ignition sources in the industry. The valve's logic lights the pilot with a 24-V hot surface igniter system, **Figure 31.84**. Then, as in any other intermittent ignition system, the pilot lights the main burners. Using a 24-V HSI system instead of a high-voltage spark to light the pilot

(B)

simplifies the electronics, and because there is no need for a noisy spark generator or high-voltage ignition transformer, it provides a quiet ignition system.

The 24-V hot surface igniter in the smart valve is made of a material different from that used for the conventional silicon carbide line-voltage igniters. It is designed to be stronger and less brittle. In fact, it is well protected by the pilot burner and grounding strap. The ground strap is there to provide a ground electrode for the flame rectification system. The other electrode is the flame rod, **Figure 31.84**. Once the flame is proved, the 24-V hot surface igniter is deenergized and the electronic fan timer within the module is energized. The electronic fan timer tells when to start timing the fan–on delay and the fan–off delay.

The smart valve system is easy to troubleshoot because of the simplified wiring and modular electrical connections. A

voltmeter can be used at the valve and electrical plug connections, **Figure 31.85**. **Figure 31.86(A)** is a sequence of operation for a smart valve control. **Figure 31.86(B)** is a systematic troubleshooting chart. **SAFETY PRECAUTION:** *Because there are different models and makes of gas valves, electronic modules, and IFCs, always consult with the valve and module or IFC manufacturer for specific information on systematic troubleshooting and sequence of operation to avoid personal injury.*•

PULSE FURNACE

The pulse furnace, **Figure 31.76(C)**, ignites minute quantities of gas 60 to 70 times per second in a closed combustion chamber. The process begins when small amounts of fuel gas and air enter the chamber. This mixture is ignited with a spark igniter and is forced down a tailpipe to an exhaust decoupler. The pulse is reflected back to the combustion chamber, igniting another gas and air mixture, and the process is repeated. Once this process is started, the spark igniter can be turned off because the pulsing will continue on its own 60 to 70 times per second. This furnace also uses heat exchangers to absorb much of the heat produced. Air is circulated over the exchanger and then to the space to be heated.

31.23 TWO-STAGE GAS FURNACES

Modern two-stage gas furnaces use a two-stage gas valve and a two-speed combustion blower motor with two pressure switches to prove the draft. Modern two-stage furnaces are usually controlled by an IFC. **Figure 31.76(B)** shows a modern IFC for a two-stage gas furnace. **Figure 31.87** shows the two-stage gas valve, two-speed combustion blower motor, and dual pressure switches to prove the draft. One

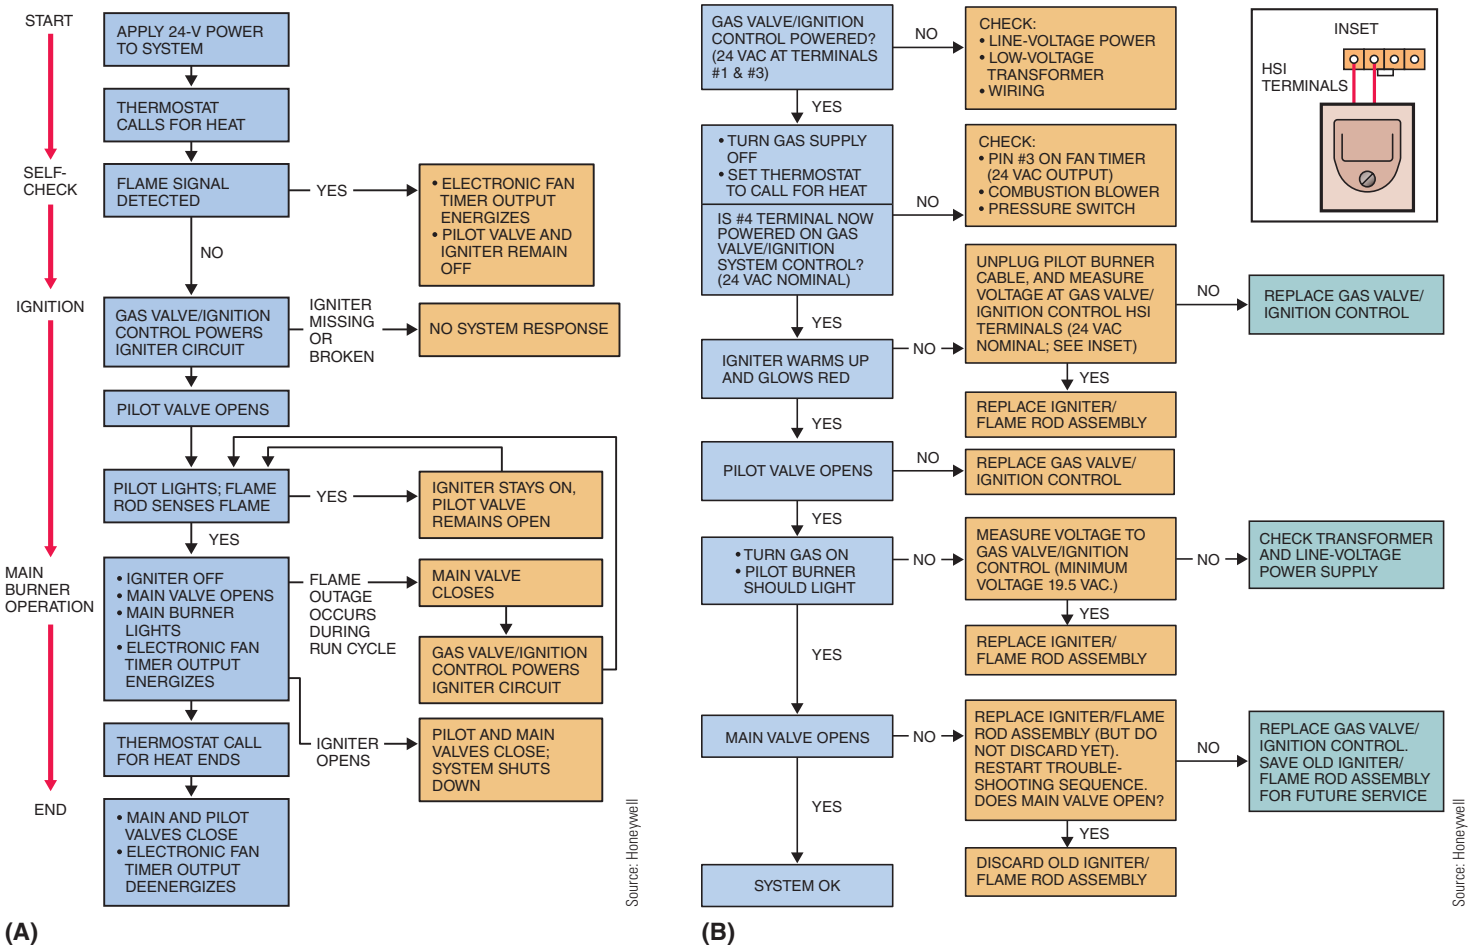
pressure switch is a low-pressure switch and the other is a high-pressure switch to prove the low and high speeds on the combustion blower motor.

31.24 MODULATING GAS FURNACES

The industry has always needed a furnace that adjusts to the heat loss of a structure. For example, a house that requires a 100,000-Btu/h furnace on the coldest day of winter, which may be 0°F, may require only 60,000 Btu/h of heat when it is 20°F. The furnace begins to cycle off and then back on as the weather warms. The warmer the weather, the more cycle times per day. These additional cycle times cause the furnace to be less efficient. An oversized furnace with a steady-state efficiency of 80% is estimated to have a seasonal efficiency as low as 50%. When cycling can be reduced or eliminated, the efficiency of the furnace becomes greater. *A modern modulating gas furnace can adjust to the heat loss of a structure and have longer run times, thus less cycling. This makes it a very efficient furnace.*

Modern modulating gas furnaces use a modulating gas valve instead of a staged gas valve. They also come with a variable-speed warm-air blower to adjust the speed and amount of warm air being circulated. Two-stage combustion blower motors are standard on most modulating gas furnaces, and an advanced intelligent IFC monitors and controls the furnace operations to vary the heating input and warm airflow. Modern modulating gas furnaces also have a variable operating solenoid or servo valve within the gas valve that is fed with a varying or proportional milliamp signal from the IFC. This servo valve acts as a capacity controller. It varies the input rate of the furnace proportionally to

Figure 31.86 (A) The smart valve sequence of operation. (B) A smart valve troubleshooting chart.



the signal of the controller. This allows the furnace to operate over a heating output range between 40% and 100%. The controller gets its proportional signal from a variable-output programmable thermostat, which will be covered in detail below.

Modulating gas furnaces may have supply and return air sensors installed in the supply and return air system. Usually, these sensors are thermistors that send an analog signal to the IFC. They can sense the temperature of the return and discharge air and relay this information to the furnace controller. The controller can then calculate the temperature rise of the furnace and proportionally adjust the modulating gas valve to maintain a comfortable discharge air temperature. The IFC monitors the thermostat inputs and all other temperature inputs from the furnace and provides stable operation of the variable input gas valve, variable warm air blower motor, and two-speed inducer motor. The modulating gas furnace also has the ability to adjust itself to changes in gas heating values and air density.

The variable-output programmable thermostat is not a conventional on–off thermostat. It sends a varying or proportional signal to the furnace controller. It can sense the exact heating or cooling requirements of the conditioned space by a "fuzzy logic" control routine resident in its software. These routines calculate the room's load by evaluating recent room conditions from a sensor within the thermostat or remote to the thermostat and reactions to supplying heating and cooling. The thermostat and IFC then calculate a heating or cooling load factor. This load factor is used to determine when, for how long, and at what firing rate and airflow the furnace should be activated. This control routine optimizes furnace efficiency and reduces temperature swing in the controlled space. Modulating furnaces will have longer run times, allowing greater comfort levels in the conditioned space. Temperature swings in the conditioned space will not vary by more than one-half degree from the thermostat set point. **Figure 31.88** shows the internals of a variable-output programmable thermostat used in a modulating furnace.

Figure 31.87 A two-stage gas furnace showing the two-stage gas valve, the two-stage combustion blower motor, and dual pressure controls. The first stage of heating puts out a manifold pressure of 1.75 in. WC by energizing the first solenoid valve in the gas valve. The first stage of heating usually operates at about 50% to 70% of the total furnace heating output. The second stage of heating puts out a manifold pressure of 3.5 in. WC by energizing the second solenoid valve in the gas valve. This is 100% of the total furnace output. Two-stage gas furnaces control the temperature in the conditioned space much more closely to the set point of the thermostat. Because of this, room temperature swings are smaller and comfort levels are increased. A sequence of operation for a two-stage furnace is given in Section 31.22.

31.25 VENTING

Conventional gas furnaces use flue gas temperature and natural convection to vent the products of combustion (flue gases). The hot gas is vented quickly, primarily to prevent cooling of the gas, which produces condensation and other corrosive actions. However, these furnaces lose some efficiency because considerable heat is lost up the flue. High-efficiency furnaces (90% and higher) recirculate the flue gases through a special extra heat exchanger to keep more of the heat available for space heating in the building. The gases are then pushed out of the flue by a small fan. Plastic pipe is used to handle the resulting condensation and corrosion in the flue because it is not damaged by the corrosive materials.

Figure 31.88 Internal view of a variable-output programmable thermostat for a modulating furnace. A variable-speed warm-air blower provides varied airflow through the furnace's ductwork to meet the conditioned space demands. A brushless, permanent-magnet, internally commutated motor (ICM) with variable-speed capabilities can deliver airflows as low as 300 cfm. Modulating furnaces orchestrate the use of the variable-speed warm-air blower, variable-input gas valve, supply and return air sensors, advanced IFC, and variable-input thermostat to achieve a targeted temperature rise. For a detailed review of ICMs, refer to Unit 17, "Types of Electric Motors."

High-efficiency furnaces may have efficiencies of up to 97%. **SAFETY PRECAUTION:** *Regardless of the type, a gas furnace must be properly vented.*•

Venting must provide a safe and effective means of moving the flue gases to the outside air. In a conventional furnace, it is important for the flue gases to be vented as quickly as possible. Conventional furnaces are equipped with a draft hood that blends some room air with the rising flue gases, **Figure 31.89(A)**. The products of combustion enter the draft hood and are mixed with air from the area around the furnace. Approximately 100% additional air (called *dilution* air) enters the draft hood at a lower temperature than the flue gases. The heated gases rise rapidly and create a draft, bringing the dilution air in to mix and move up the vent.

All furnaces must have the correct amount of excess air. Excess air is made up of combustion air and dilution air. Combustion air consists of both primary and secondary air. The amount of air required for gas-burning appliances is determined by the appliance size and is mandated by local codes or the National Fuel Gas code, which is considered the standard by many states. Obviously, the larger the furnace, the more excess air is needed. One rule of thumb is that a grill with a free area of 1 in^2 per 1000 Btu/h must be provided below the furnace (if the structure is over a crawl space) and above the furnace (to the attic space) to allow adequate air for combustion. For a 100,000-Btu/h furnace, this would be 100 in^2 of free area. This grill must be larger than 10 in. × 10 in. = 100 in^2 to allow for the space the louvres take up

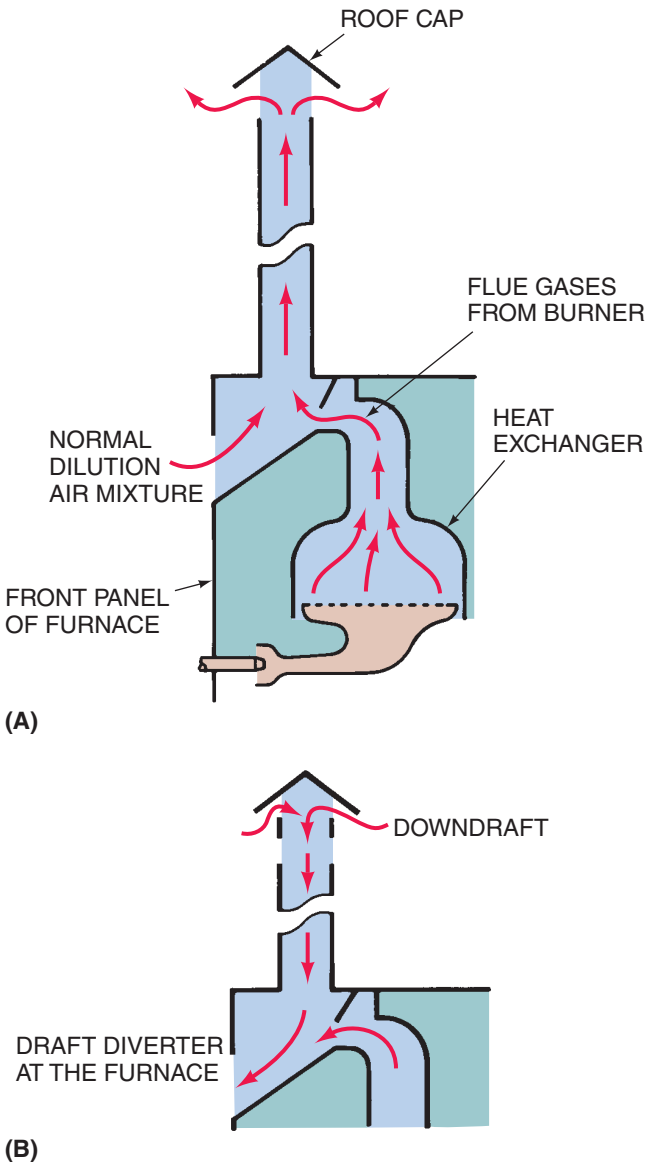
Figure 31.89 Draft hood operation.



(approximately 30% of the grill area is louvres), so the grill would have to be 100/0.70 = 142.9 in^2 or 12 in. × 12 in. The vent above the furnace is for dilution air; the vent below is for combustion air. This example of figuring out the ventilation air for this situation is only one possibility.

In the past, excess air was merely extracted from the volume of air in the structure. Structures today are built to allow less infiltration of air around the windows and doors, so makeup air for the furnace must be considered. Even old structures are being tightened up by adding storm windows and weather stripping around the doors, so there is less infiltration. A furnace installed in an older structure that has been tightened may have venting problems, as evidenced by flue gases spilling out of the draft diverter rather than exiting out the flue. If wind conditions produce a downdraft, the opening in the draft hood provides a place for the gases and air to go, diverting them away from the pilot and main burner flame. The *draft diverter* helps reduce the chance of the pilot flame being blown out and the main burner flame being altered, **Figure 31.89(B)**.

Venting categories were created when high-efficiency furnaces were introduced. Following are the four venting categories listed by the American National Standards Institute (ANSI). Based on ANSI Standard Z21.47A-1990, they set required temperature and pressure venting standards for the proper venting of gas furnaces.

- Category I—Furnace has a nonpositive vent pressure and operates with a vent gas temperature at least 140°F above its dew point (conventional, or standard-efficiency, furnace).
- Category II—Furnace has a nonpositive vent pressure and operates with a vent gas temperature less than 140°F above its dew point (no longer manufactured because of condensate problems at start-up).
- Category III—Furnace has a positive vent pressure and operates with a vent gas temperature at least 140°F above its dew point (mid-efficiency furnace).
- Category IV—Furnace has a positive vent pressure and operates with a vent gas temperature less than 140°F above its dew point (high-efficiency condensing furnace).

SAFETY PRECAUTION: *Make sure replacement air is available in the furnace area. Remember it takes 10 ft^3 of air for each 1 ft^3 of natural gas to support combustion. To this is added 5 ft^3 more to ensure enough oxygen. Another 15 ft^3 is added at the draft hood, making a total of 30 ft^3 of air for each 1 ft^3 of gas. A 100,000-Btu/h furnace would require 2857 ft^3/h of fresh air (100,000 ÷ 1050 Btu/h × 30 ft^3 = 2857 ft^3/h). All of this air must be replaced in the furnace area and also must be vented as flue gases rise up the vent. If the air is not replaced in the furnace area, it will become a negative pressure area, and air will be pulled down the flue. Products of combustion will then fill the area.*•

Type B vent or approved masonry materials are required for conventional gas furnace installations. *Type B* venting systems consist of metal vent pipe of the proper thickness that is approved by a recognized testing laboratory, **Figure 31.90**. The venting system must be continuous from the furnace to the proper height above the roof. Type B vent pipe is usually of a double-wall construction with air space between. The

Figure 31.90 A section of type B gas vent.

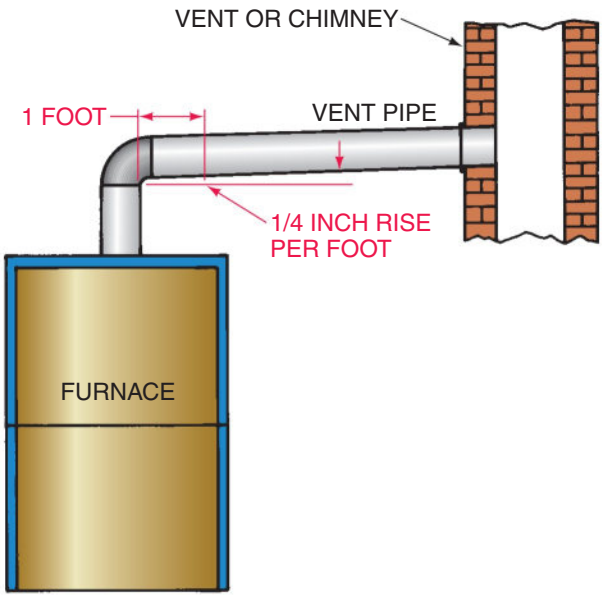
Figure 31.91 The minimum rise should be ¼ in. per foot of horizontal run.



inner wall may be made of aluminum and the outer wall may be constructed of steel or aluminum.

The vent pipe should be at least the same diameter as the vent opening at the furnace. The horizontal run should be as short as possible. Horizontal runs should always be sloped upward as the vent pipe leaves the furnace. A slope of ¼ in. per foot of run is the minimum recommended, **Figure 31.91**. Use as few elbows as possible. Long runs lower the temperature of the flue gases before they reach the vertical vent or chimney and they reduce the draft. Do not insert the vent connector beyond the inside of the chimney wall and make sure that there are no obstructions when the gases are vented into a masonry chimney, **Figure 31.92**. If two or more gas appliances are vented into a common flue, the common flue size should be calculated based on recommendations from the National Fire Protection Association (NFPA) or local codes. The top of each gas furnace vent should have an approved vent cap to prevent the entrance of rain and debris and to help prevent wind from blowing the gases back into the building through the draft hood, **Figure 31.93**.

Figure 31.92 The vent pipe should not extend beyond the inside of the flue lining.

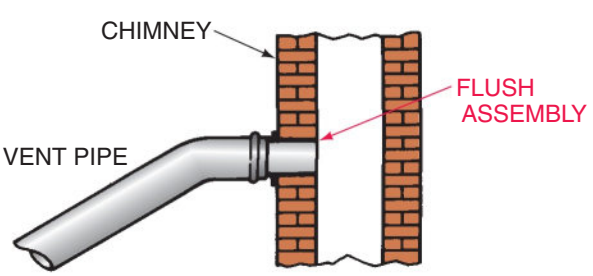


Figure 31.93 (A)–(B) Gas vent caps.

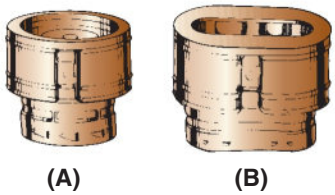
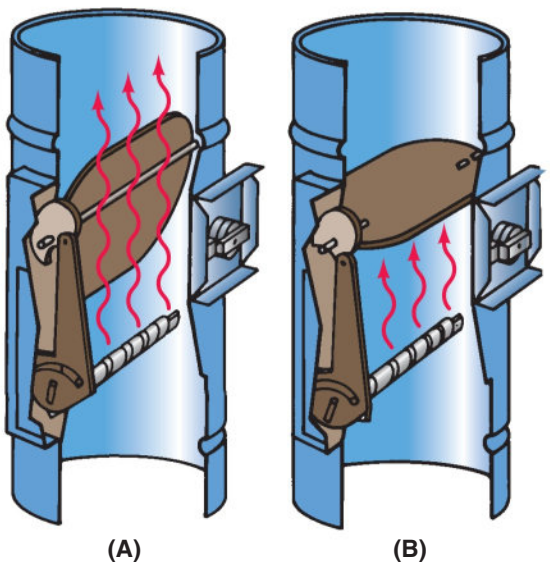


Vertical vents can be masonry with lining and glazing or prefabricated metal chimneys approved by a recognized testing laboratory. Metal vents reach operating temperatures quicker than masonry vents do. It takes a long running cycle to heat a heavy chimney. The warmer the gases, the faster they rise and the less damage there is from condensation and other corrosive actions. Masonry chimneys tend to cool the flue gases and must be lined with a glazed-type tile or have a vent pipe installed inside the chimney. The corrosive materials in the flue gas that come from the condensation that occurs at start-up and from short running times in mild weather will destroy the mortar joints of an unlined chimney. When an unlined chimney must be used, a special corrosion-resistant flexible liner can often be installed. It is worked down into the chimney and connected at the bottom to the furnace vent. This provides a corrosion-proof vent system.

When the furnace is off, heated air can leave the structure through the draft hood. Automatic vent dampers that close when the furnace is off and open when the furnace is started can be placed in the vent to prevent air loss. Several types of dampers are available. One type uses a helical bimetal with a linkage to the damper. When the bimetal expands, it turns the shaft fastened to the helical strip and opens the damper, **Figure 31.94**. Another type uses damper blades constructed

Figure 31.94 (A)–(B) A rotating helix and vent damper operated with a bimetal helix.

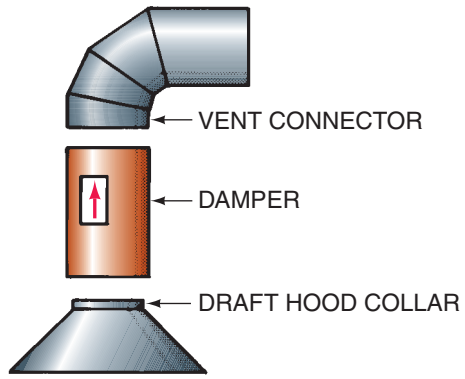


Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

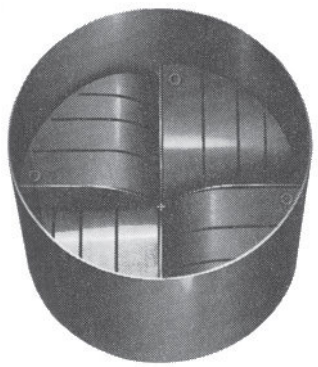
of bimetal. When the system is off, the damper is closed. When the vent is heated by the flue gases, the bimetal action on the damper blades opens them, **Figure 31.95**.

In high-efficiency systems, a small combustion blower is installed in the vent system near the heat exchanger. This blower mainly operates when the furnace is on so that heated room air is not being vented 24 hours a day. Heated room air will only be vented if the furnace is non-direct-vented because these furnaces get their combustion air from the conditioned space. However, if the furnace is direct-vented, it will have a sealed combustion chamber and will get its combustion air from the outside through an air pipe usually made of PVC plastic, **Figure 31.71**. There is no possible way for conditioned room air to be vented because the sealed combustion chamber never receives conditioned room air. Since conditioned room air is not used for combustion, the conditioned room is not depressurized, or pulled into a slight vacuum by the furnace. This cuts down on the amount of outside air infiltrating the room, and so less cold, infiltrated air will have to be reheated. Direct venting also minimizes the interaction of the furnace with other combustion appliances.

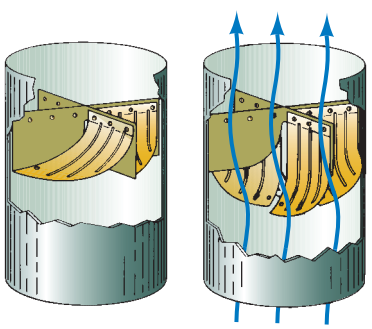
Figure 31.95 (A)–(B) An automatic vent damper with bimetal blades. (C) Cutaway view.



(A)



(B)



(C)

As mentioned earlier in this unit, combustion blowers can be either forced- or induced-draft systems. In an induced-draft system, the combustion blower is at the outlet of the heat exchangers, producing a negative pressure that actually sucks the combustion gases out of the heat exchanger. In a forced-draft system, the combustion blower is before the heat exchangers and causes a positive pressure that blows the combustion gases through the heat exchanger. This blower will vent gases at a lower temperature than is possible with natural draft, allowing the heat exchanger to absorb more of the heat from the burner for distribution to the conditioned space, **Figure 31.75**. When combustion blowers are used for furnace venting, the room thermostat normally energizes the blower. Blowers can be operated by airflow switches or a centrifugal switch on the motor.

31.26 GAS PIPING

Installing or replacing gas piping can be an important part of a technician's job. The first thing a technician should do is to become familiar with the national and local codes governing gas piping. Local codes may vary from national codes. A technician should also be familiar with the characteristics of natural gas and LP gas in the particular area in which he or she works. Pipe sizing and furnace Btu ratings will vary from area to area due to varying gas characteristics.

The piping should be kept as simple as possible and the pipe should run as directly as possible. Distributing or piping gas is similar to distributing electricity. The piping must be large enough and there should be as few fittings as possible in the system because each fitting creates a resistance. Pipe that is too small will, along with other resistances in the system, cause a pressure drop, and the proper amount of gas will not reach the furnace. The specific gravity of the gas must also be taken into consideration when designing the piping. Systems should be designed for a maximum pressure drop of 0.35 in. WC. The amount of gas to be consumed by the furnace must also be determined. The gas company should be contacted to determine the heating value of the gas in that area. It can also furnish pipe sizing tables and helpful suggestions. Most natural gas will supply 1050 Btu/ft^3 of gas. To determine the

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

gas to be consumed in 1 h by a typical natural gas, use the following formula:

$$\frac{\text{Furnace Btu Input per Hour}}{\text{Gas Heating Rating in Btu/ft}^3} = \text{Cubic Feet of Gas Needed per Hour}$$

Suppose the Btu rating of the furnace were 100,000 and the gas heating rating were 1050. Then

$$\frac{100{,}000}{1050} = 95.2\text{ft}^3 \text{ of Natural Gas Needed per Hour}$$

Tables give the size (diameter) of pipe needed for the length of the pipe needed to provide the proper amount of gas for the furnace. The designer of the piping system would have to know whether natural gas or LP gas were going to be used because the pipe sizing would be different due to the differences in specific gravities of the gases. Steel or wrought iron pipe should be used. Aluminum or copper tubing may also be used, but each requires treatment to prevent corrosion. Aluminum and copper pipes are used only in special circumstances.

SAFETY PRECAUTION: *Ensure that all piping is free of burrs and that threads are not damaged,* **Figure 31.96**. *All scale, dirt, or other loose material should be cleaned from pipe threads and from the inside of the pipe. Any loose particles can move through the pipe to the gas valve and keep it from closing properly. It may also stop up the small pilot light orifice.*•

When assembling threaded pipe and fittings, use a joint compound, commonly called *pipe dope*. Do not apply this compound on the first two threads at the end of the pipe because it could get into the pipe and plug the orifice or prevent the gas valve from closing, **Figure 31.97**. Also be careful when using Teflon tape to seal the pipe threads because it can also get into the pipe and cause similar problems.

At the furnace the piping should provide for a drip trap, a shutoff valve, and a union, **Figure 31.98**. A manual shutoff valve within 2 ft of the furnace is required by most local codes. The drip trap is installed to catch dirt, scale, or condensate (moisture) from the supply line. A union between the tee and the gas valve allows the gas valve or the entire furnace to be removed without disassembling other piping. Piping should be installed with a pitch of ¼ in. for every 15 ft of run in the direction of flow. This will prevent trapping moisture that could block the gas flow, **Figure 31.99**. Small amounts

Figure 31.96 Ensure that threads are not damaged. Deburr pipe. Clean all scale, dirt, and other loose material from pipe threads and from the inside of the pipe.

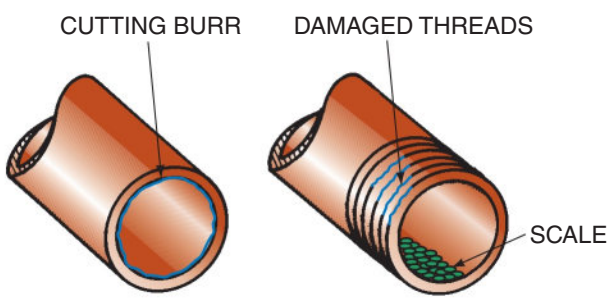


Figure 31.97 Pipe dope should be applied to male threads, but do not apply it to the last two threads at the end of the pipe.

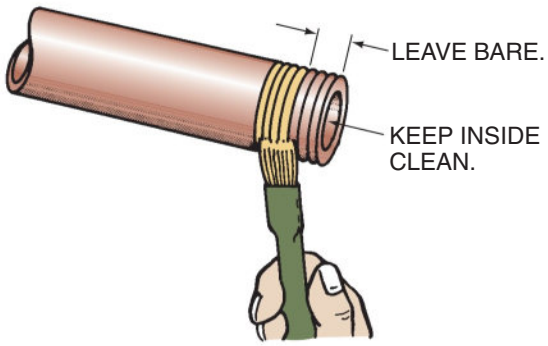

Figure 31.98 A shutoff valve, drip trap, and union should be installed ahead of the gas valve.

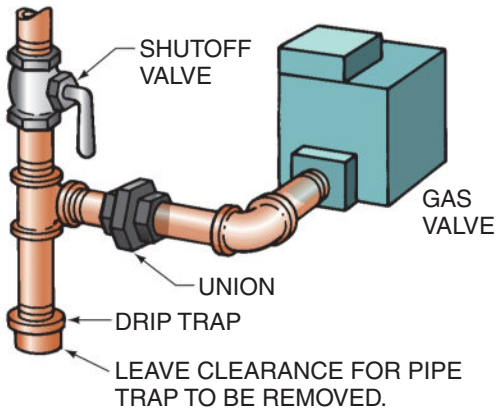

Figure 31.99 Piping from the furnace should have a rise of ¼ in. for each 15 ft of horizontal run.

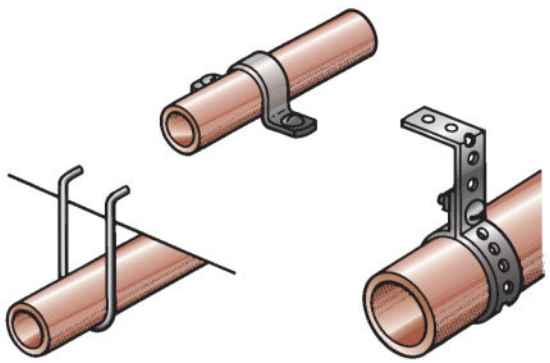
Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 31.100 Piping should be supported adequately with pipe hooks or straps.

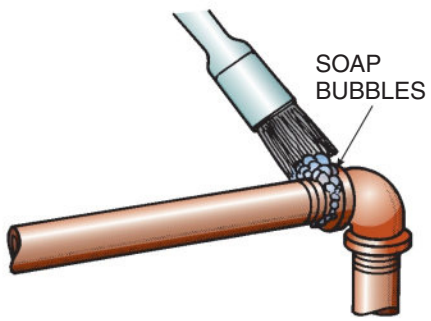


of moisture will move to the drip leg and slowly evaporate. Use pipe hooks or straps to support the piping adequately, **Figure 31.100**.

SAFETY PRECAUTION: *When completed, test the piping assembly for leaks. There are several methods for doing this, one being to use the gas in the system. Do not use other gases, and especially do not use oxygen.* • Turn off the manual shutoff to the furnace. Make sure all joints are secure. Turn the gas on in the system. Watch the gas meter dial to see if it moves, indicating that gas is passing through the system. A check for 5 to 10 min will indicate a large leak if the meter dial continues to show gas flow. An overnight standing check is better. If the dial moves, indicating a leak, check each joint with soap and water, **Figure 31.101**. A leak will make the soap bubble. When you find the leak and repair it, repeat the same procedure to ensure that the leak has been repaired and that there are no other leaks.

Leaks can also be determined with a manometer. Install the manometer in the system to measure the gas pressure. Turn the gas on and read the pressure in in. WC on the instrument. Then turn the gas off. There should be no loss of pressure. Some technicians use an overnight standing period with no pressure drop as their standard. Use soap and water to locate the leak, as before. **NOTE:** *If a standing pilot system that is not 100% shut off is being checked, the pilot light valve must be closed because it will indicate a leak.* • A high-pressure test is more efficient. For a high-pressure leak check, use air pressure from a bicycle tire pump. Ten pounds of pressure for 10 min with no leakdown will prove there are no leaks. **SAFETY PRECAUTION:** *Do not let this pressure reach the automatic gas valve. The manual valve must be closed during the high-pressure test.* •

Figure 31.101 Apply liquid soap to joints. Bubbling indicates a leak.



If there are no gas leaks, the system must be *purged,* that is, the air must be bled off to rid the system of air or other gases. **SAFETY PRECAUTION:** *Purging should be done in a well-ventilated area. It can often be performed by disconnecting the pilot tubing or loosening the union in the piping between the manual shutoff and the gas valve. Do not purge where the gas can collect in the combustion area.* • After the system has been purged, allow it to set for at least 15 min to allow any accumulated gas to dissipate. If you are concerned about gas collecting in the area, wait for a longer period. Moving the air with a hand-operated fan can speed this up. When it is evident that no gas has accumulated, the pilot can be lit. **SAFETY PRECAUTION:** *Be extremely careful, because gas is explosive. The standing leak test must be performed and all conditions satisfied before a gas system is put in operation. Be aware of and practice any local code requirements for gas piping.* •

31.27 GAS FURNACE WIRING DIAGRAMS AND TROUBLESHOOTING FLOWCHARTS

A wiring diagram in both schematic and pictorial form is shown in **Figure 31.102(A)**. The diagram is for a modern two-stage gas furnace with a direct-spark ignition system and an integrated furnace controller. Notice that in the schematic diagram the IFC is shown as an empty box; the pictorial diagram shows the IFC wiring terminals. It is beyond the scope of this text to explain the internal operations of the IFC. Although service technicians do not troubleshoot the circuits within the IFC board, they do troubleshoot circuits coming to and from the IFC board by following the input/output troubleshooting procedure. Troubleshooting guides can be followed more easily as the technician comes to understand the IFC's sequence of operation.

The IFC is a complicated microprocessor or small computer and must be handled with care. A small static discharge can damage the IFC. Service technicians must make sure they are physically grounded before attempting IFC troubleshooting. To prevent electrical static discharge from the body, some technicians even wear a grounding strap on their wrist, which is securely wired to ground, when they are replacing an IFC board. An IFC board is shipped in a reusable static shielding bag, **Figure 31.102(B)**. The service technician must be careful not to expose the IFC board to a static shock once it is removed from the bag. As mentioned, the service technician must be securely grounded before handling the board. When voltage-troubleshooting the IFC board with a voltmeter, make sure the voltmeter leads do not touch other parts of the board.

(B)

This can lead to short circuits and damage the board. The voltmeter leads should be kept as short as possible. Applying some electrical tape to the bottom part of the voltmeter leads can shorten their conducting length.

The first step in systematically troubleshooting a furnace that has an IFC is to obtain the electrical diagram of the furnace and the sequence of operation of the IFC. Then the service technician must obtain a systematic troubleshooting guide or flowchart like the one in **Figure 31.103**. The sequence of operation for the two-stage gas furnace in the electrical diagrams in **Figure 31.102(A)** is listed in Section 31.22. This sequence of operation, the electrical diagrams, and the systematic troubleshooting guide are the technician's most important tools for furnace troubleshooting.

Figure 31.104(A) is another example of both pictorial (connect) and schematic (ladder) diagrams for a modern gas furnace incorporating a furnace and fan control module. **Figure 31.104(B)** is a flowchart for systematically troubleshooting a gas furnace that has an IFC and DSI system. **Figure 31.105(A)** is an example of a connect and ladder diagram for a gas furnace having both an IFC and a 115-V hot surface ignition system. **Figure 31.105(B)** is a flowchart for systematically troubleshooting a different furnace that has an IFC and a spark ignition system.

31.28 TROUBLESHOOTING THE SAFETY PILOT-PROVING DEVICE—THE THERMOCOUPLE

The thermocouple generates a small electrical current when one end is heated. When the pilot flame is lit and heating the thermocouple, it generates a current that energizes a coil holding a safety valve open. This valve is manually opened when lighting the pilot; the coil only holds it open. If the pilot flame goes out, the current is no longer generated and the safety valve closes, shutting off the supply of gas.

To light the pilot, turn the gas valve control to PILOT position. Depress the control knob and light the pilot. Hold the knob down for approximately 45 sec, release, and turn the valve to the ON position. The thermocouple may be defective if the pilot goes out when the knob is released. **Figure 31.106** describes the no-load test for a thermocouple. It is important to remember that the thermocouple only generates enough current to *hold in* the coil armature. The armature is pushed in when the valve handle is depressed.

To check under load conditions, unscrew the thermocouple from the gas valve and insert the thermocouple testing adapter into the valve. The testing adapter allows you to take voltage readings while the thermocouple is operating. Screw the thermocouple into the top of the adapter, **Figure 31.107**, and relight the pilot. Check the voltage produced with a millivoltmeter using the terminals on the adapter. The pilot flame must cover the entire top of the thermocouple rod. If the thermocouple produces at least 9 mV under load (while connected to its coil), it is good; otherwise, replace it.

Check the manufacturer's specifications to determine the acceptable voltage for holding the different valve coils. If the thermocouple functions properly but the flame will not continue to burn when the knob is released, the coil in the safety valve must be replaced. This is normally done by replacing the entire gas valve. Thermopiles can generate much more voltage than thermocouples, sometimes in the range of 500 mV (0.5 V) to 750 mV (0.750 V). When more power is required to operate the circuit, the thermopile is a good choice. **Figure 31.108** is a systematic troubleshooting guide for a standing pilot gas furnace system.

31.29 TROUBLESHOOTING SPARK IGNITION AND INTERMITTENT PILOT SYSTEMS

Most spark ignition or intermittent pilot light assemblies have internal circuits or printed circuit boards. The technician can troubleshoot only the circuit to the board, not circuits within the board. If the trouble is in the circuit board, the board must be changed. **Figure 31.109** shows how one manufacturer diagrams spark ignition. One is a pictorial diagram and the other is a line drawing. Notice that the manufacturer has placed the terminal board at the bottom of the pictorial and to the side of the line diagram. Components are not placed in the same position in the diagrams.

The spark ignition board in the previous example has terminals that provide for adding other components, such as an

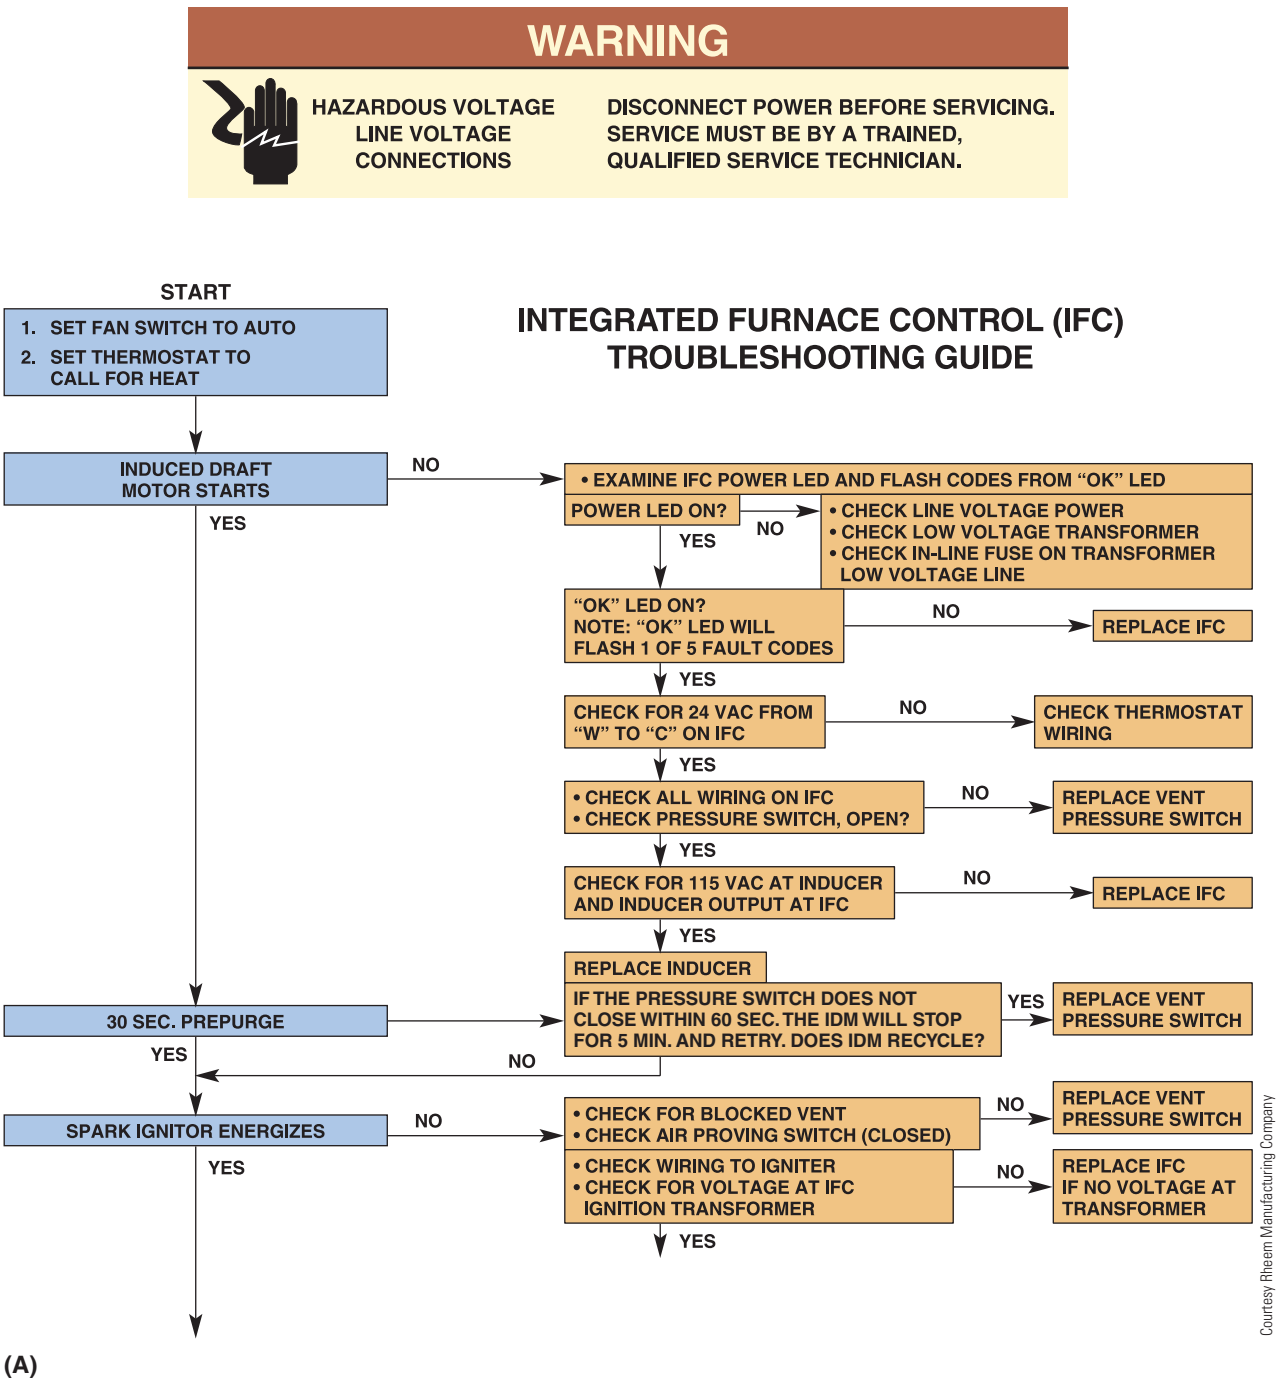
Figure 31.103 A troubleshooting guide for a spark ignition system with an integrated furnace controller (IFC).



electronic air cleaner and a vent damper shutoff motor. This is handy because the installing technician only has to follow the directions to wire these components when they are used in conjunction with this furnace. The electronic air cleaner is properly interlocked to operate only when the fan is running. This component is not always easy to wire into the circuit to achieve the proper sequence, particularly in two-speed fan applications.

The following reference points can be used for the circuit board illustrated:

1. **SAFETY PRECAUTION:** *When the front panel is removed, all procedures come to a stop until the switch is blocked closed. This should only be done by a qualified service technician.*
2. The fan motor is started through the 2A contacts and in single speed.

Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 31.106 The thermocouple no-load test. Operate the pilot flame for at least 5 min with the main burner off. (Hold the gas cock knob in the PILOT position and depress.) Disconnect the thermocouple from the gas valve while still holding the knob down to maintain the flame on the thermocouple. Attach the leads from the millivoltmeter to the thermocouple. Use direct-current voltage. Any reading below 20 mV indicates a defective thermocouple or poor pilot flame. If the pilot flame is adjusted correctly, test the thermocouple under load conditions.

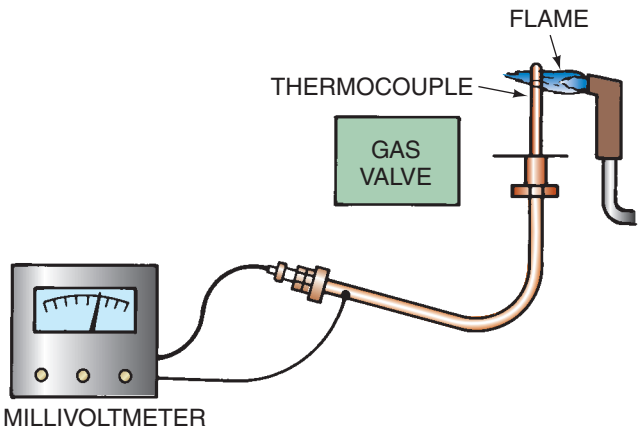

Figure 31.107 The thermocouple test under load conditions. Disconnect the thermocouple from the gas valve. Screw the thermocouple test adapter into the valve, and screw the thermocouple into the test adapter. Light the pilot and main burner and allow them to operate 5 min. Attach one lead from the millivoltmeter to either connecting post of the adapter and the other lead to the thermocouple tubing. Any reading under 9 mV would indicate a defective thermocouple or insufficient pilot flame. Adjust the pilot flame. Replace the thermocouple if necessary. Ensure that the pilot, pilot shield, and thermocouple are positioned correctly. Too much heat at the cold junction would cause a satisfactory voltage under no-load conditions but an unsatisfactory voltage under a load condition.

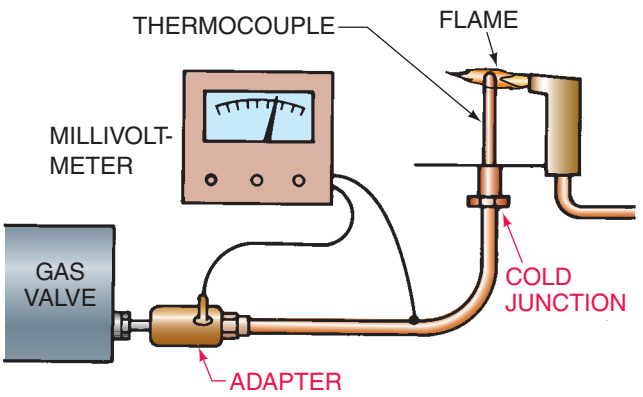

3. Leaving the probe on the C terminal, move the other probe to positions 2, 3, and 4. 24 V should be detected at each terminal, or there is no need to proceed.
4. The key to this circuit is to have 24 V between the C terminal and the GAS-1 terminal. At this time, the pilot should be trying to light. The spark at the pilot should be noticeable. It makes a ticking sound with about one-half second between sounds.
5. If the pilot light is lit and the ticking has stopped, the 6H relay should have changed over. The NC contacts in the 6H relay should be open and the NO contacts should be closed. This means that there should be 24 V between the C terminal, which is the same as the GAS-2 terminal, and the GAS-3 terminal. The 6H relay is actually a bimetallic pilot-proving relay, **Figure 31.56(C)**, and heat from the pilot changes its position. If it will not pass power, it must be replaced.
6. When the circuit board will pass power to the GAS-3 terminal (probe position 5) and the burner will not light, the gas valve is the problem. Before changing it, be sure that its valve handle is turned in the correct direction and the interconnecting wire is good. The procedure of leaving one probe on the C terminal and moving the other probe can be done quickly when a furnace has a circuit board with terminals, which makes troubleshooting easier.
7. If the R terminal has 24 V and the W terminal does not, the thermostat and the interconnecting wiring are the problem. A jumper can be placed from R to W for a moment; if the spark starts to arc, the problem is the wiring or the thermostat.
8. The fan is started through the circuit board and is also part of the sequence of operation. The fan is started when the 2A relay is deenergized through the time-delay circuit. This is accomplished when the 6H relay in the circuit board changes position. When 24 V is detected from terminal C to terminal GAS-3, the time-delay circuit starts timing. When the time is up, the contacts open and deenergize the fan relay coil; the contacts close, and the fan starts.
9. The voltmeter can be relocated to the COM terminal and the LO terminal. When relay 2A is passing power, 115 V should be detected here. If there is power to the fan motor and it will not start, open up the fan section and check the motor for continuity. Check the capacitor. See if the motor is hot. If the motor cannot be started with a good capacitor, replace the motor. **Figure 31.110** shows a flowchart for systematically troubleshooting an intermittent pilot module. **SAFETY PRECAUTION:** *Not all ignition modules are alike. The service technician must consult with the ignition module manufacturer for specific systematic troubleshooting charts or procedures.*•

31.30 COMBUSTION EFFICIENCY

Given the high and ever-increasing cost of fuel, it is essential that adjustments be made to produce the most efficient but safe combustion possible. It is also necessary to ensure that an overcorrection that would produce carbon monoxide is not made.

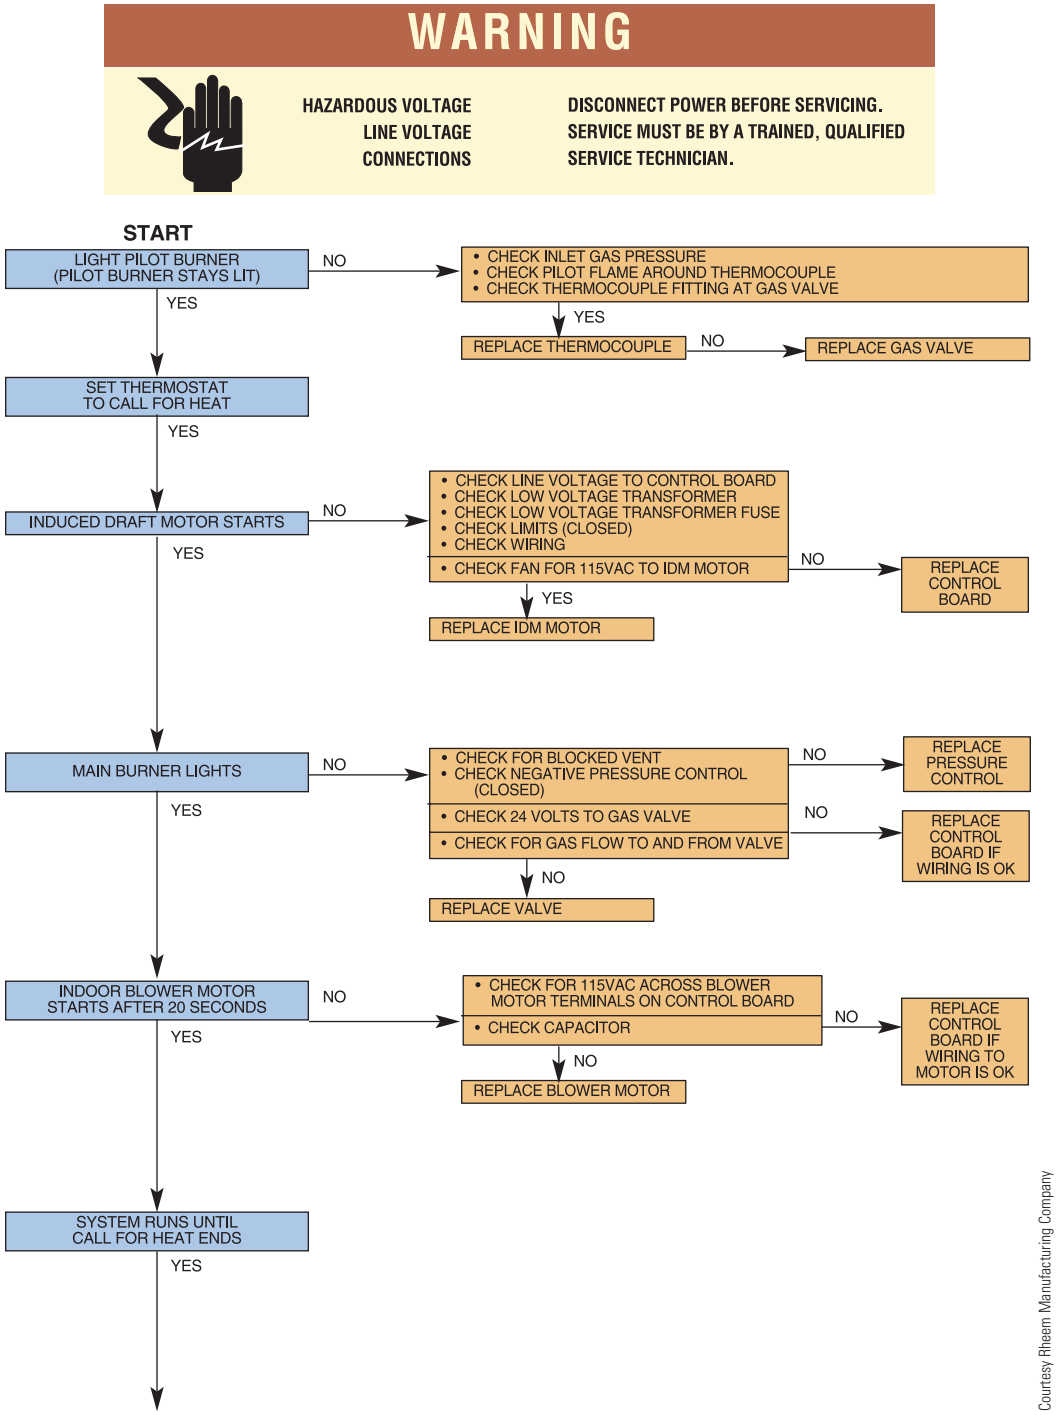
Figure 31.108 A guide for systematically troubleshooting a standing pilot furnace.



Courtesy Rheem Manufacturing Company

Atmospheric gas burners use primary air, which is sucked in with the gas, and secondary air, which is pulled into the combustion area by the draft produced when ignition takes place. **SAFETY PRECAUTION:** *Incomplete combustion produces carbon monoxide. Enough secondary air must be supplied so that carbon monoxide will not be produced.* *Primary air intake can be adjusted by turning the shutters near the orifice. This adjustment is made so that the flame has the characteristics specified by the manufacturer. Generally, however, the flame is blue with a small orange tip when it is burning efficiently,* **Figure 31.111**.

Modern furnaces often do not have an air adjustment because of the types of burners used. With the inshot burner, air adjustment is not as critical. Conversion burners used to convert coal or oil furnaces or boilers to gas-fired normally have secondary air adjustments, and these must be adjusted in the field for maximum efficiency. The carbon dioxide test is used to get the necessary information from the flue gases to make this adjustment.

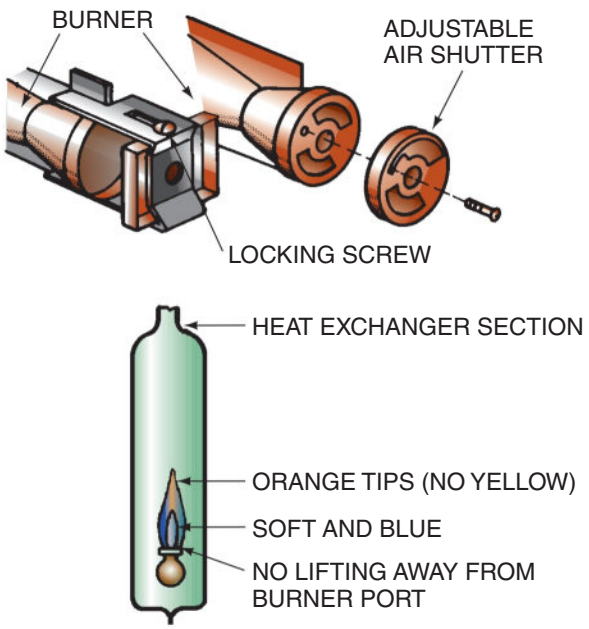
Figure 31.111 Main burner flame adjustment. The air shutter is turned to produce the proper flame. To check the flame, turn the furnace on at the thermostat. Wait a few minutes to ensure that any dust or other particles have been burned and no longer have an effect on the flame. The flames should be stable, quiet, soft, and blue with slightly orange tips. They should not be yellow. They should extend directly upward from the burner ports without curling downward, floating, or lifting off the ports, and they should not touch the side of the heat exchanger.



Carbon dioxide in the flue gases is actually a measurement of the excess secondary air supplied. As the secondary air is decreased, the percentage of carbon dioxide in the flue gases increases, and the chance of producing carbon monoxide becomes greater.

If the correct amount of air is being supplied and perfect combustion is taking place, a specific amount of carbon dioxide by volume will be present in the flue gases. This is called the *ultimate carbon dioxide content*. The following table indicates the ultimate percentage of carbon dioxide content for various gases (these figures assume perfect combustion and are not used as the carbon dioxide reading for a gas-burning appliance):

For Perfect Combustion	
Natural gas	11.7–12.2
Butane gas	14.0
Propane gas	13.7

SAFETY PRECAUTION: *A gas furnace is never adjusted to produce the ultimate carbon dioxide content because there is too much danger of producing carbon monoxide. Therefore, the accepted practice is to adjust the secondary air to produce excess air—resulting in less carbon dioxide by volume in the flue gases.*

HVAC GOLDEN RULES

When making a service call to a residence:

- Always carry the proper tools and avoid extra trips through the customer's house.
- Make and keep firm appointments. Call ahead if you are delayed. The customer's time is valuable also.
- Keep customers informed if you must leave the job for parts or other reasons. Customers should not be upset when you inform them of your return schedule if it is reasonable.

Here are some simple, inexpensive procedures that may be included in the basic service call:

- Leave the furnace and area clean.
- If a standing pilot is used, perform a service check.
- Clean or replace dirty filters.
- Lubricate bearings when needed.
- Check the burner compartment to ensure burners are clean and burning correctly.
- Replace all panel covers.

PREVENTIVE MAINTENANCE

Gas equipment preventive maintenance consists of servicing the air-side components: filter fan, belt and drive, and the burner section. Air-side components are the same for gas as for electric forced-air heat, so only the burner section will be discussed here.

The burner section consists of the actual burner, the heat exchanger, and the venting system for the products of combustion. The burner section of the modern gas furnace does not need adjustment from season to season. It will burn efficiently and be reliable if it is kept clean. Rust, dust, or scale must be kept from accumulating on top of the burner where the secondary air supports combustion or in the actual burner tube where primary air is induced into the burner. When a burner is located in a clean atmosphere (no heavy particles in the air as in a manufacturing area), most of the dust particles in the air will burn and exit through the venting system. The burner may not need cleaning for many years. A vacuum cleaner with a crevice tool may be used to remove small amounts of scale or rust deposits.

The burner and manifold may be removed for more extensive cleaning inside the burner tube where deposits may be located. Each burner may be removed and tapped lightly to break the scale loose. An air hose should be used to blow

(*Continued*)

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

PREVENTIVE MAINTENANCE (*Continued*)

down through the burner ports while the burner is out of the system. The particles will blow back out of the primary air shutter and out of the system. **SAFETY PRECAUTION:** *Wear goggles when using compressed air for cleaning. This cleaning function cannot be accomplished while the burners are in the furnace.*•

Burner alignment should be checked to make sure that no flame impingement on the heat exchanger is occurring. The burners should set straight and feel secure while in place. Large deposits of rust scale may cause flame impingement and must be removed.

A combustion analysis is not necessary as routine maintenance on the modern gas furnace. The primary air is sometimes the only adjustment on new furnaces. Many times, even the primary air cannot be adjusted because the burner is an inshot burner. All gas burners should burn with a clear flame, with only orange streaks in the flame. **There should never be any yellow or yellow tips on the flame. If yellow tips cannot be removed from the flame by adjustments, the burner contains dirt or trash and should be removed for cleaning.**

Observe the burner for correct ignition as it is lit. Often, the crossover tubes that carry the burner flame from one burner to the next get out of alignment and the burner lights with an irregular pattern. Sometimes it will "puff" when slow ignition of one of the burners occurs.

The pilot light flame should be observed for proper characteristics. It should not have any yellow tips and it should not impinge on the burner. It should impinge on the thermocouple only. If the pilot flame characteristics are not correct, the pilot assembly may have to be removed and cleaned. Compressed air usually will clear any obstructions from the pilot parts. **SAFETY PRECAUTION:** *Do not use a needle to make the orifice holes larger. If they are too small, obtain the correct size from a supply house.*•

The venting system should be examined for obstructions. Birds may nest in the flue pipe, or the vent cap may become damaged. Visual inspection is the first procedure. Then, with the furnace operating, the technician should strike a match in the vicinity of the draft diverter and look for the flame to pull into the diverter. This is a sign that the furnace is drafting correctly.

Observe the burner flame with the furnace fan running. A flame that blows with the fan running indicates a crack in the heat exchanger. This would warrant further examination of the heat exchanger. It is difficult to find a small crack in a heat exchanger and one may only be seen with the heat exchanger out of the furnace housing. Extensive tests have been developed for proving whether or not a gas furnace heat exchanger has a crack. These tests may be beyond what a typical technician would do because the recommended tests require expensive equipment and experience.

High-efficiency condensing furnaces require maintenance of the forced-draft blower motor if it is designed to be lubricated. The condensate drain system should be checked to be sure it is free of obstructions and that it drains correctly. Manufacturers of condensing furnaces sometimes locate the condensing portion in the return air section where all air must move through the coil. This is a finned coil and will collect dirt if the filters are not cleaned. Routine inspection of this condensing coil for obstruction is a good idea.

All installations should be checked by setting the room thermostat to call for heating and by making sure the proper sequence of events occurs. For example, when checking a standard furnace, the pilot may be lit all the time and the burner should ignite. Then the fan should start. Some furnaces may have intermittent pilot lights. The pilot should light first, the burner next, and then the fan should start. With a condensing furnace, the power vent motor may start first, the pilot light next, then the burner, and the fan motor last. Always know the sequence of operation for the furnace.

Some technicians disconnect the circulating fan motor and allow the furnace to operate until the high-limit control shuts it off. This proves the safety device will shut off the furnace. Technicians will often perform a combustion analysis test to check furnace efficiency and then make an air shutter adjustment. The adjustment should produce from 65% to 80% of the ultimate carbon dioxide content, which would produce 8% to 9.5% carbon dioxide in the flue. It is important that manufacturers' specifications be followed when making any adjustments.

The flue-gas temperature should also be taken if the percent of combustion efficiency is to be determined. The percent combustion efficiency is an index of the useful heat obtained. It is not possible to obtain 100% efficiency because, except on direct-vented furnaces, heated air does leave the building through the flue.

Average gas-burning furnaces manufactured before 1982 should produce 75% to 80% efficiency. Modern digital furnace efficiency testing equipment is available and provides good accuracy, **Figure 31.112**.

Test equipment is also available for checking the carbon monoxide content in the flue gases. Carbon monoxide–free combustion is defined as less than 0.04% carbon monoxide in an air-free sample of the flue gas. Carbon monoxide can be produced by flame impingement on a cool surface and by insufficient primary air (yellow flame) as well as insufficient secondary air.

Other adjustments that can be checked and compared with manufacturers' specifications are suction at the draft hood, draft at the chimney, gas pressure, and gas input.

31.31 SERVICE TECHNICIAN CALLS

SERVICE CALL 1

The manager of a retail store calls. *There is no heat. This is an upflow gas furnace with a standing pilot and air conditioning. The low-voltage transformer is burned out because the gas valve coil is shorted. This causes excess current for the transformer. The furnace is located in the stockroom.*

The technician arrives at the job and knocks on the store's service entrance door. After being invited in, the technician then asks the manager his account of the problem and listens very carefully, while maintaining a comfortable distance from the manager. After the customer is finished talking and all of his questions are answered, the technician starts work on the furnace.

The technician goes to the room thermostat and turns the fan switch to ON to see whether the indoor fan will start. It will not, so the technician suspects that the low-voltage power supply is not working. The thermostat is set to call for heat. The technician goes to the stockroom where the furnace is located. The voltage checked at the transformer secondary indicates 0 V. The technician turns the power off and uses the ohmmeter to check continuity of the transformer. The secondary (low-voltage) coil has an open circuit, so the transformer is changed. Before connecting the secondary wires, the technician checks the continuity of the low-voltage circuit. There is only 2 Ω of resistance in the gas valve coil. This is so low that it will cause a high current flow in the secondary circuit. (The resistance should be at least 20 Ω.) The technician goes to the truck and checks the continuity of another gas valve and finds it to be 50 Ω, so the gas valve is also changed.

The system is started with the new gas valve and transformer. A current check of the gas valve shows that it is pulling only 0.5 A, which is not overloaded. If the technician had just installed the transformer and turned the power on, it is likely that another transformer failure would have occurred quickly.

The technician changes the air filters and calls the store manager back to the stockroom for a conference before leaving. The store manager is informed that the boxes of inventory must be kept away from the furnace because they may present a fire hazard. The technician makes a quick check to make sure the job site is clean before leaving. Billing information and a work description with costs are then politely presented to the manager. After the technician makes sure his hands are clean, handshakes are exchanged and the technician leaves the job site.

SERVICE CALL 2

A customer in a residence reports that *fumes can be smelled and are probably coming from the furnace in the hall closet. The furnace has not been operated for the past two weeks because the weather has been mild. Because the fumes might be harmful, the dispatcher tells the customer to shut the furnace off until a technician arrives. The flue is stopped up with a shingle laid on top of the brick chimney by a roofer who had been making repairs.*

The technician arrives and starts the furnace. A match is held at the draft diverter to see whether the flue has a negative pressure. The flue-gas fumes are not rising up the flue for some reason; the match flame blows away from the flue pipe and draft diverter. The technician turns off the burner and examines it and the heat exchanger area with a flashlight. There is no soot that would indicate the burner had been burning incorrectly. The technician goes to the roof to check the flue and notices a shingle on top of the chimney. After the shingle is lifted off, heat rises out of the chimney.

The technician goes back to the hall closet and starts the furnace again. A match is held at the draft diverter, and the flame is drawn toward the flue. The furnace is now operating correctly. The technician changes the furnace filter and oils the fan motor before leaving the job.

SERVICE CALL 3

A customer requests that an efficiency check be performed on a furnace. *This customer thinks that the gas bill is too high for the conditions and wants the system completely checked out.*

The customer wants to watch the complete procedure of the service call. Before getting started, the technician asks the customer many pertinent questions. While the customer is talking, the technician shows respect by keeping eye contact and being a courteous listener. The technician is careful not to interrupt the customer and never lets the customer feel stupid about a technical topic. When talking about a technical topic, the technician makes sure to use clear, concise, everyday language the customer can understand. The technician never wants the customer to think he is bragging about his technical training skills. The technician will run an efficiency test on the furnace burners at the beginning and then at the end, so the customer can see the difference.

The furnace is in the basement and easily accessible. The technician turns the thermostat to 10°F above the room temperature setting to ensure that the furnace will not shut off in the middle of the test. He then goes to the truck and gets the flue-gas analyzer kit. **SAFETY PRECAUTION:** *Be careful not to touch the stack; the stack temperature is taken at the heat exchanger side of the draft diverter.* A sample of the flue gas is drawn into the sample chamber after the flue-gas temperature has stopped rising and the indoor fan has been running for about 5 min. This ensures that the furnace is up to maximum temperature.

The flue-gas reading shows that the furnace is operating at 80% efficiency. This is normal for a standard-efficiency furnace. After the test is completed and recorded, the technician shuts off the gas to the burner and allows the fan to run to cool down the furnace.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

When the furnace has cooled enough to allow the burners to be handled, the technician takes them out. The burners are easily removed in this furnace by removing the burner shield and pushing the burners forward one at a time while raising up the back. They will then clear the gas manifold and can be removed. There is a small amount of rust, which is normal for a furnace in a basement. The draft diverter and the flue pipe are removed so that the technician and customer can see the top of the heat exchanger. All is normal—no rust or scale.

With a vacuum cleaner the technician removes the small amount of dirt and loose rust from the heat exchanger and burner area. The burners are taken outside where they are blown out with a compressed air tank at the truck. **SAFETY PRECAUTION:** *The technician wears eye protection.* After the cleaning is complete, the technician assembles the furnace and tells the customer that it was in good condition and that there will be no difference in efficiency. Modern gas burners do not stop up as badly as the older ones, and the air adjustments will not allow the burner to get out of adjustment more than 2% or 3% at the most.

The technician oils the fan motor and changes the filter. The system is started and allowed to get up to normal operating temperature. While the furnace is heating to that temperature, the technician checks the fan current and finds it to be running at full load. The fan is doing all the work that it can. The efficiency check is run again, and the furnace is still operating at about 80%. It is now clean, and the customer has peace of mind. The technician thoroughly cleans the work site and washes his hands before presenting the customer with the billing information. The customer and technician shake hands and the technician thanks him for his business, letting the customer know that his company values the business. The thermostat is set before leaving.

SERVICE CALL 4

A customer indicates that *the pilot light will not stay lit. The pilot light goes out after it has been lit a few minutes. The heat exchanger has a hole in it very close to the pilot light. The pilot light will light, but when the fan starts it blows out the pilot light.*

The technician arrives, checks the room thermostat to see that it is set above the room temperature, and then goes to the basement. The standing pilot light is not lit, so the technician lights it and holds the button down until the thermocouple will keep the pilot light lit. When the gas valve is turned to ON, the main burner lights. Everything is normal until the fan starts, then the pilot light flame starts to wave around and after a short period it goes out. The thermocouple cools, and the gas to the main burner shuts off. The technician shows the customer the hole in the heat exchanger. He turns the gas valve off and explains to the customer that the furnace cannot be operated in this condition because of the potential danger of gas fumes.

Given that this furnace is 18 years old, the technician advises that the customer really should consider getting a new one. The heat exchanger can be changed, but that requires considerable labor plus the price of the heat exchanger. The customer decides to replace the furnace.

SERVICE CALL 5

A residential customer calls. *There is no heat. The main gas valve coil is shorted, and the low-voltage transformer is burned. This symptom in an electronic intermittent ignition system,* ***Figure 31.109****, can lead the technician to believe that the printed circuit board is defective.*

When the technician arrives he notices that the indoor fan is running. It cannot be stopped by turning the room thermostat to OFF. (The low-voltage circuit holds the fan motor off in this system.) A low-voltage problem is suspected. The technician goes to the furnace and checks the output of the low-voltage transformer; the meter reads 0 V at the transformer. The transformer is burned. **SAFETY PRECAUTION:** *The technician turns off the power and replaces the transformer.* When the power is restored, the electronic ignition circuit lights the pilot light. Everything seems normal, but the transformer becomes extra hot and smells like it is burning.

The technician turns off the power and changes the electronic circuit board and 1-A fuse. When power is restored, the pilot lights and everything is normal for a moment, but the transformer is still getting hot. The technician turns off the power and fastens a clamp-on ammeter to the low-voltage system, using 10 wraps of wire to amplify the ampere reading, **Figure 12.55**. The amperage is normal. When power is restored, the pilot lights again and the amperage is normal (about 0.5 A). When the pilot proves and it is time for the main gas valve to be energized, the current goes up to 3 A and the transformer begins to heat up.

The technician turns off the power and uses the ohmmeter to check the resistance of all power-consuming components in the circuit. When the main gas valve coil in the gas valve is checked, it shows 2 Ω of resistance. The gas valve is replaced. Power is restored. The pilot light is lit and proved. The main gas valve opens and the burner ignites. The system operates normally.

The technician turns off the power, and reinserts the original circuit board, and then restores the power. The furnace goes through a normal start-up.

SERVICE CALL 6

A residential customer indicates that although the furnace is heating the house, it is blowing cold air just before the fan goes off at the end of each heating cycle. *The warm-air fan's off–delay timing is set too long. The furnace has an IFC with*

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

programmable DIP switches for the fan's off–delay timing, **Figures 31.45(A)** *and* **(B)**. *These switches have to be repositioned to shorten the fan's programmed off–delay timing. This will shut the fan off sooner after each heating cycle and prevent the cooler air from being blown into the conditioned space.*

Before arriving at the residence, the service technician stops to refuel the service van and clean up from a previous service call. The technician uses the gas station's bathroom to change into a clean uniform. After washing his hands and face, the technician looks in the mirror to make sure his hair is still combed neatly. The technician has a few tattoos on his forearms, so he makes sure they are hidden by the long sleeves of his uniform. After tucking in his uniform and wiping down his shoes with a clean, moist paper towel, the technician drives to the service call location.

After knocking and politely introducing himself, the technician waits to be invited in before entering the house. After politely listening to the customer, the technician begins work. He takes the front panel off the furnace, putting some duct tape on the door switch to keep the furnace running while the front panel is removed. He then turns the thermostat 10°F higher than the room temperature to initiate a heating cycle. Once the furnace has run for 5 min, the thermostat is turned down. As usual, the flame goes out but the warm-air fan remains running. The technician times the fan's run time with a wristwatch once the flame goes out and finds that the off–delay timing for the fan is 180 sec. The technician then checks the DIP switches on the IFC and finds that switch 1 is in the up position and switch 2 is in the down position, **Figure 31.45(B)**. According to the faceplate of the IFC, the DIP switches in this position will give a 180-sec off–delay time for the warm-air fan. The service technician then changes the switches so that both switch 1 and switch 2 are in the up position, **Figure 31.45(A)**. This will give the warm-air fan a 60-sec off–delay time.

The technician then cycles the furnace through a complete cycle and checks the fan's off–delay timing again. The timing is now 60 sec as planned. The technician notices that the air coming from the furnace just before it shuts off is much warmer than it was with the longer off–delay timing. The technician explains to the homeowner what has been adjusted and how it pertains to the warm-air fan's off–delay timing, hands the customer the billing information with all costs explained in detail, thanks the customer, and sets the thermostat to the proper temperature before leaving the house.

SERVICE CALL 7

A residential customer says that the furnace is not heating the house. No airflow is coming from any of the warm-air ducts. *The combustion blower motor is burned out and the draft pressure switch is not closing, preventing the burners from firing,* **Figure 31.70(B)**.

Before taking the front cover off the furnace, the service technician notices a self-diagnostic light flashing through a clear plastic inspection hole on the front panel of the furnace, **Figure 31.113**. A technician must always look into this inspection hole before removing the front cover. Taking the front cover off the furnace will many times take power away from the IFC board and reset the self-diagnostic flashing lights. The technician makes note of the flashing intervals. The front cover is then removed, which interrupts power to the IFC and resets the self-diagnostics. The furnace door switch is taped closed with duct tape to keep the furnace running while the door is off. The diagnostic light is blinking in intervals of three flashes, indicating that the draft pressure switch is open, **Figure 31.82** and **Figure 31.45(B)**.

The service technician turns power to the furnace off to make sure the IFC is reset, then turns the power back on. The combustion blower motor does not come on, which prevents the draft pressure switch from closing. The technician then shuts off power to the furnace and unplugs the wire leads going to the combustion blower motor from the IFC. An ohmmeter reading of infinity across the combustion blower motor leads proves to the technician that the combustion blower motor is open. A new combustion blower motor is

Figure 31.113 A furnace with a clear plastic inspection hole on the front panel for observing the self-diagnostic flashing light.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

installed and plugged into the IFC. The technician must take care that he is grounded so as not to cause a static shock, which can easily damage the delicate IFC.

Power is turned back on. The combustion blower motor is operating, the pressure switch has closed, and the hot surface igniter is glowing red. The burners light in about 5 sec. The technician politely explains to the customer what was wrong with the furnace and that the problem has been remedied. The technician then makes sure the furnace operates successfully through three complete heating cycles.

SERVICE CALL 8

A residential customer complains that there is no heat in the house but the warm-air blower runs continuously. *The burner high-limit control has opened due to a dirty return air filter.*

Once arriving at the customer's residence, the service technician parks the service van on the street so as not to block the driveway. The technician maintains a comfortable distance from the door while waiting for the customer to answer the bell. After introducing himself and his business and waiting until the customer invites him in, the technician politely listens to the customer's account of the problem. After answering the customer's questions and asking a few questions of the customer, the technician asks to see the furnace. The customer then leads the technician to the basement and work is started.

The service technician notices that the self-diagnostic status light is blinking with only one flash, **Figure 31.81(A)**. The self-diagnostic code on the faceplate of the IFC indicates one flash is for an open burner limit switch. Because the warm-air fan is running continuously, the technician pulls out the furnace filter. The filter is completely plugged. No or low airflow will heat up the heat exchanger until the burner's high-limit control opens, **Figure 31.47(A)**. The technician then interrupts power to reset the IFC. When power is resumed, the furnace runs fine. He installs a new filter and the furnace continues to run correctly. The technician politely advises the customer to replace the furnace filter at least monthly, and sometimes even more often, to avoid having this problem again.

The service technician then hands the customer the billing information and they exchange handshakes. The technician leaves the customer his company's business card and thanks the customer for their valued business.

Solutions for the following service calls are not provided here. Please discuss the solutions with your instructor.

SERVICE CALL 9

A residential customer calls to report that *the furnace stopped in the middle of the night. The furnace is old and has a thermocouple for the safety pilot.*

The technician arrives and goes directly to the thermostat. The thermostat is set correctly for heating, but the thermometer shows a full 10°F below the thermostat setting. This unit has air-conditioning, so the technician turns the fan switch to ON to see if the indoor fan will start; it does.

The furnace is in an upstairs closet. The technician sees that the pilot light is not burning. This system has 100% shutoff, so there is no gas to the pilot unless the thermocouple holds the pilot-valve solenoid open. The technician positions the main gas valve to the PILOT position and presses the red button to allow gas to the pilot light. The pilot light burns when a lit match on an extender is placed next to it. The technician then holds the red button down for 30 sec and slowly releases it. The pilot light goes out.

What is the likely problem and the recommended solution?

SERVICE CALL 10

A residential customer calls. *The furnace is not heating the house. The furnace is located in the basement and is very hot, but no heat is moving into the house. The dispatcher tells the customer to turn the furnace off until a service technician can get to the job.*

The technician has some idea of what the problem is from the symptoms and knows what kind of furnace it is from previous service calls, so he brings some parts along. When the technician arrives, the room thermostat is set to call for heat. From the service request it is obvious that the low-voltage circuit is working because the customer says the burner will come on. The technician then goes to the basement and hears the burner operating. When the furnace has had enough time to get warm and the fan has not started, the technician takes the front control panel off the furnace and notices that the temperature-operated fan switch dial (circular dial type, **Figure 31.46**) has rotated as if it were sensing heat. **SAFETY PRECAUTION:** *The technician carefully checks the voltage entering and leaving the fan switch.*•

What is the likely problem and the recommended solution?

SERVICE CALL 11

A residential customer calls. *There is no heat. The furnace is in the basement, and there is a sound like a clock ticking.*

Making sure not to block the driveway, the service technician puts on protective shoe coverings, rings the doorbell, and then steps back to a comfortable distance from the door. When the customer comes to the door, the technician politely introduces himself while handing out his business card. Once invited in, the technician politely listens to the customer and

asks where the furnace is located. The service technician then goes to the basement, locates the furnace, and removes the furnace door. The technician hears the arcing sound. On removing the shield in front of the burner, the technician sees the arc. He lights a match on an extender and places it near the pilot to see whether there is gas at the pilot and whether it will light. It does. The arcing stops, as it should. The burner lights after the proper time delay.

What is the likely problem and the recommended solution?

SUMMARY

- Forced-hot-air furnaces are normally classified as upflow, downflow (counterflow), horizontal, low-boy, or multipoise.
- Multipoise furnaces can be installed in any position, which adds versatility. Multiple safety controls such as bimetallic flame rollout or overtemperature limits must be designed into the furnace for safety.
- Auxiliary limit switches, which sense room return-air temperature, interrupt the burner operation when the temperature gets too hot.
- Vent limit or draft safeguard switches are normally closed switches and are usually mounted on the draft hood or near the exit of the exhaust vent pipe. They monitor the draft hood temperature and open when there is any spillage of flue gas.
- Furnace components consist of the cabinet, gas valve, manifold, pilot, burners, heat exchangers, blower, electrical components, and venting system.
- Gas fuels are natural gas, manufactured gas (used in few applications), and LP gas (propane, butane, or a mixture of the two).
- Inches of water column is the unit used when determining or setting gas fuel pressures.
- A water manometer or digital manometer measures gas pressure in inches of water column.
- For combustion to occur, there must be fuel, oxygen, and heat. The fuel is the gas, the oxygen comes from the air, and the heat comes from the pilot flame or other igniter.
- Gas burners use primary and secondary air. Excess air is always supplied to ensure as complete combustion as possible.
- Gas valves control the gas flowing to the burners. The valves are controlled automatically and allow gas to flow only when the pilot is lit or when the ignition device is operable.
- Some common gas valves are classified as solenoid, diaphragm, or heat motor valves.
- A servo pressure regulator is an outlet or working pressure regulator. It monitors gas outlet pressure when gas flow rates and inlet pressures vary widely.
- A redundant gas valve has two or three valve operators that are physically in series with one another but wired in parallel.
- Ignition at the main burners is caused by heat from the pilot or from an electric spark. There is also direct-spark or direct-burner ignition, in which the spark or hot surface igniter ignites the gas at the burners.
- The thermocouple, the bimetal, and the liquid-filled remote bulb are three types of safety devices (flame-proving devices) that ensure gas does not flow unless the pilot is lit.
- The manifold is a pipe through which the gas flows to the burners and on which the burners are mounted.
- The orifice is a precisely sized hole in a spud through which the gas flows from the manifold to the burners.
- The burners have holes or slots of various designs through which the gas flows.
- Inshot burners are usually made of aluminized steel and have crossover porting for good flame retention, proper flame carryover to each main burner, and excellent flame stability.
- Modern gas furnaces use either induced- or forced-draft systems.
- Forced-draft systems have a combustion blower motor on the inlet of the heat exchanger. They push or blow combustion gases through the heat exchanger and create a positive pressure in the heat exchanger.
- A blower circulates heated air. The blower is turned on and off by a fan switch, which is controlled either by time or by temperature.
- Modern heat exchangers come in many sizes, shapes, and materials.
- Modern condensing furnaces may have two or even three heat exchangers.
- Many modern gas furnaces use electronic modules or integrated furnace controllers (IFCs) to control operations. These controllers often have dual-in-line-pair (DIP) switches, which can be switched to reprogram the furnace to make it more versatile.
- The limit switch is a safety device. If the fan does not operate or if the furnace overheats for another reason, the limit switch causes the gas valve to close.
- High-limit switches come in a variety of styles, such as bimetallic snap action, helical bimetal, or liquid-filled. They are either manual or automatic resettable.

Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- In a flame rectification system, the pilot flame, or main flame, can conduct electricity because it contains ionized combustion gases that are made up of positively and negatively charged particles. The flame acts as a switch.
- Flame rectification systems can be classified as either single-rod (local-sensing) or dual-rod (remote-sensing).
- A direct-vented high-efficiency gas furnace has a sealed combustion chamber.
- A positive pressure system can be vented vertically or through a sidewall. Its flue pipe pressure is positive the entire distance to its terminal end.
- The dew point temperature is the temperature at which the condensation process begins in a condensing furnace. The DPT varies depending on the composition of the flue gas and the amount of excess air. As excess air decreases, the DPT increases.
- Excess air consists of combustion air and dilution air. Combustion air is primary air and/or secondary air. Primary air enters the burner before combustion takes place. Secondary air is air present after combustion and supports combustion.
- Dilution air is excess air after combustion and usually enters at the end of the heat exchanger.
- Furnace efficiency ratings are determined by the amount of heat that is transferred to the heated medium.
- Electronic ignition modules come in 100% shutoff, non-100% shutoff, continuous retry with 100% shutoff, and many other custom control schemes that are manufacturer-dependent.
- Twinning involves the side-by-side operation of two furnaces connected by a common ducting system.
- Modern two-stage gas furnaces use a two-stage gas valve and a two-speed combustion blower motor with two pressure switches to prove the draft.
- Modern modulating gas furnaces adjust to the heat loss of a structure. They use a modulating gas valve instead of a staged valve.
- One of the first steps in systematically troubleshooting a furnace with an integrated furnace controller is to obtain the electrical diagram of the furnace and the IFC sequence of operation.
- **SAFETY PRECAUTION:** *Venting systems must provide a safe and effective means of moving the flue gases to the outside atmosphere. Flue gases are mixed with other air through the draft hood. Venting may be by natural draft or by forced draft. Flue gases are corrosive.*•
- Gas piping should be kept simple with as few turns and fittings as possible. It is important to use the correct pipe size.
- **SAFETY PRECAUTION:** *All piping systems should be tested carefully for leaks.*•
- The combustion efficiency of furnaces should be checked and adjustments made when needed.
- Preventive maintenance calls should be made periodically on gas furnaces.

REVIEW QUESTIONS

1. The four types of gas furnace airflow patterns are _____, _____, _____, and _____.
2. Describe the function of a multipoise or multipositional furnace.
3. Describe the function of a draft safeguard switch.
4. Where are auxiliary limit switches used in heating applications?
5. The specific gravity of natural gas is
   A. 0.08.
   B. 1.00.
   C. 0.42.
   D. 0.60.
6. What is a water and digital manometer?
7. The pressure at the manifold for natural gas is typically
   A. 10 psig.
   B. 8 in. WC.
   C. 5.5 psia.
   D. 3.5 in. WC.
8. What is the approximate oxygen content of air?
9. The typical manifold pressure for propane gas is _____ in. WC.
10. Why is excess air supplied to all gas-burning appliance burners?
11. The purpose of the gas regulator at a gas burning appliance is to
    A. increase the pressure to the burner.
    B. decrease the pressure to the burner.
    C. filter out any water vapor.
    D. cause the flame to burn yellow.
12. True or False: All gas valves snap open and closed.
13. Which of the following features does an automatic combination gas valve have?
    A. Pressure regulator
    B. Pilot safety shutoff
    C. Redundant shutoff feature
    D. All of the above
14. What is the function of the servo pressure regulator in a modern combination gas valve?
15. What is a redundant gas valve?
16. Briefly describe an intermittent pilot gas valve system.
17. Briefly describe a direct burner gas valve system.
18. Where are inshot burners used in heating applications?

19. Describe the difference between a forced-draft system and an induced-draft system.
20. What is an integrated furnace controller (IFC)?
21. What is meant by the warm-air blower's off–delay timing?
22. What are dual-in-line-pair (DIP) switches?
23. What is a flame rollout safety switch used for in heating applications?
24. Describe the two types of pilot lights.
25. True or False: A thermocouple develops direct current and voltage.
26. Describe how a thermocouple flame-proving system functions.
27. Describe how a bimetallic flame-proving system functions.
28. Describe how a liquid-filled flame-proving system functions.
29. Explain why the preceding flame-proving systems are called safety devices.
30. Describe a flame rectification flame-proving system.
31. What is a hot surface ignition system?
32. Describe the difference between a single-rod (local-sensing) and a dual-rod (remote-sensing) system as they pertain to flame rectification.
33. Flame current is measured in _____.
34. What is a direct-vented furnace?
35. What is a non-direct-vented furnace?
36. What is meant by a furnace that has a positive pressure venting system?
37. Define the dew point temperature as it applies to a condensing furnace.
38. What is excess air?
39. What is dilution air?
40. What are four factors that determine the efficiency of a furnace?
41. What is a 100% shutoff system?
42. What is the difference between a hard and a soft lockout?
43. What is meant by prepurging a heat exchanger?
44. When would a combustion blower ever interpurge a furnace's heat exchange?
45. What is a smart valve system?
46. An orifice is a drilled hole in a _____.
47. A _____ distributes gas to the various burners.
48. True or False: An orifice measures the quantity of gas to the burner as well as directs the gas stream.
49. Name four types of gas burners.
50. The _____ _____ transfers heat from the hot gas to the airstream to heat the structure.
51. Name two types of fan switches.
52. When the limit switch circuit opens, it opens the circuit to the _____ _____.
53. Describe the function of the draft diverter.
54. Describe how a two-stage furnace operates.
55. Describe how a modulating furnace operates.
56. What is a variable-output programmable thermostat?
57. Why is a metal vent often preferred rather than a masonry chimney?
58. Describe how a vent damper shutoff functions.
59. Describe why you should never use a flame to leak check a gas system.
60. What is the first step a service technician should take when systematically troubleshooting a furnace that contains an IFC?
61. A _____ _____ sample is taken from the flue gas to check the efficiency of a gas furnace.

UNIT 32

OIL HEAT

OBJECTIVES

After studying this unit, you should be able to

- describe various types of fuel oil.
- list and describe the characteristics associated with fuel oil.
- describe different methods for storing fuel oil.
- explain how oil tanks are sized.
- explain the importance of periodic oil tank inspection.
- describe how fuel oil and air are prepared and mixed in the oil burner unit for combustion.
- list products produced as a result of combustion of fuel oil.
- list the components of gun-type oil burners.
- describe basic service procedures for oil burner components.
- sketch wiring diagrams of the oil burner primary control system and the fan circuit.
- state tests used to determine oil burner efficiency.
- explain corrective actions that may be taken to improve burner efficiency, as indicated from the results of each test.
- describe preventive maintenance procedures.

SAFETYCHECKLIST

- ✔ Do not reset any primary control too many times because unburned oil may accumulate after each reset. If a puddle of oil is ignited, it will burn intensely. If this should happen, stop the burner motor but allow the furnace blower to run. The air shutter should be shut off to reduce the air to the burner. Notify the fire department. Do not try to open the inspection door to put the fire out; let it burn itself out with reduced air.
- ✔ Do not start a burner if the heat exchanger is cracked or otherwise defective. The flue gases from combustion should never mix with the circulating air.
- ✔ Do not start the burner with the fuel pump bypass plug in place unless the oil delivery system is configured as a two-pipe system with both a supply and return line. Without the return line, there is no place for the excess oil to go except to possibly rupture the shaft seal.
- ✔ When conducting flue-gas efficiency tests, avoid burns by not touching the hot flue-gas pipe.
- ✔ Ignition is produced by an arc of 10,000 V or more. Keep your distance from this arc.
- ✔ Observe all electrical safety precautions.
- ✔ Inspect oil burners and lines for leaks.
- ✔ When installing oil tanks, make certain that all codes are followed.
- ✔ Oil tanks need to be inspected periodically to minimize damage to the environment in the event of tank leakage.

32.1 INTRODUCTION TO OIL-FIRED, FORCED-WARM-AIR FURNACES

The oil-fired, forced-warm-air furnace has two main systems: a heat-producing system and a heat-distributing system. The *heat-producing system* consists of the oil burner, fuel supply components, combustion chamber, and heat exchanger. The *heat-distributing system* is composed of the blower, which moves the air through the ductwork, and other related components, **Figure 32.1**.

Following is a brief description of how such a furnace operates. When the thermostat calls for heat, the ignition system is powered and the oil burner motor starts, which turns the fuel

Figure 32.1 An oil-fired furnace.

pump and combustion air blower wheel. An oil-air mixture is sprayed into the combustion area, where it is ignited. After the flame has been produced and the heat exchanger is up to temperature, the furnace blower comes on and distributes the heated air through the ductwork to the space to be heated. When this space has reached a predetermined temperature, the thermostat will cause the burner to shut down. The furnace blower will continue to run until the heat exchanger cools to a set temperature.

32.2 PHYSICAL CHARACTERISTICS

The physical appearance and characteristics of forced-air furnaces vary to some extent. The **low-boy furnace** is often used when there is not much headroom, **Figure 32.2**. Low-boys may have a cooling coil on top, if space permits, to provide air-conditioning. An **upflow furnace** is a vertical furnace in which the air is taken in at the bottom and is forced across the heat exchanger and out the top, **Figure 32.1**. This furnace is installed with the ductwork above it and is often located in a hallway closet or in a basement area. A **downflow furnace** looks similar to an upflow except that the air is drawn in from the top and forced out the bottom. In the downflow configuration, the supply ductwork that carries the heated air to the occupied space is located just below or in the floor below the furnace. The cooler air coming from the occupied space to the appliance enters at the top of the furnace. A *horizontal* furnace is usually installed in a crawl space under a house or in an attic, **Figure 32.3**. These units are available with right-to-left or left-to-right airflow.

Oil-fired forced-air heating is a popular method of heating residences and light commercial buildings. Millions of furnaces of this type are being used in the United States at the present time. It is essential that the air-conditioning and heating technician understand proper installation and servicing techniques involved with oil burners. Safety is always a concern of technicians, but with the high cost of energy, efficiency in the combustion process is also extremely important.

Figure 32.2 A low-boy oil-fired furnace.

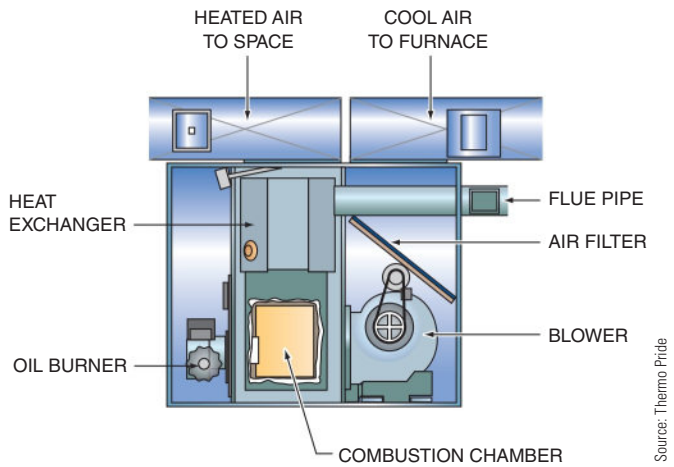

Figure 32.3 A horizontal, oil-fired forced-air furnace.

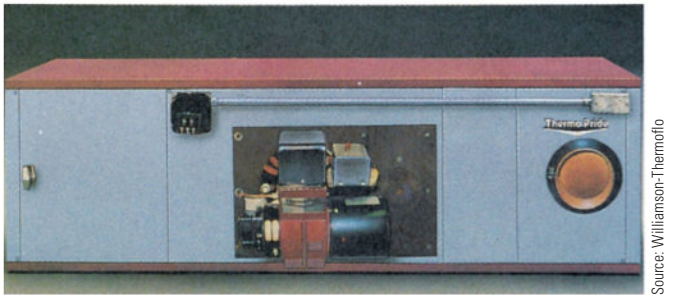
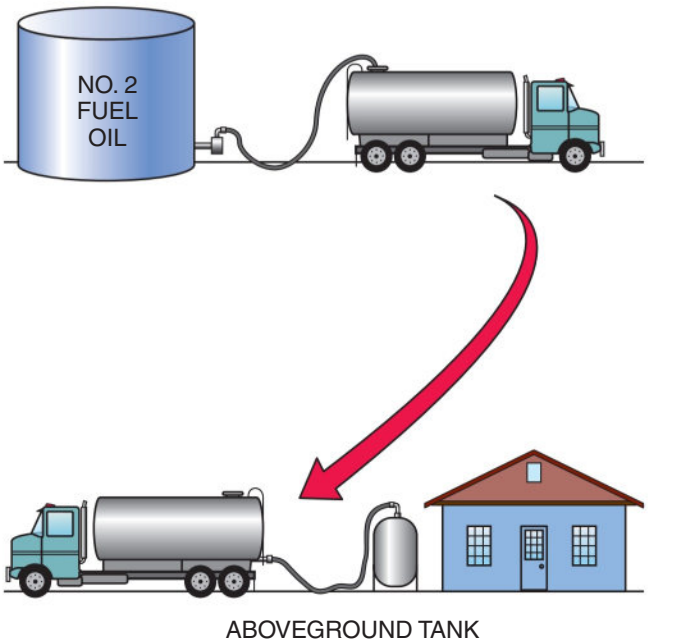


32.3 FUEL OILS

Fuel oil as we know it is a fossil fuel, as is natural gas, discussed in Unit 31. Fuel oil is a combination of liquid hydrocarbons containing hydrogen and carbon in chemical combination. Some of these hydrocarbons in the fuel oil are light, and others are heavy. Combustion occurs when the hydrocarbons unite rapidly with oxygen (O_2). Heat, carbon dioxide (CO_2), and water vapor are produced when the combustion occurs.

Fuel oil is delivered to the customer in liquid form and stored in tanks, either aboveground or underground, **Figure 32.4**. The oil used in residential and most commercial systems in the United States is basically diesel fuel that has been dyed red for tax purposes. Taxes are higher when diesel

Figure 32.4 A local oil dealer delivers the fuel oil in small trucks to aboveground or underground storage tanks.



Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. fuel is used for transportation. By dyeing the fuel, authorities can identify the cheaper, lower-taxed product. If the dyed fuel is found in the tanks of motor vehicles or trucks, heavy fines can be levied.

Fuel oil is derived from crude oil by a process called distillation. There are six grades of fuel oil, and a numbering system, 1 through 6, is used to identify each grade. The lower-numbered oils are called *light oils* because they weigh less per gallon than the higher-numbered oils. The reason for this is the carbon content. Oils are hydrocarbons made up of carbon and hydrogen, and since carbon is heavier than hydrogen, it can be concluded that the higher-numbered oils contain more carbon than the lower-numbered oils. The higher-numbered fuel oils also have higher heat content than the lower-numbered oils. The lightest of the fuel oils, Number 1, is most commonly known as kerosene.

Since fuel oil is made up of carbon and hydrogen, it is classified as a hydrocarbon. Recall from earlier units that other pure hydrocarbons, such as methane, ethane, propane, and butane, are very good refrigerants but are typically not used because of their high flammability. **Figure 32.5** shows the molecular structure of some very common hydrocarbons. Methane, **Figure 32.5(A)**, is the base molecule for refrigerants such as R-22 and R-12. Ethane, **Figure 32.5(B)**, is the base molecule for refrigerants such as R-123 and R-134a.

The most common fuel oil in use is Number 2. It is used in most residences and commercial installations. The heavier oils are used in large commercial and industrial installations. Number 2 fuel oil has a heat content of 137,000 to 141,800 Btu/gal and weighs 6.960 to 7.296 lb/gal. (This text will use the average of 140,000 Btu/gal, which is an industry standard.) Number 6 fuel oil has a heat content of about 153,000 Btu/gal and weighs 8.053 to 8.448 lb/gal. We will use Number 2 fuel oil in all of our examples because it is the most common.

The American Society for Testing and Materials (ASTM) publishes standards for a number of industries, including the oil heat industry, and it has established minimum standards for the production and refinement of oil used for heating purposes. The fuel oil standards set acceptable ranges for fuel oil characteristics, which include

- flash point,
- ignition point,
- viscosity,
- carbon residue,
- water and sediment content,
- pour point,
- ash content, and
- distillation quality.

Figure 32.5 Chemical composition of some common hydrocarbons.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

FLASH POINT

The *flash point* has to do with the maximum safe storage and handling temperature for the fuel. It is the lowest temperature at which vapors above the liquid fuel oil ignite for a short period of time when exposed to a flame. The lighter the oil, the lower the flash point. The minimum flash point for Number 2 oil is about 100°F.

IGNITION POINT

The *ignition point* is significantly higher than the flash point. The ignition point for Number 2 fuel oil is approximately 500°F, which is about 400 degrees higher than its flash point. Once the ignition point is reached, the fuel will continue to burn because vapors will continue to rise from the liquid.

VISCOSITY

Viscosity is the thickness of the oil under normal temperatures. This thickness can be compared with other oils and fluids. The heavier oils are thicker at the same temperatures. Viscosity is expressed in Saybolt Seconds Universal (SSU), which describes how much oil will drip through a calibrated hole at a certain temperature. As the temperature becomes colder, the same oil will have a reduced flow through the calibrated hole. **Figure 32.6** shows the viscosity of various oils. Warmer oil has a lower viscosity and is therefore desirable to ensure better flow through the oil lines as well as through the system filters, pumps, and nozzles.

CARBON RESIDUE

Carbon residue is the amount of carbon left in a sample of oil after it is changed from a liquid to a vapor by being boiled in an oxygen-free atmosphere. Properly burned oil does not have any appreciable carbon residue.

WATER AND SEDIMENT CONTENT

Ideally, the process of oil refining and delivery should occur in such a manner that no water or sediment is present in the oil once it arrives at its final destination. In the real world, however, this is impossible to expect. At the very least, a strong effort should be made to ensure that the water, sediment, and

Figure 32.6 This graph shows the viscosities of the different grades of fuel oil.

other contaminant levels are as low as possible under the given set of conditions.

Sediment can form as a result of rust forming on the internal pipe and tank surfaces, which may be made of iron or steel. In addition, sludge can form in the tank when the water, in the form of condensation, reacts with the fuel oil. Higher condensation concentrations are present when the oil tank is not filled to capacity and the bare steel walls are exposed to the moisture/humidity in the air above the oil level. Sludge and sediment can lead to clogged oil lines, nozzles, and filters. Oil impurities and fuel-line restrictions can cause poor flame characteristics and inefficient burning of the fuel. Following proper tank installation and maintenance procedures will help minimize fuel-related problems that occur after product delivery.

POUR POINT

Pour point is the lowest temperature at which the fuel can be stored and handled. Number 2 fuel oil is one of the lower pour-point fuels. The oil does not freeze, but there are waxes in the oil that become thick so that it will not flow correctly. Combustion will stop, and a no-heat call will result. Number 2 fuel oil can be successfully stored and used down to about 20°F. If the storage temperature is expected to be colder than 20°F, blending the fuel oil with 25% kerosene, known as fuel oil Number 1, will lower the pour point of the fuel. Other commercially available pour-point suppressants are available as well. Storing the oil in a basement or underground tank will often keep the oil warm enough for adequate flow. The heavier oils may have to be heated to facilitate flow when low temperatures are encountered.

ASH CONTENT

The *ash content* indicates the amount of noncombustible materials contained in the fuel oil. These materials pass through the flame without burning and are contaminants. They can also be abrasive and wear down burner components. The refinery is responsible for keeping the ash content within the required tolerances. Many states have inspection departments that regularly check oil that is distributed within the state.

DISTILLATION QUALITY

Oil must be turned into a vapor before it can be burned. *Distillation quality* describes the ability of the oil to become vaporized. The lighter oils turn into a vapor more easily than the heavier oils. However, there are many reasons to use the heavier oils. They are less expensive and have more heat content per gallon. Heavier oils are less volatile, do not ignite as easily, and are therefore safer in some situations, for example, on board a ship and in many large buildings and commercial establishments that must store the oil on the premises.

32.4 OIL STORAGE

Once oil is delivered to the customer, it must be stored until it is needed. For this reason, heating with fuel oil requires the installation of a storage tank on the property. Fuel oil storage tanks are available in a variety of shapes and sizes and can be installed either indoors or outside. Outdoor oil tanks can be installed either aboveground or underground. Whether an aboveground or an underground tank should be used is determined mainly by the ground conditions at a particular location.

When possible, tanks should be installed aboveground for environmental reasons. Aboveground tanks can be inspected more easily, and if a leak should be found, it can be repaired easily without major environmental impact. In addition, aboveground tank installations are less expensive than underground installations. When installing an oil tank, be sure to follow all local codes. Some of the codes, regulations, and organizations that govern the installation of oil tanks are the following:

- International Code Council (ICC), an organization that is a combination of three other agencies: The International Fire Code Institute (IFCI), the Building Officials and Code Administrators (BOCA), and the Southern Building Code Congress International (SBCCI)
- National Fire Protection Agency 30 (NFPA 30), the code that covers flammable and combustible liquids including those in aboveground oil tanks that contain more than 660 gallons
- National Fire Protection Agency 31 (NFPA 31), the code that covers the installation of oil-burning equipment and aboveground and underground oil tanks that contain less than 660 gallons

Always check the local codes in your area, since they may differ from those set forth by these organizations. Also, be sure to comply with the clearances required between oil storage tanks and property lines, electric meters, combustion sources, open flames, windows, doors, air intakes and other relevant property elements. And when replacing older furnaces and boilers, consider the age of the oil tank as well. Old oil tanks should be replaced. You wouldn't take the 30-year-old gas tank from your old clunker and put it in your brand-new car, would you?

SIZING OIL TANKS

Oil storage tanks are available in a wide range of sizes, from about 100 gallons to over 1,000 gallons, and selecting the right size tank for a particular job or application can be a confusing process. A delicate balance of concerns need to be

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

addressed when selecting the proper tank size. Two of the main issues are the frequency of oil deliveries and the quality of oil with respect to the storage time.

Larger oil tanks obviously hold more oil, so the oil company will have to make fewer deliveries to structures that have larger oil tanks. Although this may seem to be a benefit, it has a major drawback. Larger amounts of oil will sit in the tank longer and can degrade. Moisture, heat, and oxygen all contribute to the formation of sludge in the tank, which ultimately clogs the filters, nozzles, piping, and strainers on the equipment. So, in order to benefit from a larger tank without sacrificing the quality or integrity of the oil, the oil heat industry has recommended that the tank be sized to hold approximately one-third of the annual oil consumption. For example, if a house is expected to use 1,000 gallons of oil a year, the tank should be sized to hold about 333 gallons. So, in this case, the oil tank used should be sized to hold 275 or 330 gallons.

UNDERGROUND TANKS

Tanks that are to be installed underground must be protected against corrosion. The two most popular types of tanks for in-ground residential fuel storage are the STI-P3 tanks and fiberglass tanks. Fiberglass tanks, **Figure 32.7**, are not subject to corrosion, but steel tanks are. What follows is a brief description of the steel tank and the methods by which this type of tank is protected from corrosion.

The acronym STI-P3 stands for "Steel Tank Institute—Protected 3 Ways." These steel tanks, **Figure 32.8**, are manufactured with an external corrosion-resistant coating that prevents the rapid deterioration of the base metal. In addition, these tanks also have dielectric bushings and sacrificial anodes. Dielectric bushings provide a noncorrosive barrier at the point where dissimilar metals are joined. It is typically at this point in any piping circuit that oxidation and corrosion take place. The sacrificial anodes are rods usually manufactured from either zinc or magnesium. The rods are secured to the base metal of the tank and serve to protect it from corrosion. The anode material oxidizes and corrodes before the base metal does and since the anode rods are in contact with the steel tank, the steel will not corrode. However, once the anodes have completely corroded, the steel tank will begin to corrode. Therefore, it is beneficial to replace the anodes prior to this point. Field technicians can perform tests to determine the condition of the anodes even though the tank is buried in the ground. Replacing the anodes, however, involves exposing the tank, which can be a very complicated process. To illustrate this, refer to the two angled "bags" at the bottom of the underground tank in **Figure 32.8**. These are the anodes. Accessing them once the tank has been installed requires a great deal of digging.

ABOVEGROUND TANKS

For many years, aboveground oil storage tanks were constructed of either 12- or 14-gauge steel. Over the past decade, technological advances have paved the way for a new generation of tanks that are made of steel, fiberglass, or a combination of steel and plastic. Modern, residential aboveground tanks are typically fabricated from 12-gauge steel and hold between 275 and 330 gallons of oil. Smaller tanks are available and some applications call for the twinning, or joining, of smaller tanks to create larger storage capacity. The capacities of residential fiberglass tanks typically range from 240 to 300 gallons. Polyethylene/steel tanks are constructed as a tank within a tank, **Figure 32.9**. The inner oil-holding tank is made of polyethylene and the outer galvanized-steel tank is intended to protect the inner tank. The outer tank provides secondary containment in the event that the inner tank develops a leak.

INDOOR OIL STORAGE

When oil tanks are located outside, the temperature of the fuel oil will change as the outside ambient temperature changes. This can lead to oil flow issues as well as condensation problems. When the option presents itself, indoor oil storage is preferable. By storing the oil inside, there will be less temperature fluctuation of the fuel and there will also be less moisture and condensation on the interior surfaces of the tank. Condensation in the tank increases the rate of sludge formation, leading to tank corrosion. In addition, warmer fuel oil has better flow characteristics and helps the oil burner provide more even combustion and more even heating.

OIL TANK INSPECTION AND MAINTENANCE

For the most part, oil storage tanks do not require much maintenance. What follows in this section are some key points and suggestions that should be followed to help maintain both the integrity of the tank itself and the valuable oil contained within it.

- Aboveground tanks should be painted periodically and inspected on a regular basis. Deficiencies should be addressed promptly to reduce the possibility of premature tank failure.
- STI-P3 tanks should be checked periodically to ensure that the protective anodes are still in good working order. Remember that these anodes are *designed* to deteriorate in order to protect the integrity of the tank itself.
- Tank piping should be inspected regularly for imperfections and leaks. Always check for loose or missing vent and fill caps.
- Tanks should be checked for water at least once a year. If water is present in the tank, the source should be identified and the situation corrected. Tanks are tested for water content by placing a water-sensing paste on the oil tank stick. In the presence of water, the paste changes color, **Figure 32.10**. There are different brands of water-sensing pastes on the market and the initial and final colors can vary from one product to another. The important thing is to pay attention to the color change, not the color.
- Visually inspect aboveground tanks for damage to the fill and vent pipes, caps, oil lines, tank legs, and oil tank gauges. Do not fill a tank that has any deficiencies.
- Check aboveground tanks for traces of oil under the tank. Check the tank for any corrosion if oil is found. Also check the drain on the tank for potential leaks.

32.5 FUEL OIL SUPPLY SYSTEMS

In order to get the fuel oil from the storage location to the oil burner itself, oil lines must be run between these two components. Two common piping configurations are the one-pipe system and the two-pipe system. In a one-pipe system, **Figure 32.11**, only one pipe runs between the oil storage tank and the oil burner. As oil is needed, it flows from the tank and through the oil line to the burner—where it is ultimately atomized, mixed with air, and ignited. Since there is only one pipe, there is a lower potential for oil line leaks.

In a two-pipe setup, **Figure 32.12**, one pipe is the supply and the other acts as the return. Oil flows at maximum

pump capacity from the tank to the burner, and whatever oil the system needs for combustion, it takes. Any oil that is not needed is pumped back to the tank via the return line.

The location of the fuel storage tank in relation to the burner determines, for the most part, whether a one-pipe or a two-pipe system will be used. If the oil tank is located above the oil burner, a one-pipe system may be used. The oil will flow by gravity from the tank, through a fuel filter, **Figure 32.11**, and then on to the burner itself. When the oil storage tank is located below the oil burner, a two-pipe system is sometimes used.

Whenever oil is supplied to the heating appliance by means of a one-pipe system, it is important that all of the air in the connecting fuel line be bled out to ensure proper fuel flow. Bleeding the line must also be done if the oil tank has been allowed to run dry. Air bleeding is not an issue with a two-pipe system, as air is eliminated automatically through the return pipe. Here are some key points to keep in mind regarding fuel oil lines and other tank-related piping:

- Oil lines are typically made of copper and should be sized at a minimum of 3/8" OD.
- Never use PVC pipe for oil lines.
- Use only flare connections to join copper oil lines, **Figure 32.13**. Do not use compression fittings.
- When needed, use only a nonhardening, oil-resistant pipe joint compound.
- When installing oil lines, make the runs as short as possible, using as few fittings as possible. Avoid kinking the lines.
- Be sure that all oil lines are secured and otherwise protected from damage.
- When oil lines are run outside, make certain that they are well insulated.
- Underground oil lines should be installed with secondary containment. Oil lines that come in contact with the earth or concrete must be protected, **Figure 32.13**.

Figure 32.13 A sleeve over oil lines and flare connections.

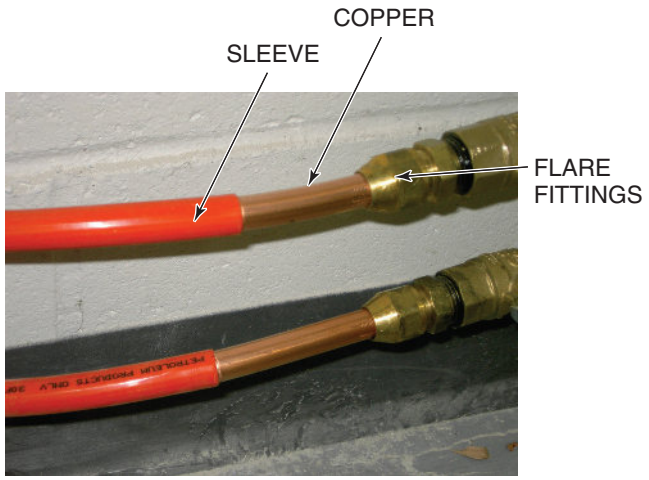

Photo by Eugene Silberstein

Figure 32.14 A vent alarm.

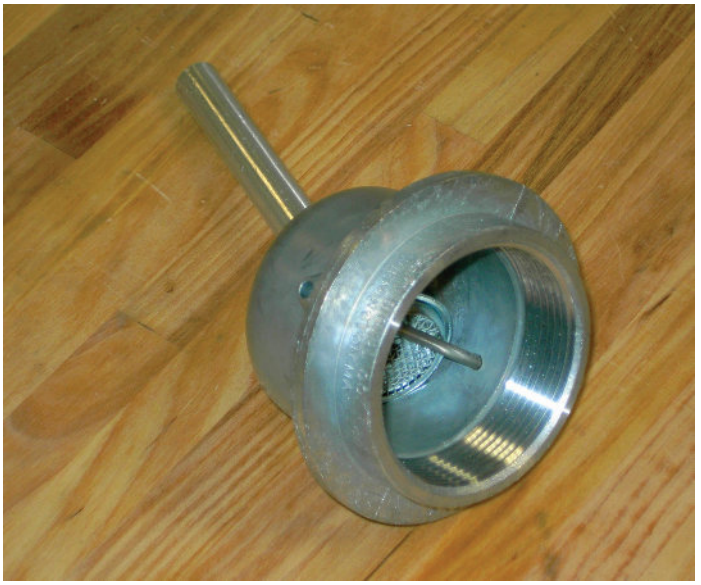

Photo by Eugene Silberstein

- There should be a shutoff valve on the suction line at the oil burner.
- Fill and vent pipes should be pitched toward the tank opening to prevent the formation of oil traps.
- A vent alarm, **Figure 32.14**, should be installed in all tanks at the vent pipe. While the oil tank is being filled, the vent alarm will whistle. As the tank nears capacity, the whistling sound will stop, alerting the oil delivery person that the tank is nearly full. The National Oilheat Research Alliance (NORA) recommends a "No whistle, no fill" policy. If there is no whistle from the alarm, it is possible that the tank has been removed but the fill line is still in place. Following this policy will prevent filling a structure with oil.

OIL DEAERATORS

The oil deaerator, **Figure 32.15**, is an oil piping component that allows a one-pipe system to function as a two-pipe system. This is accomplished by connecting two pipes between the deaerator and the fuel pump on the oil burner, but only one pipe between the deaerator and the oil storage tank. This helps eliminate the air problems that are typically found in one-pipe oil supply systems.

In operation, the fuel travels from the oil tank, through the oil filter, and into the deaerator. It is in the deaerator that any air that is mixed with the oil is separated from the fuel. The fuel then passes on to the fuel pump. At the fuel pump, the desired amount of oil will be pushed through the burner for combustion, while the remaining oil is pumped back to the deaerator instead of to the oil storage tank, **Figure 32.16**.

AUXILIARY FUEL SUPPLY SYSTEMS

In some installations, oil burner units will be located above the fuel oil supply tank at a height that will be beyond the lift capabilities of the burner pump. This occurs primarily in commercial applications. Heights exceeding 15 ft from the bottom of the tank are beyond the capabilities of even the two-stage systems. In such cases, an auxiliary fuel system must be used to get the fuel supply to the burner.

A fuel oil booster pump is used to pump the oil to an accumulator or reservoir tank, **Figure 32.17**. The booster pump, wired separately from the burner unit, pumps the fuel oil through its own piping system. The accumulator tank is kept full, and check valves are used to maintain the prime of the booster pump when it is not operating. An adjustable pressure regulator valve is a part of the fuel oil booster pump, and it must be set to maintain a fuel oil pressure of 5 psi, measured at the accumulator tank. Failure to properly adjust this regulator could result in seal damage to the fuel unit.

FUEL-LINE FILTERS

A filter should be located between the tank and the pump to remove any fine, solid impurities from the fuel oil before it reaches the pump, **Figure 32.18**. Filters may also be located in the fuel line at the pump outlet to further reduce the impurities that may reach the tiny oil passages in the nozzle, **Figure 32.19**. Different types of filter media are available. **Figure 32.20** shows a cutaway view of one type of oil filter.

NOTE: *Be sure to replace the gaskets on the fuel filter when changing the filter cartridge,* **Figure 32.21**. •

In many cases, systems are equipped with dual in-line oil filtration systems, **Figure 32.22**. This helps ensure that the oil

reaching the appliance is as clean as possible. Make certain that all filters are installed with the arrow on the device pointing in the direction of fuel flow, **Figure 32.23**. Sometimes a sludge/water isolator is installed in the fuel line as well. This device is located before the filter and is nothing more than an empty canister, **Figure 32.24**, that has a drain plug at the bottom. The fuel oil enters from the side and leaves from the top. Since water and sediment are heavier than the fuel oil, these substances fall to the bottom of the canister. Periodically, the drain plug is removed and the water and sediment are removed.

OIL SAFETY VALVES (OSV)

Another system component commonly found in the piping arrangement of an oil-fired heating appliance is the oil safety valve. Located in the suction line, the oil safety valve (OSV) is a device that stops oil flow in the event of a leak in the suction line, which is the line that carries oil from the tank to the oil burner. When the pump on the oil burner operates, a vacuum is created in the oil line, causing oil to flow from the tank to the pump. The OSV senses this vacuum and opens to allow oil flow. In the event of a suction-line leak, the vacuum will be lost and the valve will close.

32.6 COMBUSTION

Combustion is the burning of fuel to generate heat. The combustion process is the same regardless of the fuel being burned. In order for combustion to take place, there must be ample supplies of fuel, heat, and oxygen. If any of these three components is missing, the process cannot occur. If, during combustion, the supply of one or more of these three components is depleted, the process will stop.

During combustion, the oxygen reacts with fuel oil to produce heat, carbon dioxide, and water vapor, **Figure 32.25**. If only these three by-products are produced, perfect combustion will have occurred. Perfect combustion exists only in theory—achieving the delicate balance required among the components is not possible in the real world. When combustion is incomplete, carbon monoxide, soot or free carbon, and other undesirable substances form in addition to the heat, carbon dioxide, and water vapor, **Figure 32.26**. Carbon monoxide is a colorless and odorless gas. Even in small quantities, it is highly toxic and dangerous. Fortunately, with the proper use of combustion analysis equipment, **Figure 32.27**, the carbon monoxide level can be measured. In addition, combustion testing provides important data to aid in troubleshooting.

When combustion takes place in the presence of nitrogen, nitric oxide (NO) and nitrogen dioxide (NO_2) can form. These are classified as mono-nitrogen oxides and are collectively referred to as NO_X gases. These gases are pollutants and can react to form smog (tropospheric ozone) and, in some cases, toxic compounds. If there is significant exposure to NO_X gases, individuals can experience reduced lung function that, in the case of those who already suffer from asthma or other breathing ailments, can lead to death.

32.7 PREPARATION OF FUEL OIL FOR COMBUSTION

Fuel oil must be prepared for combustion. It must first be converted to a gaseous state by forcing it, under pressure, through a nozzle. The nozzle breaks the fuel oil up into tiny droplets, a process called **atomization**, **Figure 32.28**. The oil droplets are then mixed with air, which contains oxygen. The lighter hydrocarbons form envelopes of gas around the droplets. Heat is introduced at this point with a spark. The vapor ignites (combustion takes place) and the temperature rises, causing the droplets to vaporize and burn.

High-pressure gun-type oil burners are generally used to achieve combustion. Oil is fed under pressure to a nozzle, and air is forced through a tube that surrounds this nozzle. Usually the air is swirled in one direction and the oil in the opposite direction. The oil forms into tiny droplets and combines with the air. The ignition transformer or ignitor sends a high-voltage spark between two electrodes located near the front of the nozzle, and combustion occurs.

32.8 BY-PRODUCTS OF COMBUSTION

The correct ratio of fuel oil to air must be maintained for efficient combustion. The fuel to be burned is made of carbon and hydrogen. To burn 1 lb of fuel oil, it must be mixed with about 3 lb of oxygen for complete combustion to take place. Since air is made up of approximately 79% nitrogen and 21% oxygen, 14.4 lb of air would be needed to give 3 lb of oxygen (3 lb of oxygen/0.21 lb of oxygen per lb of air = 14.4 lb of air). Since 1 lb of air takes up 13.33 ft^3 at standard atmospheric conditions, about 192 ft^3 (13.33 ft^3 of air per pound × 14.4 lb of air = 192 ft^3) of air would be needed to burn a single pound of fuel oil. This is the correct amount of air needed for perfect and complete combustion, but, as with fuel gases, it would be dangerous to set up a burner for exactly the correct amount of air. If the air were restricted for some reason, incomplete combustion would occur.

Practical combustion requires excess air to ensure that all of the carbon and hydrogen particles come in contact with enough oxygen for complete combustion. The air supplied to an oil burner is normally in excess of the exact amount needed. Most oil burners are set up to burn with approximately 50% excess air. When 1 lb of oil with 50% excess air is burned, 21.6 lb, or 288 ft^3, of air must be furnished (21.6 lb × 13.33 ft^3/lb of standard air = 287.9 ft^3 of air). One gallon of Number 2 fuel oil weighs approximately 7 lb, so 1 lb of oil is one-seventh of a gallon; this is 0.88 pint, or nearly the contents of a soda can. **Figure 32.28** is a picture of the process of atomizing oil to mix with air.

When the correct amounts of oil and air are mixed and the mixture is ignited, heat is given off by the appliance for use in heating. The typical oil-burning appliance produces nearly 85% of usable heat energy, with approximately 15% escaping with the flue gases. Since a gallon of fuel oil contains about 140,000 Btu of heat, 119,000 Btu are used for heating and the remaining 21,000 Btu push the by-products of combustion up the flue (140,000 × 0.85 = 119,000 and 140,000 × 0.15 = 21,000).

The by-products of combustion result from the chemical reaction during which the stored energy in the fuel is released as heat. The nitrogen in the air just heated and passes through the combustion process. Since air contains about 79% nitrogen, 227.5 ft^3 of heated nitrogen rises up the flue (288 × 0.79 = 227.5 ft^3 of nitrogen).The oxygen in the excess air also just passes through the combustion process and is not combined with the carbon and hydrogen particles of the fuel oil and burned. Of the 288 ft^3 of air, the combustion process uses only 192 ft^3, so 96 ft^3 pass through and are only heated. This air contains 21%, or 20 ft^3, of oxygen (96 × 0.21 = 20 ft^3). The other by-products of combustion are CO_2 and water vapor. The flue gases contain 27 ft^3 of CO_2 and more than a pound of water vapor per pound of fuel. The flue gases must remain hot enough both to prevent the water vapor from condensing and to rise up the flue to the outside.

32.9 GUN-TYPE OIL BURNERS

In a *gun-type* burner, oil and air are prepared for burning by being forced into the burner head for mixing and ignition. Modern oil burners are high-pressure burners, **Figure 32.29**, because the oil is delivered through the burner at a minimum pressure of 100 psi.

All new oil burners utilize a high-speed flame-retention design. This design is a radical improvement over the conventional burner design of a few decades ago. The benefits of flame-retention burners include the following:

- Faster motor speeds (3450 rpm versus 1725 rpm) for better mixing of the atomized oil and the combustion air
- Higher air static pressure
- Improved air-oil mixing
- Lower emissions
- Higher efficiency
- Cleaner combustion (less soot formation)
- Lower system maintenance requirements
- A hotter flame (300°F–500°F hotter)

As part of the improved burner design, the air-oil mixture is swirled at high pressure to produce a tightly formed flame. **Figure 32.30** compares a conventional burner flame and a burner with a flame-retention design. The flame created by a conventional oil burner is erratic, so there are large temperature fluctuations in the flame and it is common for unburned fuel to remain behind in the combustionarea. The flame of the flame-retention burner is tighter and has a more uniform temperature. Since the flame is tight and uniform, there is substantially less unburned fuel left behind.

The main parts of a gun-type oil burner are the burner motor, blower or fan wheel, pump, nozzle, air tube, electrodes, transformer/igniter, and primary control, **Figure 32.31**.

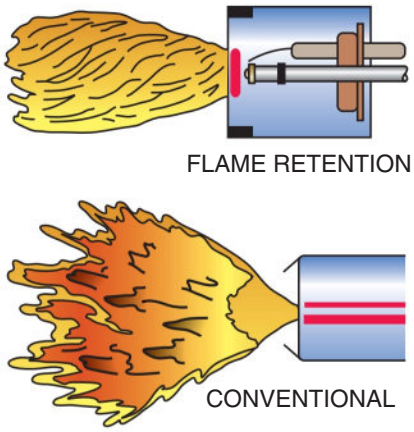
Figure 32.30 Diagram that compares the flames created by conventional and flame-retention oil burners.



BURNER MOTOR

The oil burner *motor,* **Figure 32.32,** provides power for both the fan and the fuel pump. A flexible coupling, **Figure 32.33,** is used to connect the shaft of the motor to the shaft of the pump, **Figure 32.34**. The motor speeds may be either 1750 or 3450 rpm. The fuel pump rpm should always match the motor rpm. Most flame-retention burners have motors that operate at 3450 rpm; most conventional burners are equipped with motors that operate at 1725 rpm.

The most common type of motor in modern oil burners is the permanent split-capacitor (PSC) motor. The PSC motor is manufactured and designed to operate with a start winding, a run winding, and a run capacitor. By design, both the start

and run windings are energized whenever the motor is operating. These motors have relatively low starting torque but, since they are operating under a relatively low load, they are perfect for this application. The main benefits of this type of motor are that they have excellent running efficiency and have no external or mechanical control relays or contacts to wear out. The wiring diagram for a simple, single-speed PSC motor is shown in **Figure 32.35**. Refer to Unit 17, "Types of Electric Motors," for more information regarding electric motors.

BURNER BLOWER

The burner blower is a squirrel-cage design with adjustable air inlet openings in a collar attached to the blower housing. These provide a means for regulating the volume of air being drawn into the blower. The blower forces air through the air tube to the combustion chamber, where it is mixed with the atomized fuel oil to provide the oxygen necessary to support combustion, **Figure 32.36**.

FUEL OIL PUMPS

Just like the burner fan or blower, the fuel pump, **Figure 32.37**, is connected to the shaft of the burner motor and turns at the same speed as the motor. The pump performs

Figure 32.37 An oil pump.

three major functions in the system. First, it moves the fuel oil from the storage tank to the burner for ignition. Second, it filters or pulverizes particulate matter that may have found its way past the filter. Third, the pump regulates the pressure at which the oil is fed through the burner into the combustion area. Oil pumps are typically set at the factory to deliver oil at a minimum pressure of 100 psig. Nozzles are rated at 100 psig but, most of the time, have oil at a higher pressure flowing through them.

Two types of oil pumps are mainly used on gun-type burners: the single-stage pump and the two-stage pump, **Figure 32.38**. Fuel pumps are manufactured with gear sets that facilitate the movement of oil through the system, **Figure 32.39**. Pumps that have one set of gears to pull oil from the storage tank are referred to as one-stage, or single-stage, pumps, **Figure 32.40**. Single-stage pumps can be used in conjunction with one-pipe or two-pipe systems so long as the vacuum necessary for operation does not exceed 12 in. Two-stage pumps, **Figure 32.41**, have two sets of gears: one set to pull oil from the oil storage tank and one set to push oil onto the nozzle. The additional gear set, called the suction pump gear, allows for a greater vacuum to lift the oil farther than a single-stage gear set can. Two-stage pumps can operate at vacuum levels as high as 17 in. Two-stage pumps are highly recommended for high-lift applications. Refer to the next section for more information regarding pump pressures and vacuums.

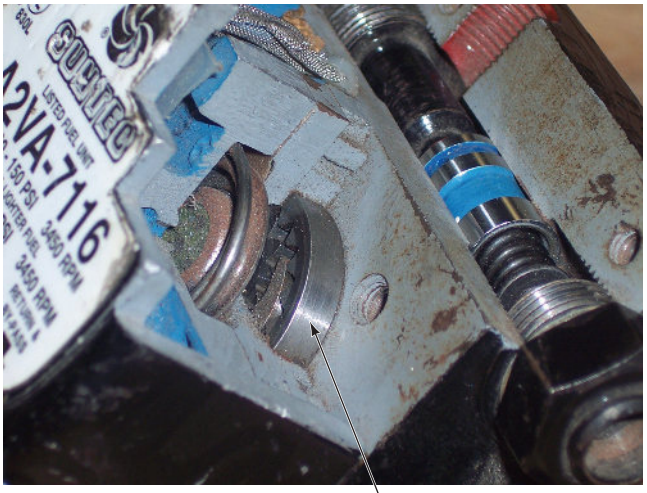
Figure 32.39 Gear set on an oil pump.



Source: Oilheat Associates, Inc. Photo by John Levey

Oil pumps are equipped with a bypass plug, **Figure 32.42**. This plug will either be left in place or removed, depending on the type of piping configuration used. For a one-pipe installation, **Figure 32.11**, the bypass plug needs to be removed so that any unused oil can be recirculated back to the inlet of the pump. In a two-pipe configuration, **Figure 32.12**, or in a system piped with a deaerator, the bypass plug is left in place.

Built into each pump is a pressure-regulating valve, **Figure 32.40**. The pump provides more pressure than needed. The pressure-regulating valve can be set so that the fuel oil being delivered to the nozzle is under a specific pressure. Although nozzles are rated at 100 psig, most of today's burners operate with oil pressures of 140 psig and above. Higher nozzle pressures yield more oil flow in a nozzle. The chart in **Figure 32.43** shows nozzle capacities at various pressures. As mentioned previously, the rate of fuel flow through the oil pump is greater than the flow of fuel through the nozzle line and nozzle. The excess oil is diverted back to the inlet side of the pump in one-pipe systems and to the storage tank in two-pipe systems. **NOTE:** *Fuel pumps are equipped with screens at the inlet,* **Figure 32.44**, *to prevent particulate matter from entering the pump. Before replacing what is thought to be a defective pump, be sure to check this screen. If the screen is indeed clogged, replace it—as well as the gasket,* **Figure 32.45**. •

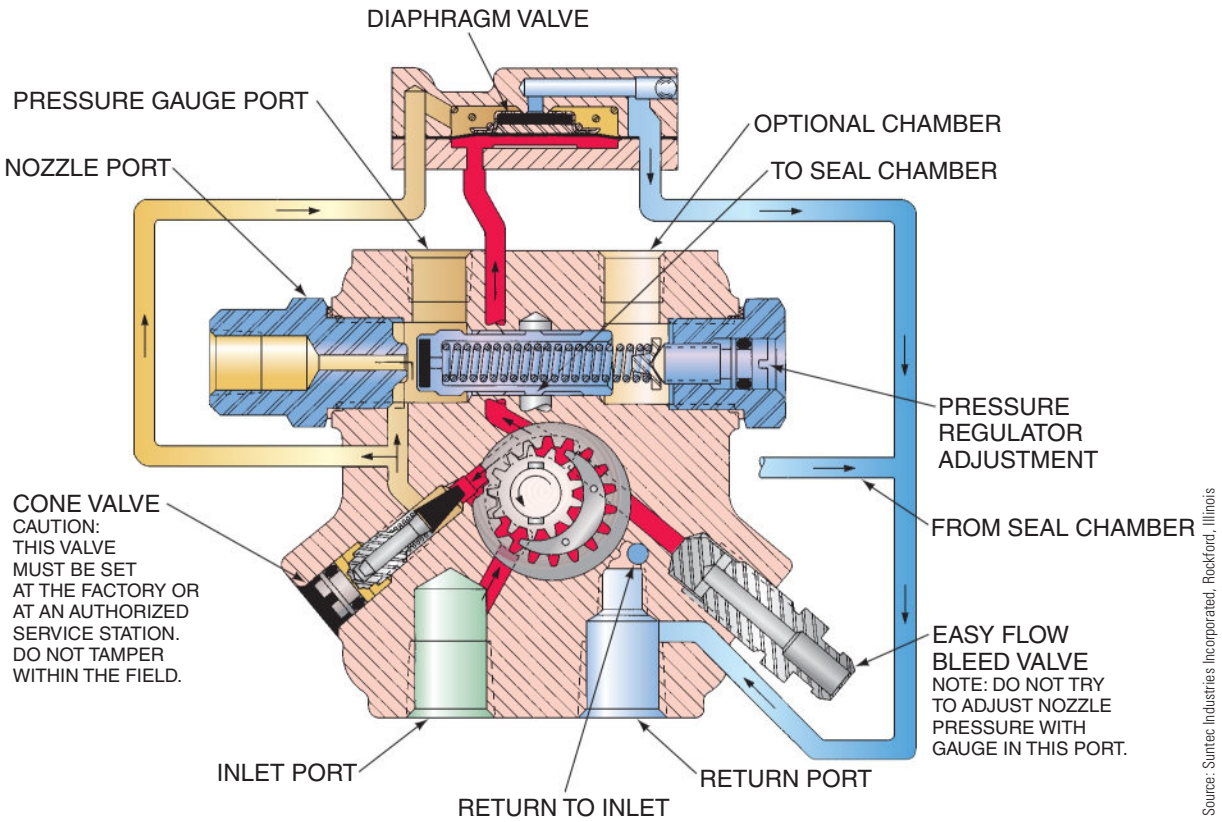
Figure 32.40 A single-stage fuel oil pump showing the flow of oil.



PUMP PRESSURES. Oil pumps generate a vacuum during the process of pulling oil from the storage tank. This vacuum is measured in inches of mercury. Field technicians can estimate the expected vacuum by using the following guidelines:

- Estimate 1 inch of vacuum for each foot of vertical lift between the oil tank and the oil burner.
- Estimate 1 in. of vacuum for every 10 ft of horizontal run between the oil tank and the oil burner.
- Estimate 1 in. of vacuum for each oil filter.
- Estimate 3 in. of vacuum for an oil safety valve (OSV).

So, a system that has the oil burner 5 ft above the tank at a distance of 40 ft will have an approximate vacuum at the oil burner of 9 in. of mercury, not including the filters and other components. Adding an oil filter and an OSV valve will increase the expected vacuum to about 13 in. of mercury vacuum.

Excessive vacuum at the inlet of the pump can cause cavitation (oil changing to a vapor) and oil foaming. This will have a negative effect on system operation and efficiency. During normal system operation when the pump is operating within its design vacuum range, there should be no bubbling or foaming of the oil, **Figure 32.46(A)**. As the vacuum level in the oil supply line increases, the amount of foaming at the inlet of the pump increases and the amount of oil that is being pumped decreases, **Figure 32.46(B)**. At extremely high vacuums, the oil is nearly completely foam upon entering the pump, **Figure 32.46(C)**. **NOTE:** *If there is an exceptionally high vacuum at the inlet of the pump, the technician should check for crimped or kinked oil supply lines or a dirty oil filter.* •

NOZZLE

The *nozzle* prepares the fuel oil for combustion by atomizing, metering, and patterning the fuel oil. The process of atomization is best described as breaking the fuel oil down into tiny droplets. To give some idea of how small these droplets are, 1 gallon of fuel oil, when atomized, creates approximately 55,000,000,000 (55 billion) droplets of oil. By atomizing the oil, the surface area of the oil is increased, leading to its rapid vaporization and ignition. It should be noted that fuel oil will not burn in the liquid state, so atomization is necessary in order for the combustion process to occur. The smallest of the atomized droplets will be ignited first. The larger droplets (there are more of these) provide more heat transfer to the heat exchanger when they are ignited. Atomization of fuel oil is a complex process. The straight lateral

movement of the flowing fuel oil must be changed to a circular motion. This is accomplished in the swirl chamber of the nozzle. **Figure 32.47** shows a cutaway view of a nozzle—as well as a diagram showing some of the parts, including the swirl chamber, that make up this precision element of the oil burner.

The orifice, or bore size, of the nozzle is designed to allow a certain amount of fuel through at a given pressure to produce the amount of heat desired in Btu/h. Each nozzle is marked as to the amount of fuel it will deliver. A nozzle marked 1.00 will deliver 1 gallon of fuel oil per hour (gph) if the pressure at the inlet of the nozzle is 100 psig. With Number 2 fuel oil at a temperature of 60°F, approximately 140,000 Btu would be produced each hour. A 0.8 nozzle

would deliver 0.8 gph, and so on. By increasing the pressure of the fuel oil, the quantity of oil that the nozzle allows to flow through it will increase as well. For example, refer to **Figure 32.43** to see that a nozzle rated to deliver 0.75 gallons of fuel per hour at 100 psig will deliver about 0.92 gallons per hour if the oil pressure is increased to 150 psig.

The nozzle must be designed so that the spray will ignite smoothly and provide a steady, quiet fire that will burn

cleanly and efficiently. It must provide a uniform spray pattern and angle that is best suited to the requirements of the specific appliance. There are three basic spray patterns—hollow, semisolid, and solid—with angles from 30° to 90°, **Figure 32.48**.

Hollow cone nozzles generally produce a more stable spray angle and pattern than do solid cone nozzles of the same flow rate. These nozzles are often used where the flow rate is under 1 gph. *Solid cone* nozzles distribute droplets fairly evenly throughout the pattern. These nozzles are often used in larger burners. *Semisolid cone* nozzles are often used in place of the hollow or solid cone nozzles. The higher flow rates tend to produce a more solid spray pattern, and the lower flow rates tend to produce a more hollow spray pattern. Nozzle manufacturers often offer nozzles with hybrid spray patterns that are a combination of the three just mentioned.

Figure 32.49 shows some different spray patterns that are available.

The angle of the spray should be selected by following the manufacturer's recommendations. Oil burner and nozzle combinations will vary depending on the appliance in which the burner is installed. If the manufacturer's literature is not available, the following guidelines can be followed. If the combustion chamber is round or square, a nozzle with a larger spray angle is desired, **Figure 32.50(A)**. If the combustion chamber is deep, a nozzle with a smaller spray angle is desired, **Figure 32.50(B)**.

The high-pressure oil burner nozzle is a precision device that must be handled carefully. **SAFETY PRECAUTION:** *Do not attempt to clean these nozzles. Metal brushes or other cleaning devices will distort or otherwise damage the precision-machined surfaces. When the nozzle is not performing properly, replace it. Use a nozzle changer designed specifically for this purpose to remove and install a nozzle,* **Figure 32.51.**•

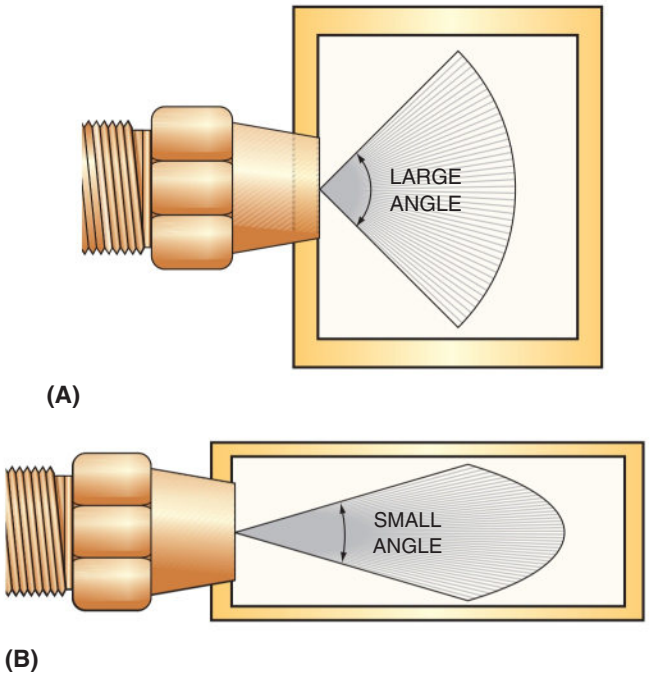

Figure 32.51 A nozzle wrench.

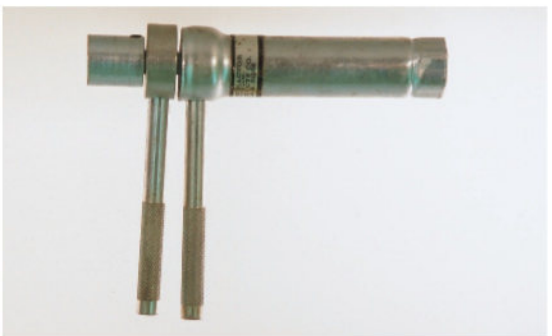

Photo by Bill Johnson

Certain conditions can cause the nozzle to drip after the burner has been shut off. Nozzle dripping at the end of the cycle is the result of expanding air bubbles in the nozzle line. When the nozzle line contains high pressure oil, any air bubbles in the line are small in size, **Figure 32.52** (top). At the end of the cycle, as the pressure in the nozzle line decreases, the air bubbles expand and push oil through the nozzle, **Figure 32.52** (bottom). This can cause a rumble at the end of the cycle, which is actually an ignition of the dripped oil. Components within the oil pump should eliminate this, but they sometimes fail to work correctly. To avoid an after-fire drip at the nozzle, a solenoid-type cut-off valve can be installed, **Figure 32.53**.

AIR TUBE

Air is blown into the combustion chamber through the *air tube*, **Figure 32.54**. Within this tube the straight or lateral movement of the air is changed to a circular motion that is opposite that of the circular motion of the fuel oil pattern leaving the nozzle. The air moving in a circular motion in one direction mixes with the fuel oil moving in a circular motion in the opposite direction in the combustion chamber. The air tube of some burners contains a stationary disc, **Figure 32.55**, referred to as an end cone. The end cone increases the static air pressure and reduces the air volume. The increase in static pressure causes an increase in air velocity to create a better air-oil mixture. The circular air pattern is achieved by vanes located in the retention head. The head of the air tube chokes down the air and the fuel oil mixture, causing a higher velocity, **Figure 32.56**. End cones are often referred to as flame-retention heads, as they are designed to retain the flame on the end of the air tube. This creates more turbulence within the air-oil mixture, resulting in greater burning efficiency. It also provides for

Figure 32.52 (top) Air bubbles are small when under pressure. (bottom) When the pressure in the nozzle line drops, the bubbles expand and oil is pushed from the nozzle.

more complete burning once the atomized air-oil mixture is ignited. It is in the air tube that the atomized oil from the nozzle mixes with the air. The nozzle, therefore, is positioned inside the air tube, **Figure 32.57**.

The amount of air required for the fuel oil preignition treatment is greater than the amount required for combustion. Prior to ignition, approximately 2000 ft^3 of air is needed per gallon of fuel oil, so the air blown into the combustion chamber is greater than what would be needed for the theoretical perfect combustion. Should the amount of air exceed the 2000 ft^3, the burner flame will be long and narrow and possibly impinge on or strike the rear of the

combustion chamber. Airflow adjustments should be made only after analyzing the products of combustion, the flue gases. This is discussed in detail in Section 32.17, "Combustion Efficiency."

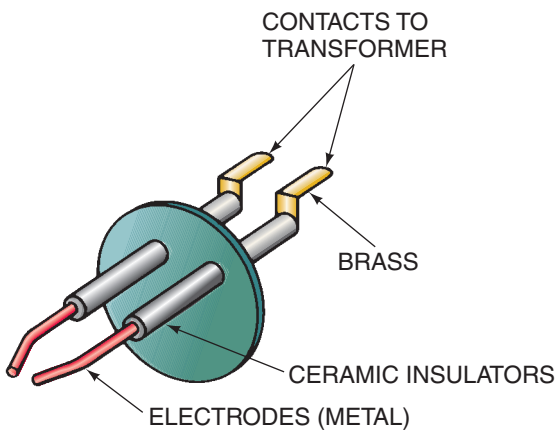
ELECTRODES

Two electrodes are positioned close to the orifice of the nozzle, **Figure 32.58**. The electrodes are metal rods insulated with ceramic material to prevent an electrical ground. The rear portions of the electrodes are made of metal and are designed to come in contact with a high-voltage power source, **Figure 32.59**, which is either an ignition transformer or a solid-state igniter. The electrodes provide the heat necessary to both vaporize the atomized oil droplets and ignite the vaporized air-oil mixture. A high-voltage spark is generated between the electrodes to facilitate these processes. The exact position of the electrode tips varies from manufacturer to manufacturer, so be sure to check the literature that accompanies the oil burner for specific information regarding adjusting the electrodes. Refer to Section 32.17, "Service Procedures," for more information regarding electrode positioning. **Figure 32.57** shows the nozzle assembly and the electrodes in position within the air tube.

Figure 32.58 Electrode location with respect to the nozzle.

Source: Oilheat Associates, Inc. Photo by John Levey

Figure 32.59 An electrode assembly.



The type of primary control used determines the length of time that the electrodes will provide a spark. The two most commonly encountered ignition strategies are called **interrupted ignition** and **intermittent ignition**. Interrupted ignition employs an electrode spark for a brief period at the beginning of the burner's run cycle. This spark is intended to facilitate the lighting of the burner; then, once the burner flame has been established, the spark stops. On systems with intermittent ignition, the spark is generated continuously during the burner's run cycle. Intermittent ignition used to be referred to as constant ignition, but it isn't any more. Of the two types, interrupted ignition is a better option for a number of reasons. Here are a few:

- Because the spark is only generated for a short period at the beginning of the cycle, transformer/igniter life is extended.
- The elimination of the constant spark reduces burner operation noise.
- Combustion problems become more evident.
- The useful life of the electrodes is lengthened because sparks are generated for shorter periods of time.
- NO_x emissions are reduced (Refer to section 32.6 for more information on NO_x gases)

IGNITION TRANSFORMER

Some oil burners use a *step-up transformer* to provide high voltage to the electrodes that produce the spark for ignition. The transformer is typically located on top of the oil burner, **Figure 32.60**, but can be found on the side of the burner, depending on the model of the unit. Step-up transformers are constructed with more turns in the secondary winding than in the primary. Notice in **Figure 32.61** that the size of the secondary winding is substantially larger than the primary winding. The ignition transformer is supplied with 115 V at its primary winding; the voltage output of the ignition transformer, at the secondary winding, is between 10,000 V and 14,000 V. The voltage at the secondary winding of the transformer is directly related to the voltage supplied to the device.

The ignition transformer has springs, **Figure 32.62**, that allow the secondary winding of the transformer to come in contact with the back, or flat portion, of the electrodes, **Figure 32.63**. The transformer is hinged, so the springs and the back end of the electrode rods can be accessed. Ignition transformers are not intended to be serviced in the field. When there is voltage present at the primary winding and no

Figure 32.61 Clear transformer shows the size difference between the primary and the secondary windings on the ignition transformer.

voltage present at the secondary winding, the ignition transformer needs to be replaced.

Service technicians can test the operation of the ignition transformer by using a tool designed for such purposes, **Figure 32.64**. The ignition transformer tester is connected to the primary winding of the ignition transformer. The display on the tester will indicate if the transformer is good or in need of replacement, **Figure 32.65**. **SAFETY PRECAUTION:** *Be very careful around the high-voltage ignition transformer parts. The arc is much like the arc on a lawn mower or automobile spark plug. It normally will not hurt you, but you may react in such a way that you hurt yourself.*•

SOLID-STATE IGNITER

Newer oil burners do not utilize the ignition transformer discussed in the previous paragraphs. Instead, they are manufactured with solid-state igniters, **Figure 32.66**. These devices perform the same function as their older predecessors, but there are some differences. For instance, the solid-state version is much lighter than the step-up transformer, as the output voltage is generated by solid-state circuitry as opposed

Photo by Bill Johnson

to multiple coils of wire. The voltage output of a solid-state igniter is typically higher than that of the conventional step-up transformer: in the range of 14,000 V to 20,000 V. Some of the benefits of the solid-state igniter are as follows:

- Higher voltage at the output results in faster fuel vaporization and ignition.
- Solid-state igniters are not greatly affected by a drop in supply voltage.
- Solid-state igniters use less electricity than ignition transformers do.

Solid-state igniters can be field tested with the aid of an igniter tester, **Figure 32.67**. Be sure to follow the directions on the device to ensure proper use. **NOTE:** *Quite often, a solid-state igniter tester can be used to field test both solid-state igniters and ignition transformers. An ignition transformer tester, on the other hand, cannot be used to field test a solid-state igniter. When using a solid-state igniter tester, make certain that you follow all instructions and that you only use the tester in conjunction with the ignition devices designated by the manufacturer.*

PRIMARY CONTROL UNIT

The oil burner **primary control** provides a means for operating the burner and shutting the burner down on safety in the event that combustion does not occur. As long as line voltage is supplied to the primary control, meaning that the limit controls are all closed, the primary control will turn the burner on and off in response to the low-voltage operating controls (thermostat). When the thermostat closes its contacts, low voltage is supplied to a coil that energizes and closes a switch by magnetic force. This switch transfers line voltage to the burner, and it begins to operate. If the burner does not ignite or if it flames out during the combustion cycle, the safety function of the primary control must shut down the burner

to prevent large quantities of unburned oil from accumulating in the combustion chamber.

STACK RELAY. Older burner installations may have a bimetal-actuated switch, called a *stack switch* or *stack relay,* **Figure 32.68**, as a safety feature. This switch is installed in the stack (flue) between the heat exchanger and the draft damper. This device is a heat-sensing component and is wired to shut down the burner if it does not detect heat in the stack. Although this type of primary control is no longer used on new installations, technicians will encounter the stack relay on some service calls, so it is important to understand how it operates.

Constructed with a bimetal strip that extends into the flue pipe, the stack relay senses the temperature of the flue gases to determine whether or not the burner is firing. When the burner is firing, the bimetal strip senses the rise in temperature in the flue pipe and the strip warps. This warping action causes some electrical contacts in the relay to open and others to close, **Figure 32.69**. The contacts that are in the closed position when the flue pipe is cold are referred to as the cold contacts. Those that are in the closed position when the flue pipe is hot are referred to as the hot contacts. So when the burner is firing, the hot contacts are closed and the cold contacts are open, **Figure 32.70(A)**. When the burner is not firing, the cold contacts are closed and the hot contacts are in the open position, **Figure 32.70(B)**. The wiring diagram for a stack relay is covered later in this unit.

CAD CELL RELAY. Although there are still many stack relays in operation, all new oil burners are equipped with cad cell

relays. The main component of this relay is the cad cell, **Figure 32.71**, which is made from a chemical compound called cadmium sulfide that changes its resistance in response to the amount of light the material is exposed to. The cad cell is made up of the cadmium sulfide, a ceramic disc, a conductive grid, and electrodes is encased in glass, **Figure 32.72**. It is positioned in the oil burner so that it can sense the light that is produced when the air-oil mixture is ignited, **Figure 32.73**.

When the oil burner is off, no light is being generated and the resistance of the cad cell is very high, about 100,000 Ω. When the burner is firing, the resistance of the cad cell typically drops to under 1000 Ω. In order to properly sense the light, the cad cell must be kept clean. A dirty cad cell may lead to operational problems with the burner. The cad cell relay circuitry is discussed later on in this unit.

Older cad cell primary controls, such as the one shown in **Figure 32.74**, are designed to operate with intermittent duty

Figure 32.72 A diagram of the face and side of a cad cell.

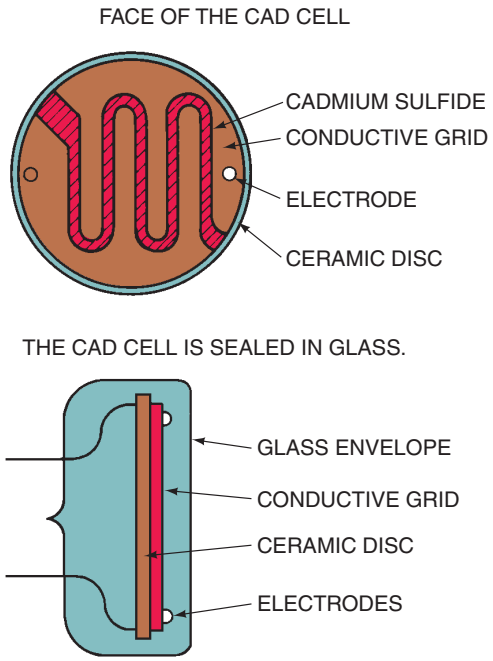

Figure 32.73 Typical cad cell location in an oil burner.

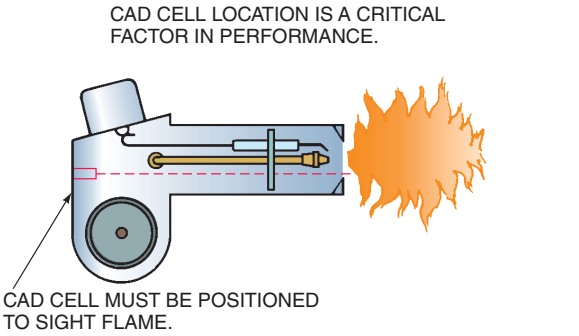

Figure 32.74 A cad cell relay.

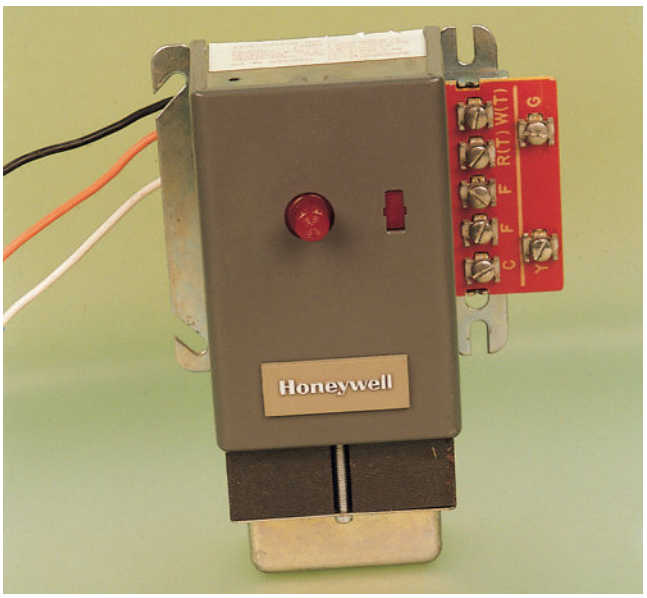

Photo by Bill Johnson

ignition. As mentioned earlier in this unit, with intermittent ignition the spark is produced the entire time the burner is operating. When configured in this manner, the same wire powers the burner motor and the ignition. For the cad cell relay in **Figure 32.74**, the wire that powers the burner motor and the ignition is the orange wire, while the black and white wire are L1 and Neutral wires, respectively. Cad cell relays that are configured like this cannot be used in conjunction with an interrupted ignition system. This is because there is

no way to separately power the burner motor and ignition circuits.

Newer generation cad cell primary controls, **Figure 32.75**, are designed to operate with interrupted duty ignition. The interrupted ignition control strategy produces an ignition spark for a short period of time when burner operation is called for and then cycles off. In order to de-energize the ignition process while still energizing the burner motor, these two circuits must be wired separately. In addition, there are other features such as "valve-delay-on" and "motor-delay-off" that are incorporated into these controls that allow for the burner's blower to operate without having fuel be pumped through the nozzle into the heat exchanger. As can be seen in **Figure 32.75**, there are many more wires that are connected to this device than the older, intermittent ignition cad cell relay shown in **Figure 32.74**. These additional wires are used to independently energize and de-energize the burner motor, ignition, and oil valve circuits at the desired times to enhance system performance.

The operational feature known as "valve-delay-on" is sometimes referred to as pre-purge. During the valve-delay-on period, the burner motor and the fuel pump are operating. Air is being moved through the combustion chamber by the blower, but no fuel is being pumped to the nozzle. This is because the oil valve, **Figure 32.53**, is not energized at this point. After the valve-delay-on time period has elapsed, the solenoid on the oil valve is energized and pressurized fuel is delivered to the nozzle. The purpose of the valve-delay-on feature is to help ensure a clean start by allowing the burner motor to reach its full speed before introducing atomized fuel to the combustion chamber. The valve-delay-on feature helps to improve the fuel-air mixture, which will help reduce the amount of soot, or unburned carbon, buildup.

Figure 32.75 A cad cell primary control that is used for interrupted duty ignition.

Photo by Eugene Silberstein

Figure 32.76 The diagnostic LED on a newer generation interrupted duty primary control.

Photo by Eugene Silberstein

The operational feature known as "motor-delay-off" is sometimes referred to in our industry as post-purge. During the motor-delay-off period, the solenoid on the oil valve closes at the end of the cycle but the burner motor and the fuel pump continue to operate. Since no oil is being introduced to the chamber, combustion stops, but air is still moving through the combustion chamber. This process allows for a cleaner shutdown at the end of the cycle.

NOTE: *The valve-delay-on and motor-delay-off features cannot be accomplished with older cad cell relays that do not have the capability to energize and de-energize the burner motor, the oil valve, and the ignition circuits separately.* •

Newer generation cad cell primary controls are also typically equipped with diagnostic LEDs, **Figure 32.76**. These low-powered indicator lights provide information to the service technician which can be used to effectively troubleshoot the oil burner. As can be seen in the figure, the manufacturer has provided information on the side of the primary control that is used to interpret the LED's code.

Unlike older generation primary controls, newer devices are also equipped with a feature called **limited recycle.** Limited recycle limits the number of times that an oil burner will try to restart if the flame is lost during the operating cycle. This will help keep the appliance cleaner since less soot will be produced. If the number of attempted restarts is reached, the burner will go into lockout mode.

32.10 OIL FURNACE WIRING DIAGRAMS

Figure 32.77 is a wiring diagram for a typical forced-warm-air oil furnace. The diagram is designed to be used with an air-conditioning system as well. It includes wiring for the fan circuit for air distribution, the oil burner primary control circuit, and the 24-V control circuit. Note that the diagram illustrates the circuitry for a multispeed blower motor.

Figure 32.78 The furnace blower or fan runs using the thermally (temperature) activated fan switch in the heating cycle. If the coil on the fan relay were to be energized while in the HEAT mode, the fan would switch from low speed to high speed.

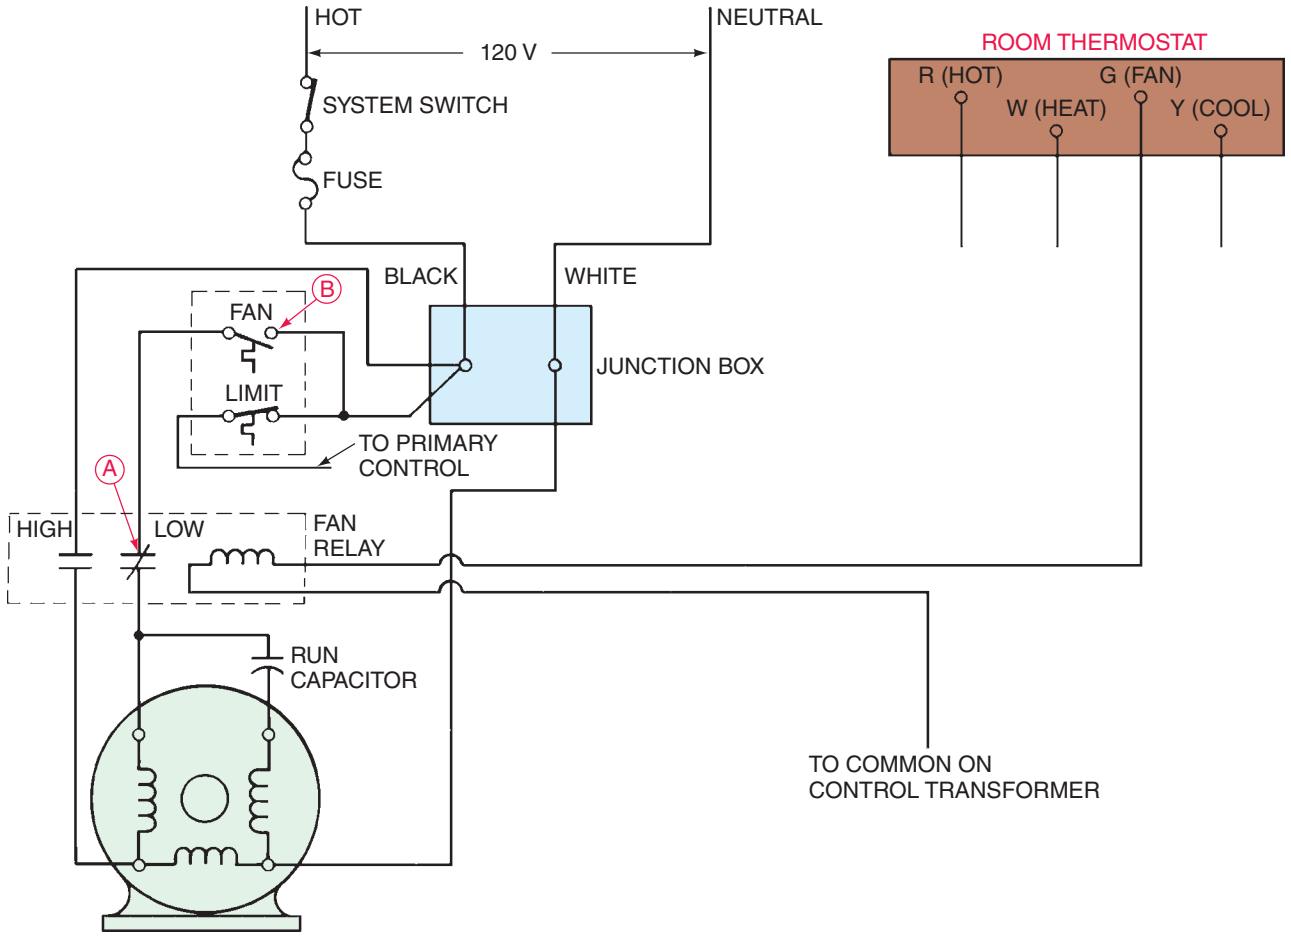

Figure 32.78 illustrates the wiring for the operation of the blower fan motor only. The fan relay (A) protects the blower motor from current flowing in the high- and low-speed circuits at the same time. If the normally open (NO) contacts on the high-speed circuit close, the NC contacts on the low-speed circuit will open. The NO fan limit switch (B) is operated by a temperature-sensing bimetal device. When the temperature at the heat exchanger reaches approximately 140°F, these contacts close, providing current to the low-speed terminal on the blower motor. The high-speed circuit can be activated only from the thermostat. The high speed on the blower motor is *not* used for heating. It will operate only when the thermostat is set to FAN ON manually or for cooling (air-conditioning). The fan circuit for heating would be from the power source (hot leg) through the temperature-actuated fan limit switch, to the NC fan relay, to the low-speed blower motor terminal, and back through the neutral wire.

Figure 32.79 shows the oil burner wiring diagram. The burner is wired through an NC limit switch (A). This limit switch is temperature actuated to protect the furnace and the building. If there is an excessive temperature buildup from the furnace overheating, this switch will open, causing the burner to shut down. Overheating could result from the burner being overfired, from a fan problem, from airflow restriction, or from similar problems. The wiring can be followed from the limit switch to the primary control (B).

The black wire and orange wire at the primary are both at a potential of 120 V, but the orange wire is powered by the 24-V control circuit (C), while the black wire is powered when limit switch (A), the system switch, is closed and the fuse is good. When the thermostat calls for heat, these contacts close, providing current to the ignition system, burner motor, and fuel valve, if one is used. The return is through the neutral (white wire) to the power source. The transformer in the primary control reduces the 115-V line voltage to 24 V for the thermostat control circuit.

If there is a problem in the start-up of the burner, the safety device (stack switch or cad cell) will shut it down. **Figure 32.80** illustrates the wiring for the 24-V thermostat control circuit.

Figure 32.79 The power to operate the burner motor and transformer passes through the NC limit switch to the primary. On a call for heat, the thermostat energizes an internal 24-V relay in the primary control. If the primary safety circuit is satisfied, power will pass through the orange wire to the burner motor and ignition transformer.

The letter designations on the diagram indicate what the wire colors would normally be: R (red), "hot" leg from the transformer; W (white), heat; Y (yellow), cooling; G (green), manual fan relay.

It will occasionally be necessary to convert a system from one designed for heating only to one that will also accommodate air-conditioning. A heating-cooling system requires a larger 24-V control transformer than the one normally supplied with a heating-only system. To make this conversion, a 40-VA transformer is required in addition to the one supplied in the normal primary control circuit. When adding a cooling package, the larger 40-VA transformer is required because of the added cooling relay and fan-relay load in the 24-V control circuit. The thermostat in such a conversion should also have an isolating subbase so that one transformer is not connected electrically with the other. A fan relay (A) is also needed in the fan circuit to activate the high-speed fan.

Power-consuming devices must be connected to both legs (that is, connected in parallel). Power-passing devices will be wired in series through the hot leg.

32.11 WIRING DIAGRAM FOR THE STACK SWITCH SAFETY CONTROL

The bimetal element of the stack switch is positioned in the flue pipe. When the bimetal element is heated, proving that there is ignition, it expands and pushes the drive shaft in the direction of the arrow, **Figure 32.81**. This closes the hot contacts and opens the cold contacts.

Figure 32.82 is a wiring diagram showing the current flow during the initial start-up of the oil burner. The 24-V room thermostat calls for heat. This will energize the 1K coil, closing the 1K1 and 1K2 contacts. Current will flow through the safety switch heater and cold contacts. The hot contacts remain open. The closing of the 1K1 contacts provides current to the oil burner motor, oil valve, and ignition transformer. Under normal conditions ignition and heat will be produced from the combustion of the air-oil mixture. This will provide heat to the stack switch in the flue pipe, causing

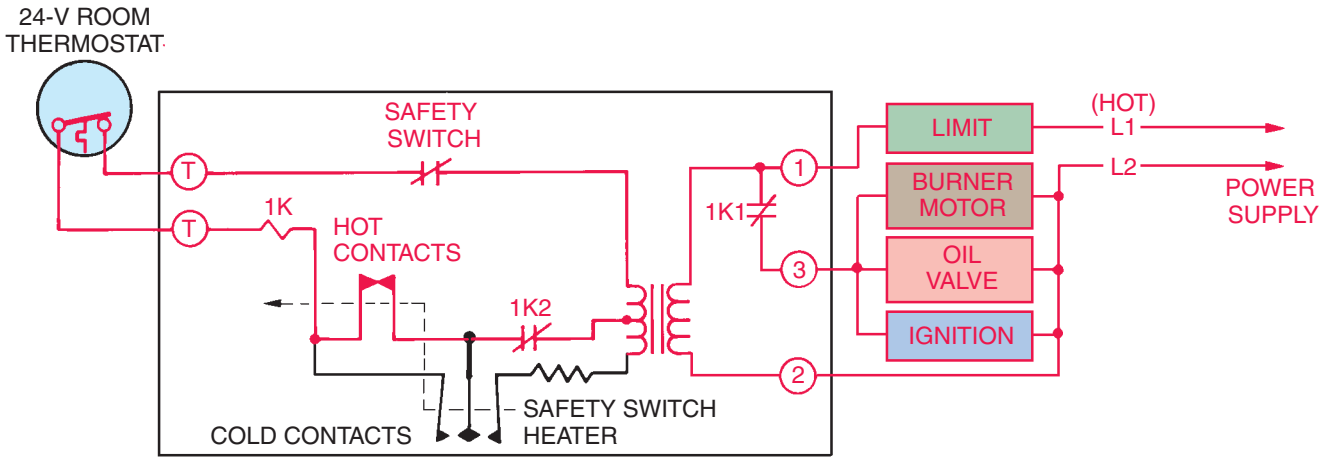
Figure 32.83 Typical stack switch circuitry with flame on, hot contacts closed, and cold contacts open. The safety switch heater is not in the circuit.



the hot contacts to close and the cold contacts to open. The current flow is shown in **Figure 32.83**. The circuit is completed through the 1K2 contact, the hot contacts to the 1K coil. The 1K1 contact remains closed and the furnace continues to run as in a normal safe start-up. The safety switch heater is no longer in the circuit.

If there is no ignition and consequently no heat in the stack, the safety switch heater remains in the circuit. In approximately 90 sec the safety switch heater opens the safety switch, which causes the burner to shut down. To start the cycle again, depress the manual reset button. Allow approximately 2 min for the safety switch heater to cool before attempting to restart.

32.12 WIRING DIAGRAM FOR CAD CELL PRIMARY CONTROL WITH INTERMITTENT IGNITION

In early generation primary control circuits, the cad cell discussed earlier may be coupled with a triac, which is a form of a solid-state device designed to pass current when the cad cell circuit resistance is high (no flame). When the burner fires, the cad cell senses light from the burner's flame and its resistance drops. This causes the triac to open, stopping current flow through it. When the burner is not firing, the resistance of the cad cell is high and the triac is essentially closed, allowing current to pass through the triac.

The circuit in **Figure 32.84** shows how the triac and the cad cell are wired in the primary control. The red lines indicate the electrical paths through which electric current is flowing. The burner represented by this diagram is currently firing and the resistance of the cad cell is low. This means that the resistance between the two F terminals is low. This low resistance causes the triac to stop passing electric current through the safety switch heater. If the safety switch heater remains in the circuit too long, the burner will shut down. It should be clear from this diagram that the burner motor, the oil valve, and the ignition are all powered by the same orange wire. Since these three elements will all be energized and de-energized at the same time, this type of primary control allows for only intermittent duty ignition operation. The ignition spark will be produced during the entire operating cycle.

In **Figure 32.85** there is no flame and a high resistance in the cad cell. By design, the triac will then conduct current that will pass through the safety switch heater. If this current continues through the heater, it will open the safety switch and cause the burner to shut down. To recycle, press the reset button.

The technician must be able to check the cad cell. It connects to the primary control on the outside at terminals F and F. To check the resistance reading of the cad cell, disconnect the two yellow wires at the F and F terminal block. With the furnace off, it should be dark inside the combustion chamber. Set the ohmmeter to check out 1000 Ω. Calibrate the meter to 0 Ω with the meter leads touching each other. Now place the meter leads on the two yellow wires. The meter should read a very high resistance, maybe even infinity, as if the leads were held apart in air. Now jump out the T to T terminals and the furnace should fire. As the furnace fires, the resistance will become less on the two yellow wires. It should be somewhere around 600 to 1000 Ω. The cad cell is good if this test proves out. The furnace should run for a short while and then lock out. This is a safety feature to prevent someone from running the furnace without the cad cell protection. In most modern installations the cad cell is preferred over the thermal stack switch. It acts faster, has no mechanical moving parts, and is consequently considered more dependable.

SAFETY PRECAUTION: *Care should be taken not to reset any primary control too many times because unburned oil may accumulate after each reset. Once ignited, a puddle of oil will burn intensely. If this should happen, the technician should stop the burner motor but should allow the furnace fan to run. The air shutter should be shut off to reduce the air to the burner. Notify the fire department. Do not try to open the inspection door to put the fire out. Let the fire burn itself out with reduced air.*•

32.13 WIRING DIAGRAM FOR CAD CELL PRIMARY CONTROL WITH INTERRUPTED IGNITION

The cad cell shown in **Figure 32.75** can be used for interrupted duty ignition. This type of primary control has separate wires to control the operation of the burner motor, the oil valve, and the ignition, **Figure 32.86**. This type of control is powered constantly through L1 and has another power lead that is interrupted if the limit switch is open. There are three color-coded wires that feed power to the burner motor, the ignition, and the oil valve. Be sure to check the color-coding for the particular primary control you are working on, as different primary controls may be color-coded differently. For example, some manufacturers color-code the constant L1 power lead red, while others color code the equivalent wire black.

The diagram of the primary control shown in **Figure 32.86** shows a set of dry alarm contacts. In the event the primary control goes into lockout or latch-up mode, the dry alarm contacts on the primary control close. When these contacts close, an auto-dialer, if connected and used, has the capability to send a signal to the homeowner, alarm company, and/or oil company, alerting them that a problem with the oil burner is present. Lockout occurs when the burner cannot successfully start. If the control goes into lockout three times on a single call for heat, the control goes into the restricted lockout mode called latch-up.

A sample wiring diagram for an oil-fired furnace using an interrupted ignition-duty primary control is shown in **Figure 32.87**. In this diagram it can be seen that an uninterrupted 120-V power supply is reaching the primary control via the red wire, while a switched 120-V power lead, through the limit switch, is connected to the primary control via the black wire, **Figure 32.88**.

If the limit switch is closed, on a call for heat, the space thermostat closes its contacts and power is passed to the coil on the burner relay, **Figure 32.89**. The energizing of the burner relay coil causes the contacts on the burner relay to close, making the connection between the T-T contacts on the primary control, **Figure 32.90**.

Once the T-T contacts have closed, the oil burner motor and the ignition circuits are energized, allowing the motor to come up to speed. This valve-delay-on period varies from primary control to primary control, but is often in the 10-second range, **Figure 32.91**. Once the valve-delay-on period has elapsed, the oil valve circuit is energized and pressurized oil is delivered to the nozzle for atomization and combustion, **Figure 32.92**.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

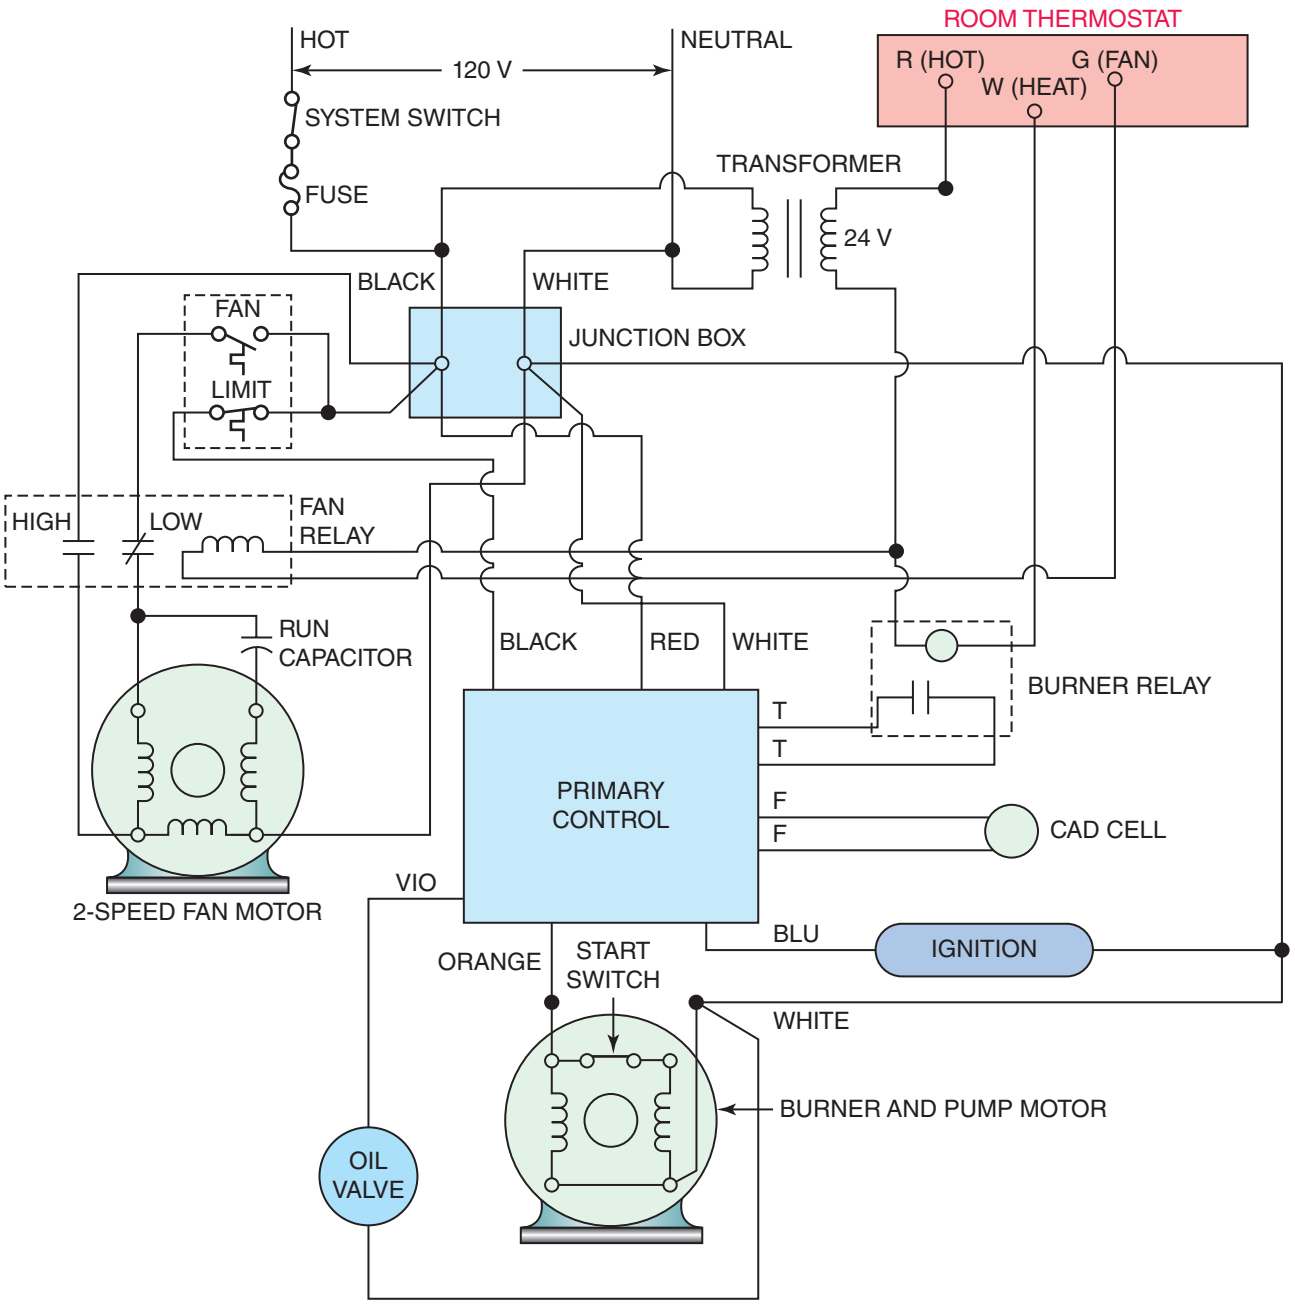
Figure 32.87 Typical wiring diagram of a furnace using an interrupted duty cad cell primary control.



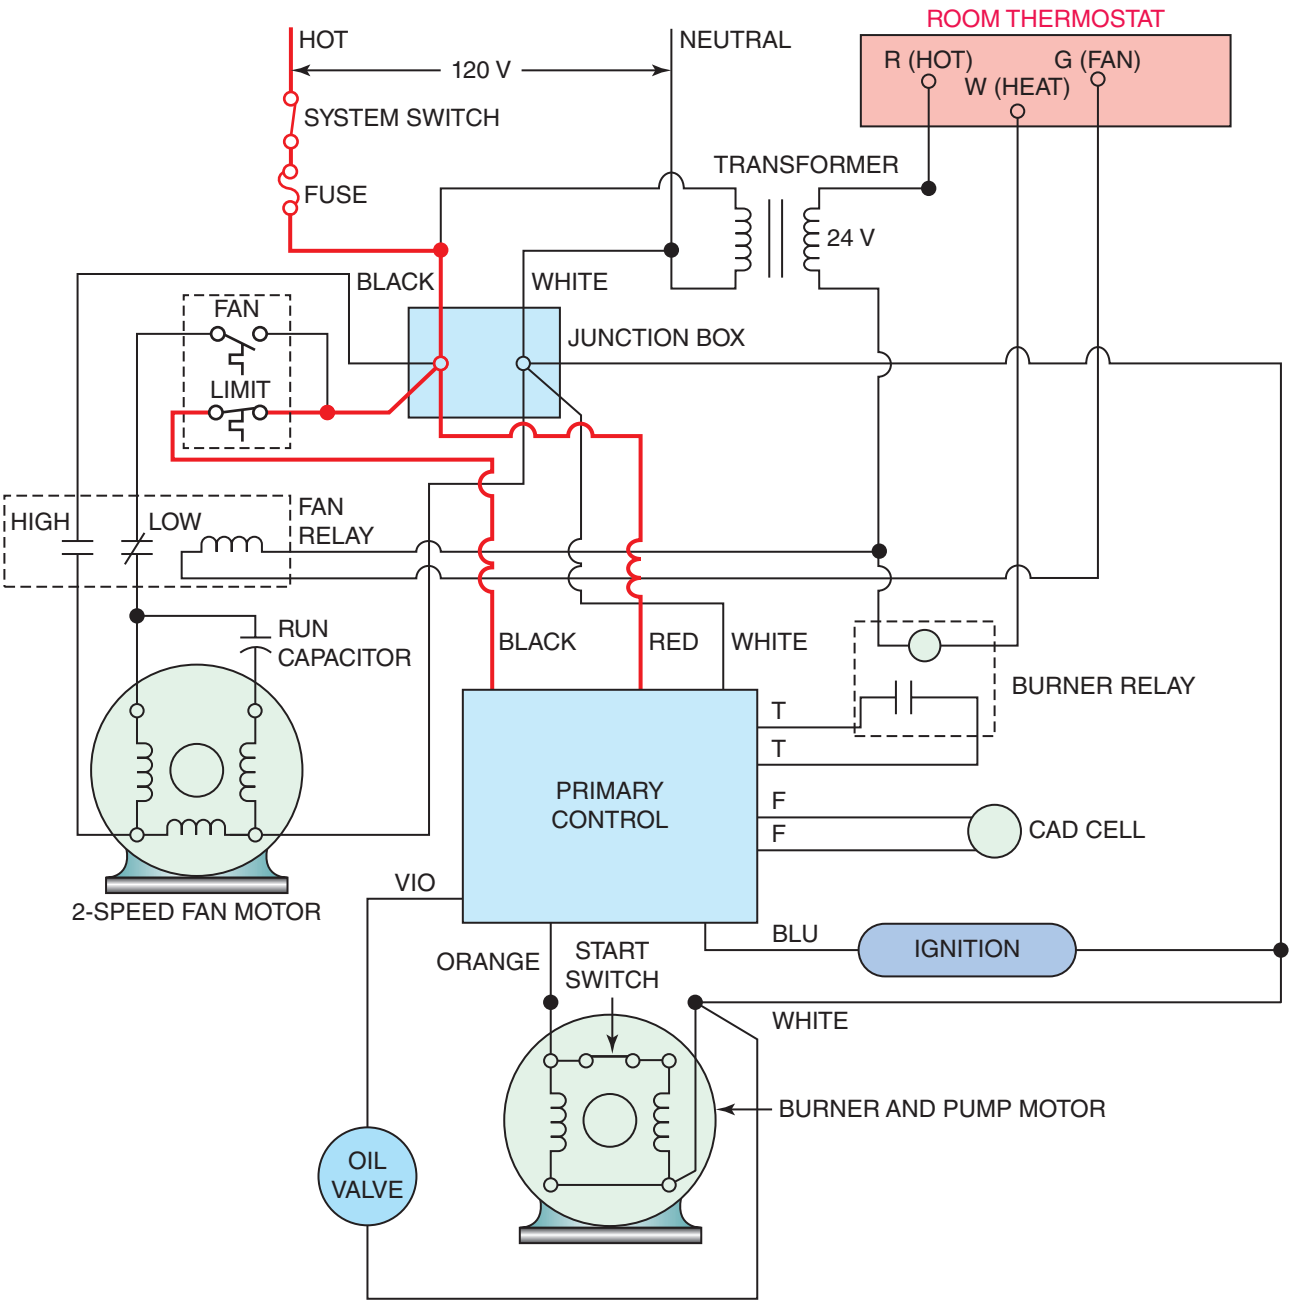
32.14 COMBUSTION CHAMBER

The atomized oil and air mixture blown from the air tube into the combustion chamber is ignited by a spark from the electrodes. The atomized oil must be burned in suspension; that is, it must be burned while in the air in the combustion chamber. If the flame hits the wall of the combustion chamber before it is totally ignited, the cooler wall will cause the oil vapor to condense, and efficient combustion will not occur. Combustion chambers should be designed to avoid this condition. They may be built of steel or a refractory material. **Figure 32.93** shows a flame in a combustion chamber.

The combustion chamber is supposed to be matched to the burner flame at the factory. It would be a rare case where the flame and combustion chamber were not a fit from the beginning. On older systems, the technician may encounter several replacement nozzles lying around the furnace. It is always best to follow the manufacturer's recommendations regarding nozzle size.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

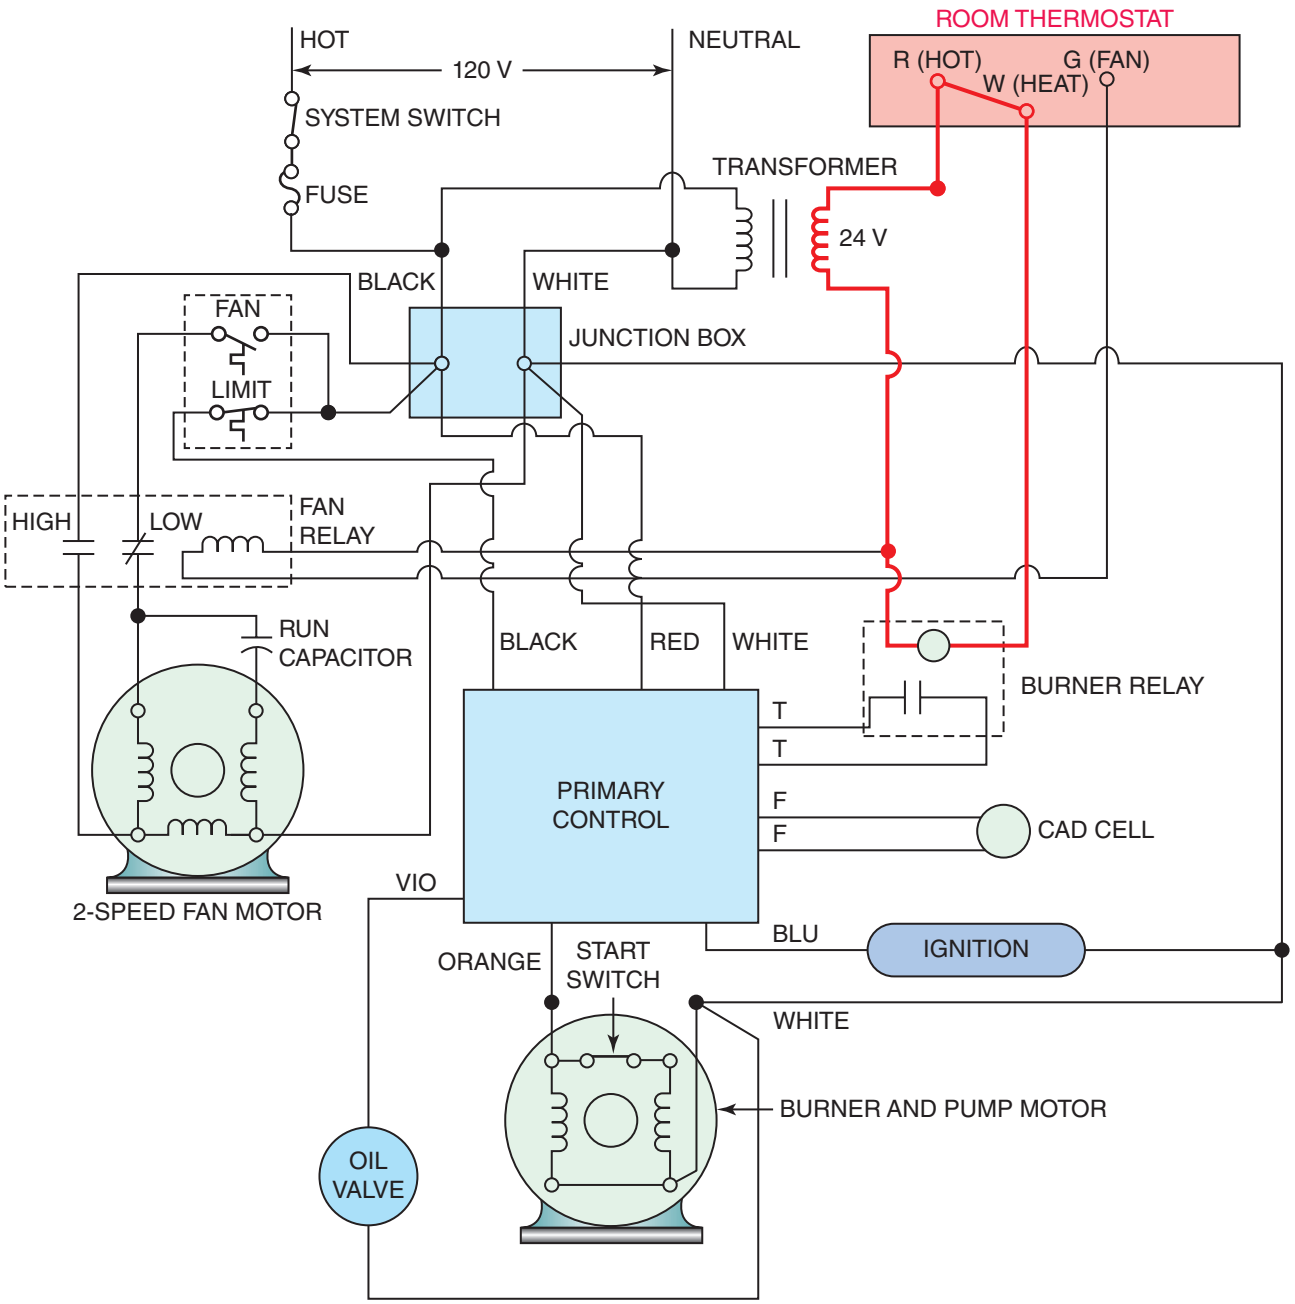
Figure 32.88 When the limit switch is closed, line voltage is supplied to the primary control at two points.



Recall from our earlier discussion on nozzles that the spray angle of the nozzle is, at least in part, determined by the shape and configuration of the combustion chamber. Nozzles with smaller spray angles are intended for use in conjunction with deeper combustion chambers; nozzles with large spray angles are intended for use with square or round combustion chambers. Oil burner manufacturers often can supply original equipment manufacturer (OEM) guides that provide information regarding the original nozzle size intended for use on a specific furnace with a specific model of oil burner. This information is extremely valuable to the service technician.

The combustion chamber is merely a firebox, or a box to contain the fire. They sometimes develop cracks. There is no connection between the combustion chamber and the recirculating air, so the chamber oftentimes may be repaired. The repair kit may consist of a wet blanket material that can be installed through the hole after the burner is removed. The wet blanket is placed over the crack and the furnace is reassembled and fired. The blanket will

Figure 32.89 On a call for heat, the low voltage control circuit energizes the coil on the burner relay.



become hard and is fireproof. The other option is to replace the combustion chamber.

32.15 HEAT EXCHANGER

A heat exchanger in a forced-air system takes heat from the combustion in the furnace and transfers it to the air that is circulated to heat the building, **Figure 32.94**. The heat exchanger is made of material that will cause a rapid transfer of heat. Modern exchangers, particularly in residential furnaces, are made of sheet steel, which is frequently coated with special substances to resist the corrosion caused by the acids produced by combustion.

The heat exchanger is also designed to keep flue gases and other combustion materials separate from the air circulated through the building. **SAFETY PRECAUTION:** *The flue gases from combustion should never mix with the circulating air. A technician who discovers a crack in a heat exchanger may be tempted to repair it by welding it closed. Many state codes prohibit this type of repair.*•

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

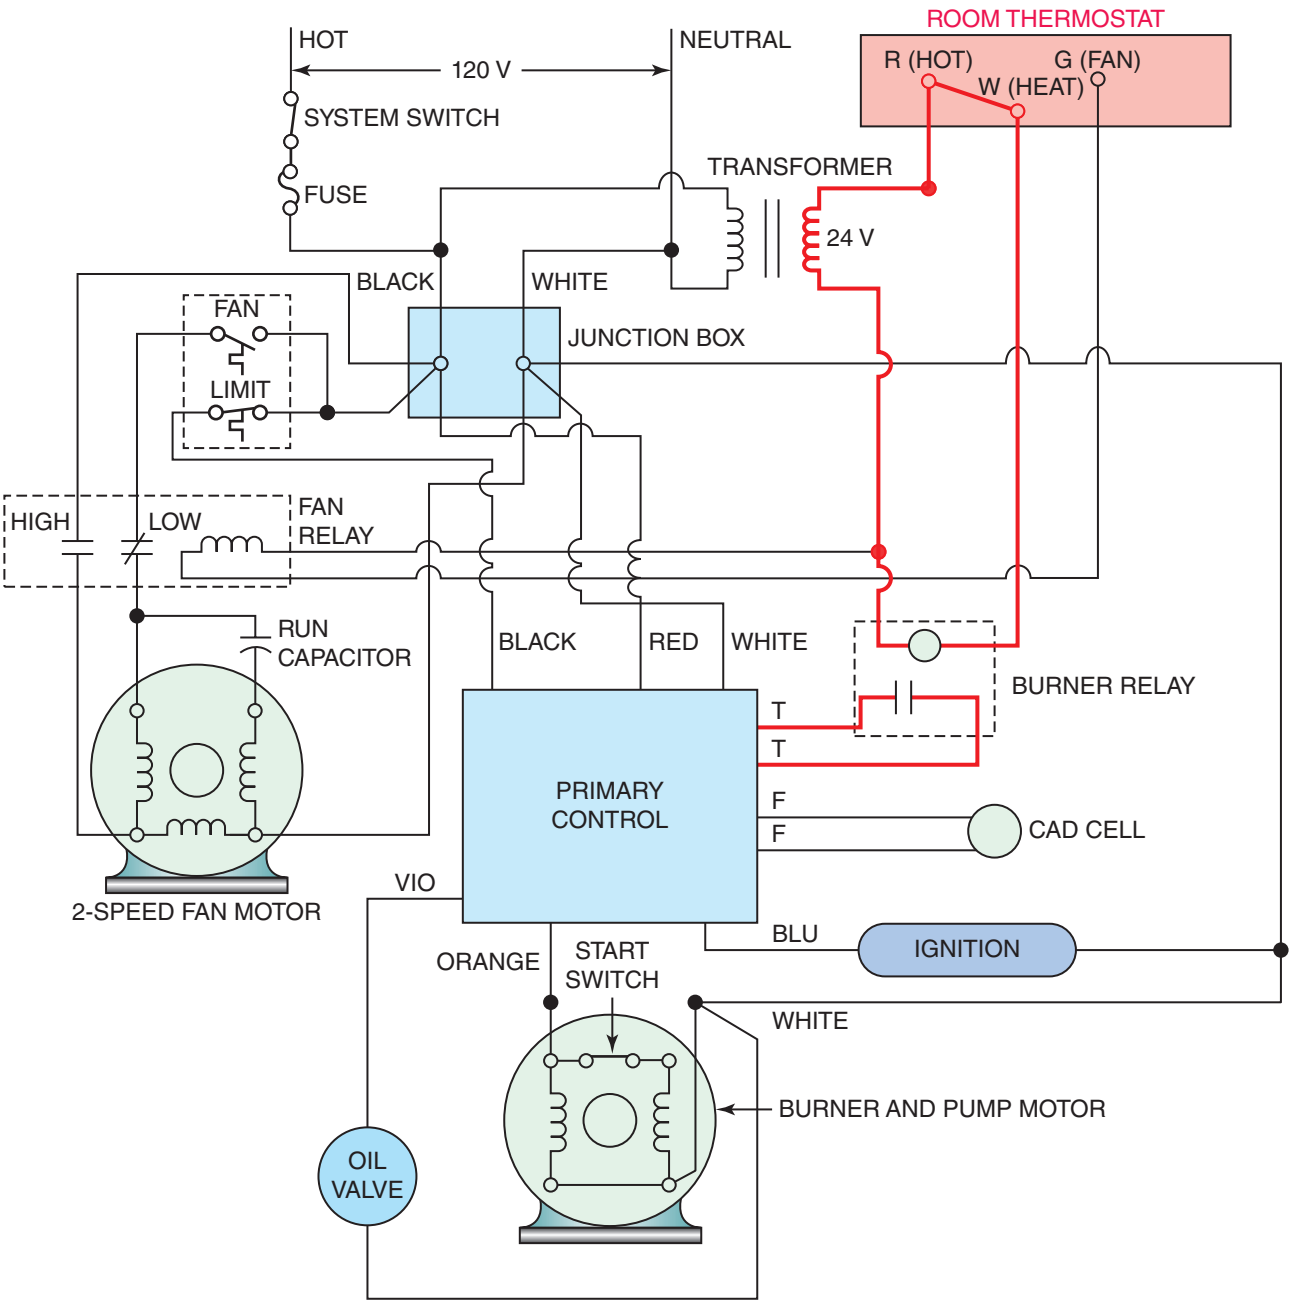
Figure 32.90 When the coil on the burner relay is energized, the contacts on the relay close, completing the T-T circuit.



A technician often inspects heat exchangers and combustion chambers. A mirror made of chrome-plated steel is an ideal tool for this job, **Figure 32.95**, and new products on the market allow technicians to inspect heat exchangers with more accuracy and reliability than ever before. These products include a small video camera on the end of a long, snakelike, flexible rod that can be inserted into the furnace. The tip of the rod contains a light so the technician can inspect the heat exchanger by monitoring the screen on the device, **Figure 32.96**.

One way a technician can determine if there is a crack in the heat exchanger is to insert the probe from the combustion analyzer into the supply air duct far from the furnace location. If there is a measurable quantity of carbon monoxide in the supply airstream, a leak in the heat exchanger should be suspected. Damage to the heat exchanger can be the result, among other things, of insufficient airflow through the appliance or an oversized furnace that cycles on and off too often.

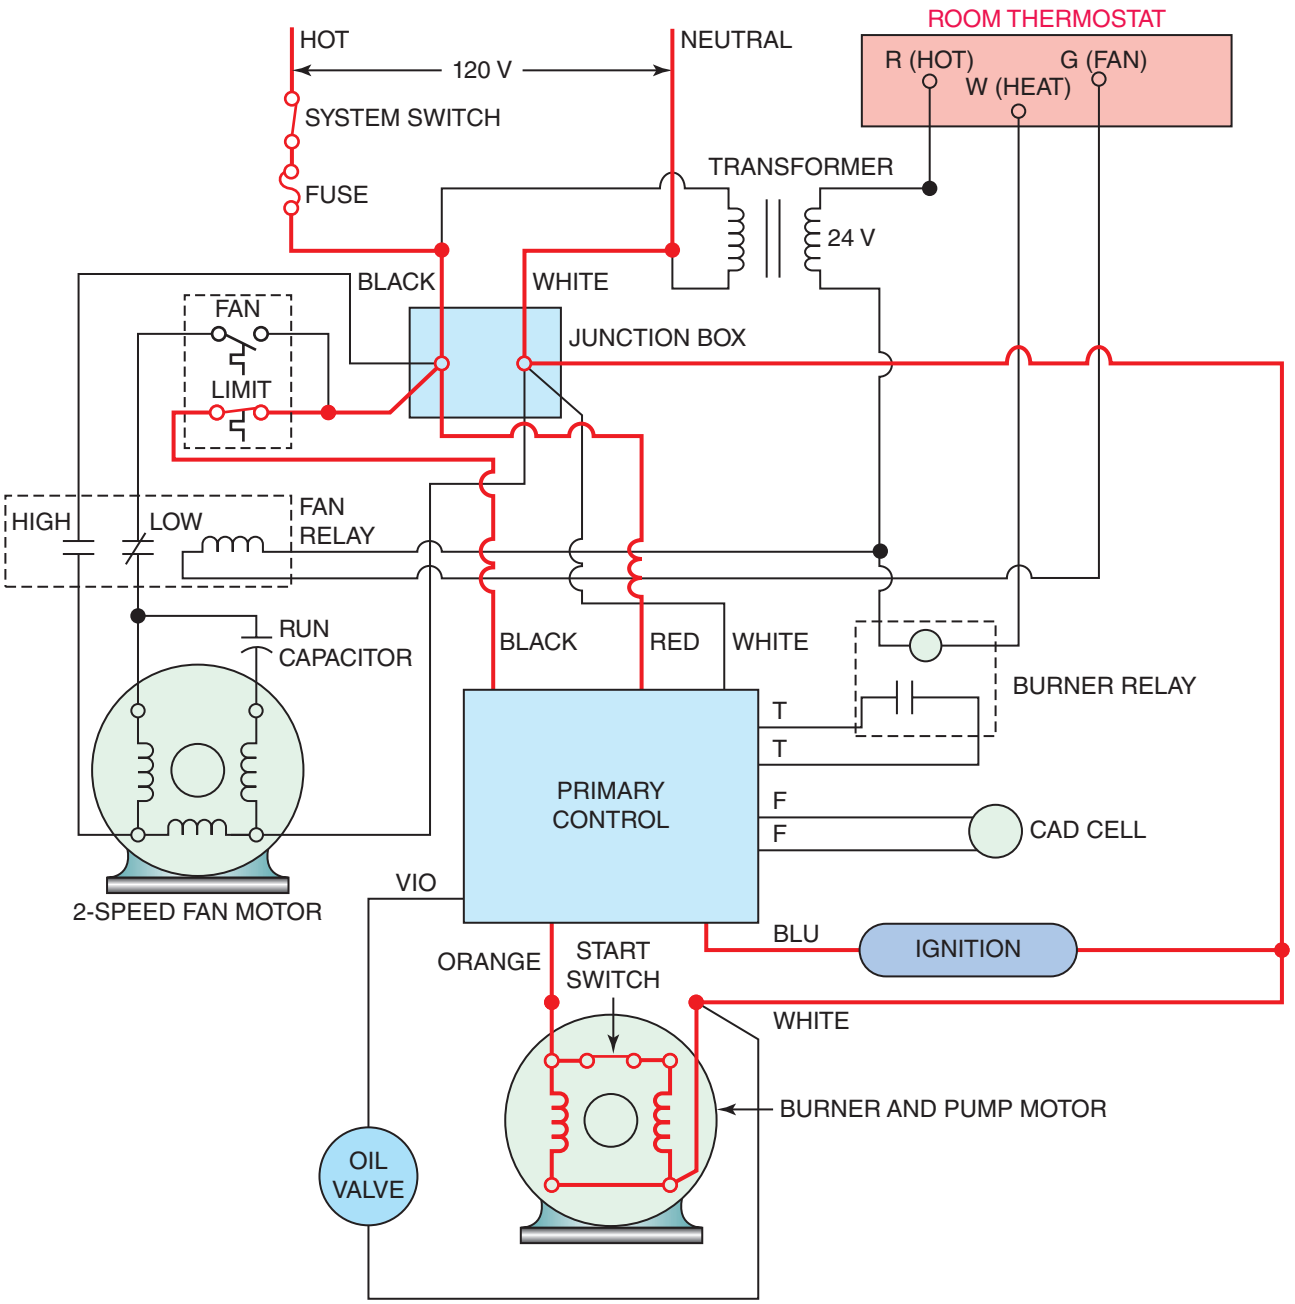
Figure 32.91 Closing the T-T contacts initiates burner operation by powering the burner motor and the ignition circuit.



Oil furnaces should have the correct airflow across the heat exchanger. A check of the rise in air temperature may be performed if the installation is new or if it is suspected that the airflow is not correct. Often, for air-conditioning equipment the quantity of airflow must be known. The unit capacity may be found on the unit nameplate or calculated from the oil burner nozzle size. For example, the unit may have a 0.75-gph nozzle and a 65°F temperature rise. What should the cfm be?

Since one gallon of Number 2 fuel oil can produce about 140,000 Btu of heat energy per hour, a 0.75-gph nozzle will produce approximately 105,000 Btu per hour:

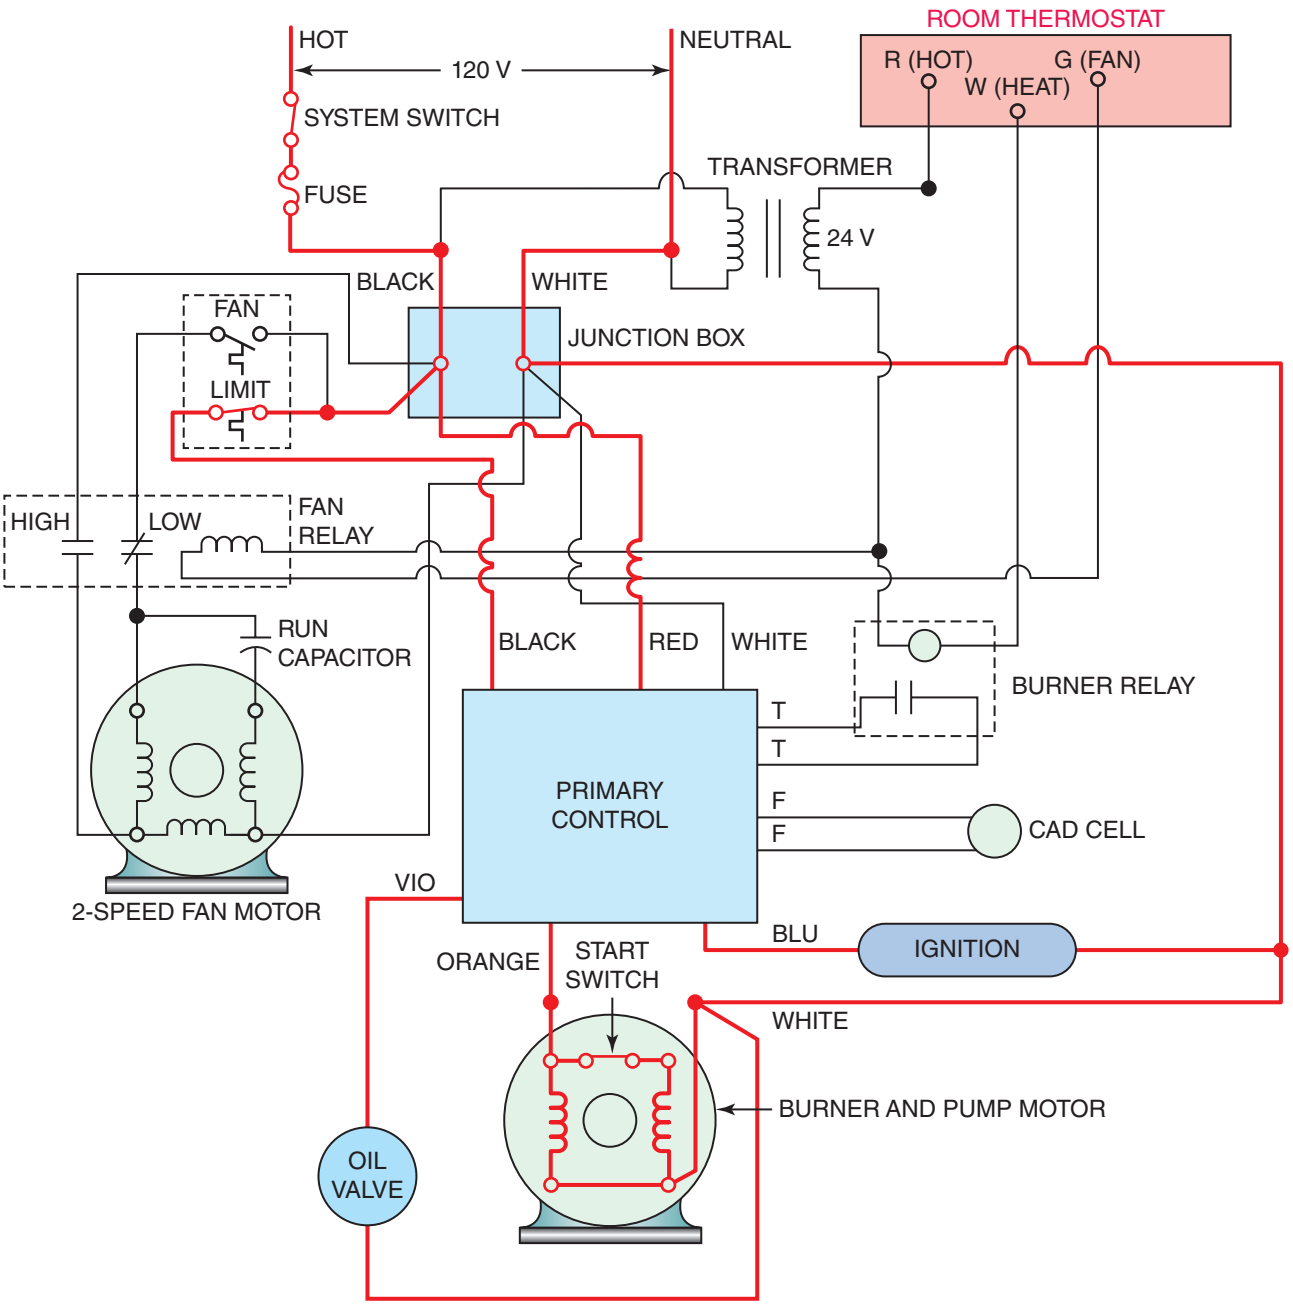
$$140{,}000 \text{ Btu/gal} \times 0.75 \text{ gal/h} = 105{,}000 \text{ Btu/h}$$

The 105,000 Btu/h is the input of the furnace. There will be a certain percentage of this heat that is wasted up the chimney. If we assume that the heating appliance is 80% efficient, the heat output will be

$$105{,}000 \text{ Btu/h} \times 0.80 = 84{,}000 \text{ Btu/h}$$

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 32.92 After the valve-delay-on period has elapsed, the oil valve's solenoid coil is energized and pressurized oil is pumped to the nozzle.



This result represents the amount of heat that is being added to the air in the structure. The following formula calculates the air volume (in cubic feet per minute) that is required to transfer this amount of heat:

$$Q_s = \text{cfm} \times 1.08 \times \Delta T$$

where Q_s = The quantity of heat in Btu/h
cfm = The air volume in cubic feet per minute
1.08 = A constant
ΔT = The temperature rise across the furnace

In this example, the Q_s is 84,000 Btu/h and the ΔT is 65°F. Plugging these values into the formula gives

$$\begin{aligned} 84{,}000 \text{ Btu/h} &= \text{cfm} \times 1.08 \times 65 \\ 84{,}000 \text{ Btu/h} &= \text{cfm} \times 70.2 \\ \text{cfm} &= 84{,}000 \div 70.2 \\ \text{cfm} &= 1196.6 \end{aligned}$$

So, the required airflow is about 1200 cfm.

32.16 CONDENSING OIL FURNACE

Since energy prices have increased and the need for fossil-fuel conservation has become so evident, some manufacturers have worked to design more efficient oil furnaces. The **condensing oil furnace** is one of the product designs intended to achieve increased efficiency.

The condensing oil furnace, like the more conventional furnace, has two systems: the combustion or heat-producing system and the heated-air circulation system. The combustion system includes the burner and its related components: the combustion chamber, as many as three heat exchangers, and a vent fan and pipe. The heated-air circulation system includes the blower fan, housing, motor, plenum, and duct system. The following describes the operation of a condensing oil furnace manufactured by Yukon Energy Corporation, **Figure 32.97**.

The burner forces air and fuel oil into the combustion chamber where they are mixed and ignited. Much of this combustion heat is transferred to the main heat exchanger, which surrounds the combustion chamber. Combustion gases still containing heat are forced through a second heat exchanger where additional heat is transferred. Gases still containing some heat are forced through a third heat exchanger, where nearly all the remaining heat is removed. The third heat exchanger is a coil-type exchanger in which the temperature is reduced below the dew point, low enough for a change of state to occur, which results in moisture condensing from the flue gases. This is a latent-heat, high-efficiency exchange. About 1000 Btu are transferred to the airstream for each pound of moisture condensed (1 lb water = about 1 pint), so this can result in considerable savings. The remaining exhaust gases are vented to the outside, normally forced

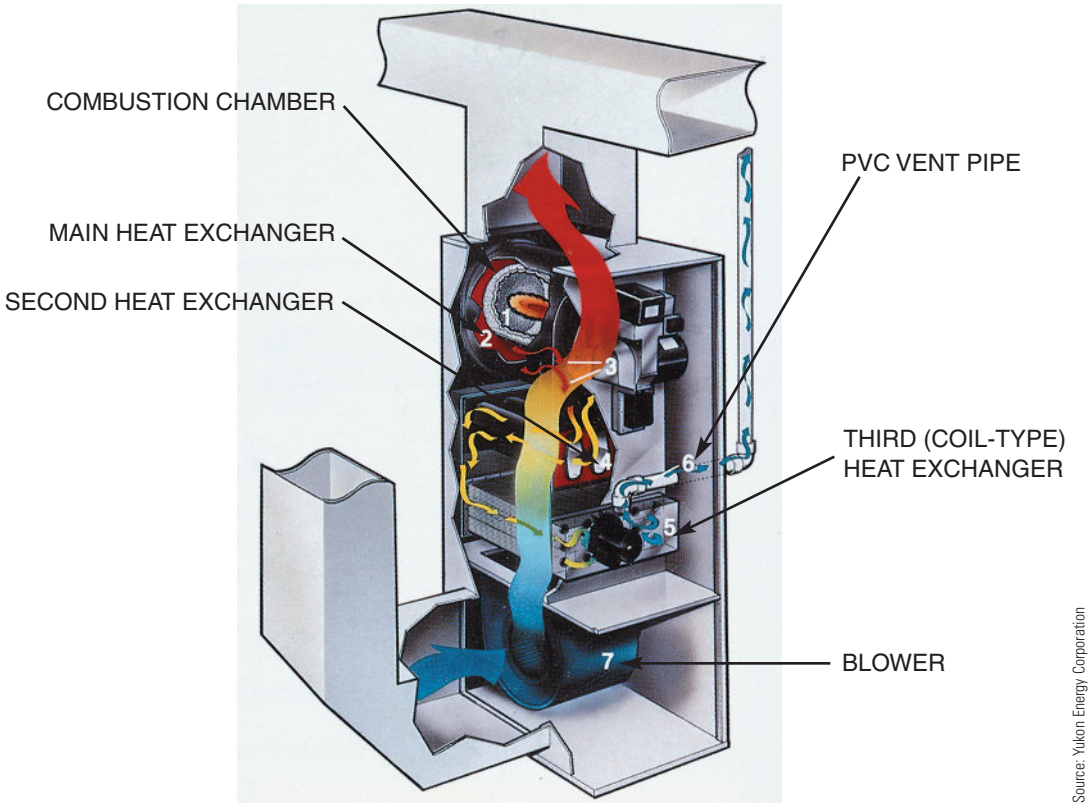
Figure 32.97 A condensing oil furnace.



out by a blower through polyvinyl chloride (PVC) pipe. The condensing coil must be made of stainless steel to resist the acid in the flue gases. A drain is located at the condensing coil to remove the condensate to a container or to a suitable area or drain outside.

In the heated-air circulation system, the blower draws air through the return air duct and moves it across the condensing heat exchanger where the air is preheated by removing the sensible and latent heat from the coil. The air then passes around the second heat exchanger where additional heat is added. The circulating air then moves over the main heat exchanger, after which it is circulated to the rooms to be heated through the duct system. The leaving air is approximately 60°F warmer than when it entered the furnace through the return air duct.

Condensing oil furnaces have a 90+ AFUE. They also can be installed without a chimney because they are vented through a PVC pipe.

32.17 SERVICE PROCEDURES

PUMPS

The performance of residential and commercial fuel oil systems without booster pumps from tank to nozzle can be determined with a vacuum gauge and a pressure gauge. Before the vacuum and pressure checks are made, however, the following should be determined:

1. The tank has sufficient fuel oil.
2. The tank shutoff valve is open.
3. The tank location is noted (above or below burner).
4. The type of system is noted (one- or two-pipe).

Connect the vacuum and pressure gauges to the fuel oil unit as shown in **Figure 32.98**. If the tank is above the level of the burner, the supply system will typically be a one-pipe system, but may sometimes be a two-pipe system. When the tank is above the burner and the unit is operating, the vacuum gauge should read 0 in. Hg. If the gauge indicates a vacuum, one or more of the following may be the problem:

- The fuel line may be kinked.
- The line filter may be clogged or blocked.
- The tank shutoff valve may be partially closed.

If the supply tank is below the burner level, the vacuum gauge should indicate a reading: generally, 1 in. Hg for every foot of vertical lift and 1 in. Hg for every 10 ft of horizontal run. The lift and horizontal run combination should not total more than 17 in. Hg. (Remember, the lift capability of a dual-stage pump is approximately 15 ft.) Vacuum readings in excess of this calculated value may indicate a tubing size too

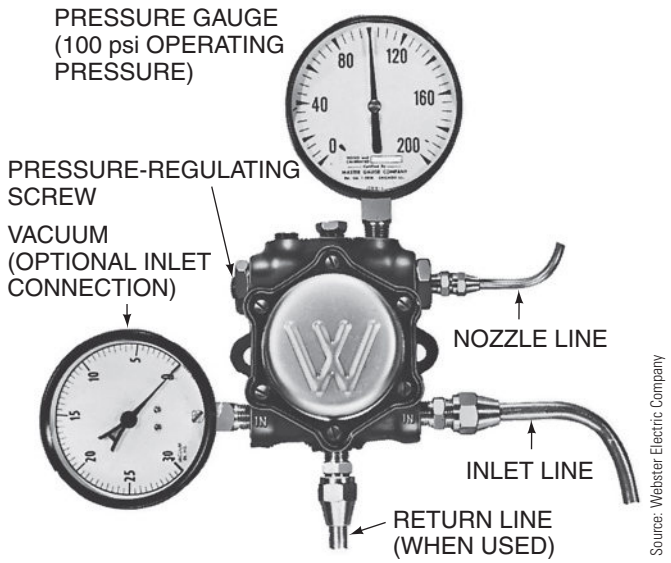
Figure 32.98 A pump with a pressure gauge and a vacuum gauge in place for tests and servicing.



small for the run, but may also be an indication of a kinked or partially blocked line. This may cause the oil to foam.

The pressure gauge measures the performance of the pump and its ability to supply a steady, even pressure to the nozzle. The pressure regulator should be adjusted to the manufacturer's specifications, which is always above 100 psi. See **Figure 32.99** for an illustration of a pressure-adjusting valve. To adjust the regulator, with the pressure gauge in place, turn the adjusting screw until the gauge indicates 100 psi. With the pump shown in **Figure 32.99**, the valve-screw cover screw should be removed and the valve screw turned with a 1/8-in. Allen wrench. Some pumps require a screwdriver instead of an Allen wrench to adjust the regulator. With the regulator set and the unit in operation, the pressure gauge should give a steady reading. If the gauge pulsates, one or more of the following may be the problem:

- Partially clogged supply filter element
- Partially clogged unit filter or screen
- Air leak in fuel oil supply line
- Air leak in fuel oil pump cover

A pressure check of the pump cutoff is necessary if oil enters the combustion chamber after the unit has been shut down. To make this check, insert the pressure gauge in the outlet for the nozzle line, **Figure 32.100.** With the gauge in place and the unit running, record the pressure. When the unit is shut down, the pressure gauge should drop about 20% and hold. If the gauge drops to 0 psi, the fuel oil cutoff inside the pump is defective, and the pump may need to be replaced or an external solenoid installed, **Figure 32.53**. If the pressure gauge holds but there is still an indication of improper fuel oil shutoff, the problem may be one of the following:

- Possible air leak in fuel unit (pump)
- Possible air leak in fuel oil supply system
- Air trapped in the nozzle line

BURNER MOTOR

If the burner motor does not operate:

1. Press the reset button if there is one. Newer oil burners are equipped with permanent split-capacitor motors

Figure 32.99 A fuel pump and a pressure-adjusting valve.

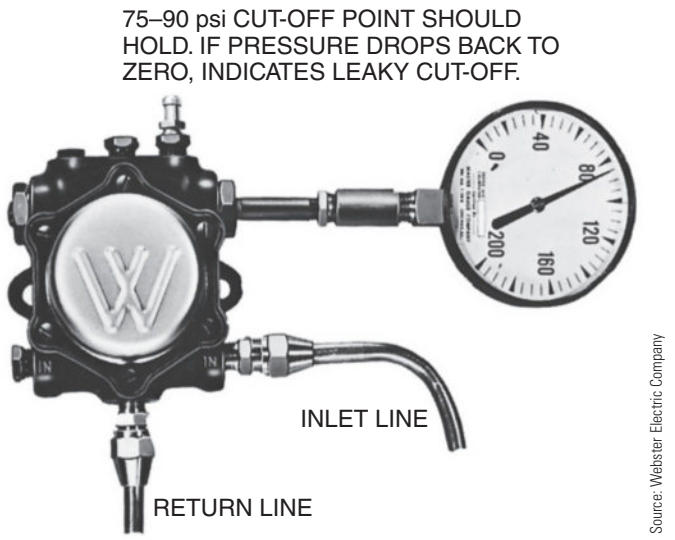
Figure 32.100 A pressure gauge in place to check the valve differential.



that do not have reset buttons—they may just reset automatically from the internal overload. **NOTE:** *Reset may not function if the motor is too hot. Wait for the motor to cool down.* •

2. Check the electrical power to the motor. This can be done with a voltmeter across the orange and white or black and white leads to the motor. If there is power to the motor and nothing is binding it physically and it still does not operate, it should be replaced.

BLEEDING A ONE-PIPE SYSTEM

When starting an oil burner with a one-pipe system for the first time or whenever the fuel-line filter or pump is serviced, air will get into the system piping. The system must be bled to remove this air. The system should also be bled if the supply tank is allowed to become empty.

To bleed the system, ¼-in. flexible, transparent tubing should be placed on the vent or bleed port, and the free end of the tube placed in a container, **Figure 32.101**. Turn the bleed port counterclockwise (usually a turn from ⅛ to ¼ is sufficient). Then start the burner, allowing the fuel oil to flow into the container. Continue until the fuel flow is steady and there is no further evidence of air in the system; then shut the valve off.

CONVERTING A ONE-PIPE SYSTEM TO A TWO-PIPE SYSTEM

Most residential burners are shipped from the manufacturer for use with a one-pipe system. To convert these units to a two-pipe system, do the following:

1. Shut down all electrical power to the unit.
2. Close the fuel oil supply valve at the tank.

Figure 32.101 A diagram of a fuel oil pump.

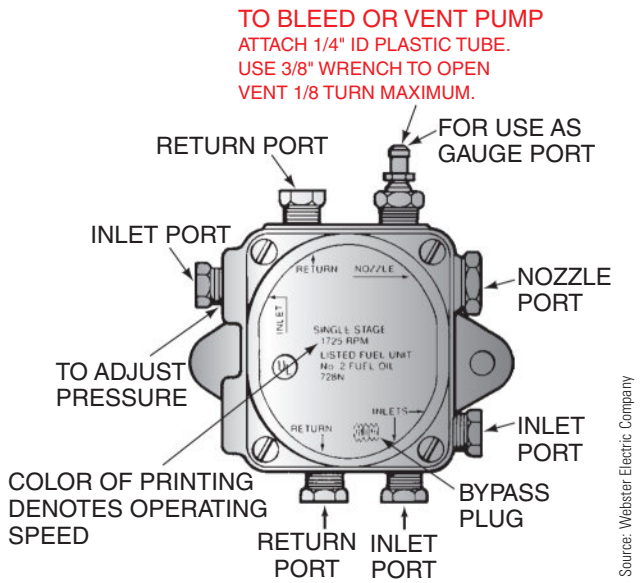


Figure 32.102 Installation of the bypass plug for conversion to a two-pipe system.

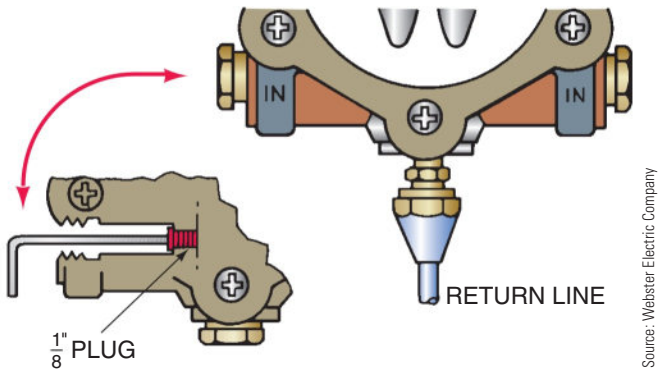


3. Remove the inlet port plug from the unit, **Figure 32.102**.
4. Insert the bypass plug shipped with the unit into the deep seat of the inlet port with an Allen wrench.
5. Replace the inlet port plug and install the flare fitting and copper line returning to the tank.

NOTE: *Make certain that the specific manufacturer's instructions are followed when converting a one-pipe system to a two-pipe system.* **The procedure just outlined is for Webster pumps only.** *Pumps manufactured by Danfoss, for example, do not use a bypass. In addition, pumps manufactured by Suntec require that the bypass plug be installed in the return port.* •

SAFETY PRECAUTION: *Do not start the pump with the bypass plug in place unless the return line to the tank is installed. Without this line, there is no place for the excess oil to go, except possibly to rupture the shaft seal.* •

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

NOZZLES

Nozzle problems may be discovered by observing the condition of the flame in the combustion chamber, taking readings on a pressure gauge, and analyzing the flue gases. (Flue-gas analysis is discussed in 32.17, "Combustion Efficiency.") The following are common conditions that may relate to the nozzle:

- Smoke
- Flame changing in size and shape
- Flame impinging (striking) on the sides of the combustion chamber
- Sparks in the flame
- Low carbon dioxide reading in the flue gases (less than 8%)
- Delayed ignition
- Odors

When nozzle problems are apparent, the nozzle should be replaced. The nozzle is a delicate, finely machined component, and wire brushes and other cleaning tools should not be used on it. Generally, a nozzle should be replaced annually as a normal servicing procedure. **SAFETY PRECAUTION:** *Nozzles should be removed and replaced with a special nozzle wrench. Never use adjustable pliers or a pipe wrench.•* When the nozzle has been removed, keep the oil from running from the tube by plugging the end of the nozzle assembly. If oil leaves this tube, air will enter and cause an erratic flame when the burner is put back into operation. It may also cause an afterdrip or afterfire when the burner is shut down.

NOTE: *Do not attempt to clean the nozzle strainer. If the nozzle strainer is clogged, the cause should be determined. Clean the fuel oil nozzle line and the fuel unit (pump) strainer. Change the supply filter element. There may also be water in the supply tank, and the fuel oil may otherwise be contaminated.•*

It is important that nozzles do not overheat. Overheating causes the oil within the swirl chamber to break down into a varnish-like substance, which will build up. The following are major causes of overheating and varnish buildup:

- Fire burning too close to the nozzle
- Firebox too small
- Nozzle too far forward
- Inadequate air-handling components on burner
- Overfired burner

SAFETY PRECAUTION: *Do not allow an afterdrip or afterfire to go unchecked. Any leakage or afterfire will result in carbon formation and clogging of the nozzle. Check for an oil leak, air in the line, or a defective cutoff valve, if there is one. An air bubble behind the nozzle will not always be pushed out during burning. It may expand when the pump is shut off and cause an afterdrip.•*

IGNITION SYSTEM

Of all phases of oil burner operation and servicing, ignition problems are among the easiest to recognize and solve. Ignition service mostly consists of making the proper gap adjustment, cleaning the electrodes, and making all connections secure.

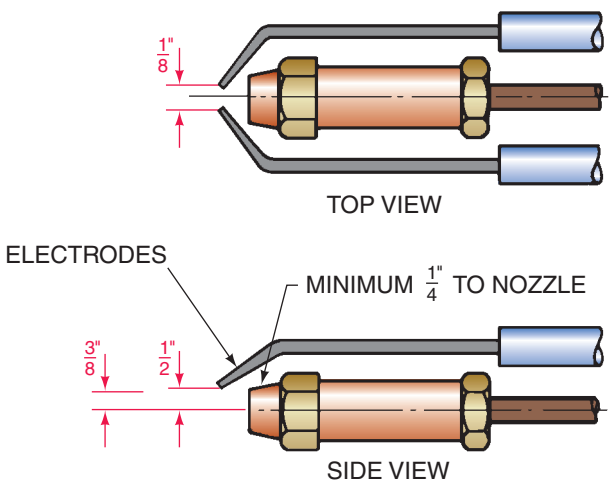
To check the ignition transformer, do the following:

1. Turn off power to the oil burner unit.
2. Swing back the ignition transformer.
3. Shut off the fuel supply or disconnect the burner motor lead.
4. Disconnect the wires from the primary winding of the ignition transformer.
5. Connect the ignition transformer tester, as shown in **Figure 32.64**.
6. Turn the ignition transformer tester on.
7. Observe the display on the tester to determine whether the transformer is good. **SAFETY PRECAUTION:** *Follow the manufacturer's instructions and keep your distance from the 10,000-V leads.•*

To check the electrodes, do the following:

1. Ensure that the three spark gap settings of the electrodes are set properly. Check **Figure 32.103** for the settings of

Figure 32.103 Electrode adjustments. Electrodes cannot be closer than ¼ in. to any metal part.



Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. the gap, height above the center of the nozzle, and distance of the electrode tips forward from the nozzle center.
2. Make sure that the tips of the electrodes are not in the oil spray. **NOTE:** *Oil burner manufacturers have special gauges that help technicians properly position the electrode tips with respect to the nozzle orifice and to each other. When they are available, it is advisable to use these gauges, which can be easily obtained by calling the burner manufacturer.* •

ELECTRODE INSULATORS. Wipe the insulators clean with a cloth moistened with a solvent. If they are cracked or remain discolored after a good cleaning, they should be replaced.

32.18 COMBUSTION EFFICIENCY

Until a few years ago, the heating technician was primarily concerned with ensuring that the heating equipment operated cleanly and safely. Technicians made adjustments by using their eyes and ears. The high cost of fuel, however, now requires the technician to make adjustments using test equipment to ensure efficient combustion.

Fuels consist mainly of hydrocarbons in various amounts. In the combustion process, new compounds are formed and heat is released. The following are simplified formulas showing what happens during a perfect combustion process:

$$C + O_2 \rightarrow CO_2 + \text{heat}$$

$$H_2 + \tfrac{1}{2}\, O_2 \rightarrow H_2O + \text{heat}$$

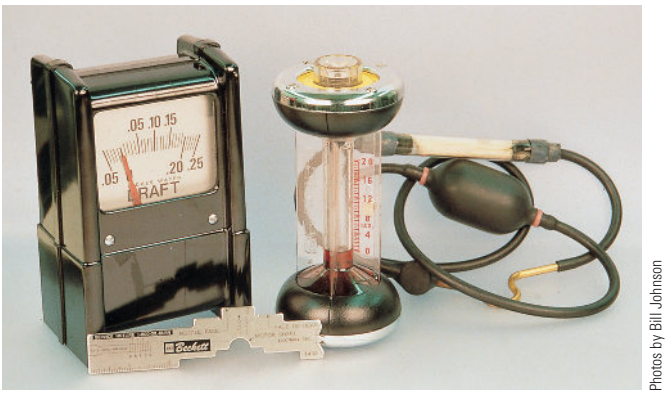
During a normal combustion process, carbon monoxide, soot, smoke, and other impurities are produced along with heat. Excess air is supplied to ensure that the oil has enough oxygen for complete combustion, but even then the air and fuel may not be mixed perfectly. The technician must make adjustments to achieve near-perfect combustion, producing the most heat while reducing the quantity of unwanted impurities. On the other hand, too much excess air will absorb heat, which will be lost in the stack (flue gas) and reduce efficiency. Air contains only about 21% oxygen, so the remaining air does not contribute to the heating process.

The following tests can be made for proper combustion:

1. Draft
2. Smoke
3. Net temperature (flue stack)
4. Carbon dioxide

Technicians develop their own procedures for combustion testing. Making an adjustment to help correct one problem will often correct or help to correct others. Compromises have to be made also. When correcting one problem, another may be created. In some instances, problems may be caused by the furnace design. Some technicians use individual testing devices for each test, **Figure 32.104**.

Figure 32.104 Combustion efficiency testing equipment. (A) A draft gauge, nozzle gauge, and CO_2 tester. (B) A smoke tester.



Photos by Bill Johnson

(A)

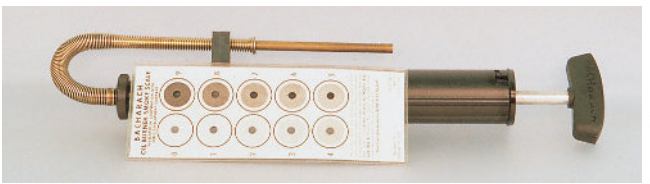


Photo by Bill Johnson

(B)

Figure 32.105 A combustion efficiency analyzer.

Courtesy Bacharach, Inc., Pittsburgh, PA, USA

Others use electronic combustion analyzers with digital readouts, **Figure 32.105**. To make these tests with the individual testing devices, a hole must be drilled or punched in the flue pipe 12 in. from the furnace breaching, on the furnace side of the draft regulator, and at least 6 in. away from it. The hole should be of the correct size so that the stem or sampling tube of the instrument can be inserted into it.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

SAFETY PRECAUTION: *The manufacturer's instructions furnished with the instruments should be followed carefully. The procedures indicated here are very general and should not take the place of the manufacturer's instructions.*•

DRAFT TEST

Correct draft is essential for efficient burner operation. The draft determines the rate at which combustion gases pass through the furnace, and it governs the amount of air supplied for combustion. The draft is created by the differences in temperature of the hot flue gases; it is negative pressure in relation to the atmosphere. Excessive draft can increase the stack temperature and reduce the amount of carbon dioxide in the flue gases. Insufficient draft may cause pressure in the combustion chamber, resulting in smoke and odor around the furnace. To obtain maximum efficiency, adjust the draft before you make other adjustments.

To perform the test, do the following:

1. Drill a hole into the combustion area for the draft tube. (On some furnaces, a bolt may be removed and the bolt hole used for access.)
2. Place the draft gauge on a level surface near the furnace and adjust to 0 in.
3. Turn the burner on and let it run for at least 5 min.
4. Insert the draft tube into the combustion area to check the overfire draft, **Figure 32.106**.
5. Insert the draft tube into the flue pipe to check the flue draft.

The overfire draft should be set to the manufacturer's specifications, typically, −0.02 in. WC. The flue draft should be adjusted with the draft regulator to maintain the proper overfire draft. Most residential oil burners require a flue draft of −0.04 in. to −0.06 in. WC. These are updrafts and are negative in relationship to atmospheric pressure. Longer flue passages require a higher flue draft than shorter flue passages.

Figure 32.106 Checking overfire draft.

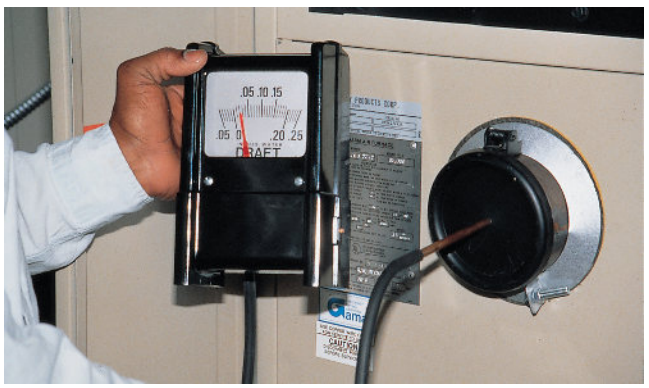

Photo by Bill Johnson

SMOKE TEST

Excessive smoke is evidence of incomplete combustion. Incomplete combustion will result in wasted fuel and higher energy bills. Excessive smoke also results in soot buildup on the heat exchanger and other heat-absorbing areas of the furnace. Soot is an insulator, so a buildup results in less heat being absorbed by the heat exchanger and increased heat loss to the flue. A 1/16-in. layer of soot can cause a 4.5% increase in fuel consumption, **Figure 32.107**.

The smoke test is accomplished by drawing a prescribed number of cubic inches of smoke-laden flue products through a specific area of filter paper. The residue on the filter paper is then compared to a scale furnished with the testing device. The degree of sooting can be read off the scale. A smoke tester such as the one illustrated in **Figure 32.108** may be used.

To perform the smoke test, **Figure 32.109**, do the following:

1. Turn on the burner and let it run for at least 5 min or until the stack thermometer stops rising.
2. Ensure that filter paper has been inserted in tester.
3. Insert the sampling tube of the test instrument into the hole in the flue.

Figure 32.107 The effect of soot on fuel consumption.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 32.109 Making a smoke test.

Photo by Bill Johnson

4. Pull the tester handle the number of times indicated by the manufacturer's instructions.
5. Remove the filter paper and compare it with the scale furnished with the instrument.

Excessive smoke can be caused by

- improper fan collar setting (burner air adjustment).
- improper draft adjustment (draft regulator may be required or need adjustment).
- a poor fuel supply (pressure).
- the oil pump not functioning properly.
- a defective or incorrect nozzle.
- excessive air leaks in the furnace (air diluting flame).
- an improper fuel-to-air ratio.
- a defective firebox.
- improper burner air-handling parts.

NET STACK TEMPERATURE

The net stack temperature is important because an abnormally high temperature is an indication that the furnace may not be operating as efficiently as possible. The net stack temperature is determined by subtracting the air temperature around the furnace (burner inlet air) from the measured stack or flue temperature. For instance, if the flue temperature reading is 650°F and the basement air temperature where the furnace is located is 60°F, the net stack temperature would be 650°F − 60°F = 590°F. The manufacturer's specifications should be consulted to determine the normal net stack temperatures for a particular furnace.

To determine the stack temperature, **Figure 32.110**, do the following:

1. Insert the thermometer stem into the hole in the flue.
2. Turn on the burner and allow it to run for at least 5 min or until the stack thermometer stops rising in temperature.

Figure 32.110 Making a stack gas temperature test.

Photo by Bill Johnson

3. Subtract the basement or ambient temperature from the stack temperature reading.
4. Compare the temperature to the manufacturer's specifications.

A high stack temperature may be caused by

- excessive draft through the combustion chamber.
- a dirty or soot-covered heat exchanger.
- lack of baffling.
- an incorrect or defective combustion chamber.
- overfiring (check nozzle size and pressure).

CARBON DIOXIDE TEST

The carbon dioxide test is an important combustion efficiency test. A high carbon dioxide reading is good. If the test reading is low, it indicates that the fuel oil has not burned efficiently or completely. The reading should be considered along with all of the other test readings. Under most normal conditions, a carbon dioxide reading greater than 10% should be obtained. If problems exist that would be very difficult to correct but the furnace is considered safe to operate and has a net stack temperature of 400°F or less, a carbon dioxide reading of 8% could be acceptable. However, if the net stack temperature is over 500°F, a reading of at least 9% carbon dioxide should be obtained. **SAFETY PRECAUTION:** *A CO_2 reading over 12.5% can be dangerous.*•

To perform the carbon dioxide test, **Figure 32.111**, do the following:

1. Turn on the burner and operate it for at least 5 min.
2. Insert the thermometer and wait for the temperature to stop rising.
3. Insert the sampling tube into the hole previously made in the flue pipe.
4. Remove a test sampling, using the procedure provided by the manufacturer of the test instrument.
5. Mix the fluid in the test instrument with the sample gases from the flue according to instructions.
6. Read the percentage of carbon dioxide from the scale on the instrument.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 32.111 Performing a carbon dioxide test.

Photo by Bill Johnson

A low percentage carbon dioxide reading may be caused by one or more of the following:

- High draft or draft regulator not working properly
- Excess combustion air
- Air leakage into the combustion chamber
- Poor oil atomization
- A worn, clogged, or incorrect nozzle
- Oil-pressure regulator set incorrectly

ELECTRONIC COMBUSTION ANALYZERS

Electronic combustion analyzers provide information similar to that provided by the test instruments already described. Electronic analyzers may measure carbon monoxide and oxygen concentrations rather than carbon dioxide percentages, but from the manufacturer's instructions the technician can determine acceptable levels and necessary corrections to be made on the furnace. Generally, the tests are made from samplings from the same position in the flue as used with the other instruments. Electronic instruments are easier to use and save time. The readings appear on a convenient digital readout system, **Figure 32.105**.

HVAC GOLDEN RULES

When making a service call to a residence, do the following:

- Ask the customer about the problem. The customer can often help you solve the problem and save you time.
- Check the humidifiers, where applicable. Annual service is highly recommended for health reasons.
- Be prepared and do not let any fuel oil escape on the ground or floor around the furnace. The customer will notice the odor.

Added Value to the Customer

Here are some simple, inexpensive procedures that may be included in the basic service call.

- Check flame characteristics; a smoke test is good insurance and may lead to extra paying service work.
- Replace all panels with the correct fasteners.
- Inspect heat exchanger for soot buildup.

PREVENTIVE MAINTENANCE

Oil heat, like gas heat, has air-side and burner-side components. Because the air-side components have been discussed in the electric heat unit, only the burner section will be discussed here.

Oil heat requires more consistent regular service than any other heating system discussed in this book. The reason is that the unit uses fuel oil that must be properly metered and burned for the best efficiency. Burning efficiency is accomplished by ensuring the correct fuel supply and properly adjusting and maintaining the burner section. This includes the combustion chamber, the heat exchanger, and the flue system. They must all be working perfectly for proper burning efficiency. Improper combustion will cause soot to form on the heat exchanger, which will reduce the rate of heat transfer in the appliance. The condition will deteriorate and cause combustion efficiency to worsen. It will pay the customer to have the system serviced each year before the season starts, using the appropriate portions of the following procedures. These procedures may look like a long service call for each furnace every year, but for a typical furnace a competent service technician should be able to accomplish the maintenance portions in an hour. Corrective actions are not considered as part of maintenance. We will start discussion of the preventive maintenance procedures at the tank and move to the flue.

Every year, the service technician should check the tank for water accumulation in the bottom. A commercial paste that changes color when in contact with water may be spread on the oil-tank measuring stick and inserted into the tank. If there is water in the bottom of the tank, when the stick is pulled out of the oil the paste will show the level of the water. If the tank is leaking, it should be replaced. Often, an aboveground tank may be substituted. Aboveground tanks are easier to

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

PREVENTIVE MAINTENANCE FOR REFRIGERATION (*Continued*)

inspect and, in the event of a leak, pose less of a danger to the environment.

The oil lines should be inspected for bends, dents, and rust where they leave the ground and enter the house. A small pinhole in a supply line will cause air to be pulled into the system if the tank is below the burner. This will cause an erratic flame at the burner. The burner may also have an afterburn when the unit stops, caused by the expanding air in the system. Any flame problems, problems priming the pump, or afterburn problems should prompt you to check the supply line for leaks.

A vacuum test may be performed by disconnecting the oil supply line from the tank and letting the system pump the oil supply line into a vacuum and shutting the pump off. The line should stay in a vacuum if it is leak-free. **NOTE:** *Oil and air may leak backwards through the pump. This may be prevented by disconnecting the oil return line and holding your finger over it once the pump is stopped.*

The gun burner should be removed from the unit and the combustion chamber inspected to make sure the refractory is in good condition. Look for signs of soot, and vacuum it out as needed. While the burner is out, change the oil nozzle; be sure to replace the old one with the correct nozzle and use only a nozzle wrench. Check the burner head for overheating and cracks. Examine the static tube for signs of oil or soot, and clean as needed. Set the electrodes using a gauge, and examine the insulators for cracks and soot deposits. Clean as needed and change if cracked. Examine the flexible coupling for signs of wear. Make sure the cad cell is clean and aligned correctly and that the bracket is tight. Lubricate the burner motor. When returning the gun burner to the furnace, be sure to install the gasket and tighten all bolts.

Change the in-line oil filter. Change the gasket and tighten it correctly. This will help ensure a good start.

Start the furnace and while it is heating up to operating temperature, prepare to perform a combustion analysis. Check the draft.

Insert the thermometer in the flue and when it reaches the correct temperature, perform a smoke test. If the fire is smoking, adjust the air until the correct smoke spot is obtained. If you suspect any problem, check the oil pressure to be sure that you have the proper pressure at the nozzle. When the smoke is correct, perform a combustion analysis and adjust to the correct carbon dioxide reading.

When all of this is accomplished, the furnace should operate correctly for the next year.

32.19 DIAGNOSTIC CHART FOR OIL HEAT

The oil-burning appliances discussed here are the forced-air type. (Many of the same rules apply to oil boilers as far as their burner operation is concerned.) These oil-burning systems may be the primary heating systems in homes and businesses. Two basic types of oil safety controls are the cad cell and the stack switch. Both are discussed in the text. Only the basic procedures are discussed here. For more specific information about any particular step of the procedure, refer to descriptions of the particular oil heat unit as it is discussed in the text or consult the manufacturer. Always listen to customers; their input can help you to locate the problem. Remember, they are present most of the time and often pay attention to how the equipment functions.

Problem	Possible Cause	Possible Repair
Furnace will not start—no heat	Open disconnect switch	Close disconnect switch.
	Open fuse or breaker	Replace fuse or reset breaker and determine why it opened.
	Faulty wiring	Repair or replace faulty wiring or connections.
	Defective low-voltage transformer	Replace transformer and look for possible overload condition.
	Primary safety control off—needs reset	Check for oil accumulation in the combustion chamber; if none, reset the control and observe fire and flame characteristics.
	Tripped burner motor reset	Press reset button, check amperage; if too much, check motor or pump for binding.
Furnace starts after reset but shuts off after 90 sec	Cad cell may be out of alignment or dirty	Check cad cell for alignment and smoke on lens—if there are smoke deposits on the lens, adjust the burner for correct fire.
	Defective cad cell	Replace cad cell and reset.
	Defective primary control	Change primary control.

Problem	Possible Cause	Possible Repair
Furnace starts but no ignition occurs	No fuel	Fill fuel tank.
	Electrodes out of alignment	Align electrodes.
	Defective ignition transformer	Replace transformer.
	Defective oil pump	Replace oil pump.
	Restricted fuel filter	Replace filter.
	Defective coupling between pump and motor	Replace coupling.
Burner runs and ignition occurs, but fan does not start	Faulty wiring or connections in fan circuit	Repair or replace faulty wiring or connectors.
	Defective fan switch	Replace fan switch.
	Defective fan motor	Replace fan motor.
Burner has delayed ignition, makes noise on start-up	Electrode out of alignment	Align electrodes.
	Clogged nozzle	Change nozzle and line filter.
	Transformer weak	Change transformer.
	Too much or too little air	Adjust air.
	Nozzle position in burner	Adjust nozzle position.
Burner makes noise on shutdown	Fuel cutoff at fuel pump	Check fuel cutoff using gauges. If not correct, change the fuel pump or add a solenoid in the nozzle line.
High stack temperature	Too much air to burner	Correct air by adjustment.
	Too much draft	Adjust or add draft regulator.
	Overfired	Change to correct nozzle size with correct oil pressure.
Smoking	Too little air	Correct air by adjustment.
	Not enough draft	Clean flue and clean furnace heat exchanger on the oil side.
Smoke in conditioned space	Cracked heat exchanger	Replace heat exchanger.
	Smoke puffing out around burner or inspection door and pulling in through fan compartment	See preceding smoking problem.
Oil smell	Oil leak or spill during service	Clean up oil spill or leak.

32.20 SERVICE TECHNICIAN CALLS

SERVICE CALL 1

A new customer calls requesting *a complete checkup of the oil furnace, including an efficiency test. This customer will stay with the service technician and watch the complete procedure.*

The technician reads on his work order that this is a new customer. The technician parks his service truck on the street, makes certain he has his company-issued photo identification around his neck, and walks to the front door. After ringing the bell, the technician stands back and waits for the customer to open the door. The technician introduces himself and the company and hands the customer his business card.

The technician explains to the customer that the first thing to do is run the furnace and perform an efficiency test. By running a test before and after adjustment, the technician can report results. The thermostat is set to about 10°F above the room temperature to allow time for it to warm up while the technician sets up. This will help ensure that the furnace will not shut off during the test. The technician gets the proper tools and goes to the basement where the furnace is located. The customer is already there and asks whether the technician

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

would mind an observer. The technician explains that a good technician should not mind being watched.

The technician inserts the stack thermometer in the flue and observes the temperature; it is no longer rising. A sample of the combustion gas is taken and checked for efficiency. A smoke test is also performed. The unit is operating with a slight amount of smoke, and the test shows the efficiency to be 65%. This is about 15% to 20% lower than normal.

The technician then removes a low-voltage wire from the primary, which shuts off the oil burner and allows the fan to continue to run and cool the furnace. The technician then removes the burner nozzle assembly and replaces the nozzle with the correct nozzle. Before returning the nozzle assembly to its place, the technician also sets the electrode spacing and then changes the oil filter, changes the air filter, and oils the furnace motor. The furnace is ready to start again.

The technician starts the furnace and allows it to heat up. When the stack temperature has stopped rising, the technician pulls another sample of flue gas. The furnace is now operating at about 67% efficiency and is still a little smoky in the smoke test. The technician checks the furnace nameplate and notices that this furnace needs a 0.75-gph nozzle but has a 1-gph nozzle. It is common (but poor practice) for some technicians to use what they have, even if it is not exactly correct.

This technician removes the nozzle just installed as an exact replacement and then gets more serious about the furnace because it has been mishandled. The technician installs the correct nozzle, starts the unit, and checks the oil pressure. The pressure has been reduced to 75 psig to correct for the oversized nozzle. The technician looks up the appliance information and determines that, for the particular furnace and oil burner configuration, the pump pressure should be 100 psig. He adjusts the pressure accordingly.

The air to the burner is adjusted; meanwhile, the stack temperature is reading 660°F (this is a net temperature of 600°F because the room temperature is 60°F). The technician runs another smoke test, which now shows minimum smoke. The efficiency is now 73%. This is much better.

The customer has been kept informed all through the process and is surprised to learn that oil burner service is so exact. The technician sets the room thermostat back to normal and leaves a satisfied customer. **SERVICE CALL NOTE:** *The technician used a "wet kit" to perform the combustion efficiency test. If the technician had been using an electronic test kit, the smoke test would have been performed first, to avoid potential damage to the instrument.*•

SERVICE CALL 2

A residential customer calls and reports that the *oil furnace in a basement under the family room is making a noise when it shuts off. The oil pump is not shutting off the oil fast enough.*

The technician is running a little late on his present service job and calls to alert the customer that he will be arriving about 20 minutes later than scheduled. The home-owner thanks the technician for the update. The technician arrives, apologizes for the delay, and asks the customer for some information regarding the problems she is having with the system. Once he has heard the system complaint, he turns up the room thermostat above the room temperature to keep the furnace running. The technician removes a low-voltage wire from the primary control of the furnace to stop the burner. The fire does not extinguish immediately but shuts down slowly with a rumble. The technician determines that the installation of a solenoid valve in the oil line will eliminate the problem. He calls the office to get the price for the repair. The technician explains the situation to the customer, along with the cost of repair, and the customer gives her approval.

The technician installs a solenoid in the small oil line that runs from the pump to the nozzle and wires the solenoid coil in parallel with the burner motor so that it will be energized only when the burner is operating. The technician disconnects the line where it goes into the burner housing and places the end in a bottle to catch any oil that may escape. The burner is then turned on for a few seconds. This clears any air that may be trapped in the solenoid out of the line leading to the nozzle.

The technician reconnects the line to the housing and starts the burner. After it has been running for a few minutes, he shuts the burner down. It has a normal shutdown. The start-up and shutdown are repeated several times. The furnace operates correctly. The technician then returns the room thermostat to the correct setting before leaving. He presents the bill to the customer, explains what was done, and demonstrates to the customer that the noises on shutdown are gone. The technician gets the customer's signature on the work order, thanks the customer for her loyalty to the company, and leaves for his next job.

SERVICE CALL 3

A customer from a duplex apartment calls. There is no heat. The customer is out of fuel. The customer had fuel delivered last week, but the driver filled the wrong tank. This system has an underground tank and it is sometimes hard to get the oil pump to prime (pull fuel to the pump). The technician is misled for some time, thinking that there is fuel and that the pump is defective.

The technician arrives to find the customer very upset that there is no heat. After expressing sympathy and assuring the customer that he will make every effort to find out what the problem is and fix it, the technician goes to the room thermostat. It is set at 10°F above the room temperature. Then he goes to the furnace, which is in the garage at the end of the apartment. The furnace is off because the primary control has tripped. The technician examines the combustion chamber with a flashlight for any oil buildup that may have accumulated if the customer has been resetting the primary. **SAFETY PRECAUTION:** *If a customer has repeatedly reset the primary to get the furnace to fire and the technician then starts the furnace, the excess oil would be dangerous.*• There is no excess oil in

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

the combustion chamber, so the reset button is pushed. The burner does not fire.

The technician suspects that the electrodes are not sparking or that the pump is not pumping. The first thing to do is to fasten a piece of flexible tubing to the bleed port side of the oil pump. The end of the hose is placed in a bottle to catch any fuel that may escape, then the bleed port is opened and the primary control is reset. The burner and pump motor start. No oil is coming out of the tubing, so the pump must be defective. Before changing the pump, the technician decides to make sure there is oil in the line and removes the line entering the pump. There is no oil in the line. The technician opens the filter housing and finds very little oil in the filter. The technician now decides to check the tank, and he determines that there is no oil in the tank.

When the technician tells the customer that the oil tank is empty, the customer shows the receipt for the delivery. The technician calls his supervisor and, after some investigation, finds out that the oil truck driver delivered oil to the wrong tank, even though the truck had been sent out to fill the correct tank. While waiting for the oil truck, the technician apologizes for the confusion.

After the oil is delivered, technician starts the furnace, bleeds the pump until a full line of liquid oil flows, and then closes the bleed port. The burner ignites and goes through a normal cycle. The furnace is not under contract for maintenance, so the technician suggests to the occupant that a complete service call including a nozzle change, electrode adjustment, and filter change be arranged. The customer agrees. The technician completes the service and turns the thermostat to the normal setting before leaving. Upon returning to the office, the technician suggests to his service manager that the oil tanks be labeled with the apartment number to avoid this confusion in the future.

Solutions for the following service calls are not provided here. Please discuss the solutions with your instructor.

SERVICE CALL 4

A customer calls reporting a smell of smoke when the furnace starts up. This customer does not have the furnace serviced each year.

The technician goes to the furnace in the basement, followed by the customer. The technician turns the system switch off and goes back upstairs and sets the thermostat 5°F above the room temperature so the furnace can be started from the basement. When the technician gets back to the basement, he starts the furnace and observes a puff of smoke. The technician inserts a draft gauge in the burner door port; the draft is +0.01 in. WC positive pressure.

What is the likely problem and the recommended solution?

SERVICE CALL 5

A retail store manager calls stating that there is no heat in the small store.

When the technician arrives, he discovers the room thermostat is set at 10°F higher than the room temperature. The thermostat is calling for heat. The technician goes to the furnace in the basement and discovers it needs resetting in order to run. The technician examines the combustion chamber with a flashlight and finds no oil accumulation. He then resets the primary control. The burner motor starts, and the fuel ignites. The burner runs for 90 sec and then shuts down.

What is the likely problem and the recommended solution?

SERVICE CALL 6

A customer reports that there is no heat and the furnace will not start when the reset button is pushed.

The technician arrives and checks to see that the thermostat is calling for heat. The set point is much higher than the room temperature. The technician goes to the garage where the furnace is located and presses the reset; nothing happens. The primary is carefully checked to see whether there is power to the primary control. It shows 120 V. Next, the circuit leaving the primary, the orange wire, is checked. (The technician realizes that power comes into the primary on the white and black wires, the white being neutral, and leaves the orange wire on.) There is power on the white to black but none on white to orange, **Figure 32.80**.

What is the likely problem and the recommended solution?

SUMMARY

- Number 2 fuel oil is most commonly used in heating residences and light commercial buildings.
- Fuel oil is composed primarily of hydrogen and carbon in chemical combination.
- Important fuel oil characteristics include flash point, ignition point, viscosity, water content, and pour point.
- Oil can be stored in aboveground or underground tanks.
- Oil tanks should be periodically inspected for damage.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

- Oil tank installations should meet or exceed code guidelines.
- Gun-type oil burner parts are the burner motor, blower or fan wheel, pump, nozzle, air tube, electrodes, ignition system, and primary controls.
- The pump can be single- or dual-stage.
- Air is blown through the air tube into the combustion chamber and mixed with the atomized fuel oil.
- The ignition system provides the high voltage that produces the spark across the electrodes.
- Ignition can be interrupted or intermittent.
- Interrupted ignition systems provide a spark only at the beginning of the cycle.
- Intermittent ignition provides a continuous spark.
- Fuel storage and supply systems can be of a one-pipe or two-pipe design.
- An auxiliary or booster supply system must be used when the burner is more than 15 ft above the storage tank.
- The atomized oil and air mixture is ignited in the combustion chamber.
- The heat exchanger takes heat caused by the combustion and transfers it to the air that is circulated to heat the building.
- The performance of the pump can be checked with a vacuum gauge and a pressure gauge.
- One-pipe systems must be bled before the burner is started for the first time or whenever the fuel supply lines have been opened.
- To convert a pump from a one-pipe to a two-pipe system, insert a bypass plug in the return or inlet port.
- Nozzles should not be cleaned or unplugged; they should be replaced.
- Electrodes should be clean, all connections should be secure, and the spark gap should be adjusted accurately.
- Combustion efficiency tests should be performed when servicing oil burners and corrective action taken to obtain maximum efficiency.
- Preventive maintenance procedures should be performed annually.

REVIEW QUESTIONS

1. How many grades of fuel oil are normally considered as heating oils?
2. What two elements make up fuel oil?
3. The most common fuel oil used for residential and light commercial is
   A. Number 1.
   B. Number 2.
   C. Number 3.
   D. Number 4.
4. As the temperature of an oil sample decreases,
   A. the viscosity of the oil increases.
   B. the oil will flow better through oil lines and nozzles.
   C. the viscosity of the oil decreases.
   D. Both B and C are correct.
5. If oil is to be stored at temperatures lower than 20°F,
   A. waxes in the oil can reduce the oil's ability to flow properly.
   B. kerosene can be added to lower the oil's pour point.
   C. Both A and B are correct.
   D. Neither A nor B is correct.
6. Explain why periodic oil tank inspection is desired.
7. If it is expected that an oil-fired appliance will burn 850 gallons of oil per year, how big should the oil storage tank be?
   A. 1500 gallons
   B. 1000 gallons
   C. 550 gallons
   D. 275 gallons
8. How many pounds of oxygen are required to burn 1 pound of Number 2 fuel oil?
9. Explain the concept of excess air when it is used to describe the combustion process.
10. Before fuel oil can be burned, it must be
    A. dripped.
    B. decompressed.
    C. vitalized.
    D. atomized.
11. What products of combustion are produced with ideal combustion when fuel oil is burned?
12. When incomplete combustion occurs, what additional by-products of combustion are created?
13. The minimum nozzle pressure for residential and light commercial gun-type oil burners is
    A. 100 psig.
    B. 175 psia.
    C. 200 psig.
    D. 250 psia.
14. Two types of oil burner pumps are _____ stage and _____ stage.
15. Describe the three functions of the oil burner nozzle.
16. Describe three common spray patterns for an oil burner nozzle.
17. The purpose of the electrodes of an oil burner is to
    A. create a blue flame.
    B. establish best efficiency.
    C. put out the flame electronically.
    D. ignite the fuel oil at start-up.
18. What is the purpose of the ignition transformer?
19. Explain the differences between an ignition transformer and a solid-state igniter.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

20. List the advantages a solid-state igniter has over an ignition transformer.
21. Which of the following is the typical output voltage of the ignition transformer?
    A. 24 V
    B. 200,000 V
    C. 115 V
    D. 10,000 V
22. What are the two functions of the primary control on an oil burner?
23. List the two types of primary controls that are commonly found on oil-fired heating equipment.
24. Describe the operation of a stack relay.
25. Explain the difference between the hot contacts and the cold contacts on a stack relay.
26. The purpose of the cad cell in an oil burner control circuit is to
    A. make sure that the burner ignites by sensing the flame.
    B. turn the burner off when the room temperature is satisfied.
    C. start the burner when the thermostat calls for heat.
    D. prevent the furnace from overheating.
27. Explain why it is important to keep the cad cell clean at all times.
28. A one-pipe system may be used when the oil tank is higher or lower than the oil pump. True or false.
29. Describe where a two-pipe system is used.
30. When is an auxiliary oil pump used?
31. The oil flame must not hit the combustion chamber because it will
    A. overheat.
    B. cool off and create soot and smoke.
    C. use too much fuel oil.
    D. prevent the furnace from starting up.
32. Describe the purpose of the heat exchanger.
33. When servicing an oil burner, a service technician must have a _____ gauge and a _____ gauge.
34. Describe the function of the flame-retention ring on a modern oil burner.

UNIT 33

HYDRONIC HEAT

OBJECTIVES

After studying this unit, you should be able to

- describe a basic hydronic heating system.
- describe reasons why it is desirable for a hydronic system to have more than one zone.
- list four heat sources commonly used in hydronic heating systems.
- explain the difference between a wet-base and a dry-base boiler.
- state the reason a boiler is constructed in sections or tubes.
- discuss the reasons why air should be eliminated from hydronic heating systems.
- explain the effects air has on a cast-iron or steel boiler.
- describe the function of the air cushion or expansion tank.
- explain the operation of circulator pumps as they apply to hydronic heating systems.
- describe the importance of the "point of no pressure change."
- describe the purpose of limit controls and low-water cutoff devices.
- state the purpose of a pressure relief valve.
- state the purpose of a zone valve.
- list the various types of zone valves that are available.
- explain how "outdoor reset" can be used to increase system efficiency.
- sketch a series-loop hydronic heating system.
- sketch a one-pipe hydronic heating system.
- explain the function of the diverter tee.
- explain the differences between a two-pipe, direct-return hydronic heating system and a two-pipe, reverse-return hydronic heating system.
- explain the application that requires the use of a balancing valve.
- list the benefits of primary–secondary pumping.
- describe the operation and function of mixing valves.
- describe the differences between radiant and conventional hydronic heating systems.
- list three common types of radiant heating system installations.
- describe a tankless domestic hot water heater used with a hydronic space-heating system.
- list preventive maintenance procedures for hydronic heating systems.
- describe the differences between passive and active solar systems.
- describe the declination angle and the effect it has on the sun's radiation during winter and summer.
- list the typical components in a liquid-based solar system and describe the function of each.
- describe the operation of a solar domestic hot water system.
- describe a swimming pool solar-heating system.

SAFETYCHECKLIST

- ☑ When checking a motor pump coupling, turn off the power and lock and tag the disconnect before removing the cover to the coupling.
- ☑ If you are checking the electrical service to a pump that has a contactor, shut off the power and remove the cover to the contactor. Do not touch any electrical connections with meter leads until you have placed one voltmeter lead on a ground source such as a conduit. Then touch the other meter lead to every electrical connection in the contactor box. The reason for this is that some pumps are interlocked electrically with other disconnects and a circuit from another source may be in the box.
- ☑ Ensure that all controls are working properly in a hot water system, because an overheated boiler has great potential for explosion.
- ☑ If an antifreeze solution is used in a solar domestic hot water system, a double-walled heat exchanger must be used.

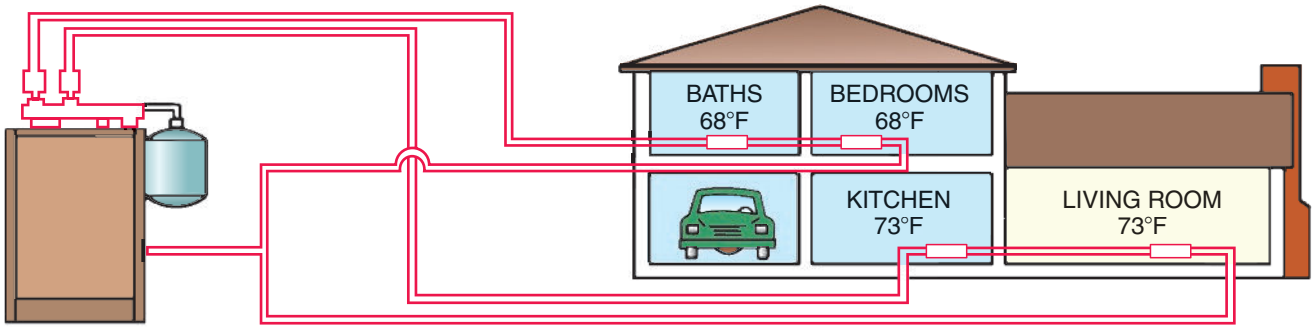
33.1 INTRODUCTION TO HYDRONIC HEATING

Hydronic heating systems are systems in which water or steam carries the heat through pipes to the areas to be heated. This text covers only hot water systems. In hot water hydronic systems, water is heated and circulated through pipes to a heat transfer component called a **terminal unit**, such as a radiator or finned-tube baseboard unit. It is from the terminal units that heat is given off to the air in the room. The cooler water is then returned to the heat source to be reheated. In most residential installations, the airflow across the radiators or terminal units is due to natural convection currents. Hot water stays in the tubing and heating units even when the boiler is not running, so there are no sensations of rapid cooling or heating, which might occur with forced-warm-air systems. Air-conditioning cannot readily be added to a structure that has hydronic heat, so a separate ducted air-conditioning system must be added.

Hydronic systems are designed with one or more zones. If the system is heating a small home or area, it may have one zone. If the house is a long ranch-type or multilevel home, there may be several zones. The rooms or areas in each zone should have similar heating requirements as well as similar occupancy patterns. For example, a two-story home with the bedrooms on the second floor and the living area on the first

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 33.1 A two-zone hydronic heating system.



floor can be easily divided into a first floor zone and a second floor zone, **Figure 33.1**.

The water can be heated using a number of heat sources such as oil, gas, and electric. Sensing elements start and stop the heat source according to the water temperature. The water is circulated through the system with one or more centrifugal pumps. Thermostatically controlled zone valves can be used to control the flow of heated water to the zone needing the heat. Flow can also be controlled by separate, thermostatically controlled circulator pumps located in each zone's piping circuit. Most residential installations use finned-tube baseboard units to transfer heat from the water to the air.

33.2 THE HEAT SOURCE

A major part of the hydronic heating system is the component that heats the water. The piping circuits and strategies that follow later on in this unit are for the most part independent of the heat source—because the strategies involve what is done with the water once it is heated. The heat used in hydronic systems can be generated by a number of different methods, including the burning of fossil fuels, the collection of solar energy, the use of electric heaters, and the use of heat pump technology.

For the most part, the heated water used in hydronic systems comes from a boiler, but geothermal heat pump systems are becoming more and more popular for low-temperature (radiant) applications. Boilers can be used for both high- and low-temperature applications, but accommodations must be made to keep the temperature of the water that returns to the boiler hot enough to prevent the flue gases from condensing—unless the boiler is of the condensing variety.

THE BOILER

A **boiler** is, in its simplest form, an appliance that heats water, using oil, gas, or electricity as the heat source. Some larger commercial boilers use a combination of two fuels. When one fuel is more readily available than another, the boiler can easily be changed over. **Figure 33.2** shows a gas-fired boiler,

Figure 33.2 A gas-fired boiler.

Source: Weil-McLain Corporation

Figure 33.3 shows an oil-fired boiler, and **Figure 33.4** shows an electric boiler.

Boilers can be used to supply water at various temperatures to the areas being heated, but the most common temperature to which water is heated in older, conventional boilers, is about 180°F. Newer technology, however, provides for a wide range of attainable boiler water temperatures that are based on the heating requirements of the space and the outside ambient temperature. Refer to the "Outdoor Reset Control" section in this unit for more on this very important topic. Hydronic systems can be designed to operate with water temperatures ranging from 90°F to over 200°F.

The temperature of the water returning to the boiler affects the operation of the boiler as well as the process of removing flue gases from the structure. As the temperature of the return water to the boiler decreases, the temperature of the flue gases

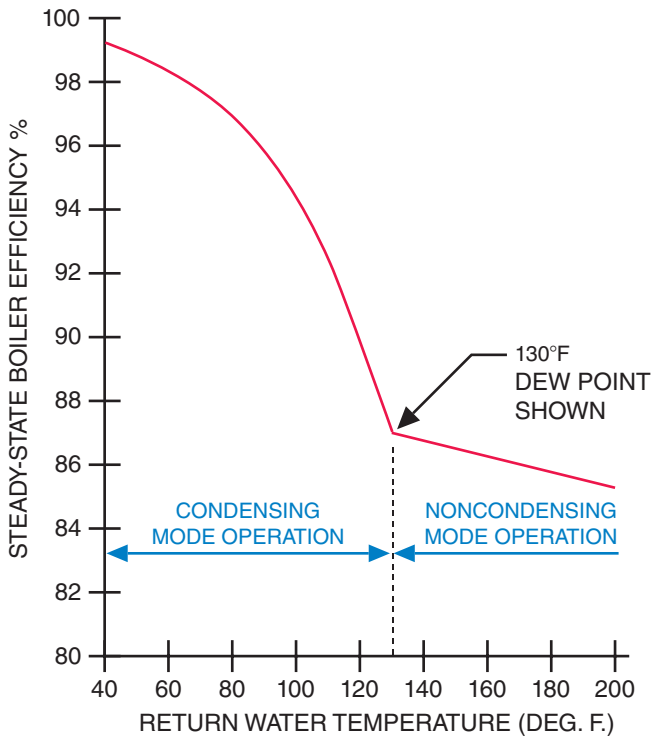
Figure 33.5 Efficiency of a boiler in both condensing and non-condensing modes.



leaving the combustion chamber will also decrease. This is because the temperature of the heat exchanger will be lower and more heat will be transferred from the hot flue gases to the cooler heat exchanger. If the temperature of the flue gases is permitted to drop below about 130°F, the flue gases may begin to condense into a liquid. Most boilers, classified as **conventional boilers**, are designed to operate with the flue-gas temperature above the 130°F dew point temperature to prevent condensation. Condensing flue gases are highly corrosive and can damage the chimney and the heating equipment. Noncondensing boilers are designed with efficiencies up to about 86%. **Figure 33.5** shows the relationship among boiler return-water temperature, system efficiency, and dew point temperature for the flue gases.

In order to increase the efficiency of boilers, additional and/or more efficient heat exchangers have been incorporated. These improved heat transfer surfaces remove more heat from the flue gases, thereby lowering the temperature of the gases. Condensing flue gases result if the flue gases cool to a temperature below their dew point temperature. But, since some systems are designed to condense the flue gases, equipment design engineers are able to plan for and design around the issue. These systems are referred to as **condensing boilers**, **Figure 33.6**. Condensing boilers are classified as 90+ because their efficiencies are over 90%. Condensing boilers are available in both gas- and oil-fired models.

CAST-IRON BOILERS. One type of boiler commonly encountered in residential and light commercial applications is the cast-iron boiler. It is often made up of individual sections. Two classifications of boiler section assemblies are the

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 33.6 Example of a wall-hung condensing boiler.

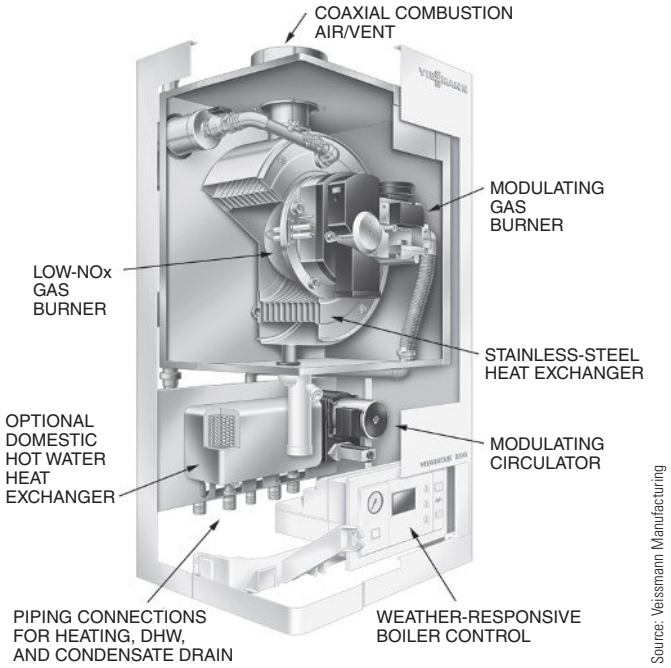


Figure 33.7 (A) Cast-iron dry-base boiler section. (B) Wet-base boiler section.

(A)

(B)

dry-base type and the wet-base type. **Figure 33.7(A)** shows a section of a dry-base boiler. The term **dry-base** means that the area under the combustion chamber is dry—there is no water there. **Figure 33.7(B)** shows a section of a wet-base boiler. In a **wet-base boiler** setup, the water being heated is located both above and below the combustion area. Multiple sections are bolted together to form the complete heat exchange surface between the burning fuel and the water being heated, **Figure 33.8**. The more sections a boiler has, the higher its capacity will be. The following are some key characteristics associated with the cast-iron boiler:

- They are very heavy appliances.
- They hold between 15 and 30 gallons of water.
- They are classified as high-mass boilers.
- They take a long time to heat up.
- They retain their heat for a long period of time.
- They have longer run times and longer off cycles.
- They are used on closed-loop systems.
- Air in the system can result in boiler corrosion.

STEEL BOILERS. The water being heated within steel boilers, **Figure 33.9**, surrounds a bundle of steel tubes through which the combustion gases pass on their way to the chimney. These tubes have a series of baffles located inside to increase the heat transfer surface area and to slow the speed of the flue gases as they pass through the tubes. Without the baffles, the hot flue gases would flow out of the appliance very quickly at a hotter temperature. By slowing the rate of flue-gas flow, more heat can be extracted from the gases, increasing the efficiency of the boiler.

COPPER WATER-TUBE BOILERS. The heat exchanger in a copper-tube boiler is constructed as a series of finned copper tubes, **Figure 33.10**, that are heated by the flue gases in the combustion chamber of the boiler, **Figure 33.11**. The heat

Source: Columbia Boiler Company

exchangers on copper-tube boilers have much less surface area than cast-iron or steel boilers do but since copper is such a good conductor of heat, they are still able to heat water quickly and efficiently.

Some key characteristics of copper-tube boilers are:

- They are much lighter than similarly sized cast-iron boilers.
- They hold only a few gallons of water.

Figure 33.10 Finned copper-tube heat exchanger assembly.

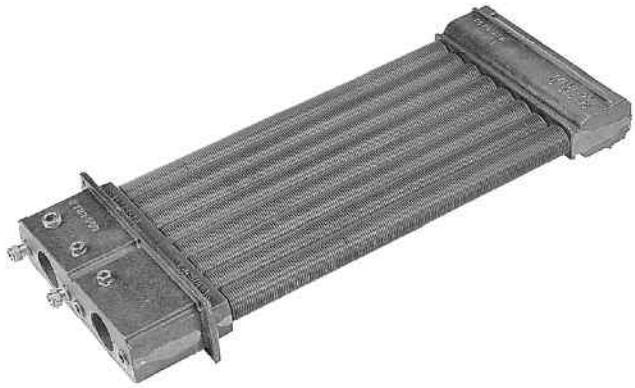

Figure 33.11 Cutaway view of a copper water-tube boiler.

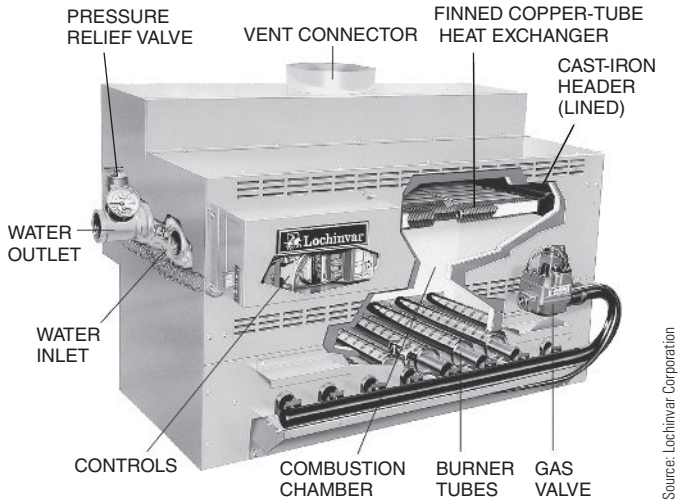

Source: Lochinvar Corporation

- They are classified as low-mass boilers.
- They heat up quickly.
- They cool down quickly.
- They have shorter run times and shorter off times.
- They are used on closed-loop systems.
- They are less susceptible to corrosion when compared to cast-iron boilers.

THE GEOTHERMAL HEAT PUMP

One heat source that is becoming popular for use in conjunction with hydronic heating systems is the geothermal heat pump. To provide heat to the occupied space, the geothermal heat pump transfers heat from the earth to a water/water-antifreeze mixture. This heat-laden water mixture then transfers its heat to the space to be heated. Geothermal heat pump systems can heat system water to a temperature as high as 130°F, so it is a good option for low-temperature, radiant,

hydronic heating systems. Refer to Unit 44, "Geothermal Heat Pumps," for more information on this topic. Radiant heating systems will be discussed later on in this unit.

33.3 THE BASIC HYDRONIC SYSTEM

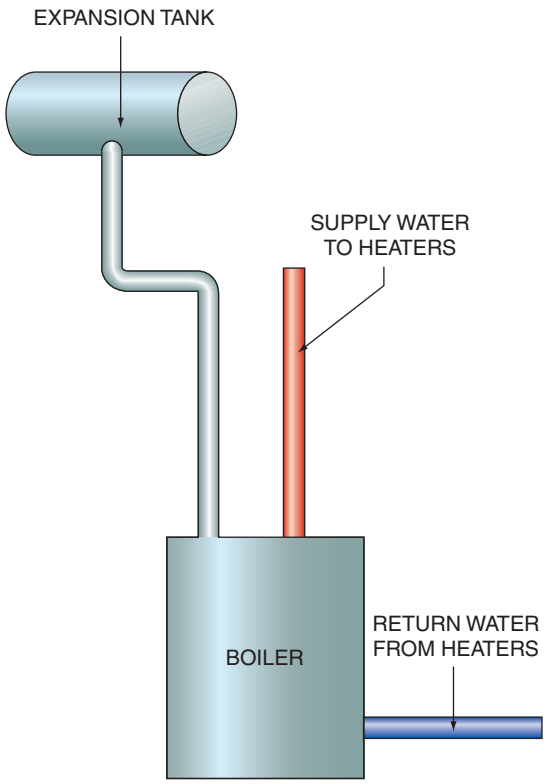
Although there are many individual parts that make up a hydronic heating system, we will begin our discussion by examining two system components to see how they function in a completely sealed water loop. This will give us a basic understanding of some of the properties of water and of the function of the circulator pump in the hydronic system. As the unit progresses, more components will be discussed to help broaden your understanding of these popular systems.

EXPANSION TANK

Hot water hydronic systems are closed-loop systems and are, ideally, air-free. As water is heated, it expands, and if the system is totally air-free, the pressure in the piping circuit will increase as the water is heated and expands. This excess pressure in the system will cause the pressure relief valve to open every time the water is heated. To prevent this from happening, an extra volume or space is provided to accommodate the additional volume of the heated water. The expansion tank, **Figure 33.12**, provides this extra volume.

Figure 33.12 An expansion tank.

Figure 33.13 A steel expansion tank.



There are two types of expansion tanks. One type is called the compression tank, or standard expansion tank, **Figure 33.13**. This tank is nothing more than a steel tank located above the boiler. Upon installation, the tank is filled with air at atmospheric pressure. As water is added to the boiler, the air that is being displaced is pushed up into the expansion tank, causing the pressure in the tank to increase, **Figure 33.14**. This creates a pressurized air cushion within the shell of the tank. As the water in the system is heated, the volume of water in the system increases and further compresses the air in the tank. Over time, however, the tank can become completely filled with water, thereby removing the air cushion. This situation can be easily identified because the pressure relief valve will open each time the water in the system is heated.

A more common type of expansion tank is the diaphragm-type expansion tank. This tank has a rubber, semipermeable membrane within its shell, **Figure 33.15**. One side of the tank contains pressurized air, whereas the other side of the tank is open to the system water. The air portion of the tank is pressurized at the factory, but it is a good idea to check the pressure with a tire gauge prior to installing the tank in a system. For residential applications, these tanks often come precharged with 12 psi of air. The tank pressure is noted on the nameplate of the tank itself, **Figure 33.16**.

To determine the actual pressure required for the expansion tank, it is necessary to measure the vertical distance

Figure 33.14 Pressure in the tank increases as water is added to the system.

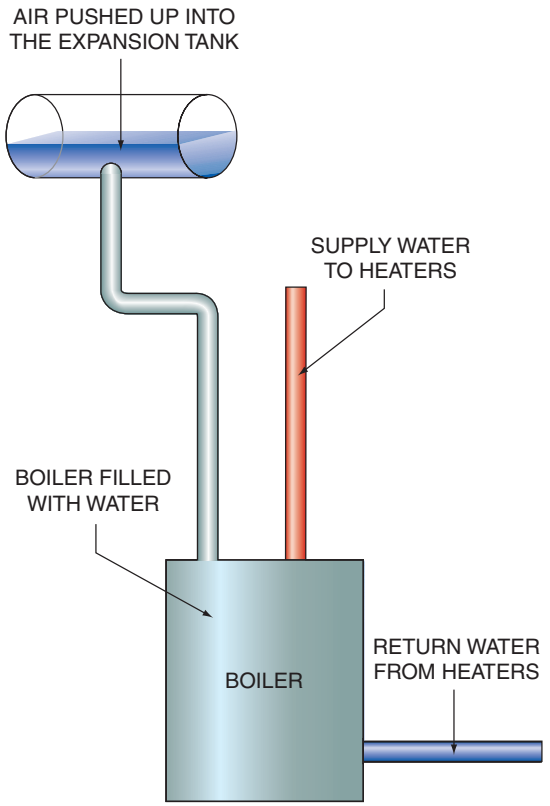

Figure 33.15 Cutaway view of a diaphragm-type expansion tank.

Photo by Eugene Silberstein

(in feet) between the highest pipe in the system and the inlet of the expansion tank and then use the following formula:

$$P_{tank} = (H \div 2.31) + 5$$

where P_{tank} = The pressure in the expansion tank in psi
H = The vertical distance between the highest pipe in the system and the inlet of the expansion tank
2.31 = The amount of vertical lift (head) for each pound of pressure

Figure 33.16 Expansion tank data tag.

Photo by Eugene Silberstein

5 = The additional pressure added to the system to ensure that there is a positive pressure at the highest pipe in the system

Consider the following residential application:

- The boiler is located in the basement.
- The opening of the expansion tank is 4 ft from the basement ceiling.
- The home has two floors, each with 9-ft ceilings.
- The second floor has baseboard heating and the highest pipe is 2 ft from the floor.

From this we can conclude that the "H" measurement is 15 ft (9 ft + 2 ft + 4 ft) and that therefore the required tank pressure is

$$P_{tank} = (H \div 2.31) + 5$$
$$P_{tank} = (15 \div 2.31) + 5$$
$$P_{tank} = 6.49 + 5$$
$$P_{tank} = 11.49 \text{ psi}$$

Since most residential applications will provide similar results, it is easy to see why the tanks are supplied by the manufacturer with a pressure of 12 psi.

CIRCULATOR/CENTRIFUGAL PUMPS

Centrifugal pumps, also called *circulators,* **Figure 33.17,** force the hot water from the heat source through the piping to the heat transfer units and back to the boiler. These pumps rely on centrifugal force to circulate the water through the system. Centrifugal force is generated whenever an object is rotated around a central axis. The object or matter being rotated tends to fly away from the center due to its velocity. This force increases proportionately with the speed of the rotation, **Figure 33.18.**

The **impeller,** **Figure 33.19,** is the part of the pump that spins and forces water through the system. It is essential

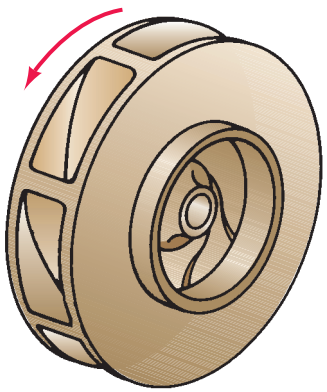

Figure 33.20 Cutaway view of a centrifugal pump.

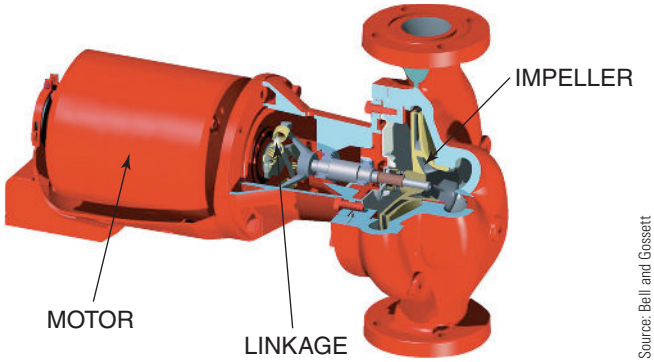

Source: Bell and Gossett

that the impeller rotate in the proper direction. The vanes or blades in the impeller must "slap" and then throw the water. The vanes of the impellers used in circulating pumps in hot water heating systems are usually enclosed, and are referred to as *closed* impellers. A cutaway of a centrifugal pump is shown in **Figure 33.20**. Pumps generally have a cast-iron body with the impeller and other moving parts made of bronze or nonferrous metals. Other pumps have stainless-steel or all bronze parts.

Centrifugal water pumps are not positive displacement pumps, as are most compressors. The term *circulating pump* is used for them because these pumps do not add much pressure to the water from the inlet to the outlet in small systems. It is important to understand how a centrifugal pump responds to pressure and load changes. The centrifugal pump is responsible for creating a pressure difference between the water at its inlet and the water at the outlet of the pump. It is this pressure differential that makes the water flow through the piping circuit. However, before water can flow through the circuit, the pressure difference generated by the pump must overcome the resistance of the piping circuit itself. Consider a pump that is operating in a system that offers no resistance to flow. If this pump were supplied with an unlimited amount of water to pump—and this water were immediately pumped to atmospheric pressure once it left the pump—it is safe to say that the amount of water moved by the pump would be the pump's maximum capacity. As resistance to flow is added, the volume of water moved by the pump will decrease, reducing the pump's capacity. A point will eventually be reached where the amount of water pumped will reach zero because the resistance of the piping arrangement is too much for the pump to overcome.

The following progressive example will demonstrate how a performance curve for a centrifugal pump is developed. See **Figure 33.21(A)–(J)**.

A. A pump is connected to a reservoir that maintains the water level just above the pump inlet. The pump meets no resistance to the flow, and maximum flow exists. The water flow is 80 gpm.

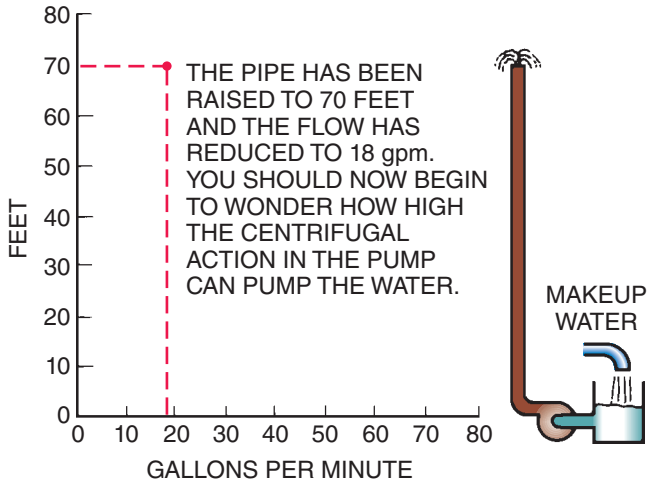
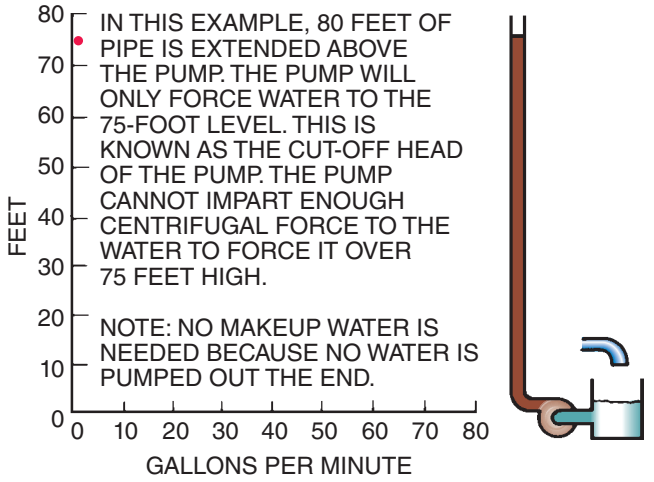
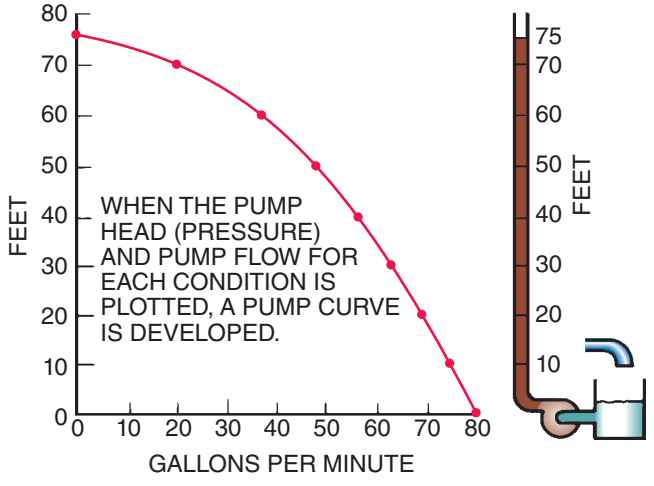
(G)



(H)



(I)



(J)

B. A pipe is extended 10 ft high (known as feet of head, or pressure), and the pump begins to meet some pumping resistance. The water flow reduces to 75 gpm.

C. The pipe is extended to 20 ft, and the flow reduces to 69 gpm.

D. When 30 ft of pipe is added, the water flow reduces to 63 gpm.

E. The pipe is extended to 40 ft. The pump is meeting more and more resistance to flow. The water flow is now 58 gpm.

F. At 50 ft, the flow slows to 48 gpm.

G. At 60 ft, the flow slows to 38 gpm.

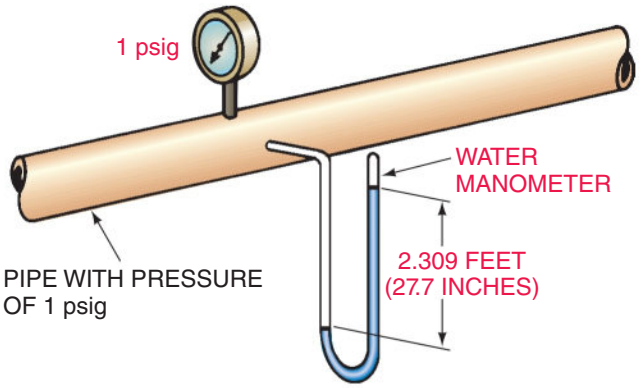
H. At 70 ft, the water flow has been reduced to 18 gpm. The pump has almost reached its pumping limit. The pump can impart only a fixed amount of centrifugal force.

I. When 80 ft of pipe is added to the pump outlet, the water will rise to the 75-ft level. If you could look down into the pipe, you would be able to see the water gently moving up and down. The pump has reached its pumping pressure head capacity. This is known as the shutoff point of the pump.

J. This is a manufacturer's pump curve; the preceding examples show how the manufacturer arrives at the pump curve. It is important to note that each pump has its own unique pump curve.

It would be awkward for manufacturers to add vertical pipe to all pump sizes for testing purposes, so they use valves to simulate vertical head. To use the valve system of measurement, liquid water vertical head must be converted to gauge readings. Gauges read in psig. When a gauge reads 1 psig, it is the same pressure that a column of water 2.309 ft (27.7 in.) high exerts at the bottom, **Figure 33.22**. This would be the same as saying that a column of water 1 ft high (feet

Figure 33.22 A gauge pressure reading of 1 psi is equal to 2.309 ft of water.



of head) is equal to 0.433 psig, because 1 psig divided by 2.3093 ft = 0.433. Some examples of water columns and pressure are shown in **Figure 33.23**. A pump manufacturer may use gauges to establish pump head (pressure) by placing a gauge at the inlet and a gauge at the outlet and reading the difference. This is known as psi difference. Psi difference is then converted to feet of head, **Figure 33.24**.

The power consumed by the motor driving a centrifugal pump is proportional to the quantity of water the pump circulates. For example, the pump operating under the conditions shown in **Figure 33.21(A)** requires more horsepower than when operating under the conditions shown in **Figure 33.21** (I). This might sound counter-intuitive. When a valve is installed in a piping circuit and closed, it would seem that the power consumption should rise due to an increase in pump head, but it does not. As the discharge valve is closed, the water begins to recirculate in the pump and the power consumption reduces. This can be demonstrated by shutting the valve at the outlet of a centrifugal pump and monitoring the amperage, **Figure 33.25**.

Figure 33.23 This figure shows that different heights of water columns exert different pressures. Each time you increase the water column 1 ft, the pressure rises 0.433 psi.

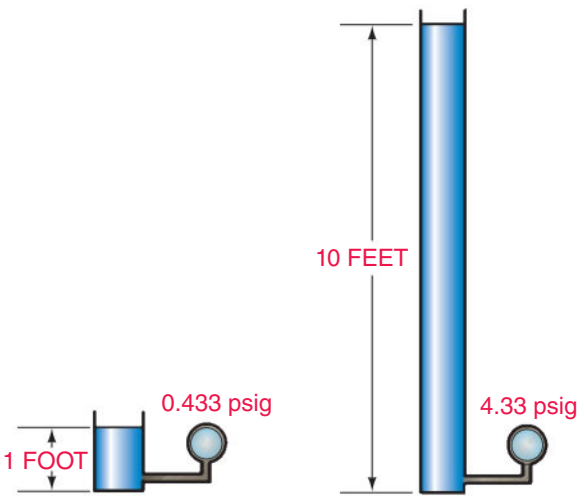


Figure 33.24 This figure illustrates how a pump manufacturer may test a pump for pumping head. More elaborate systems that measure gallons per minute at the same time are used to establish a pump curve.

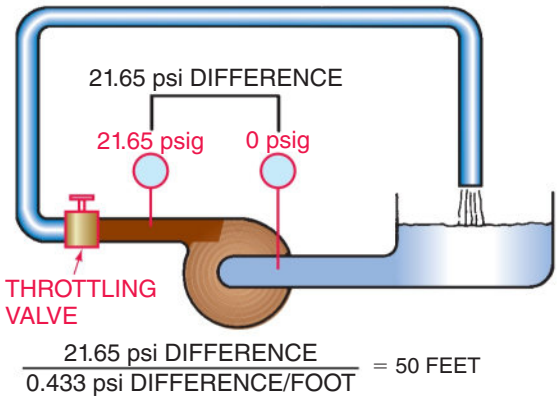

Figure 33.25 (A) Maximum flow. (B) As the flow is reduced by throttling the outlet valve, the power to drive the motor reduces the current required to turn the pump impeller in the water. (C) Throttled to 0 gpm.

33.4 THE POINT OF NO PRESSURE CHANGE

Probably one of the most important and busy locations in the hydronic hot water system is the "point of no pressure change." As its name implies, this is the point in the system where the pressure, no matter what the system is doing, will remain the same. This is a great reference point for evaluating a system and also provides a location for multiple system-component connections.

Consider a piping arrangement that contains only the two components discussed so far in this unit: the expansion tank and the circulator pump, **Figure 33.26**. Notice that, in the figure, the pump is discharging in a direction pointing toward the expansion tank. Assume that the pressure in the expansion tank prior to installation was 10 psi and that the pump generates a pressure difference of 15 psig between its inlet and outlet. When the piping loop is filled, the pressure will be 10 psi, as determined by the pressure in the expansion tank. Since the loop is completely filled and the expansion tank has a 10-psi cushion of air inside it, what will happen when the pump is turned on? Will the pump push water into the expansion tank? Will the pump pull water out of the expansion tank?

The answer is that water will neither be pushed into nor pulled out of the expansion tank and the pressure in the circuit at the inlet of the expansion tank will remain unchanged at 10 psi. Water cannot be transferred from the loop to the expansion tank because there would be nothing to replace the water that leaves the loop. Also, water cannot be relocated from the expansion tank to the loop because there is no room in the loop to accept any additional water. So, if water cannot enter or leave the expansion tank, the pressure in the loop at the inlet of the expansion tank will remain constant. This will change slightly once the water is actually heated, as the water will expand and some will be pushed into the expansion tank when heating occurs.

Figure 33.26 Simple loop with only an expansion tank and a circulator.

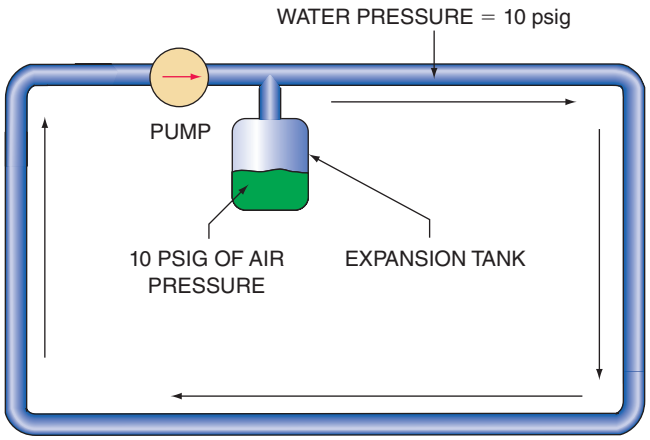

Figure 33.27 Pumping toward the expansion tank can result in a vacuum in the piping circuit.

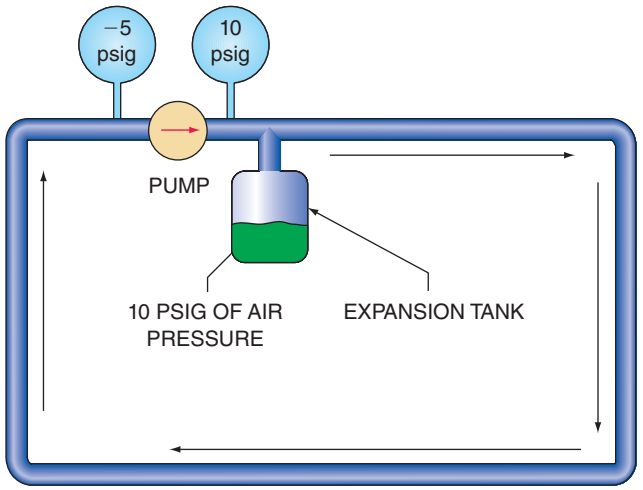

So, if the pump creates a pressure difference of 15 psi and the pressure at the outlet of the pump cannot change, the pressure at the inlet of the pump will have to drop to account for the 15-psi drop across the pump, **Figure 33.27**. This will create a vacuum in the piping circuit. If a leak should develop (at the pump's mounting flange, for example), air will be pulled into the system, creating problems. Therefore, the operating pressure range for this system will be between −5 psi and +10 psi.

By moving the pump to the other side of the expansion tank, the vacuum situation is eliminated. The pressure at the inlet of the circulator will be 10 psi and the pressure at the outlet of the pump will be 25 psig (10 psi + 15 psi), **Figure 33.28**. Relocating the pump in this manner minimizes the possibility of the system pulling into a vacuum and also reduces the effects of air in the system. We will be addressing

Figure 33.28 Point of no pressure change.

air in the next few sections, as it is an important aspect of hot water systems, but one issue needs to be mentioned here. At higher system pressures, air bubbles are smaller and are more likely to remain in solution. Air bubbles that remain in solution with the water are far less likely to have a large negative effect on system operation and performance.

As we move through this unit, the importance of the "point of no pressure change" will become more and more evident. This point in the system is the desired connection point for the following system components:

- Inlet of the circulator pump
- Inlet of the expansion tank
- Air separator
- Air vent
- Outlet of the pressure-reducing (water-regulating) valve

33.5 OTHER HYDRONIC SYSTEM COMPONENTS

The expansion tank and the circulator are the two components needed to make up even the most basic of hydronic systems. A system such as this would not, however, function effectively because a number of important operational and safety issues would not be accounted for. In addition to simply moving the water and allowing for expansion, it must also do the following:

- Separate air from the water
- Remove the air from the system
- Provide for makeup water to the system
- Provide safety controls in the event of system overpressurization
- Provide for the desired flow control
- Provide for the desired temperature control
- Allow for heat transfer from the system to the occupied space

The system components discussed in the next sections allow the system to operate as needed and desired while simultaneously ensuring that it operates in a safe and efficient manner.

AIR SEPARATOR AND AIR SCOOP

When working with hot water systems, it is important to remove any air that may be trapped in the piping circuit, the boiler, or any other system component. Air, as mentioned earlier in the unit, can lead to excessive corrosion in cast-iron and steel boilers. As the temperature of the water in the system increases, the rate of corrosion increases. Corrosion takes time to occur, so the effects of air on the structural integrity of the boiler may not be readily seen. However, there are more significant and immediate problems associated with air in a hydronic hot water system. Since air is lighter than water, air pockets will form at the highest points in the system. These trapped air pockets prevent water flow and can result in insufficient heating. In addition, trapped air can lead to noisy pipes and noisy system operation.

Figure 33.29 An air separator.

Source: Bell and Gossett

The air separator, **Figure 33.29**, is the hydronic system component that separates air from the water as it flows through the system. It is important to note that the air separator does not remove air from the system—it simply separates the air from the water. Another system component, the air vent, is responsible for venting, or removing, the air from the system. Air separators are capable of removing small "microbubbles" from the system. The new generation of air separators operates on the concept of "collision and adhesion." As water passes through the separator, it comes into contact with a mesh screen or similar material, **Figure 33.30**. The air bubbles collide with the screen and adhere to it. As more and more air bubbles adhere to the mesh, the bubbles get larger, break loose, and travel up into the air vent, where they are vented from the system.

Other air separation devices, known as air scoops, **Figure 33.31**, are installed on horizontal runs of straight pipe, which cause the air in the pipe to separate from the water and rise to the top of the pipe. Using a baffle, the air scoops then scoop the air out of the pipe, **Figure 33.32**. In order to work properly, the velocity or speed of the water must be lower than 4 ft per sec, **Figure 33.32(A)**, or the smaller bubbles will not be able to rise to the top of the device, **Figure 33.32(B)**. At the top, the trapped air is directed to the air vent for removal from the system. Air scoops are directional, so be sure to install them in the system with the arrow pointing in the direction of water flow.

AIR VENT

Once the air has been separated from the circulating water, the air vent is responsible for removing it from the system.

(A)

(B)

Air vents can be manually operated or automatic devices. They are typically located at high points in the hydronic system as well as directly above air separators and air scoops, as these are the devices that accumulate air that is separated from the water in the system. Manual air vents are the simplest of the vents, **Figure 33.33**. They are often referred to as "coin-operated" air vents or "bleeders." As the name implies, these vents are opened and closed manually as the need arises. Automatic air vents, **Figure 33.34**, rely on an internal disc that swells when water is sensed. In operation, if there is no air at the vent location, the disc will be wet and swollen, which will seal off the air vent port. As air accumulates, the disc will dry out and shrink, allowing the air to pass through to the vent port. As the air is removed and replaced with water, the disc will swell, closing off the port. Since it takes time to fully close, there is often a small amount of water loss when the device vents.

Another type of automatic air vent utilizes a float mechanism, **Figure 33.35**. The position of the float is determined by

the amount of air in the device. When there is no air in the air vent, the float is at the top of the vent and the vent port is closed, **Figure 33.36(A)**. As air accumulates in the vent, the float drops, opening the vent port and removing the air from the system, **Figure 33.36(B)**.

TEMPERATURE-LIMITING CONTROL (AQUASTAT)

The temperature-limiting control, more commonly known as the aquastat, is a temperature-controlled switch that is intended to maintain the temperature of the water in a hydronic heating system, **Figure 33.37**. If a heating system is to maintain a temperature of 180°F with a 10° differential, the boiler will cycle off when the water is heated to 180°F. When the water cools to 170°F (180°F − 10°F), the boiler cycles back on. The water temperature will, therefore, fluctuate between 170°F and 180°F. The aquastat is commonly equipped with a remote sensing bulb that is positioned in the boiler to provide accurate control of the boiler water temperature. It is an operational control that opens and closes its contacts to maintain the desired water temperature.

HIGH-LIMIT CONTROL

The high-limit control, like the aquastat, is a device that opens and closes its contacts in response to boiler water

Figure 33.37 A temperature-limiting control, or aquastat. This is the system component responsible for maintaining the boiler water at the desired temperature.

Photo by Bill Johnson

temperature. The high-limit control is not, however, an operational control. It is a safety device that will open its contacts to deenergize the heat source if the boiler water temperature rises too high. If the maximum desired boiler water temperature is 180°F, for example, the high-limit control may open its contacts when the boiler water temperature rises to 200°F. Since 200°F boiler water is above the desired level, a system problem is likely and the high-limit control will interrupt power to the heat source.

WATER-REGULATING VALVE (PRESSURE-REDUCING VALVE)

Water heating systems should have an automatic method of adding water back into the system if water is lost due to leaks. The source of this water may be at a pressure too great for the system. A *water-regulating valve*, **Figure 33.38**, is therefore installed in the water makeup line leading to the boiler and is set to maintain the pressure on its leaving side (entering the boiler) at less than the relief valve on the boiler. Low-pressure water boilers typically have a relief valve pressure setting of 30 psig.

The pressure-reducing valve should be connected to the point of no pressure change to ensure that the system is filled to the desired pressure, **Figure 33.39**. Since the pressure will change at every other point in the system as it cycles on and off, the system fill pressure will also change unless the point of no pressure change is the system connection point.

PRESSURE RELIEF VALVE

The American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Codes require that each hot water heating boiler have at least one officially rated *pressure relief valve* set to relieve at or below the maximum allowable working pressure of the low-pressure boiler. This would be 30 psig. This valve discharges excessive water when pressure is created by expansion. It also releases excessive pressure if there is a runaway overfiring emergency, **Figure 33.40**.

Figure 33.38 A pressure-reducing valve.

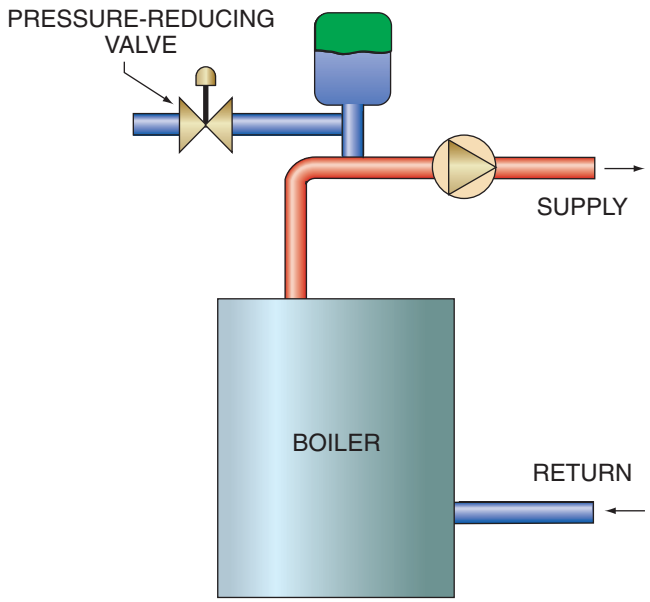
Figure 33.39 Proper location for the pressure-reducing valve.



LOW-WATER CUTOFF

The low-water cutoff valve, **Figure 33.41**, is responsible for deenergizing the system in the event the level of water in the

system drops below the desired point. In some states, low-water cutoffs are required by law, but even in states where they are not required, it is good field practice to equip all systems with one. This is especially true on radiant heating systems, as the tubing is usually below the level of the heat source and often buried in concrete. A leak in the tubing circuit can cause the system to drain itself.

ZONE VALVES

Zone control valves, or simply zone valves, are thermostatically controlled valves that regulate water flow to the various zones in a hydronic heating system. Some zone valves are equipped with gear motor actuators, whereas others have heat motor actuators, **Figure 33.42.** When a particular zone calls for heat, the zone valve is energized and it opens. On the gear motor variety of zone valve, when potential is applied to the valve, a motor-driven gear assembly slowly opens the

valve. When potential is applied to the heat motor variety of zone valve, electrical current generates heat in the valve and a bimetal strip warps to open the valve. Zone valves are often equipped with a setting that allows the valve to be opened manually. This position can be used to help troubleshoot the heating system and, in the event of zone-valve malfunction, provide temporary heat in the conditioned space.

Although there are many different system control strategies and options, here is one application that would employ zone valves. When an individual zone calls for heat, the zone valve for that zone opens. When the zone valve has completely opened, an end switch on the valve closes to start the circulator pump. This will circulate heated water from the boiler to the occupied space until the thermostat is satisfied. When the space reaches the desired temperature, the zone valve closes and the circulator is deenergized. **Figure 33.43** shows two zones being supplied with hot water by a single circulator. When either zone is calling for heat, the circulator is energized.

Zone valves are available in both two-port and three-port varieties. The piping circuit in **Figure 33.44** shows an application that uses two-port zone valves. If only one of the three heating zones is calling for heat, the other two supply circuits will be closed off and the pressure in the supply header will likely increase. Refer to the section "Pressure Differential Bypass Valve," for a discussion of valves that help alleviate the problem associated with increased system pressure due to closed zone valves.

With three-port zone valves, the water flow rate remains constant because water flows through all valves, whether or not all of them are calling for heat, as long as at least one zone is calling for heat. **Figure 33.45** shows a piping circuit that uses three-port zone valves. It can be seen that Zone 2 is the only zone calling for heat. When hot water enters zone valve #2, it leaves and flows through the terminal or heating units in that zone before returning to the boiler. When hot water flows through zone valve #1 and zone valve #3, water leaving the valves is directed right back to the boiler without flowing through the terminal units in those zones.

Figure 33.43 Gear motor zone valves on a multiple-zone loop.

Photo by Eugene Silberstein

BALANCING VALVES

When designing a hot water heating system, consideration must be given to the flow rate of the water and the friction in the system. Friction is caused by the resistance of the water flowing through the piping, valves, and fittings in the system. The flow rate is the number of gallons of water flowing each minute through the system. A system is considered to be in balance when the resistance to the water flow is the same in each flow path. A means for balancing the system should be provided in all installations. One method is to install a *balancing valve,* **Figure 33.46,** in each heating circuit branch. This valve is adjustable.

The balancing valve has pressure taps on either side where a very accurate pressure gauge can be fastened to check the pressure drop across the valve. The gauge is calibrated in in. WC. The pressure drop then can be plotted on a chart for that specific valve to show the gallons of water per minute (gpm) and then compared with the system specifications. The valve then can be adjusted to the correct flow rate. **NOTE:** *The valve adjustment is generally determined by the system designer, and the installer sets them accordingly. Be sure to read the manufacturer's instructions for the correct procedure for setting the valve.* •

PRESSURE DIFFERENTIAL BYPASS VALVE

On systems that use two-port zone valves, excessive pressure in the supply header may result when multiple zone valves close. The piping circuit may become excessively noisy as a result of the increased water velocity and water banging within the piping circuit. The pressure differential bypass valve, **Figure 33.47,** is often used to help alleviate this situation. The bypass valve is located between the supply-and-return headers of the system, **Figure 33.48**. When all, or most, of the zone valves are open, the bypass valve is in the closed position and the system operates normally.

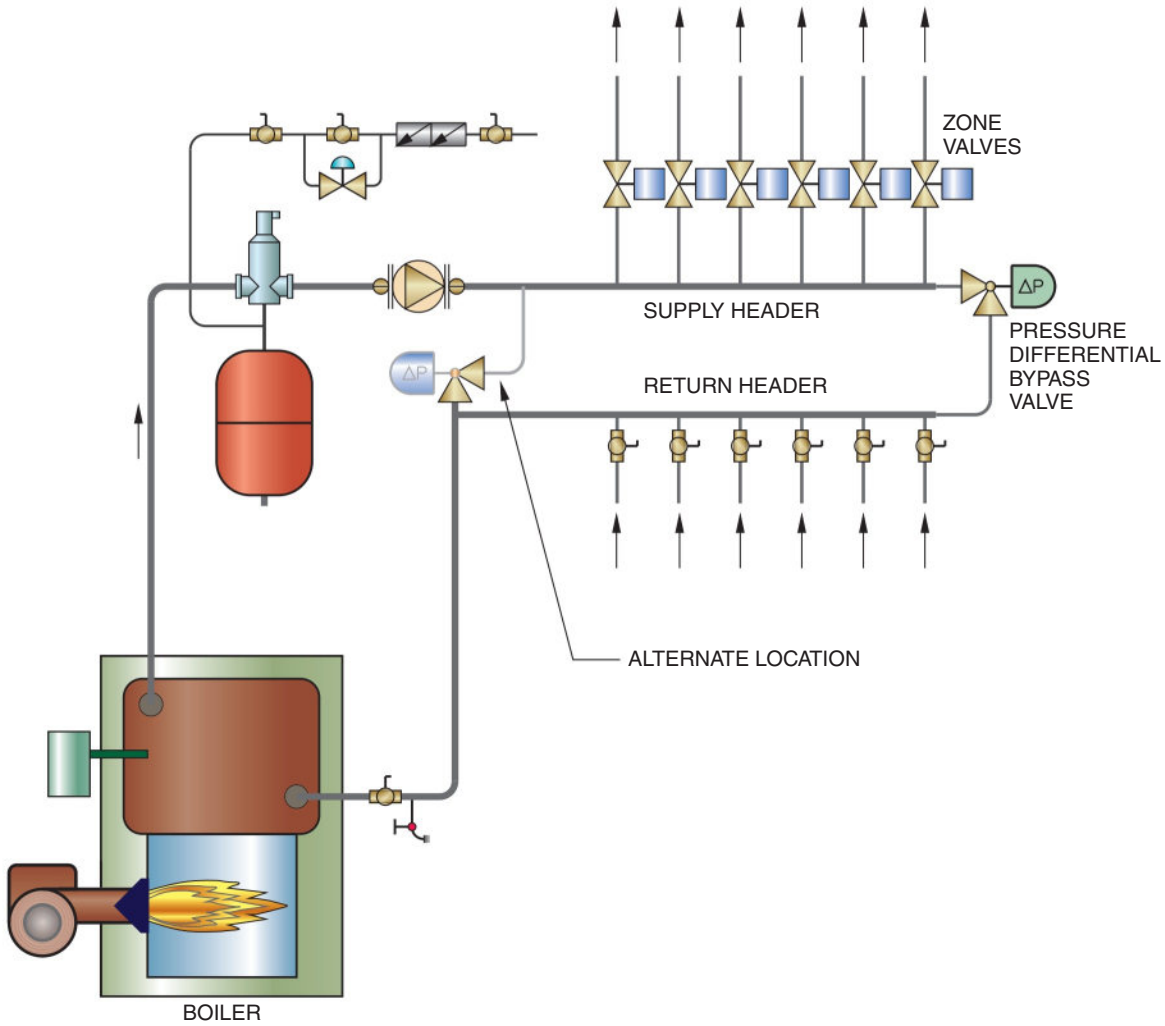
Figure 33.47 A pressure differential bypass valve.

Figure 33.48 Location of the pressure differential bypass valve on systems with zone valves.



As zone valves close, the pressure in the supply header increases and the bypass valve begins to open. The partially open valve allows the circulator to move a fixed amount of water (although only a portion of the circulated water flows through the heating zones) while the remaining hot water recirculates back to the boiler.

FLOW CONTROL VALVES

The flow control valve, **Figure 33.49**, is actually a flow check valve that prevents hot water in the system from flowing through a heating loop when no flow through that particular loop is desired—often referred to as *ghost flow*. A system using zone valves to provide a positive shutoff between the heat source and the heating loops does not need flow control valves. However, when the system utilizes only circulators, flow control valves are desirable. Some circulator manufacturers are now installing flow control valves right on the circulators themselves to ease the installation process, **Figure 33.50**.

OUTDOOR RESET CONTROL

The outdoor reset control is the device that senses the outside ambient temperature and adjusts the boiler water temperature accordingly. In theory, as the outside ambient temperature increases, the occupied space will require less heating, so cooler water can be used. Conversely, when the outside ambient temperature drops, hotter water will be needed to heat the space. When cooler water can be used, energy is saved.

The reset control measures two temperatures: the outside ambient temperature and the temperature of the water in the boiler. At the time of initial installation, the control must be set up manually to select which set of "commands" the control will obey. **Figure 33.51** shows a set of control options for a particular reset control. In this case, a reset control setting of 1.0 will cause the boiler to maintain a water temperature of 160°F if the outside ambient temperature is 20°F. The same control setting will cause the boiler water temperature to drop to 140°F if the outside ambient temperature rises to 40°F. *As of September 2012, all newly installed boilers are required to have some type of reset control strategy to automatically adjust the boiler water temperature.*

THERMOSTATIC RADIATOR VALVES

On hydronic systems with multiple zones, one common method for controlling the temperature in each individual zone is to use thermostatic radiator valves, **Figure 33.52**. These valves can be used on many different types of hydronic piping circuits, with the exception of the series loop system, which will be discussed later on in this unit. It should be noted that when the thermostatic radiator valve is installed, it should be protected from the heat that will rise from the terminal heater unit, **Figure 33.53**. If the sensing element is located above the terminal unit, the radiator valve will close before the space reaches the desired temperature.

FINNED-TUBE BASEBOARD UNITS

Most residences with modern hydronic heating systems use finned-tube baseboard heat transfer for terminal heating units, **Figure 33.54**. Air enters the bottom of these units and passes over the hot fins. Heat is given off to the cooler air, causing it to rise by convection. The heated air leaves the unit through the damper area. The damper can be adjusted to regulate the heat flow. Baseboard units are generally available in lengths from 2 ft to 8 ft and are relatively easy to install following a manufacturer's instructions. **Figure 33.55** shows a radiator and fan coil, which are other types of terminal units.

Finned-tube heating units are rated in Btuh/ft of pipe in two different flow rates, approximately 500 lb/h and 2000 lb/h. Five hundred lb/h is the equivalent of 1 gal of water flow per minute, and 4 gal/min equals 2000 lb/h.

$$1 \text{ gal/min} = 8.33 \text{ lb/min}$$

$$8.33 \text{ lb/min} \times 60 \text{ min/h} = 499.8 \text{ lb/h (Rounded to 500 lb/h)}$$

$$8.33 \text{ lb/gal} \times 4 \text{ gal/min} = 33.32 \text{ lb/min}$$

$$33.32 \text{ lb/min} \times 60 \text{ min/h} = 1999.2 \text{ lb/h (Rounded to 2000 lb/h)}$$

The manufacturer will rate the finned-tube radiation at so many Btuh/ft at different temperatures, **Figure 33.56**.

These same convectors are available in ¾-in. ID tubing. This will give you some idea of how the convectors are chosen. If a room needs 16,000 Btuh and the flow rate has been

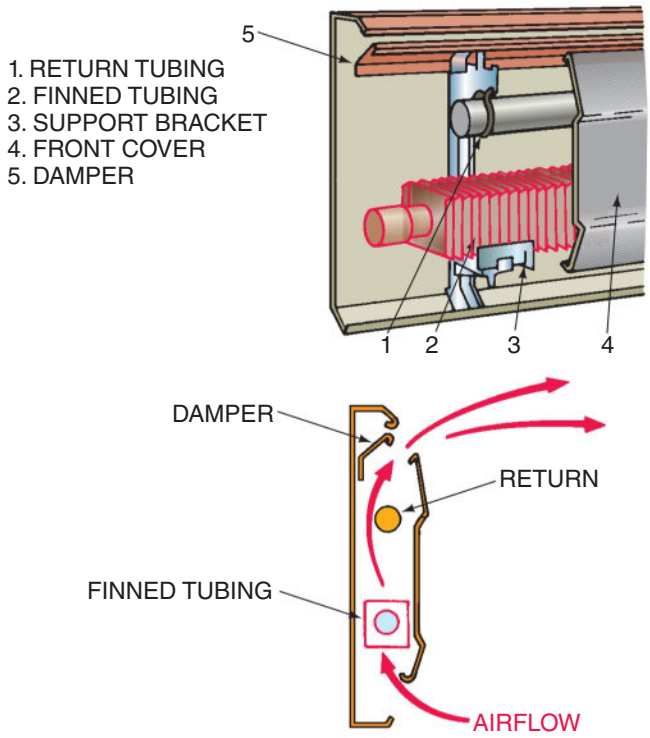
Figure 33.54 A finned-tube baseboard unit.



determined to be 1 gal/min and the system's average water temperature is 180°F, the convector length would be 27.6 ft:

$$16{,}000 \text{ Btuh} \div 580 \text{ Btuh/ft} = 27.6 \text{ ft}$$

Other types of terminal heating units are selected from manufacturers' literature in much the same manner.

When installing baseboard terminal units, provide for expansion due to heat. The hot water passing through the unit makes it expand. Expansion occurs toward both ends of the unit, so the ends should not be restricted. It is a good practice to install expansion joints in longer units, **Figure 33.57**. If using one expansion joint, place it in the center. If using two, space them evenly at intervals one-third the length of the unit. When piping drops below the floor level, the vertical risers should each be at least 1 ft long. The table in **Figure 33.58** shows the diameter of the holes needed through the floor for the various pipe sizes. The table in **Figure 33.59** lists the maximum lengths that can be installed when the water temperature is raised from 70°F to the temperature shown.

33.6 HIGH-TEMPERATURE HYDRONIC PIPING SYSTEMS

Up to this point in the unit, we have discussed the components that are used to make up hydronic heating systems. Some of these components are connected together and make up what is known as the "near-boiler piping." A common near-boiler piping configuration is shown in **Figure 33.60**. We will now start putting these pieces together to form a number

Figure 33.55 Terminal hydronic heating units. (A) Water in the radiator radiates heat out into the room. (B) The fan coil unit is similar to baseboard units but has a blower that circulates air over the hot surface of the terminal unit.

of different types of heating systems. As you will see, each of these systems will have advantages and disadvantages. It is important to evaluate each project separately, as the priorities and concerns of the equipment owner and operator will undoubtedly vary from one job to the next. The systems that will be discussed in the following sections are basic high-temperature applications, but variations or combinations of

these configurations are possible, depending on the design requirements of the system.

THE SERIES LOOP SYSTEM

The series loop system is the hydronic system that is found most often, primarily because of the low installation costs involved in executing this piping configuration. Similar to a series electric circuit, all of the terminal units are piped in series with each other so that the outlet of one heat emitter is the inlet of the next, **Figure 33.61**. The main drawback of the series loop system is that it is not possible to have individual temperature control for each area being heated. This is because there is only one path for the hot water to take, and stopping the water flow through one terminal unit will stop water flow in the entire system. Another drawback is that the first terminal units being supplied will be warmer than the later ones. This is because, as the water travels through the loop and heat is transferred from the hot water to the occupied space, the temperature of the water in the loop will drop.

Consider the series loop system in **Figure 33.62**. This system has three terminal units that are designed to provide 20,000 Btuh, 30,000 Btuh, and 50,000 Btuh, respectively. We will also assume that the water supplied by the boiler is 180°F and that the temperature of the water returning to the boiler is 160°F. From this information, we can determine the amount of water flow by using the following formula:

$$\text{Water flow (gpm)} = \frac{Q_T}{500 \times \Delta T}$$

$$\text{Water flow (gpm)} = [(20{,}000 \text{ Btuh} + 30{,}000 \text{ Btuh} + 50{,}0000 \text{ Btuh})] \div [500 \times (180°\text{F} - 160°\text{F})]$$

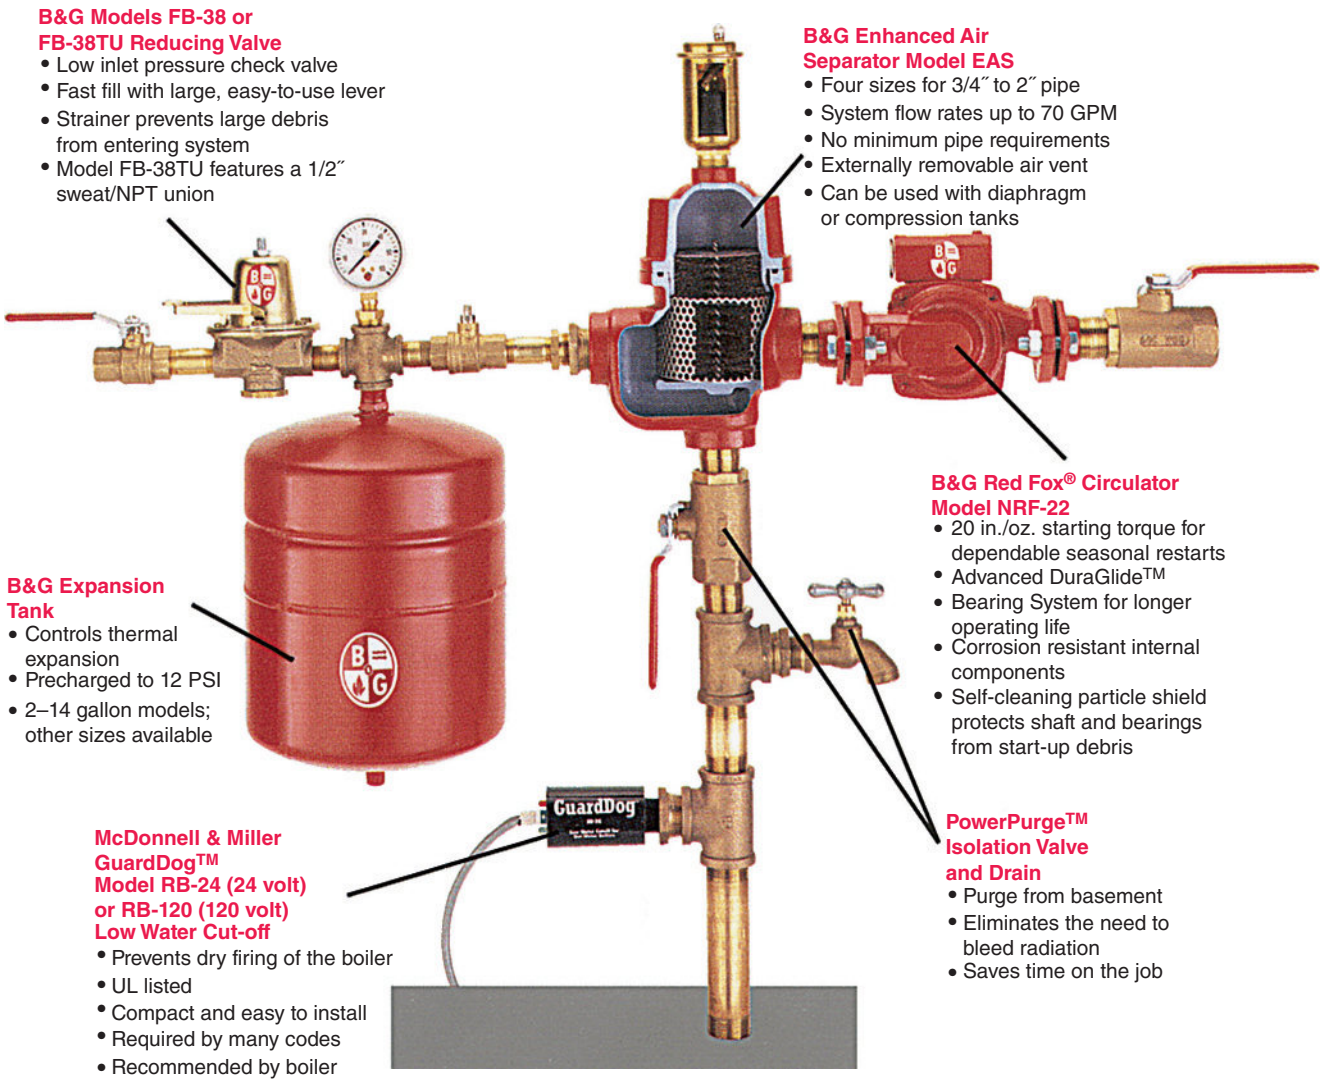
$$\text{Water flow (gpm)} = 100{,}000 \div 10{,}000$$

$$\text{Water flow (gpm)} = 10 \text{ gpm}$$

We now know that there will be 10 gpm of water flow through the piping circuit when the circulator is operating.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 33.60 Hot water supply manifold.



We can determine the temperature of the water at the outlet of the first terminal unit by using the following variation on the previous formula:

$$\Delta T = Q_1 \div (500 \times \text{gpm})$$
$$\Delta T = 20{,}000 \div (500 \times 10 \text{ gpm})$$
$$\Delta T = 20{,}000 \div (500 \times 10 \text{ gpm})$$
$$\Delta T = 4°F$$

So, if the temperature of the water entering the first terminal unit is 180°F, the temperature of the water at the outlet of the first terminal unit will be 4° less than that, or 176°F, **Figure 33.63**. The temperature of the water at the outlet of the second terminal unit can be calculated as follows:

$$\Delta T = Q_2 \div (500 \times \text{gpm})$$
$$\Delta T = 30{,}000 \div (500 \times 10 \text{ gpm})$$
$$\Delta T = 30{,}000 \div (500 \times 10 \text{ gpm})$$
$$\Delta T = 6°F$$

Since the temperature of the water entering the second terminal unit is 176°F, the temperature at the outlet of the second terminal unit is 170°F (176°F − 6°F), **Figure 33.63**. Finally, let's calculate the temperature at the outlet of the third terminal:

$$\Delta T = Q_3 \div (500 \times \text{gpm})$$
$$\Delta T = 50{,}000 \div (500 \times 10 \text{ gpm})$$
$$\Delta T = 50{,}000 \div (500 \times 10 \text{ gpm})$$
$$\Delta T = 10°F$$

Since the temperature of the water entering the third terminal unit is 170°F, the temperature at the outlet of the third terminal unit is 160°F (170°F − 10°F), **Figure 33.63**.

Using the formula a little differently, we can determine the output of a particular terminal unit if we know the temperature difference across it. Consider a terminal unit that has 8 gpm of hot water flowing through it. The temperature at the inlet of the terminal unit is 180°F and the temperature

Figure 33.61 Series loop piping circuit.

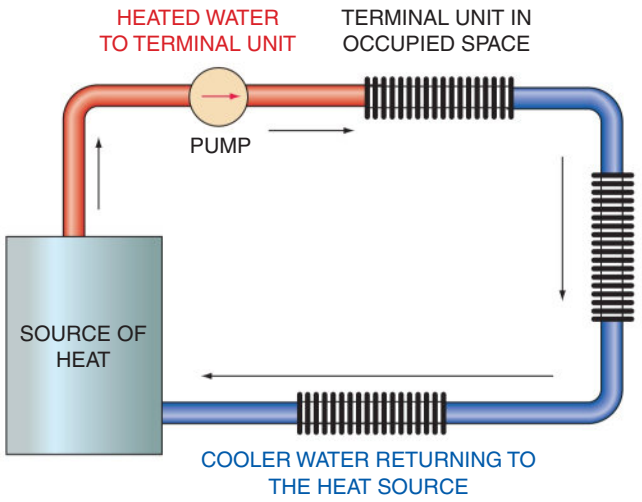

Figure 33.62 A series loop piping system with a 100,000 Btu/h output and a ΔT of 20°F across the boiler.

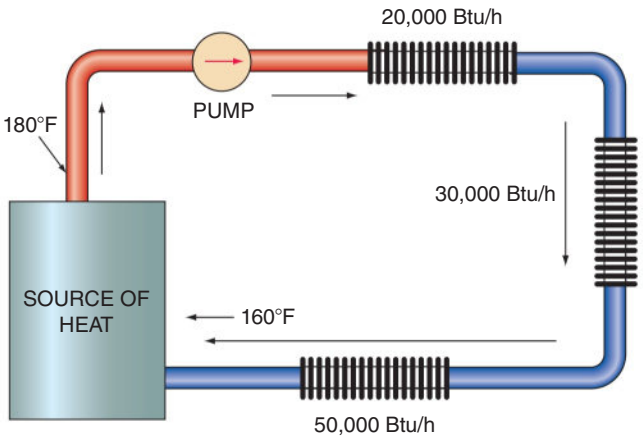

at the outlet of the terminal unit is 178°F. The capacity of the terminal unit is as follows:

$$Q = \text{Water flow (gpm)} \times 500 \times \Delta T$$
$$Q = 8 \text{ gpm} \times 500 \times (180°F - 178°F)$$
$$Q = 8 \text{ gpm} \times 500 \times 2$$
$$Q = 8{,}000 \text{ Btu/h}$$

THE ONE-PIPE SYSTEM

In a one-pipe hydronic system, one main piping loop extends around the occupied space and connects the outlet of the boiler back to the return of the boiler. Each individual terminal unit is connected to this main loop with two tees, **Figure 33.64**, one or more of which may be specially designed for use on one-pipe systems. The proper operation

Figure 33.63 The water temperature at the outlet of each terminal unit. The ΔT is determined by taking both the Btu output of each terminal unit and the water flow through each terminal unit into account.

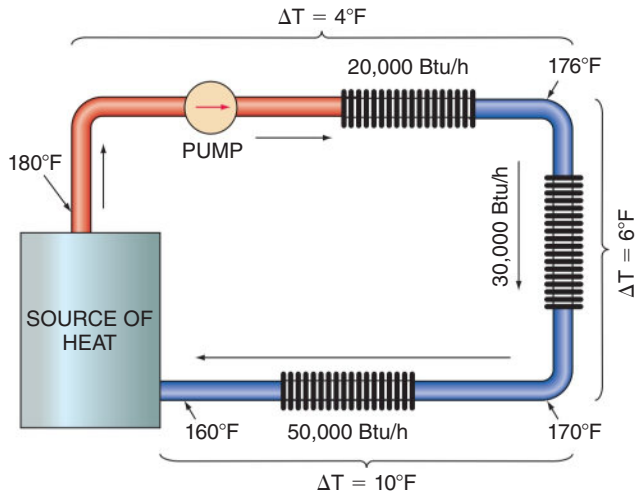

Figure 33.64 Simplified one-pipe hydronic system.

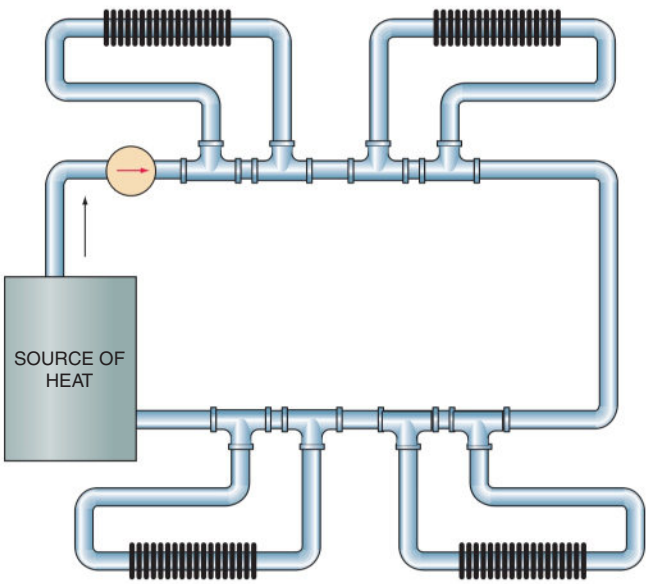

of a one-pipe hydronic system relies on the proper ratios of resistance between the terminal unit branch and the resistance to flow in the section of pipe between the two tees. Consider the setup in **Figure 33.65**. If there is a water flow of 4 gpm entering the tee at point A, 4 gpm must leave the tee. How much water will flow through the terminal unit and how much water will bypass the terminal unit depends on the resistances of each branch. If the resistance of the terminal unit branch is three times the resistance of the bypass branch, the flow through the bypass branch will be three times the flow through the terminal unit, **Figure 33.66**.

Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 33.65 Common piping between the tees. In this application, the diverter tee is located at the return side of the terminal unit.

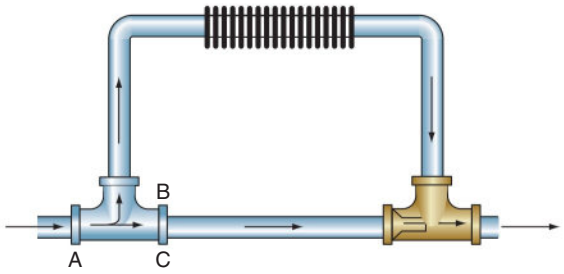

Figure 33.66 The high resistance at point B lowers the flow through that branch, while the lower resistance at point C results in greater flow through that branch.

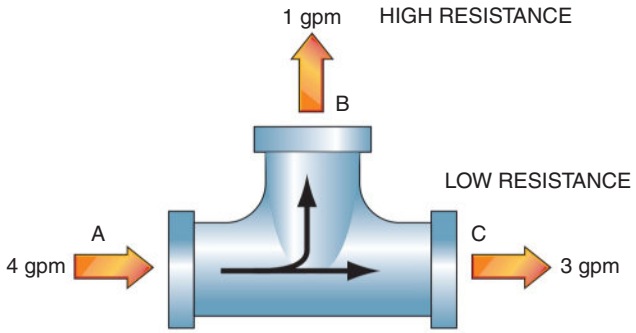

For this reason, a number of factors must be considered when laying out, evaluating, or installing a one-pipe system. These factors include the following:

- The length of the terminal unit branch circuit
- The distance between the tees
- The size of the piping in the branch circuit
- The size of the piping between the tees
- The location of the terminal unit with respect to the main loop

THE DIVERTER TEE. The special tees used in one-pipe hydronic systems are called **diverter tees** or *Monoflo tees*, **Figure 33.67**. Diverter tees are designed to increase the resistance in the main-loop pipe section between the two tees. By increasing the resistance in the main loop, more water will be directed through the terminal heating units. The diverter tee is constructed with an interior cone, **Figure 33.68**, that reduces the diameter of the pipe, thereby increasing resistance to water flow. When working with diverter tees, keep the following in mind:

- If the terminal unit is located above the hot water main and the length of the terminal unit branch is not excessive, one diverter tee should be used on the return side of the terminal unit, **Figure 33.65**.

Figure 33.67 Diverter tee for use on one-pipe systems.

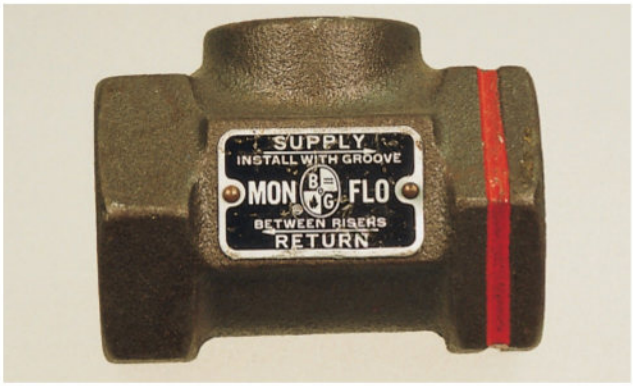

Figure 33.68 Cross-sectional view of a diverter tee.

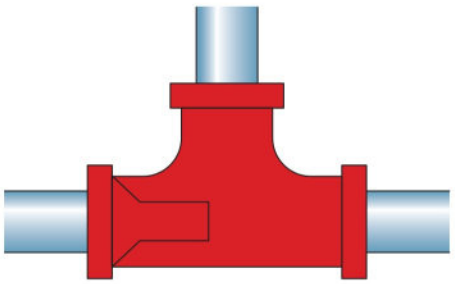

Figure 33.69 Two diverter tees are recommended if the radiator is located above the main loop and there is significant resistance in that branch.

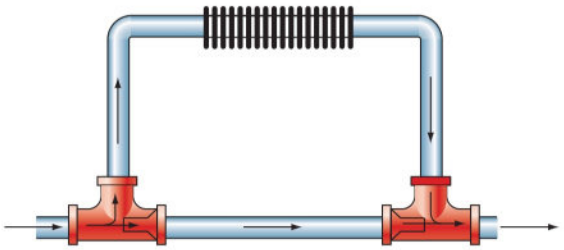
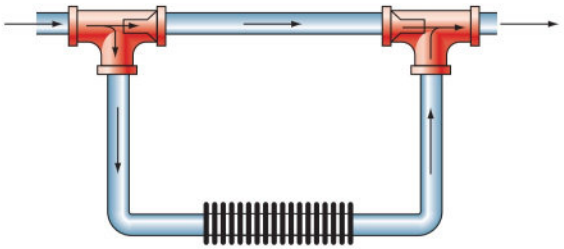


- If the terminal unit is located above the hot water main and the length of the terminal unit branch is very long, two diverter tees should be used—one on the supply side of the terminal unit and one on the return side of the terminal unit, **Figure 33.69**.
- If the terminal unit is located below the hot water main, two diverter tees should be used, **Figure 33.70**.
- If the terminal unit is located above the main hot water loop, the tees should be no closer than 6 or 12 in, depending on the manufacturer of the diverter tee.
- If the terminal unit is located below the main hot water loop, the tees should be as far apart as the ends of the

Figure 33.70 Two diverter tees are recommended if the radiator is located below the main loop.



terminal unit. If the terminal unit is 2 ft long, the tees should be 2 ft apart.

- If there are multiple terminal units, and some are above and some below the main hot water loop, it is recommended that the tees be staggered, **Figure 33.71**.
- Always check the installation literature that comes with the diverter tees to ensure that they are installed correctly and that they are pointing in the right direction.

The above information is summarized in **Figure 33.72**.

THE HEAT FORMULA AND THE ONE-PIPE HYDRONIC SYSTEM. Consider a portion of the one-pipe system shown in **Figure 33.73**. Let's assume we have a one-pipe hydronic system that has a total heating load of 100,000 Btu/h. If there is a ΔT from boiler outlet to boiler return of 20°F, the water flow through the main hot water loop will be as follows:

$$\text{Water flow (gpm)} = \frac{Q_T}{500 \times \Delta T}$$

$$\text{Water flow (gpm)} = 100{,}000 \div (500 \times 20)$$

$$\text{Water flow (gpm)} = 100{,}000 \div 10{,}000$$

$$\text{Water flow (gpm)} = 10 \text{ gpm}$$

Figure 33.71 Alternate the diverter tees if there are terminal units both above and below the main loop.

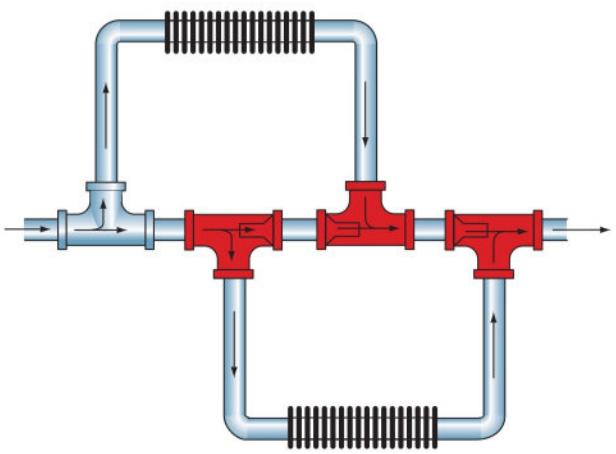


Figure 33.72 Partial water flow is diverted through the tee to and from the terminal unit.

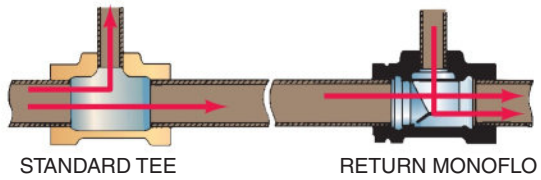
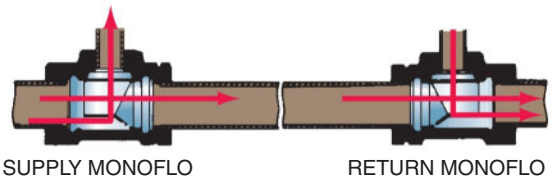


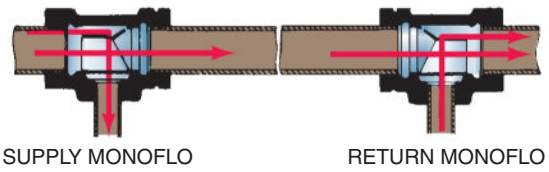
FOR RADIATORS ABOVE THE MAIN—NORMAL RESISTANCE

FOR MOST INSTALLATIONS WHERE RADIATORS ARE ABOVE THE MAIN, ONLY ONE MONOFLO FITTING NEED BE USED FOR EACH RADIATOR.



FOR RADIATORS ABOVE THE MAIN—HIGH RESISTANCE

WHERE CHARACTERISTICS OF THE INSTALLATION ARE SUCH THAT RESISTANCE TO CIRCULATION IS HIGH, TWO FITTINGS WILL SUPPLY THE DIVERSION CAPACITY NECESSARY.

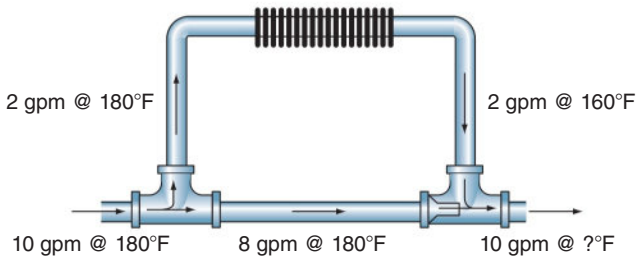


FOR RADIATORS BELOW THE MAIN

RADIATORS BELOW THE MAIN REQUIRE THE USE OF BOTH A SUPPLY AND RETURN MONOFLOW FITTING. (AN EXCEPTION IS A 3/4" MAIN, WHICH USES A SINGLE RETURN FITTING.)

Source: ITT Fluid Handling Division

Figure 33.73 The flow rate through this terminal unit is 2 gpm.



If the first terminal unit is to provide 20,000 Btu of heating, this will require that we have 2 gpm (20,000 ÷ 10,000) of hot water flowing through the terminal unit. The selected diverter tee should be capable of providing the desired flow. Since 2 gpm of water will flow through the terminal unit, 8 gpm will continue to flow through the main hot water loop. At the second tee, there will be 8 gpm of 180°F water entering

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

from the main loop and 2 gpm of 160°F water entering from the terminal unit. We can determine the mixed water temperature by using the following formula:

$$(\text{Flow 1} \times \text{Temp. 1}) + (\text{Flow 2} \times \text{Temp. 2}) = (\text{Flow 3} \times \text{Temp. 3})$$

In the above formula, Flow 1, Flow 2, Temp. 1, and Temp. 2 refer to water entering the tee, while Flow 3 and Temp. 3 refer to the water leaving the tee. Flow 3 must be the sum of Flow 1 and Flow 2. Here's how the numbers work out:

$$(\text{Flow 1} \times \text{Temp. 1}) + (\text{Flow 2} \times \text{Temp. 2}) = (\text{Flow 3} \times \text{Temp. 3})$$

$$(8\ \text{gpm} \times 180°\text{F}) + (2\ \text{gpm} \times 160°\text{F}) = (10\ \text{gpm} \times \text{Temp. 3})$$

$$1440 + 320 = 10\ \text{gpm} \times \text{Temp. 3}$$
$$1760 = 10\ \text{gpm} \times \text{Temp. 3}$$
$$\text{Temp. 3} = 1760 \div 10$$
$$\text{Temp. 3} = 176°\text{F}$$

From this we can conclude that the temperature of the water entering the second terminal unit will be 176°F, **Figure 33.74**. A sample one-pipe system using thermostatic radiator valves is shown in **Figure 33.75**.

THE TWO-PIPE DIRECT-RETURN SYSTEM

Two-pipe hydronic systems use two pipes. One pipe is used to carry water to the terminal units, while the other pipe is used to carry water from the terminal units back to the boiler, **Figure 33.76**. In a two-pipe direct-return system, the terminal unit closest to the boiler will have the shortest piping run, while the terminal unit farthest from the boiler will have

Figure 33.74 The mixed water temperature at the outlet of the terminal unit is 176°F.

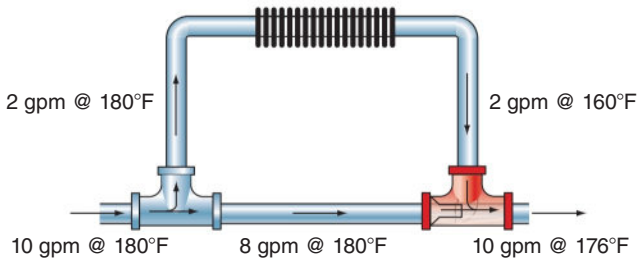


Figure 33.75 One-pipe hydronic system utilizing thermostatic radiator valves.

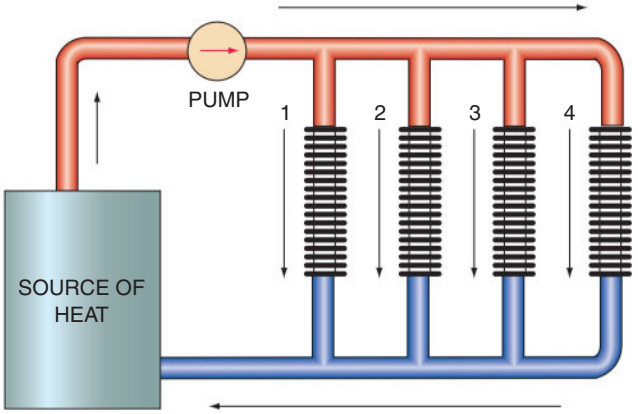
Figure 33.76 Simplified two-pipe direct-return piping arrangement.



the longest piping run. This means that the resistance of the closer terminal unit circuits is lower than that of the terminal units located far from the boiler. Consider the piping circuit shown in **Figure 33.77**. This circuit is a two-pipe direct-return system that has four terminal units numbered 1 through 4. For water to flow from the boiler through terminal unit 1 and back to the boiler, the water must travel 24 ft (3 + 9 + 5 + 7). For water to make a complete path through terminal unit 4, the water must travel 30 ft. Because the piping circuit through the more distant terminal unit location is longer, less water will flow to this location. In order to even out the water flow, balancing valves, **Figure 33.46**, are used to increase the resistance of the shorter piping loops, **Figure 33.78**.

THE TWO-PIPE REVERSE-RETURN SYSTEM

In the two-pipe reverse-return system, the first terminal unit that is supplied with water is the last to have its water return to the boiler. In other words, the terminal unit with the shortest supply pipe will have the longest return pipe and vice versa, **Figure 33.79**. By configuring the piping in this manner,

Figure 33.77 Water flowing through terminal unit 1 must travel 24 ft, while water flowing through terminal unit 4 must travel 30 ft.

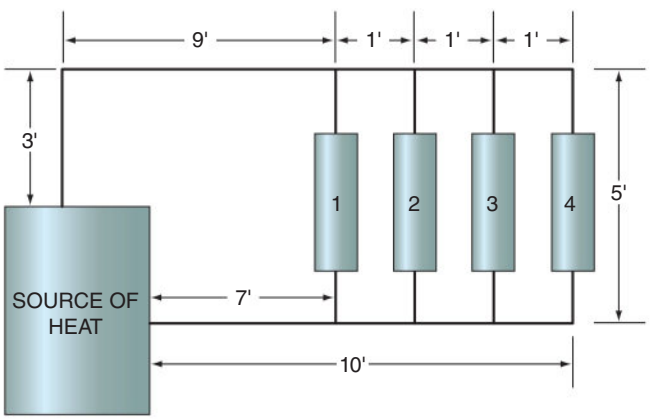


Figure 33.78 Balancing valves are used to even the resistance in each branch of a two-pipe direct-return system.

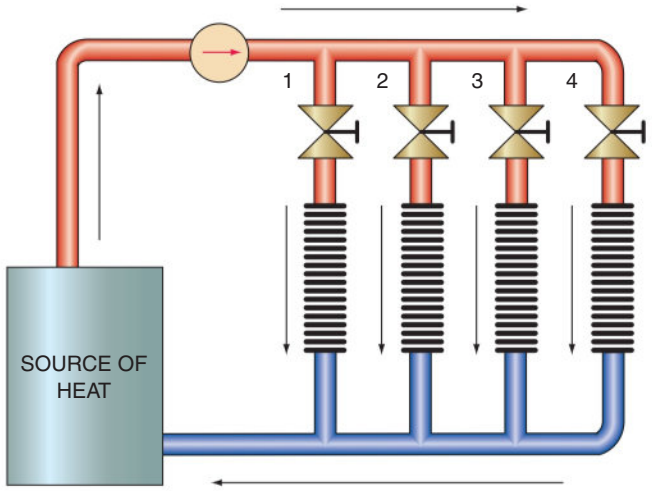

Figure 33.79 A two-pipe reverse-return piping arrangement.

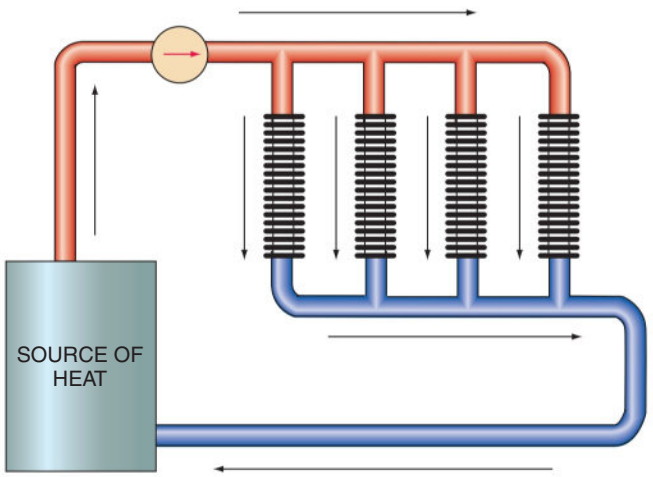

the distance traveled by the water will be the same for all terminal units in the piping arrangements. It is left as an exercise for the reader to confirm that water must flow 31 ft to get from the boiler through any of the terminal units and back to the boiler in the piping arrangement shown in **Figure 33.80**. Two-pipe reverse-return systems do not require the use of balancing valves.

PRIMARY–SECONDARY PUMPING

Primary–secondary pumping involves at least two separate piping circuits between the boiler and the terminal-unit circuits. One circuit path flows from the boiler supply back to the boiler return. Flow through this path is made possible by using a circulator pump. The secondary circuit(s) is(are) connected to this main/primary circuit and shares a portion of the piping with that circuit, **Figure 33.81**. **Figure 33.81(A)** shows

Figure 33.80 The length of the piping through any one branch is exactly the same as the length through any other branch.

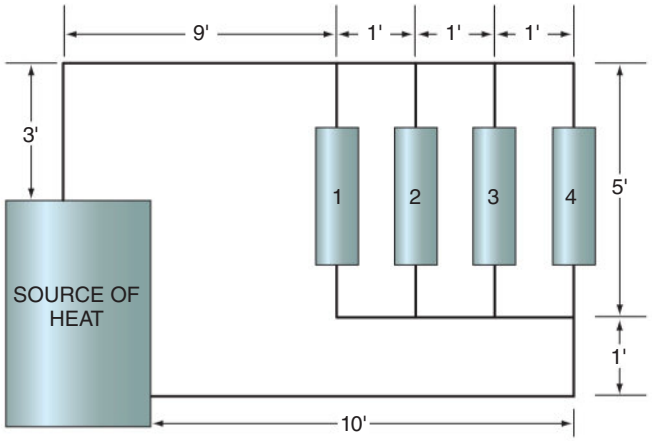

Figure 33.81 (A) Primary–secondary piping arrangement where one secondary loop is feeding three terminal units. (B) Primary–secondary piping arrangement where three secondary loops are each supplying hot water to one terminal unit.

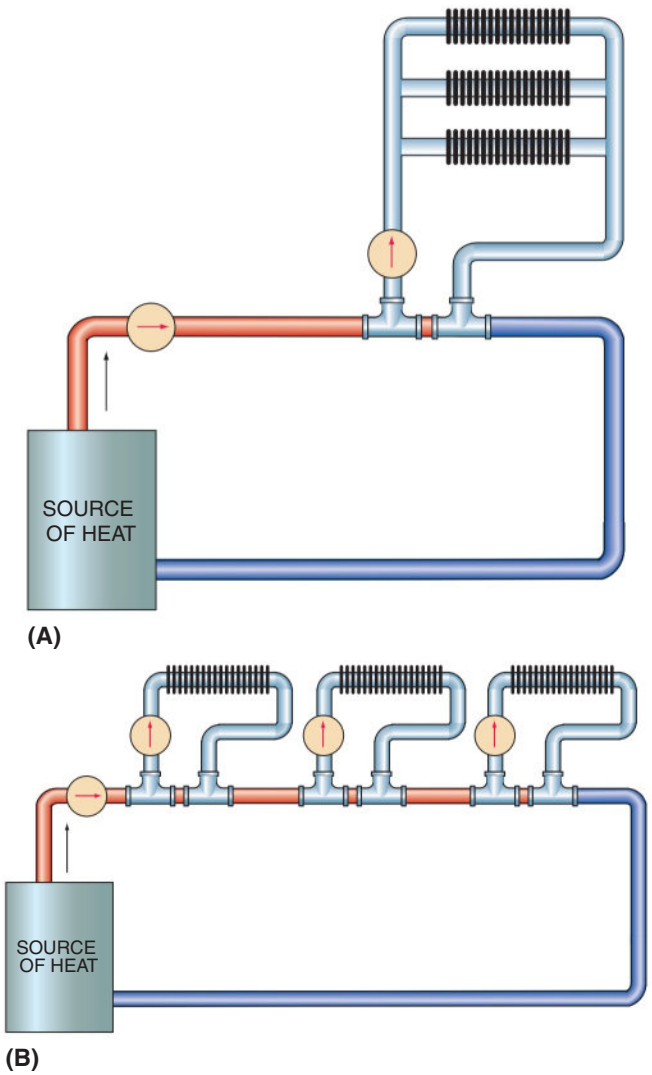

a primary–secondary pumping arrangement with one secondary circuit; **Figure 33.81(B)** shows a primary–secondary pumping arrangement with three secondary circuits. Notice that each secondary circuit has its own circulator pump that will push water into the individual secondary circuits when the corresponding pump is energized. The industry term that is used to describe any system that uses a circulator to push water into a secondary heating loop (as in the case of primary–secondary pumping) is **injection**.

Unlike the one-pipe configuration discussed earlier, the tees that are used to create a primary–secondary system are standard tees and not of the diverter or Monoflo variety. In addition, the tees are to be positioned as close to each other as possible. The space in between the two tees is referred to as *common piping*. By closely spacing these tees, the resistance of the common piping will be very low. This is a desirable condition, as we do not want water to flow through the secondary loops when there is no call for heat in them. The lower the resistance of the common piping is, the more likely it is that the water will bypass (as opposed to flow into) the secondary loops, **Figure 33.82**.

CIRCULATOR PUMPS IN PRIMARY–SECONDARY SYSTEMS. It can be seen in **Figure 33.81(B)** that primary–secondary pumping involves the use of multiple circulator pumps. One circulator pump is located in the primary loop and is typically the largest pump in the system. It is this pump that is responsible for making the heated water available to the secondary loops. When no remote areas or zones are calling for heat, all system pumps are off but, depending on system design, the boiler may be cycling on and off to maintain the water in the

Figure 33.82 More resistance between the tees results in more water flow through the terminal unit connected to the tees. Less resistance between the tees results in less water flow through the terminal unit.

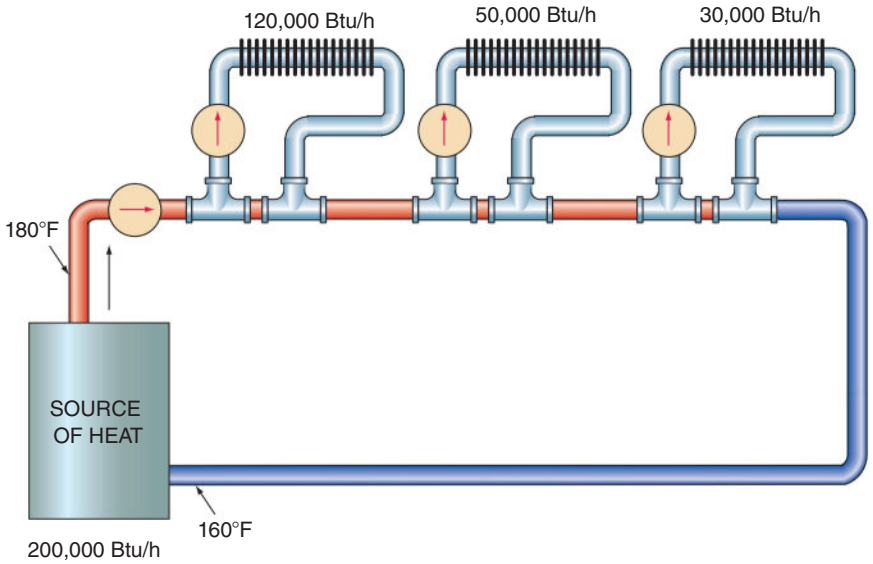
Figure 33.83 Sample one-pipe system with three terminal units providing 200,000 Btu/h of heating to the occupied space.



boiler at the desired operating temperature. When an individual zone calls for heat, both the secondary pump for that loop and the primary pump will cycle on. The primary pump will bring the heated water to the common piping section and the secondary pump will push heated water into the secondary loop to satisfy the heating requirements of the space.

Consider the primary–secondary setup in **Figure 33.83**. The system has a capacity of 200,000 Btu/h and the boiler operates with a ΔT of 20°F. There are three secondary loops with the following heating capacities:

- Zone 1: 120,000 Btu/h
- Zone 2: 50,000 Btu/h
- Zone 3: 30,000 Btu/h

The total water flow that should be made available by the system is as follows:

$$\text{Water flow (gpm)} = \frac{Q_T}{500 \times \Delta T}$$

$$\text{Water flow (gpm)} = 200{,}000 \div (500 \times 20)$$

$$\text{Water flow (gpm)} = 200{,}000 \div 10{,}000$$

$$\text{Water flow (gpm)} = 20 \text{ gpm}$$

If all three secondary loops are calling for heat, the water temperature at the outlet of each secondary loop is as shown **Figure 33.84**. Notice that the temperature of the water at the outlet of the third secondary loop is the temperature of the boiler supply water (180°F) less the 20°F that was indicated

Figure 33.84 Water temperatures at various points in the system when all three zones are calling for heat.

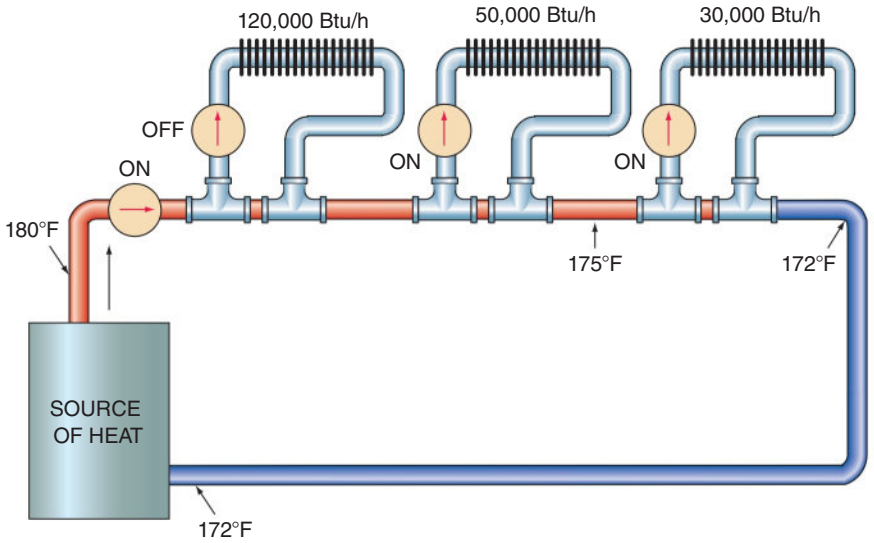
Figure 33.85 Water temperatures at various points in the system when only the second and third zones are calling for heat.



as the ΔT of the boiler. Let's now assume that the thermostat for the first secondary loop is satisfied. In that case, the corresponding secondary pump will cycle off and there will be no water flow into that loop. When the first loop is no longer active, water at a temperature of 180°F is fed to the second loop. The temperature of the water at the outlet of the second loop, **Figure 33.85**, is calculated as follows:

(Flow 1 × Temp. 1) + (Flow 2 × Temp. 2)
= (Flow 3 × Temp. 3)
(15 gpm × 180°F) + (5 gpm × 160°F)
= (20 gpm × Temp. 3)
2700 + 800 = 20 gpm × Temp. 3
3500 = 20 gpm × Temp. 3
Temp. 3 = 3500 ÷ 20
Temp. 3 = 175°F

The water temperature at the outlet of the third secondary loop will be as follows:

(Flow 1 × Temp. 1) + (Flow 2 × Temp. 2)
= (Flow 3 × Temp. 3)
(17 gpm × 175°F) + (3 gpm × 155°F)
= (20 gpm × Temp. 3)
2975 + 465 = 20 gpm × Temp. 3
3440 = 20 gpm × Temp. 3
Temp. 3 = 3440 ÷ 20
Temp. 3 = 172°F

The temperature of the water returning to the boiler will be 172°F, **Figure 33.85**. Notice that the water left the boiler at 180°F and returned at 172°F. This represents a ΔT of only 8°F across the boiler, when we originally anticipated a ΔT of 20°F. This is because the first secondary loop is not calling for heat and this loop represents 60% (0.6) of the total system capacity (120,000 Btu ÷ 200,000). Since 60% of our 20°F ΔT is 12°, we only see the portion of the system (20°F − 12°F = 8°F) that is actively being heated. Notice that when all three secondary loops are actively heating, the return temperature at the boiler reflects the ΔT of 20°F.

MIXING VALVES IN PRIMARY–SECONDARY SYSTEMS. Mixing valves are used to combine two water streams of different temperatures to produce water flow that is at a temperature between the two entering temperatures. Common types of mixing valves include three-way valves, **Figure 33.86**, and four-way valves, **Figure 33.87**. Three-way valves have two

inlet ports and one outlet port, whereas four-way valves have two inlet ports and two outlet ports.

Mixing valves can be manually set, **Figure 33.86**, or they can be thermostatically controlled, **Figure 33.88**. A manually set mixing valve is set to the desired position on the basis of the percentages of water flow desired from each inlet. At either extreme, the water at the outlet of the valve will be 100% from the hot water inlet or 100% from the cold water inlet. At any point in between, the outlet water will be a mixture

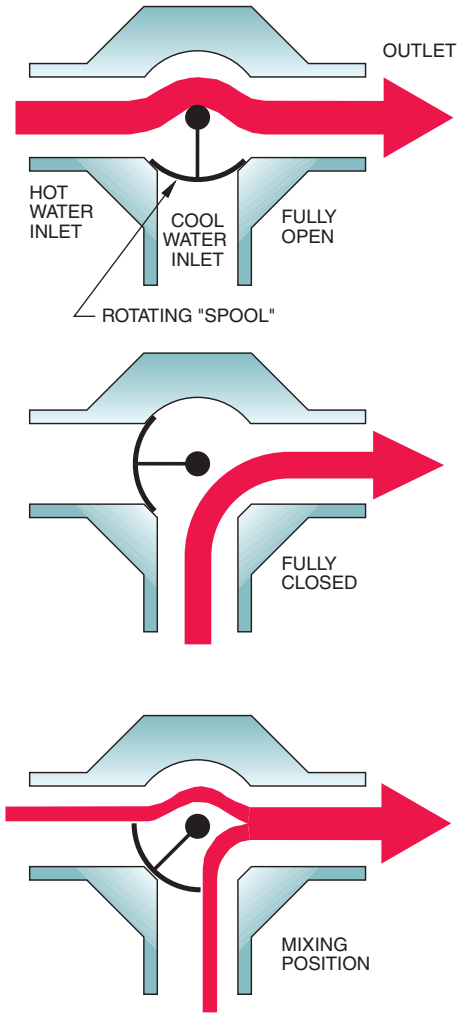
Figure 33.89 Cutaway illustration showing internal construction of a three-way valve.



of the two, **Figure 33.89**. Four-way mixing valves allow some of the water leaving the boiler to return to the boiler to keep the return-water temperature high enough to prevent flue-gas condensation, **Figure 33.90**.

One of the many benefits of primary–secondary pumping is that each individual loop can be used to supply water at different temperatures to the terminal units in that loop. For example, one portion of the structure may have baseboard heating elements installed, while another portion of the structure may have radiant heat. The area with baseboard heating elements will require higher-temperature water than will the area with radiant heat. By using primary–secondary pumping in conjunction with a mixing valve, both conditions can be met. Multitemperature combination systems will be discussed later on in this unit.

EXPANSION TANKS IN PRIMARY–SECONDARY SYSTEMS. Earlier in this unit, we discussed the location of the expansion tank with respect to the circulator pump. We concluded

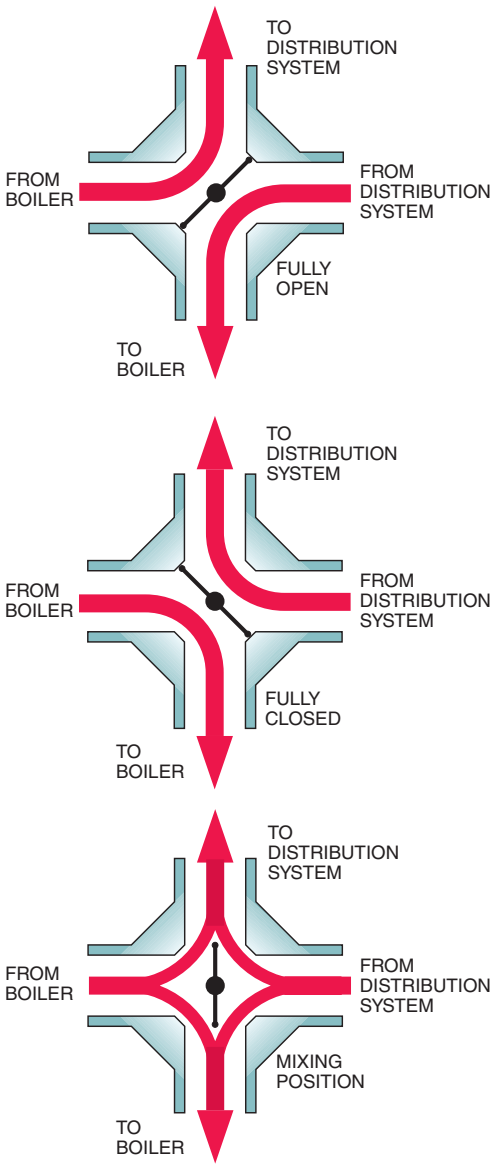
Figure 33.90 Cutaway illustration showing internal construction of a four-way valve.



that the best place for the circulator was on the supply piping coming from the boiler, pumping away from the expansion tank. This was referred to as the "point of no pressure change." Since primary–secondary systems have additional circulator pumps, it may seem logical that there should be expansion tanks in each of the secondary loops to provide for the expansion of heated water in these locations. The truth of the matter is that the common piping between the primary and secondary loops serves as the expansion tank for that loop. As water is heated, it will move from the secondary loop into the primary loop and then into the expansion tank located in the primary loop. Since we want to pump away from the point of no pressure change, the circulators in the secondary loops should be located on the pipe closest to the primary pump—and should be directed to pump into the secondary circuit and away from the common piping.

Regardless of the type of piping layout, the estimator or engineer will pay close attention to the sizing of the pipe for any system. Pipe sizing and pump size determine how much water will flow in each circuit. If the pipe is too large, it will be expensive and it may not meet the low-limit flow requirements for convectors. For example, the minimum design flow rates for convector pipes of different diameters are:

½ in. ID	0.3 gpm
¾ in. ID	0.5 gpm
1 in. ID	0.9 gpm
1¼ in. ID	1.6 gpm

If the flow rates below these are used at the convectors, the heat exchange between the water and the air will be less. The velocity of the water in the convector helps the heat exchange. Flow that is too slow is called *laminar flow.*

If a system is designed with too fast a flow, the pipe will be too small and the velocity noise of the water will be objectionable. The designer tries to reach a balance between oversized and undersized pipe. The following table lists some water velocities in ft per minute (fpm) recommended for hydronic piping systems.

Pump discharge	8 to 12 fpm
Pump suction	4 to 7 fpm
Drain lines	4 to 7 fpm
Header	5 to 15 fpm
Riser	3 to 10 fpm
General service	5 to 10 fpm
City water lines	3 to 7 fpm

33.7 RADIANT, LOW-TEMPERATURE HYDRONIC PIPING SYSTEMS

The concept of radiant heat differs a great deal from that of convective heating as it has been discussed thus far in this unit. Radiant heating systems rely on heating the shell of the structure as opposed to heating the air in the structure. The purpose of convective heating is to determine the rate at which heat is lost from the room by conduction, convection, and radiation at the desired conditions. Radiant heating involves regulating the rate at which the human body loses heat.

HOW THE BODY FUNCTIONS AS A RADIATOR

Under normal conditions, the human body produces about 500 Btu/h. The body requires about 100 Btu/h to remain alive. The rest of this heat must be rejected, making the body act as a radiator. By controlling the rate at which we give up heat, we can control our comfort level. If we give up heat too fast, we will feel cold. If we do not give up heat fast enough,

we will feel warm and uncomfortable. Typically, a room at a temperature of 68°F allows us to shed at an acceptable rate the extra 400 Btu/h that our body generates. For this reason, it is desirable that the occupied space be about 68°F—with the exception of the areas close to the ceiling and floor. Since our heads are not close to the ceiling, there is no need to keep that area heated, so it can be somewhat cooler than 68°F. In addition, we lose a lot of heat from our feet, so the floor should be somewhat warmer than 68°F. **Figure 33.91** shows room temperature changes as we go from the floor to the ceiling. This represents an ideal temperature pattern, one which radiant heating systems closely follow. **Figure 33.92** shows the same ideal temperature pattern as compared with the temperature pattern created by forced-air heating systems.

THE RADIANT SYSTEM

Like hot water hydronic systems, radiant systems rely on the circulation of hot water through a series of piping circuits. There are three main differences between radiant heating systems and conventional hot water hydronic systems. These differences are as follows:

- Radiant heating systems are nearly invisible as compared with conventional hydronic systems. The piping arrangements are concealed in the floors, walls, and sometimes ceilings of the structure.
- The piping material used in radiant heating systems is different. Instead of copper piping materials, radiant heating systems often use *polyethylene tubing*, more commonly known as **PEX tubing**, **Figure 33.93**. PEX is installed using a minimum of pipe fittings, **Figure 33.94**.
- The temperature of the water in radiant heating systems is considerably lower than the temperature of the water utilized by conventional hydronic systems. Typical hydronic systems use water as hot as 180°F, whereas radiant systems use water at an average temperature of about 110°F.

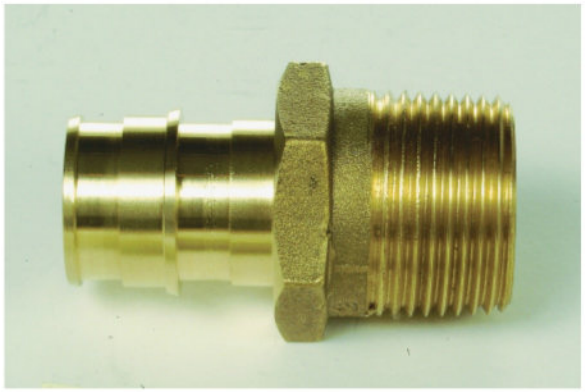
HEAT SOURCES FOR RADIANT HEATING SYSTEMS

As mentioned at the beginning of this unit, the heat source for hydronic systems is quite often a boiler. It was also mentioned that in the case of low-temperature systems such as radiant applications, geothermal heat pumps are becoming more and more popular. Here are some quick notes and suggestions regarding the heat sources used for radiant heating systems:

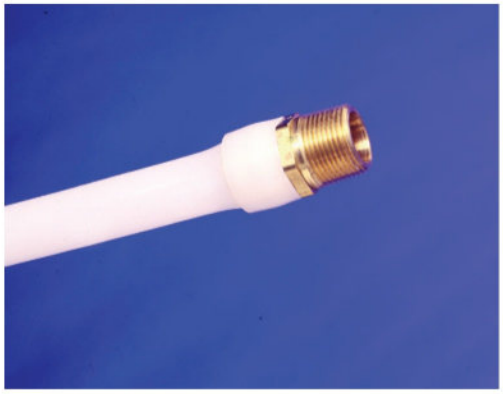
- When using a geothermal heat pump system for radiant heating, be sure to use a buffer tank. This will prevent water flow restrictions on the condenser water side, which can lead to high-pressure problems in the refrigerant circuit.
- The buffer tank serves as a storage tank for the heated water; the heat pump will cycle on and off to maintain the desired water temperature in the tank.

Figure 33.94 (A)–(C) Fittings used to connect PEX tubing.



Source: Uponor

(A)



Source: Uponor

(B)

Source: Uponor

(C)

- Larger temperature differential settings on the buffer tank increase the run time of the heat pump, but they also increase the off time of the system, thereby increasing the efficiency of the system.
- It is a good idea to use a buffer tank as well when using a copper-tube, low-mass boiler for radiant applications, This will prevent short cycling of the boiler, **Figure 33.95**.
- If direct piping is being used, **Figure 33.96**, make sure that the boiler is designed to handle the potentially low temperature of the water returning to the appliance.
- When the boiler return-water temperature may be a problem, make sure to provide a means for keeping the return-water temperature high enough to prevent flue-gas condensation, **Figure 33.97**.

RADIANT HEATING PIPING

Given the versatility of radiant heating systems, the possibilities are boundless when it comes to installation variations and custom applications. The most common types of radiant heating system applications are the following:

- Slab on grade
- Thin slab
- Dry or concrete-free applications

Figure 33.95 A buffer tank used in conjunction with a low-mass boiler.

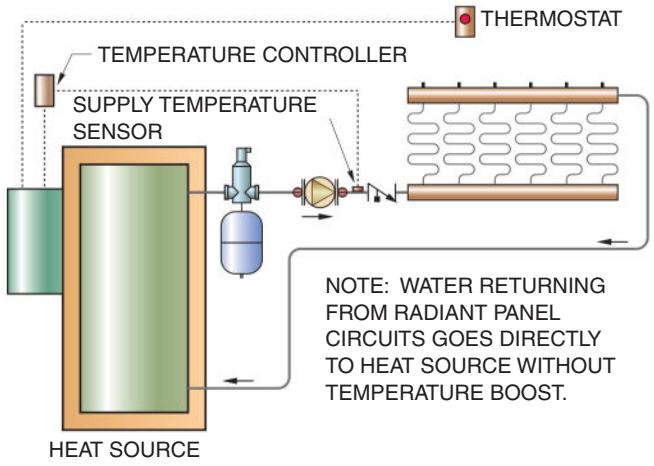
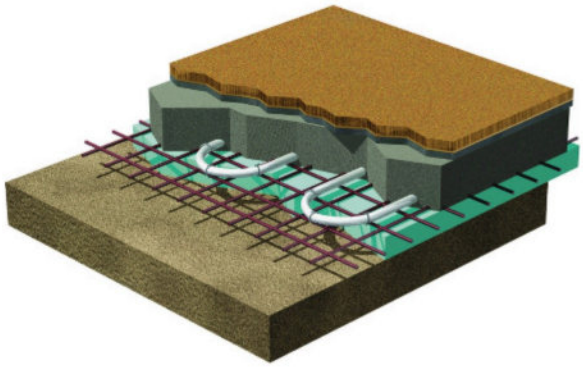
Figure 33.96 Direct piping from the heat source to the heating circuits. There is no mixing taking place in this piping arrangement.



SLAB-ON-GRADE. The slab-on-grade application is very popular, especially for new construction and projects. Since the concrete for these applications has yet to be poured, it is a relatively simple task to position the PEX tubing loops right in the concrete slab. The tubing material is secured to the steel reinforcement mesh in the floor using straps or clips specially designed for that use, **Figure 33.98**. The spacing between the PEX tubes is determined by the depth of the tubes below the concrete surface, the size of the tubes, the type of floor being installed, and the location of the tubes with respect to the outside walls of the structure. For higher system efficiency, insulation should be placed below the concrete slab as well as below a vapor barrier to prevent the ground from robbing the slab of its heat.

Figure 33.98 Cutaway view of a slab-on-grade radiant piping layout.



THIN SLAB. When there is an existing floor in place, thin-slab installations are common. The PEX tubing is stapled in place to the top of the frame floor and concrete is then poured over the existing floor. The thickness of the concrete can range from 1.5 in. to 2 in. and should completely

cover the PEX tubing with at least ¾ in. of poured material, **Figure 33.99**. To ensure that the existing floor will be able to handle the weight of the concrete, be sure to consult an engineer or architect when installing a thin-slab system.

DRY APPLICATIONS. Another option for installing radiant systems is to staple the tubing to the bottom of the flooring material. This is referred to as a staple-up job, **Figure 33.100**. When installing this type of system, it is important to space the staples closely, as the tubing should be in loose contact with the floor material for effective heat transfer. Insulation should be positioned under the stapled-up tubing as illustrated in the figure.

Another option for a concrete-free radiant heating system installation is the use of aluminum "wings" or fins, **Figure 33.101**, that can be attached to PEX tubing that is fed through the floor joists (as opposed to being stapled up to the underside of the floor). These fins are installed in sets of two and are designed to completely surround the PEX tubing, **Figure 33.102**. Installation is relatively simple, given that holes are predrilled in the material. The completed installation is illustrated in **Figure 33.103**.

PIPING ARRANGEMENTS

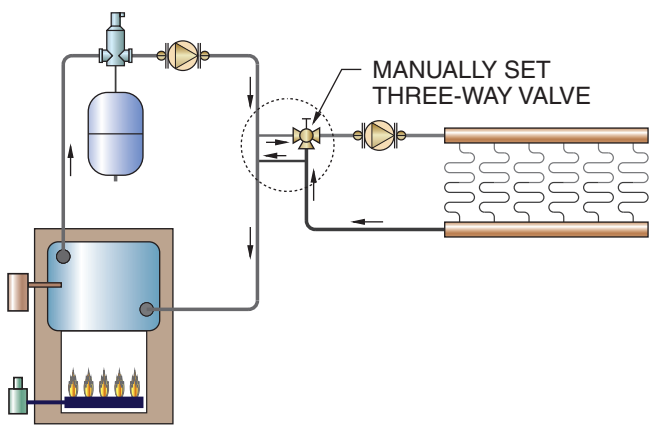
Many different configurations of piping can be utilized on radiant heating systems. What follows is intended to provide merely a small sampling of the options available—attempting to discuss all installation and piping schemes here would be beyond the scope of this text.

DIRECT PIPING. By far, the simplest configuration of piping in a radiant system is direct piping. In a direct-piping scheme, the water supplied to the boiler is pumped into the radiant heating circuits, **Figure 33.96**. This type of piping configuration is more system-friendly when the heat source is a buffer tank as opposed to a boiler. If the heat source is a boiler and the desired water temperature at the radiant heating circuits is low, there is a great chance that the flue gases in the boiler will condense, because the return-water temperature will be low as well. If a buffer tank is used, the water that returns to the boiler comes from the buffer tank, not the outlet of the radiant heating circuits.

MANUALLY SET MIXING VALVES. As mentioned earlier in the radiant section, manually set mixing valves do not respond to changes in water temperature or to changing water flow rates. For this reason, these valves are not the best option, as they do not prevent low-temperature water from returning to the boiler, **Figure 33.104**.

THERMOSTATIC MIXING VALVES. Thermostatic mixing valves will adjust their internal settings to supply water at the desired temperature to the radiant heating loops. Consider the system shown in **Figure 33.105**. As a point of reference, let's assume that the entire system is completely filled with 180°F water and the desired water temperature in the radiant loops is 110°F. The radiant loops operate with a ΔT of 20°F. Since the water temperature at the inlet of the radiant loops is 70°F higher (180°F–110°F) than desired, the hot water inlet port of the thermostatic mixing valve is completely closed. The 180°F water enters the radiant loops and leaves at 160°F. All of the 160°F water flows back into the cold inlet port of the mixing valve, **Figure 33.106**. **NOTE:** *No water from the radiant loop can return to the boiler because no water has entered the radiant loop from the hot water inlet port. Because the radiant loops are completely filled, we cannot add water without removing water, and we cannot remove water without adding water.*

Figure 33.104 An example of a hydronic system using a manually set three-way valve.



The water enters the cold inlet port of the mixing valve at 160°F and, because the water is still too hot, the hot water inlet port will remain closed. The 160°F water enters the radiant loops, and the water leaves the loops at a temperature of 140°F. This process continues until the water leaving the radiant loops is at a temperature of 100°F. Since the water enters the cold water inlet port of the mixing valve at 100°F, and since the desired water temperature is 110°F, the hot water inlet port will open slightly to mix some 180°F water with the 100°F water to provide 110°F water at the outlet of the mixing valve, **Figure 33.107**. Because some water enters the mixing valve through the hot water inlet port, the same amount of water will return to the boiler from the outlet of the radiant heating circuits.

Another application for thermostatic mixing valves is to ensure that the temperature of the return water to the boiler is high enough to prevent flue-gas condensation. The system in **Figure 33.108** utilizes a mixing valve to regulate water supplied to the heating circuits and also uses another mixing valve to regulate the temperature of the water returning to the boiler.

33.8 COMBINATION (HIGH- AND LOW-TEMPERATURE) PIPING SYSTEMS

In a case where a structure has both high- and low-temperature heating circuits, the same boiler can serve both applications by using a primary–secondary pumping arrangement, **Figure 33.109**. In the figure we can see that water is being supplied to the first two secondary loops at a temperature close to 180°F. The water in the main loop after these two secondary loops will be about 165°F. This water can then return to the boiler, while a portion of the water will mix with the water in the radiant loop to maintain the desired water temperature in that circuit. The temperature of the water returning to the boiler will be about 160°F.

33.9 TANKLESS DOMESTIC HOT WATER HEATERS

Most hot water heating boilers (oil- and gas-fired) can be furnished with a domestic hot water heater consisting of a coil inserted into the boiler. The domestic hot water is

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 33.105 Low-temperature hydronic system using a three-way thermostatic mixing valve. Since the water in the heating loop is warmer than desired, the hot water inlet port on the mixing valve is in the closed position. Under these conditions, no water can enter or leave the low-temperature heating circuit.

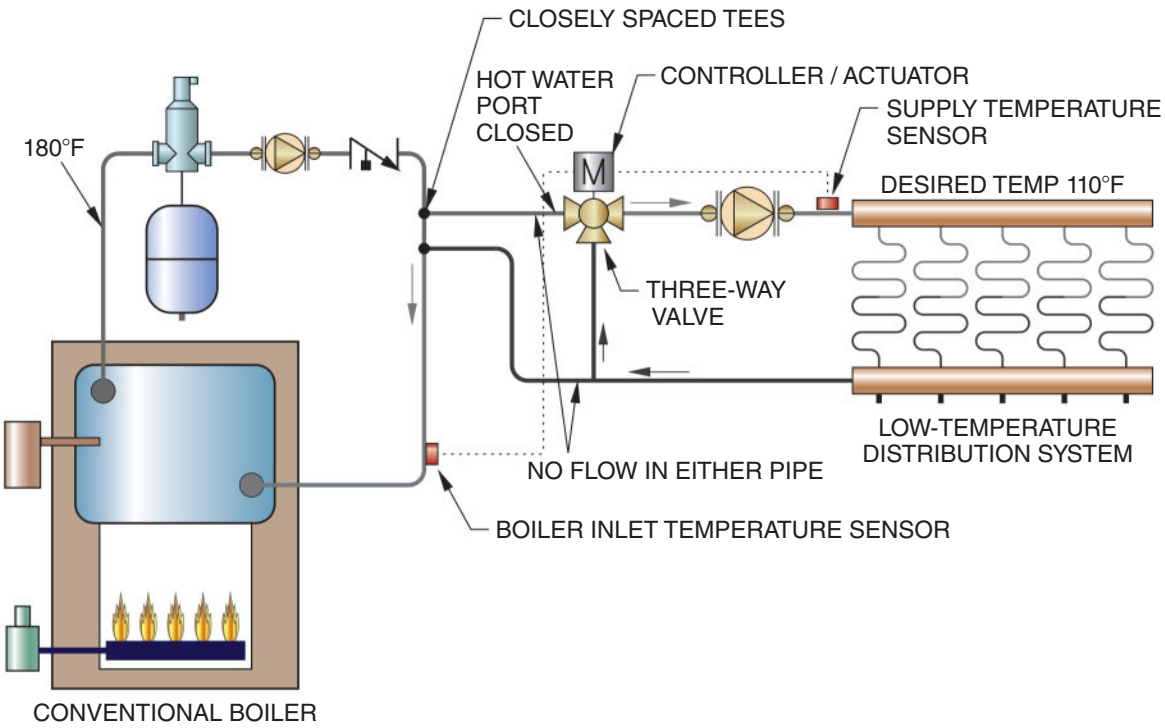

Figure 33.106 Water that is too hot for the heating loop will continue to circulate without mixing until the temperature at the outlet of the heating loop (cold water inlet) falls below the desired water temperature.

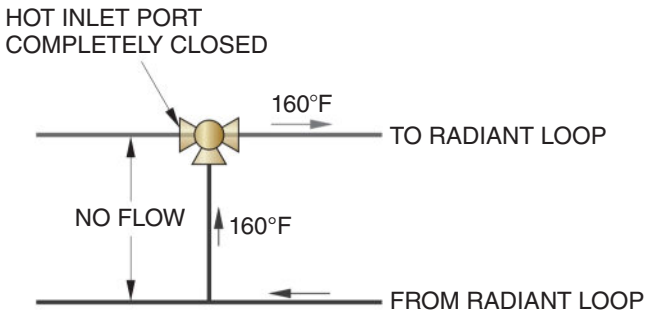

Figure 33.107 Since the water at the outlet of the heating loop is at a temperature that is lower than desired, the hot water inlet port will open slightly. This will allow hot water to enter the mixing valve—and also allow cool water from the heating loop to leave the loop and return to the boiler.

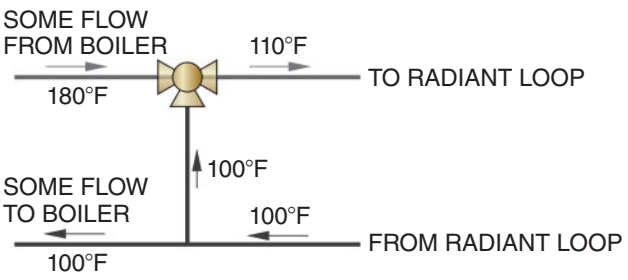

contained within the coil and heated by the boiler quickly, which eliminates the need for a storage tank. This system can meet most domestic hot water needs without using a separate tank, **Figure 33.110**. This is generally an efficient way to produce hot water.

33.10 SOLAR HEATING AS A SUPPLEMENTAL HEAT SOURCE

The sun furnishes the earth with tremendous amounts of direct energy each day. It is estimated that 2 weeks of the sun's energy reaching the earth is equal to all of the known deposits of coal, gas, and oil. The challenge facing scientists, engineers, and technicians is to better harness and use this energy. We know that the sun heats the earth, which heats the air immediately above the earth. One of the challenges is to learn how to collect, store, and distribute this heat to provide heat and hot water for homes and businesses. Many advances have been made, but the design and installation of solar systems has progressed very slowly. It is assumed, however, that as the fossil-fuel resources are further depleted and as economics or political actions cause energy crises, it will be only a matter of time before the direct energy of the sun is used extensively.

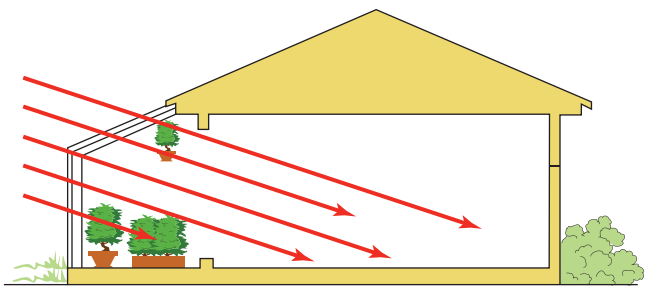
PASSIVE SOLAR DESIGN

Many structures being built presently are using passive solar designs. These designs use nonmoving parts of a building or structure to help provide heat or cooling, or they eliminate certain parts of a building that help cause inefficient heating or cooling. Some examples follow:

- In areas where there are harsh winters, more windows can be placed on the east, south, or west sides of homes and fewer on the north side. This allows warming from the morning sun in the east and from the sun throughout the rest of the day from the south and west. By eliminating windows on the north side, the coldest side of the house can be better insulated.
- Place greenhouses, usually on the south side, to collect heat from the sun to help heat the house, **Figure 33.111.**
- Design roof overhangs to shade windows from the sun in the summer but allow sun to shine through in the winter, **Figure 33.112.**

Figure 33.111 A greenhouse will allow the sun to shine into the house. It may also have a masonry floor, or barrels of water may be located in the greenhouse, to help store the heat until evening when the sun goes down. This heat then may be circulated throughout the house.



- Provide a large mass, such as a concrete or brick wall, to absorb heat from the sun and temper the inside environment naturally.
- Planting trees around the structure provides benefits in both the summer and the winter. In the summer, the shade reduces the heat load on the structure. In the winter, when the trees have no leaves, the sun helps create a solar load on the structure.
- Place latent-heat storage tubes containing phase-change materials where they can collect heat to be released at a later time, **Figure 33.113.**

Figure 33.112 An overhang may be constructed to allow the sun to shine into the house in the winter when it is lower in the sky and yet shade the window in the summer.

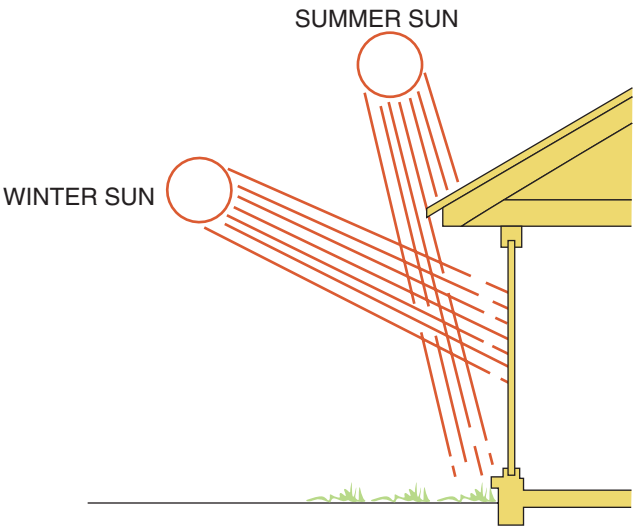


Figure 33.113 Latent-heat storage tubes may be placed in windows to store heat when the sun is shining.

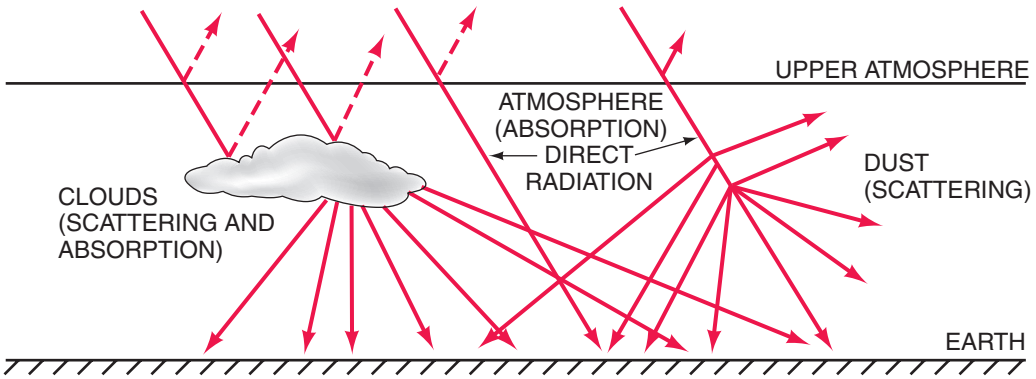
Figure 33.114 Radiation striking the earth directly from the sun is considered direct radiation. If it reaches the earth after it has been deflected by clouds or dust particles, it is called diffuse radiation.



The remainder of this unit is limited to a discussion of active solar systems. These systems use electrical or mechanical devices to help collect, store, and distribute the sun's energy. The distribution of this heat to the conditioned space is accomplished by means of the same type of equipment used in fossil-fuel furnaces.

DIRECT AND DIFFUSE RADIATION. Only a very small amount, about 0.000000045%, of the sun's energy reaches the earth. Much of the energy that does reach the earth's atmosphere is reflected into space or absorbed by moisture and pollutants before reaching the earth. The energy reaching the earth directly is direct radiation. The reflected or scattered energy is diffuse radiation, **Figure 33.114**.

SOLAR CONSTANT AND DECLINATION ANGLE. The rate of solar energy reaching the outer limits of the earth's atmosphere is the same at all times. It has been determined that the radiation from the sun at these outer limits produces 429 Btu/ft^2/h on a surface perpendicular to the direction of the sun's rays. This is known as the solar constant. The energy from the sun that has been received is often called insolation.

The earth revolves once each day around an axis that passes through the north and south poles. This axis is tilted 23.5°, so the intensity of the sun's energy reaching the northern and southern atmospheres varies as the earth orbits around the sun. This tilt or angle is called the declination angle and is responsible for differences during the year in the distribution of the intensity of the solar radiation, **Figure 33.115**.

The amount of radiation reaching the earth also varies according to the distance it travels through the atmosphere. The shortest distance occurs when the sun is perpendicular to a particular surface and is when the greatest energy reaches that section of the earth, **Figure 33.116**. The angle of the sun's rays with regard to a particular place on the earth plays an important part in the collection of the sun's energy.

Figure 33.115 The angle of declination (23.5°) tilts the earth so that the angle from the sun north of the equator is greater in the winter. The sun's rays are not as direct, and the normal temperatures are colder than during the summer.

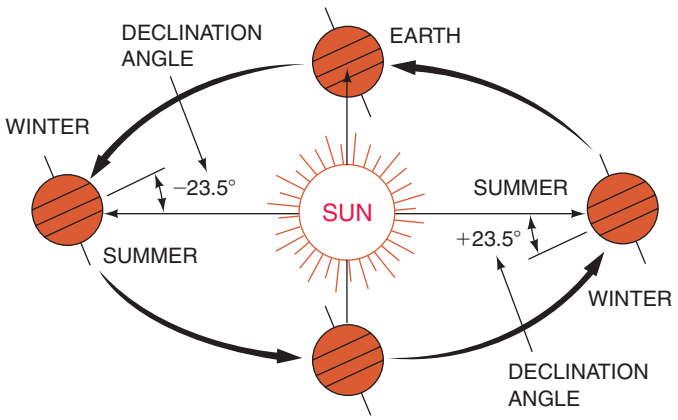


Figure 33.116 Radiation from the sun will be warmer at point 1, because that is the shortest distance it has traveled through the atmosphere.

ACTIVE SOLAR DESIGN

The systems discussed and illustrated in this unit are basic systems with a minimum of controls, check valves, pressure relief valves, and other safety protection. Manufacturers' instructions and local and state codes must be followed when installing this equipment. Active solar design utilizes collectors, storage systems, distribution devices such as pumps and fans, and control systems. These solar systems are used primarily for space heating, domestic hot water, and swimming pool heating.

LIQUID SOLAR FORCED-AIR SPACE-HEATING SYSTEMS. **Figure 33.117** illustrates a basic water drain-down liquid space-heating system, which also includes a domestic hot water tank. Drain-down systems are a type of system used in areas where water to and from and within the collectors would freeze if left in the system. When collectors are producing heat at a higher temperature than the storage water, circulator pump A moves water from storage to be heated and from the collectors back to storage. When the house thermostat calls for heat, circulator pump B moves water from storage to the heat exchanger in the furnace duct. The furnace blower moves air across the heat exchanger, warming the air, and distributes it to the house. Also shown is a domestic hot water tank heated through a heat exchanger in the water storage. When circulator pump A shuts down, the collector water will all drain to a heated area to keep from freezing in cold weather. Note that the pipe from the collector into the storage tank does not extend into the water. This provides venting and allows the collectors and piping to drain. If this space is not provided, other venting in the collector system is necessary.

An alternative design that is often preferred, particularly in colder climates, requires a closed-collector piping system using an antifreeze solution instead of water, **Figure 33.118**. The figure illustrates a closed liquid collection water storage system with air distribution to the house. The liquid in the collector system is an antifreeze and water solution. It is heated at the collectors and pumped through the coil at the heat exchanger and back to the collectors. This continues as long as the collectors are absorbing heat at a predetermined temperature.

When the room thermostat is calling for heat, three-way valve 1 allows the water to be circulated by pump B through the liquid-to-air heat exchanger and back to the liquid-to-liquid heat exchanger, where it absorbs more heat. If the room thermostat is not calling for heat, three-way valve 1 diverts the water to storage. If the storage temperature has reached a predetermined temperature, the collector solution is circulated through the purge coil through three-way valve 2. (The heat is dissipated into the air outside through this coil.) This is a necessary safety precaution because it is possible for the collector system to overheat and damage the equipment. Note that a liquid-to-liquid heat exchanger is used to heat the storage water. The collector antifreeze fluid must be kept separated from the storage water. This system is less efficient than the drain-down system, which does not require the extra heat exchanger.

In most areas, an auxiliary heating system is required to provide comfort heating at all times. A conventional hot air

Figure 33.117 Collectors use water as the liquid. This is a drain-down system because the water in the collectors would freeze on cold nights.

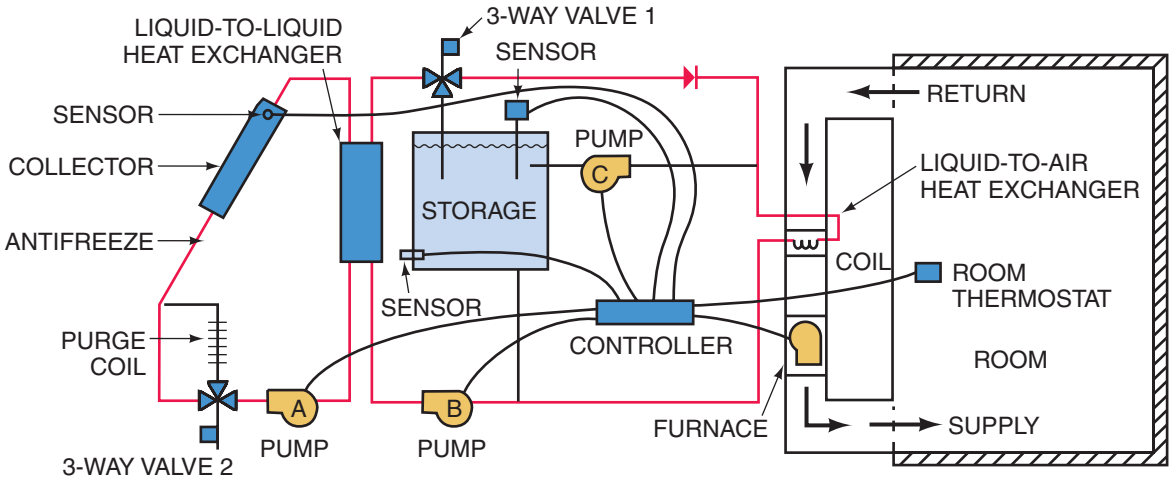
Figure 33.118 A closed liquid collection water storage system with air distribution to the house.



heating system can use the same ducts used for the solar system. In each system room thermostats may be used to provide steady, comfortable heat.

LIQUID COLLECTION/WATER STORAGE/AUXILIARY CONVENTIONAL HOT WATER BOILER. A liquid-based solar collector system may be paired with a hot water finned-tube convector heating furnace. The collector system can be of the same design as an air distribution system. It can be a drain-down water design or one that uses antifreeze in the collectors with a heat exchanger in the storage unit. Solar collector and storage temperatures may be lower than those produced by a hot water boiler. This can be compensated for—to some extent—by using more fin tubing than would be used with a conventional hot water system.

Figure 33.119(A) illustrates a design using a liquid-based solar collector with a hot water boiler system. This design uses the auxiliary boiler when the storage water is not hot enough. If the solar storage is hot enough, the boiler does not operate. Water is pumped from the storage tank and bypasses the boiler. It goes directly to the baseboard fin tubing. The three-way diverting valve automatically causes this boiler bypass. When auxiliary heat is called for, the two three-way diverting valves cause the water to bypass the storage. It would be very inefficient to pump heated water through the storage tank.

A system can be designed as two separate systems in parallel, as in **Figure 33.119(B)**. The separate systems can both be operated at the same time. With this design, the solar system can help the auxiliary system when the temperature of the storage water is below what would be satisfactory for it to operate alone. Sensors are used in either system to tell the controller when to start and stop the pumps and when to control the diverting valves.

SOLAR RADIANT HEAT

Figure 33.120 illustrates a water storage, radiant heating system with an auxiliary hot water boiler. Either water or an antifreeze solution is piped through a collector system and, in the case of an antifreeze solution, through a heat exchanger in the water storage. The heating coils may be embedded in concrete in the floor or in plaster in ceilings or walls. The normal surface temperature for floor heating is 85°F, and for wall or ceiling panels, 120°F.

Floor installations are most common. The coils are embedded in concrete below the surface. If a concrete slab on grade, it should be insulated underneath. In ceiling and wall applications, there should be coils for each room to be heated. When installations are on outside walls, they should be insulated very well between the coils and outside surfaces to prevent extreme heat loss. Radiant heating installed in the floor is very comfortable with little temperature variation from room to room. **Figure 33.121** illustrates a polybutylene pipe being installed in a floor. The pipe is tied to a wire mesh and propped on blocks to keep it near the top of the concrete slab; the concrete is poured around it, covering it anywhere from 1 to 4 in. depending on the system design. Polybutylene pipe is popular for this installation. There should be no joints in the pipe in the floor. Any joints necessary should be manifolded outside the slab. Almost any type of flooring material may be used over the slab—tile, wood, and carpeting. A controller is installed with sensors at the collectors, the water storage, and outdoors. It is also connected to the room thermostat. The controller modulates the temperature of the water being circulated in the floor according to the outside temperature and the room temperature.

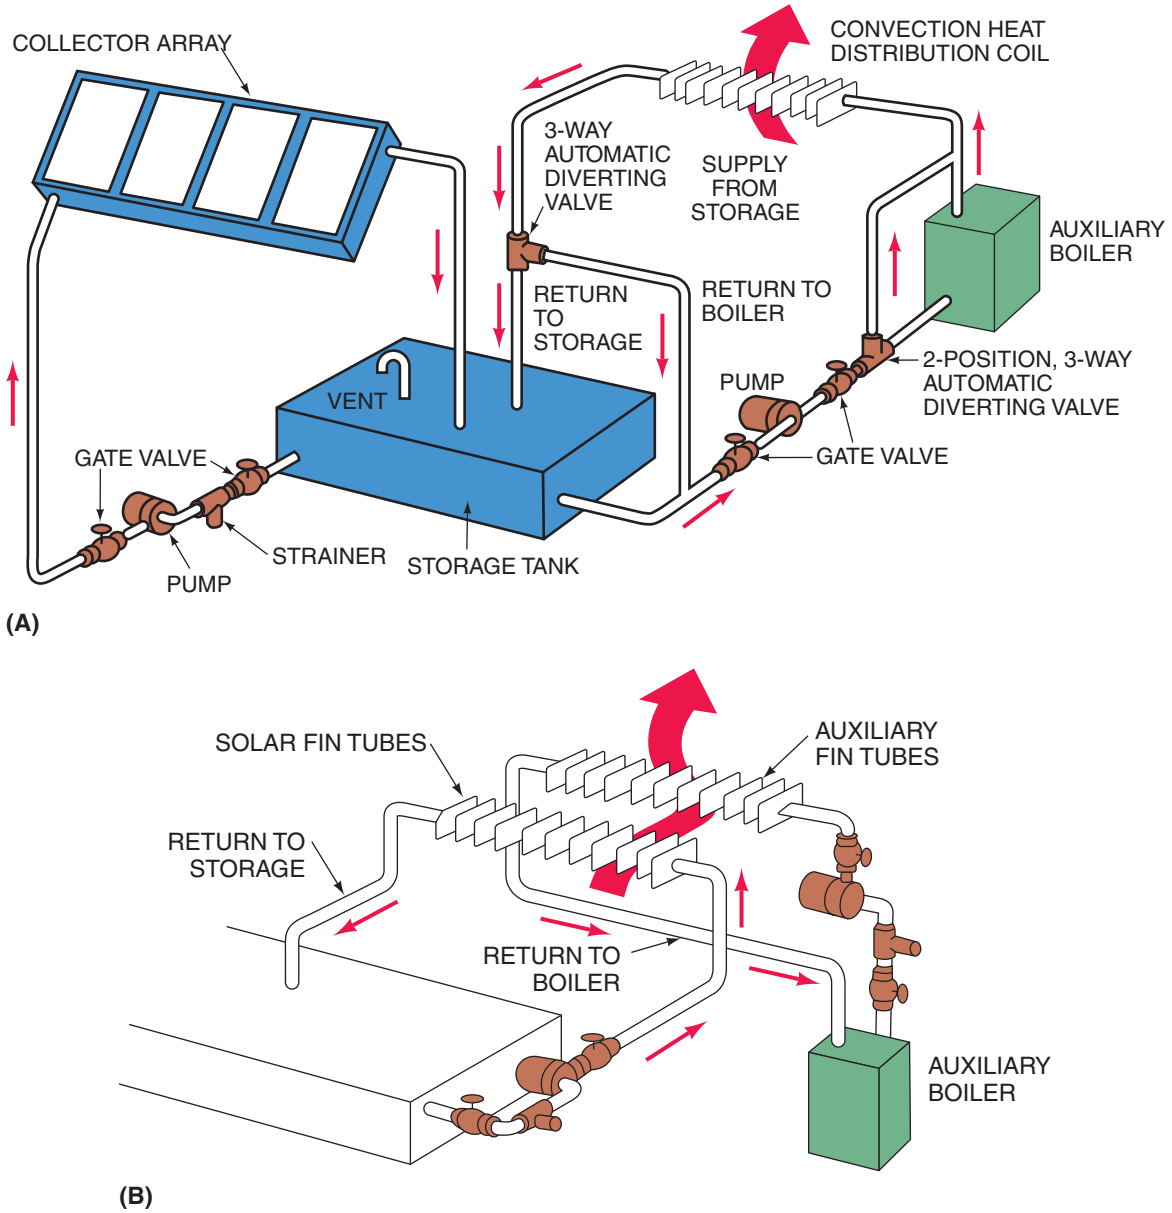
Figure 33.119 (A) A liquid-to-liquid solar space-heating system. (B) Both solar and auxiliary heat can be used at the same time.



SOLAR-HEATED DOMESTIC HOT WATER

Many solar systems are designed and installed specifically to heat or to assist in heating domestic hot water. These systems may use components similar to those used in space-heating systems, **Figure 33.122**. The heated collector water or antifreeze is pumped through the heat exchanger where it provides heat to the water in the tank. This tank must have conventional heating components also because the solar heating probably will not meet the demand at all times. If an antifreeze solution is used, the heat exchanger must have a double wall to prevent the toxic solution from mixing with the water used in the home or business, **Figure 33.123**. Many systems are designed to use a solar preheat or storage tank in conjunction with a conventional hot water tank. This gives additional solar-heated water to the system. Conventional heating (electric, gas, oil) will not have to be used as much with this extra storage, **Figure 33.124**.

SAFETY PRECAUTION: *Ethylene glycol may be used as an antifreeze if allowed by local or state codes. It is toxic and must be used only in a double-wall heat exchanger. Propylene glycol is a "food grade" antifreeze and is recommended for use in a domestic hot water system.*•

A space-heating system may include domestic hot water heating as well. This can be designed in several ways,

Figure 33.120 A solar space-heating radiant system. The radiant heating coils are normally embedded in a concrete floor.

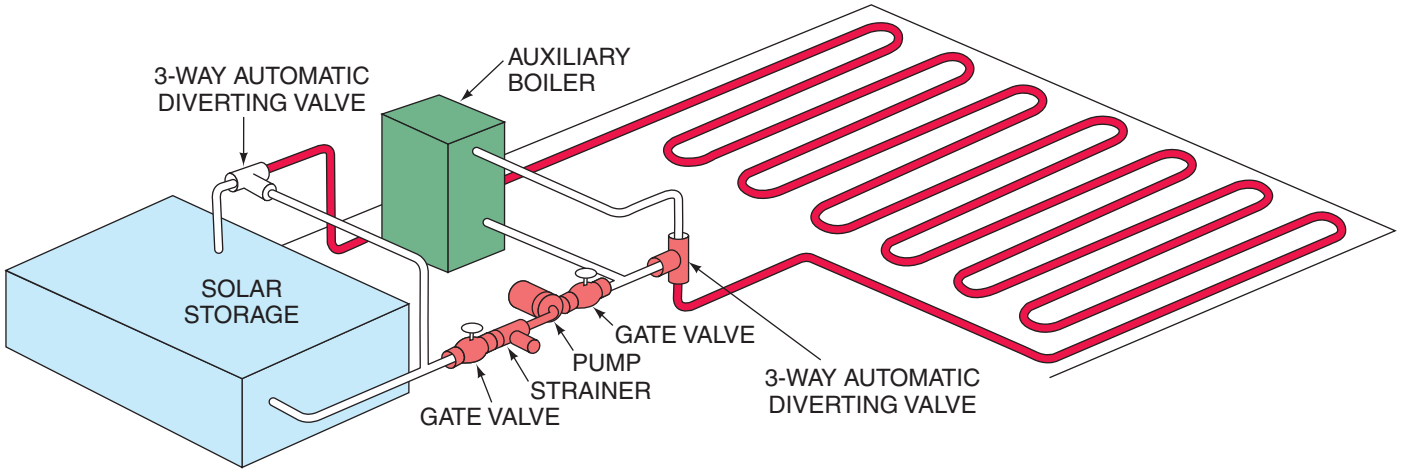

Figure 33.121 A polybutylene pipe being installed in a concrete slab to be used in a solar radiant heating system.

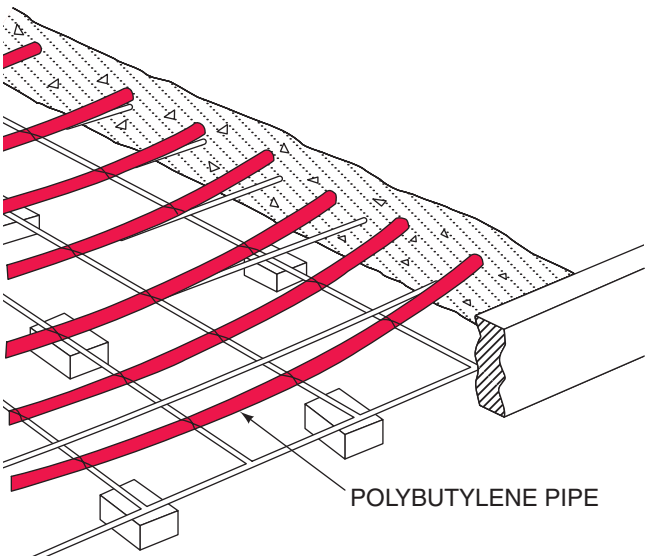

Figure 33.117. The cold makeup water is passed through the heat exchanger in the storage tank. It absorbs whatever heat is available before entering the hot water tank, thus reducing the amount of heat that must be supplied by conventional means.

LIQUID COLLECTOR DESIGN. Liquid solar collectors designed for space heating and domestic hot water systems are usually flat-plate collectors. As indicated earlier, a liquid (either water or an antifreeze solution) is passed through the collector in copper tubing, **Figure 33.125**. The liquid is heated as it passes through the collector. These collectors may use one or two panels of glass. The glass may vary in quality and design, but a low-iron tempered glass is often used. The absorber plate is usually made of copper and formed tightly around the copper tubing and/or may consist of fins welded to the tubing. These assemblies are painted black, using a paint designed for this purpose, to absorb the maximum heat from the sun.

SOLAR POOL HEATING

Many solar pool heating systems simply use the pump that circulates the pool water through the filter. The pool water is pumped through the filtering device(s) and then is diverted

HVAC GOLDEN RULES

When making a service call to a residence:

- Try to park your vehicle so that you do not block the customer's driveway.
- Look professional and be professional. Wear clean clothes and shoes. Wear coveralls for under-the-house work and remove them before entering the house.
- Check humidifiers, where applicable. Frequent service is highly recommended for health reasons.

Added Value to the Customer

Here are some simple, inexpensive procedures that may be added to the basic service call.

- Do not leave water leaks.
- Check the boiler for service needs; this may lead to more paying service work, depending on the type. Oil-heated boilers require the most extra work.
- Check for the correct water treatment.
- Lubricate all bearings on pumps and fans as needed.

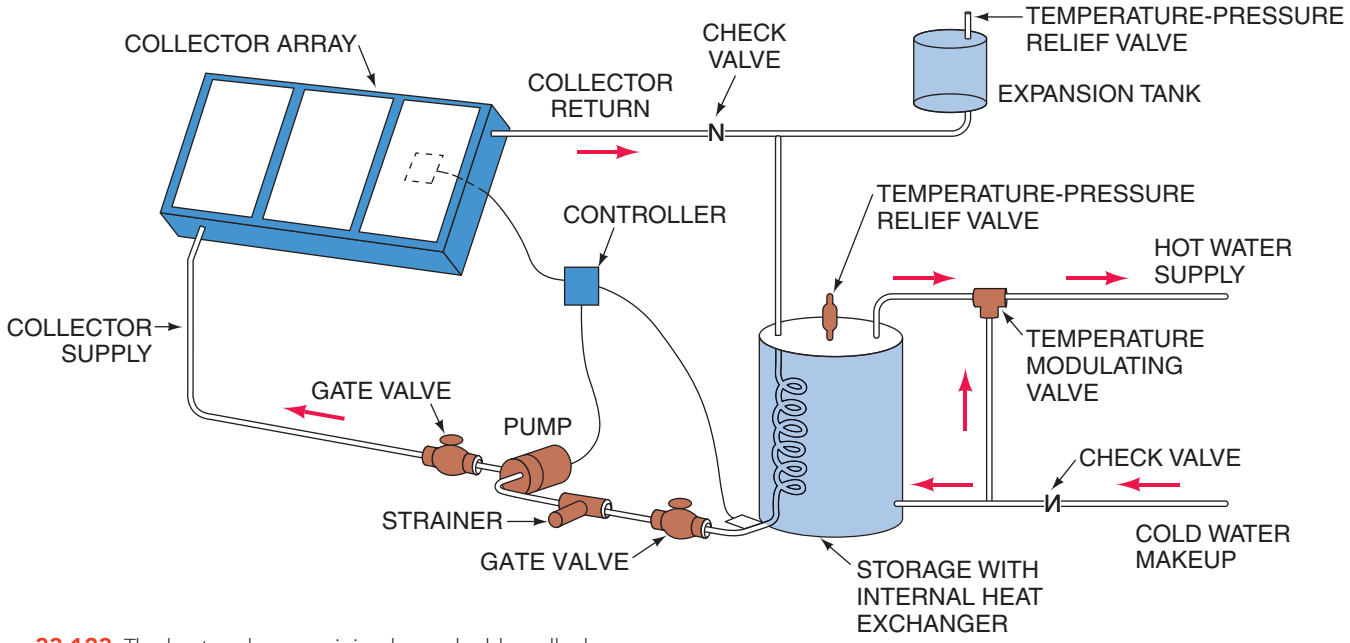

Figure 33.123 The heat exchanger piping has a double wall when an antifreeze solution is used in the collectors in a domestic hot water system.

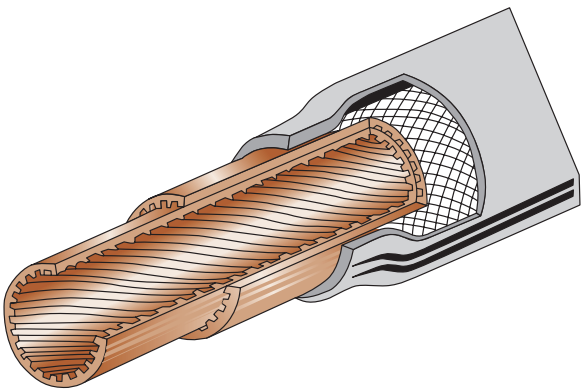

to the solar collectors, where it is heated. The water then flows back to the pool, **Figure 33.126**. This continuous flow of water through the collectors and back to the pool gradually heats the water. When the pool has reached the desired temperature level, the water bypasses the collectors and is returned directly to the pool from the filters.

Collectors for pool systems are often made of extruded plastic, **Figure 33.127**. A cross section of a collector produced by one manufacturer is shown in **Figure 33.128**. As this illustration shows, the collector receives diffuse radiation and direct radiation for optimum heating of the water passing through.

Figure 33.124 A solar preheat tank provides additional storage for a domestic hot water system.

PREVENTIVE MAINTENANCE

The air side of hydronic systems can be either natural draft or forced draft. If the system is natural draft, the convectors will be next to the floor and will be subjected to dust on the bottom side where the air enters. There are no filters on these natural-draft systems and consequently there is no filter maintenance. The coil becomes the filter, but the air moves so slowly that not much dust is picked up. The cover should be removed after several years and the coil vacuumed clean.

If the system is forced air, routine filter maintenance will be required, as described in Unit 30. Coils may become dirty after many years of good filter maintenance because all particles of dust are not filtered and some will deposit on the coil. When the coil becomes dirty, capacity will be reduced. Most coils are oversized and the capacity reduction may not be noticed for a long time.

Cleaning a coil is accomplished with approved liquid detergents mixed with water and applied to the coil. If the coil is in an equipment room, it may be cleaned in place. If the coil is in the attic or above a ceiling, it may have to be removed from the air handler for cleaning.

The fan blades may also have built-up dust deposits and need cleaning. The fan wheel may be cleaned in the fan if the motor is not in the way. This may be accomplished by scraping the dust buildup with a screwdriver blade and using a vacuum cleaner to remove it. If the fan wheel is very dirty, it may be best to remove the fan section and clean it outdoors. **NOTE:** *Do not allow water to enter the bearings or motor. Plastic bags may be used to protect them.* If the bearings get soaked, purge them with oil or grease to remove the water. If the motor gets wet, set it in the sun and use an ohmmeter to verify that the motor is not grounded. Setting the motor on an operating air-conditioning condensing unit fan outlet will quickly dry it as the warm, dry air passes over it.

The water side of a hydronic system requires some maintenance for the system to give long, trouble-free performance. Fresh water contains oxygen, which causes corrosion in the pipes. Corrosion is a form of rust. The proper procedure for starting up a hydronic system is to wash the system inside with an approved solution to remove any oils and construction debris. This may or may not have been performed on any system you may encounter. When the system is cleaned initially, it is supposed to be filled with fresh water and chemicals that will treat the initial charge of water for corrosion. Again, this may or may not have been done. If the system is several years old and no water treatment has been used, the system will surely need maintenance. It should be drained and flushed. Water treatment should be added when the system is filled with fresh water. Be sure to follow the water treatment company's instructions.

Systems with leaks have a continuous water makeup of fresh water, causing continuing corrosion because the fresh water contains oxygen. Water leaks must be repaired. It is common for water from leaks in coils to be carried away in drain lines and not be discovered. When a system has an automatic air bleed, air will not build up.

Water pumps must be maintained. They have lubrication ports for oil or grease. Keep the oil reservoir at the correct level on the pump with the correct oil. The motor will not have an oil reservoir but will require a certain amount of oil. Do not exceed the recommended amount.

When a motor has grease fittings, proper procedures must be used when applying grease. You cannot continue to pump grease into the bearings without some relief. The seal will rupture. **NOTE:** *Unscrew the relief fitting on the bottom of the bearing and allow grease to escape through the relief hole. Grease may be added until fresh grease is forced out the relief opening.*

Pumps also have couplings that should be inspected. **SAFETY PRECAUTION:** *Turn off the power and lock and tag the disconnect before removing the cover to the coupling.* Check the coupling for filings caused by wear that may be in the housing. Check for loose bolts and play in the coupling if it is rubber. Play in the coupling is natural for the spring type of coupling.

The electrical service should be checked if the pump has a contactor. **SAFETY PRECAUTION:** *Shut off the power and remove*

the cover to the contactor. Do not touch any electrical connections with meter leads until you have placed one voltmeter lead on a ground source—a conduit pipe will do—and touch the other meter lead to every electrical connection in the contactor box. The reason for this is that some pumps are interlocked electrically with other disconnects and there may be a circuit from another source in the box. Use all precautions.•

When you find burned contactor contacts, replace them; if you find frayed or burned wire, repair or otherwise correct the situation.

33.11 SERVICE TECHNICIAN CALLS

SERVICE CALL 1

A motel manager calls indicating that there is no heat at the motel. *The problem is on the top two floors of a four-story building. The system has just been started for the first time this season, and it has air in the circulating hot water. The automatic vent valves have rust and scale in them due to lack of water treatment and proper maintenance.*

Arriving at the motel, the technician asks at the front desk to speak with the manager. The technician introduces himself to the manager, who thanks the technician for arriving so promptly, and asks him about the problem with the heat. The manager brings the technician up-to-date and then shows him where the boiler room is located. The boiler is hot, so the heat source is working. The water pump is running because the technician can hear water circulating. The technician goes to the top floor to one of the room units and removes the cover; the coil is at room temperature. The technician listens closely to the coil and can hear nothing circulating. There may be air in the system, and the air vents, sometimes called bleed ports, must be located. The technician knows they must be at the high point in the system and normally would be on the top of the water risers from the basement.

The technician goes to the basement where the water lines start up through the building and finds a reference point. He then goes to the top floor and finds the top portions of these pipes. The pipes rise through the building next to the elevator shaft. The technician goes to the top floor to the approximate spot and finds a service panel in the hall ceiling. Using a ladder, he finds the automatic bleed port for the water supply over the panel. This is the pump discharge line. (See **Figure 33.34** for an example of an automatic air vent or bleed port.)

The technician removes the rubber line from the top of the automatic vent. The rubber line carries any water that bleeds to a drain. There is a valve stem in the automatic vent (as in an automobile tire). The technician presses the stem but nothing escapes. There is a hand valve under the automatic vent, so he closes the valve and removes the automatic vent. The technician then carefully opens the hand valve and air begins to flow out. Air is allowed to bleed out until water starts to run. The water is very dirty. **SAFETY PRECAUTION:** *Care should be used around hot water.*•

The technician then bleeds the return pipe in the same manner until all the air is out and water only is at the top of both pipes. The technician then goes to the heating coil where the cover was previously removed. The coil now has hot water circulating.

The technician takes the motel manager to the basement, drains some water from the system, and shows the manager the dirty water. The water should be clear or slightly colored with water treatment. The technician suggests that the manager call a water treatment company that specializes in boiler water treatment, telling him that the system will have some major troubles in the future.

The technician then replaces the two automatic vents with new ones and opens the hand valves so that they can operate correctly.

SERVICE CALL 2

A customer in a small building calls. *There is no heat in one section of the building although the system is heating well in most of the building. The building has four hot water circulating pumps, and one of them is locked up—the bearings are seized. These pumps are each 230 V, three-phase, and 2 hp.*

The technician consults the customer at the building. They go to the part of the building where there is no heat. The thermostat is calling for heat. They go to the basement where the boiler and pumps are located. They can tell from examination that the number 3 pump, which serves the part of the building that is cool, is not turning. The technician carefully touches the pump motor; it is cool and has not been trying to run. Either the motor or the pump has problems.

The technician chooses to check the voltage to the motor first. He goes to the disconnect switch on the wall and measures 230 V across phases 1 to 2, 2 to 3, and 1 to 3. This is a 230-V three-phase motor with a motor starter. The motor overload protection is in the starter, and it is tripped.

The technician still does not know whether the motor or the pump is the problem. All three windings have equal resistance, and there is no ground circuit in the motor. He turns the power on, clamps an ammeter on one of the motor leads, and presses the overload reset. The technician can hear the motor try to start, and it is pulling locked-rotor current. He pulls the disconnect to stop the power from continuing to the motor. It is evident that either the pump or the motor is stuck.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The technician turns off the power, locks it out, and then returns to the pump. It is on the floor next to the others. Removing the guard over the pump shaft coupling, the technician tries to turn the pump over by hand—remember, the power is off. The pump is very hard to turn. The question now is whether it is the pump or the motor that is tight.

The technician disassembles the pump coupling and tries to turn the motor by hand. It is free. The technician then tries the pump; it is too tight. The pump bearings must be defective. The technician gets permission from the owner to disassemble the pump. He shuts off the valves at the pump inlet and outlet, removes the bolts around the pump housing, and then removes the impeller and housing from the main pump body. The technician takes the pump impeller housing and bearings to the shop and replaces them, installs a new shaft seal, and returns to the job.

While the technician is assembling the pump, the customer asks why the whole pump was not taken instead of just the impeller and housing assembly. The technician shows the customer where the pump housing is fastened to the floor with bolts and dowel pins. The relationship of the pump shaft and motor shaft has been maintained by not removing the entire pump, so they will not have to be realigned after they are reassembled. The pump is manufactured to be rebuilt in place to avoid this.

After completing the pump assembly, the technician turns it over by hand, assembles the pump coupling, and affirms that all fasteners are right. Then the pump is started. It runs and the amperage is normal. The technician turns off the power, locks it out, and assembles the pump coupling guard. The power is turned on and the technician leaves.

SERVICE CALL 3

An apartment house manager reports that *there is no heat in one of the apartments. This apartment house has 25 fan coil units with a zone control valve on each and a central boiler. One of the zone control valves is defective.*

The technician checks in with the property manager on arrival. The manager informs the technician about the one apartment with no heat and that there have been no other complaints from the other occupants regarding a lack of heat. Since the occupant is not home, the technician is brought up to the apartment by one of the building's service personnel. Once in the apartment, the technician notices that the room thermostat is set above the room temperature. The technician goes to the fan coil unit located in the hallway ceiling and opens the fan coil compartment door, which drops down on hinges. Standing on a short ladder to reach the controls, the technician finds there is no heat in the coil and there is no water flowing.

This unit has a zone control valve with a small heat motor. The technician checks for power to the valve's coil; it has 24 V, as it should. (See **Figure 33.42** for an example of this type of valve.) This valve has a manual open feature, so he opens the valve by hand. The technician can hear the water start to flow and can feel the coil get hot. The valve heat motor or valve assembly must be changed. The technician chooses to change the assembly because the valve and its valve seat are old.

The technician obtains a valve assembly from the stock of parts at the apartment and proceeds to change it. *The technician shuts off the power and the water to the valve and water coil. He then spreads a plastic drop cloth to catch any water that may fall and places a bucket under the valve before removing the assembly.* The old valve is removed and the new valve installed. The electrical connections are made, and the system valves are opened, allowing water back into the coil.

When the technician turns on the power he can see the valve begin to move after a few seconds (this is a heat motor valve, and it responds slowly). The technician can now feel heat in the coil. He closes the compartment door, removes the plastic drop cloth, sets the room thermostat, and leaves the apartment for the manager's office. The technician discusses the repair with the manager, completes his paperwork, gets his work order signed, and leaves for his next job.

Solutions for the following service calls are not provided here. Please discuss the solutions with your instructor.

SERVICE CALL 4

A customer calls and indicates that *one of the pumps beside the boiler is making a noise*. This is a large home with three pumps, one for each zone.

The technician arrives, goes to the basement, hears the coupling, and notices there are metal filings around the pump shaft.

What is the problem and the recommended solution?

SERVICE CALL 5

A homeowner calls and states that *there is water on the floor around the boiler in the basement. The relief valve is relieving water.*

The technician goes to the basement and sees the boiler relief valve seeping. The boiler gauge reads 30 psig, which is the rating of the relief valve. The system normally operates at 20 psig. The technician looks at the flame in the burner section and sees the burner burning at a low fire. A voltmeter check shows there is no voltage to the gas valve operating coil.

What is the problem and the recommended solution?

SUMMARY

- Hydronic heating systems use hot water or steam to carry heat to the areas to be heated.
- A boiler is an appliance that heats water. In gas and oil systems, the part of the boiler containing the water is constructed in sections or tubes.
- Cast-iron and steel boilers are classified as high-mass boilers.
- Copper-tube boilers are classified as low-mass boilers.
- A limit control is used to shut the heat source off if the water temperature gets too high.
- A low-water cutoff shuts down the heat source if the water level gets too low.
- A pressure relief valve is required to discharge water when excessive pressure is created by expansion due to overheating.
- An air cushion tank or expansion tank is necessary to provide space for trapped air and to allow for expansion of the heated water.
- Zone control valves are thermostatically operated and control the flow of hot water into individual zones.
- A centrifugal pump circulates the water through the system.
- The "point of no pressure change" is the point in a hydronic system where the water pressure does not change; it is located at the inlet of the expansion tank.
- Finned-tube baseboard terminal units are commonly used in residential hydronic heating systems.
- A balancing valve is used to equalize the flow rate in different heating circuits.
- Outdoor reset control is used to change the temperature of the boiler water in response to changes in the outside ambient temperature.
- The series loop system is the most economical hydronic system to install but does not allow for individual terminal-unit temperature control.
- One-pipe systems and two-pipe reverse-return piping systems are most commonly used in residential and light commercial installations.
- A one-pipe system requires a specially designed tee to divert some water to the baseboard unit while allowing the rest to flow through the main pipe.
- Primary–secondary pumping allows for multiple-temperature operation for multizone systems.
- Mixing valves are used to achieve different water temperatures at different points in a hydronic system.
- Radiant heating systems use lower water temperatures to provide heating.
- Popular radiant heating system installation types include slab on grade, thin slab, and dry/staple-up.
- Tankless domestic hot water heaters are commonly used with hot water heating systems. The water is contained within a coil and heated by the boiler.
- Hydronic systems should be serviced with proper preventive maintenance procedures annually.
- Liquid solar forced-air space-heating systems may be the drain-down or closed-collector piping system type.
- Liquid solar space-heating systems may be combined with many types of conventional heating systems.
- Solar heating may be used to heat domestic hot water.
- Swimming pools may be heated with solar heating systems.

REVIEW QUESTIONS

1. A hydronic heating system uses _____ to move heat around in the system.
2. Describe a *zone* in a hydronic heating system.
3. Name four sources of heat commonly used for hydronic heating systems.
4. Give three reasons that air is detrimental to a hydronic heating system.
5. Explain the difference between a wet-base and a dry-base boiler.
6. Where is air vented from a hydronic heating system?
7. The "point of no pressure change" is located at the
   A. outlet of the circulator pump.
   B. inlet of the expansion tank.
   C. inlet of the pressure-reducing valve.
   D. outlet of the pressure relief valve.
8. The purpose of a limit control in a boiler is to
   A. vent the air.
   B. cycle the boiler on and off to maintain the desired water temperature in the boiler.
   C. shut the boiler off before it freezes.
   D. fill the system with water.
9. The device that relieves the pressure in a boiler when it is above the design working pressure is the _____ valve.
10. Describe the function of a low-water cutoff.
11. The relief valve setting for a typical low-pressure boiler is _____ psig.
12. Describe how an air cushion tank functions in a hydronic heating system.
13. True or False: City water does not contain air.

14. State two ways that air can get into a hydronic heating system.
15. The most common type of pump used for hydronic heating systems is the
    A. reciprocating.
    B. pulsating.
    C. scroll.
    D. centrifugal.
16. Another term for pump pressure is feet of _____.
17. Two types of zone control valves are the _____and the _____.
18. Why must expansion be considered when sizing finned-tube radiation?
19. How is expansion in hot water pipes handled?
20. Sketch the following systems: one pipe, two-pipe direct return, and two-pipe reverse return.
21. Describe the advantage of a two-pipe reverse-return system.
22. The pressure differential bypass valve is most likely found on systems equipped with
    A. two-port zone valves.
    B. diverter tees.
    C. three-port zone valves.
    D. manually adjustable mixing valves.
23. What is the heat output, in Btu/h, of a terminal unit with a ΔT of 10°F and a water flow rate of 5 gpm?
24. In a primary–secondary pumping arrangement, the largest circulator pump will be located
    A. in the primary loop.
    B. in the zone with the largest terminal unit.
    C. in the zone with the smallest terminal unit.
    D. anywhere in the system because all of the pumps are the same size.
25. The temperature of the water at the outlet of a three-way mixing valve will most likely be
    A. equal to the temperature of the water at the hot water inlet.
    B. lower than the temperature of the water at the cold water inlet.
    C. higher than the temperature of the water at the hot water inlet.
    D. higher than the temperature of the water at the cold water inlet.
26. A tankless water-heating system gets its heat from the system's _____.
27. How much of the sun's energy actually reaches the earth?
    A. 100%
    B. 25%
    C. 10%
    D. Much less than 1%
28. The varying intensity of the sun's energy that reaches the earth is due in part to the
    A. solar constant.
    B. declination angle.
    C. lunar constant.
    D. solar design strategy.
29. Drain-down systems would best be used in which geographic area?
    A. Colder climates
    B. Warmer climates
    C. Climates with very low humidity
    D. Climates with very high humidity
30. Why are solar systems intended to be used as a supplementary heat source?
    A. Because they are more expensive to operate than conventional systems
    B. Because the amount of heat generated by solar systems varies depending on a number of environmental factors
    C. Both A and B are correct
    D. Neither A nor B is correct

UNIT 34

INDOOR AIR QUALITY

OBJECTIVES

After studying this unit, you should be able to

- list various sources of indoor air pollution.
- explain procedures for eliminating contamination sources.
- describe how molds reproduce.
- discuss ventilation as it applies to indoor air quality.
- state two substances needed for mold to grow.
- describe the importance of air cleaning.
- describe the operation of electrostatic precipitators or electronic air cleaners.
- describe the operation of bi-polar ionization and polarized filtration.
- describe the operation of ultraviolet (UV) light as used for air cleaning.
- discuss reasons for cleaning air ducts.
- explain relative humidity.
- state reasons for providing humidification in winter months.
- describe various types of humidifiers.
- state reasons for installing self-contained humidifiers.
- list general factors used when sizing humidifiers.

SAFETYCHECKLIST

- ☑ Do not disturb materials containing asbestos.
- ☑ Use all electrical safety precautions when servicing or troubleshooting electrical or electronic circuits. Use common sense.
- ☑ When replacing or servicing line-voltage components, ensure that power is off, that the panel is locked and tagged, and that you have the only key.
- ☑ Handle ultraviolet (UV) lights carefully as they contain mercury.
- ☑ Dispose of non-working ultraviolet light bulbs in accordance with the manufacturer's guidelines as well as any local disposal laws.
- ☑ Do not look directly at energized ultraviolet lights.

34.1 INTRODUCTION

Scientific evidence suggests that the air in homes and other buildings is becoming increasingly polluted. In many cases, evidence indicates that indoor air is much more polluted than the outdoor air. Since many people spend as much as 90% of their time indoors, the chance of being exposed to poor quality air for extended periods of time is great. Certain groups of people, such as the young, elderly, and chronically ill, typically spend much more time indoors than other groups and are, therefore, more susceptible to the effects of indoor air pollution. These people face a serious risk from the cumulative effects of this indoor air pollution. ASHRAE Standard 62.1–2013, "Ventilation for Acceptable Indoor Air Quality," is the standard generally used by engineers and technicians in this industry to determine acceptable indoor air quality.

34.2 SOURCES OF INDOOR AIR POLLUTION

Some potential sources of indoor air pollution include:

Adhesives
Air freshener
Asbestos floor tiles
Asbestos pipe wrap
Car exhaust
Carbon monoxide
Carpets
Cleaning supplies
Drapes
Dry-cleaned goods
Fireplaces
Hobby supplies
House dust mites
Household chemicals
Humidifiers
Lead-based paints
Moisture
Mold
Personal care products
Moth repellents
Paneling
Paint supplies
Pesticides
Pet waste
Pet dander and hair
Pet products
Pressed wood furniture
Pressed wood subflooring
Pressed wood cabinets
Tobacco smoke
Radon
Stored fuels
Unvented gas stoves
Unvented clothes drier
Wood stoves

Figure 34.1 illustrates some sources and causes of indoor pollution. In older homes, outdoor air may enter through openings, joints, and spaces around windows and doors. Most modern homes and office buildings, however, are designed and constructed more tightly to help keep the outside air out in order to maximize the efficiency of heating and cooling systems. This may result in an accumulation of pollution inside. To offset the negative effects of tight construction, *mechanical ventilation* may be required.

Inadequate ventilation can increase the effects of indoor air pollution. Outdoor air in sufficient quantities must be brought

inside to mix with and dilute the pollutant emissions, and the indoor air must be exhausted to the outside to carry out pollutants. Without this ventilation, the pollutants may accumulate to the point where they can cause health and comfort problems. Mechanical ventilation can include exhaust fans in a single room, such as in a bathroom or kitchen, or an air-handling system to intermittently or continuously remove indoor air and replace it with filtered and often conditioned air from outside. Results of inadequate ventilation may include moisture condensation on windows or walls, smelly or stuffy air, dirty central heating and cooling equipment, and areas in which books, shoes, or other items become moldy. In addition to providing adequate

ventilation, other methods can be used to control indoor air contamination. These methods include eliminating the source of the contamination and providing a means for cleaning the air.

34.3 COMMON POLLUTANTS

The following is a description of some of the more common pollutants.

RADON

Radon is a colorless, odorless, and radioactive gas. The main health risk of breathing air polluted with radon is lung cancer. Consuming water that is contaminated with high radon levels may also cause health risks, but these risks are believed to be much lower than breathing air that contains radon gas. The most common source of radon is uranium in the soil or rock on which homes are built. As uranium breaks down, it releases radon gas, which can enter buildings through cracks in concrete floors and walls, floor drains, and sumps. The presence of some types of radon contamination can be identified by using a home radon test kit. Testing equipment should be approved by the Environmental Protection Agency (EPA) or be state certified. The test kit comes with detailed instructions on how to perform the test and, once completed, the test canister is sent to a laboratory for analysis. If the radon level, whether in the air or water, is determined to be above the acceptable limits, corrective action should be taken to eliminate the source. Procedures should be carried out by contractors or individuals who have satisfactorily completed the EPA Radon Contractor Proficiency Test or who are otherwise certified to perform this type of remediation.

ENVIRONMENTAL TOBACCO SMOKE

Environmental tobacco smoke (ETS) is the mixture of smoke that comes from the burning end of a cigarette, pipe, or cigar and from smoke exhaled by the smoker. It consists of more than 4000 compounds, more than 40 of which are known to cause cancer in humans or animals and many of which are strong irritants. ETS is often referred to as "secondhand smoke." To reduce exposure to environmental tobacco smoke, smoking should not be permitted indoors. Separating smokers and nonsmokers in different rooms in the same house will do very little to eliminate exposure to ETS.

BIOLOGICAL CONTAMINANTS

There are many sources of *biological contaminants*. Central air-handling systems can grow mold, mildew, and other contaminants. Viruses can be transmitted by people and animals. Dust mites, a source of biological allergens, can be found in carpeting, bedding, and other fabrics. Many allergens can become airborne under certain conditions. Water-damaged materials and wet surfaces provide opportunities for molds, mildew, and bacteria to grow.

Dust mites *(Dermatophagoides farinae)* are microscopic spiderlike insects usually found indoors. In warm, humid conditions they thrive and produce waste pellets. Their bodies disintegrate when they die, producing very small particulates that mix with household dust. These dust mites and their remains are often thought to be a primary irritant to people sensitive to dust irritants. Carpeting should be vacuumed often, but vacuum cleaners have the potential to stir up the dust in the carpeting and often raise dust levels in the air. Vacuum cleaners with high-efficiency particulate arrestor (HEPA) filters or central vacuuming systems that discharge air outside the building can be used to help control this dust. Replacing carpeting with hard surface floors is helpful in many instances, but some manufactured flooring materials contribute negatively to the quality of indoor air. Smaller area rugs can be used if cleaned regularly. Bedding should be washed often with hot water. Mattresses and pillows can be covered with plastic in order to more easily remove the dust.

Molds are simple organisms commonly present both outdoors and indoors. Molds found outside the house break down many organic substances necessary to plant, animal, and human life. Mold, a fungus, releases spores into the air. Many of the spores found indoors come from outside. However, quantities of mold growing indoors can produce many spores that are harmful to humans. Mold is usually found in areas where there is high humidity. **Figure 34.2** shows one kind of mold as seen under a microscope. Estimates indicate that there may be over 100,000 different types of mold.

To grow, molds need moisture and food, which includes paper, textiles, dirt, leaves, drywall, or wood. The molds digest this material and gradually destroy it. As long as there is moisture and food, mold will not go away. **Figures 34.3(A)** and **(B)** show examples of extreme cases of indoor mold. Molds can grow on the surface of damp inorganic matter such as glass and concrete when there is a thin, invisible layer of organic material that acts as food for the mold. Left unchecked, mold can continue to grow and cause health problems for those who are sensitive to mold as well as those who suffer from breathing disorders such as chronic obstructive

(B)

pulmonary disease (COPD) or asthma. Mold can usually be seen, or it may be smelled. It has a musty odor. It may grow in wall cavities, above ceilings, under carpets, and behind wallpaper. Because air-conditioning and heating systems are responsible for controlling humidity inside structures, the technicians in the HVAC/R field, who work with these systems, should be able to recognize mold. There are many different types, each with its unique look and description. A moisture meter may be used to help detect moisture, **Figure 34.4**.

Figure 34.4 A digital moisture meter. This meter has a pointed probe that can be inserted into carpet or wood to measure the moisture level.

Courtesy Aerotech Laboratories, Inc., 800.651.4802. www.aerotechpk.com

Molds consist of multicelled filaments called hyphae. These filaments can unite to form balls or mats and may penetrate the food material, making removal and cleanup difficult. Molds reproduce through the production of spores. Spores are released into the air after they are produced and dry out. They move with the air currents, land, germinate, and grow. Spores can survive for long periods of time in both hot and cold environments. They require only moisture and food to germinate and grow. Spores contain allergens, which are substances that have the potential to cause allergic reactions in humans. Individuals may ingest, inhale, or be exposed to spores through skin contact. Individuals may experience a temporary effect from this exposure or, in some cases, the effects can be long-lasting.

Molds can produce a variety of health problems for humans. The severity of the problems are determined, in part, by the type and quantity of the mold as well as the sensitivity of the individual. Molds produce volatile organic compounds (VOCs). Exposure to a large quantity of these VOCs can irritate mucous membranes and produce headaches, inability to concentrate, and dizziness. Some molds may have the potential to produce *mycotoxins*. As the name implies, these molds may be toxic to humans.

Sick building syndrome (SBS) is a term given to situations when people who spend considerable time in a particular building experience health problems. These illnesses may be caused by poor ventilation or biological contaminants such as molds or bacteria. Mold in buildings has become a significant issue in the United States. The United States Toxic Mold Safety and Protection Act of 2005 is a bill that was intended to protect home buyers and consumers from moving into mold-infested homes and to provide legal protection to home buyers and renters who are exposed to dangerous levels of indoor mold. This bill was expected to establish national standards, including insurance provisions, health benefits, and education programs, but it never passed and failed to become the law of the land. However, some states have passed their own legislation to protect individuals from the dangers of indoor air pollution. Some examples of this include the Mold Remediation Registration Act in Illinois and the Mold Safe Housing Act in New Jersey. Check with your local government for more information about IAQ laws and guidelines in your state.

Mold has many legal ramifications. Contractors can be sued. Insurance companies may or may not cover expenses and liability costs when presented with claims involving mold. Some sources suggest that HVAC/R and other contractors should obtain legal advice to determine their liability and that contractors should meet with their insurance representatives to ensure they have adequate coverage. To help minimize liability, it is important that HVAC/R service technicians receive approved mold-related training. This training will help enable the technician to identify potential problem areas before they become full-blown mold conditions.

MOLD REMEDIATION

The following general recommendations regarding mold remediation relate primarily to small areas of mold growth. Larger areas should be cleaned and/or materials should be removed and disposed of by contractors certified to do so.

Mold contamination is classified by levels, which are determined by the square footage of contamination. These levels are:

- Level I: contamination areas of less than 10 square feet
- Level II: contamination areas from 10 to 30 square feet
- Level III: contamination areas from 30 to 100 square feet
- Level IV: contamination areas over 100 square feet

For Level I and II mold contamination, maintenance staff members are permitted to perform the cleanup as long as they are properly trained under the Occupational Safety and Health Administration's (OSHA) Hazard Communication Standard. For Level III contamination, those performing the remediation should be trained to handle hazardous materials and should be outfitted with a respirator, gloves, and eye protection. Level IV remediators must also receive hazardous materials training. Level IV mold remediation requires the use of a full-face HEPA filter respirator and the wearing of disposable clothing that covers all parts of the body.

SAFETY PRECAUTION: *Technicians involved with removing mold should wear outer clothing designed for this purpose, including gloves, hat, and respirator or an approved alternative.*•

Removing the source of the moisture should be the first step in mold cleanup, and it should be done quickly. All leaks should be repaired, and all damp areas should be thoroughly dried and cleaned up. The humidity level may need to be decreased. Because molds can often penetrate the surfaces they are feeding on, merely cleaning the surface may not be enough. Using a household bleach or other chemicals available for that purpose may be helpful in eradicating mold growing on hard surfaces. Carpets with mold growing within the fabric or underneath should be removed, professionally cleaned, and dried. The floor beneath the carpet must be cleaned, ensuring that all mold is removed, and any moisture problems must be resolved. Wood, wallboard, or wallpaper that has been heavily contaminated with mold may need to be discarded. This should be done by contractors and technicians certified to do so. Dead molds can still cause problems to human health, so complete removal is necessary.

Air-conditioning (cooling) equipment should not be oversized. Sometimes when a house is being constructed, owners want the equipment to be oversized because they are planning on extending the house at some point in the future. However, oversized air-conditioning equipment may not run long enough to sufficiently dehumidify the space. When oversized equipment satisfies the cooling requirement, the unit shuts down, and the evaporator coil warms up. A warm evaporator coil cannot remove moisture from the air passing through it, as the coil will be at a temperature that is higher than the dew point temperature of the air stream. If this is the case, separate dehumidifiers may be needed. (Refer to Unit 42 for more on the importance of properly sized heating and cooling equipment.) In addition, the ground around the foundation should slope away from the building to ensure that water does not collect around or under the house.

Air-conditioning condensate pans and drain lines should be cleaned regularly. This will help ensure that the condensate will drain from the equipment properly. Humidification equipment should also be cleaned regularly. If mold is or has been present within a house, the HVAC/R duct system may need to be inspected. If mold is found in the ducts, they should be cleaned or replaced by qualified technicians. Clothes driers and stoves should be vented to the outside. Exhaust fans should be used and vented to the outside when bathing or showering, when cooking, or when running the dishwasher. An architect or engineer may be consulted to determine whether whole-house ventilation is needed.

POLLUTANTS FROM COMBUSTION PRODUCTS

Wood-burning or gas stoves and fireplaces, and unvented kerosene and gas space heaters may be the source of pollutants from combustion products. The pollutants released may be carbon monoxide, nitrogen dioxide, sulfur dioxide, and solid particulate matter suspended in the air. The combustion gases may come from improperly sealed stove doors, from chimneys and flues that are improperly installed or maintained, or from cracked heat exchangers. The combustion process also produces water vapor. Although not a pollutant in itself, water vapor can result in high humidity and wet surfaces. This can encourage the growth of biological pollutants such as those mentioned previously.

Carbon monoxide (CO) is a very poisonous, lighter-than-air gas. It is produced by incomplete combustion in oil or gas-fired appliances. Incomplete combustion may be a result of the lack of oxygen or the incomplete mixing of oxygen and fuel. Excess combustion air or an insufficient fuel supply can also result in the production of CO. When a flame temperature is lower than 1128°F, CO will be produced. CO combines with hemoglobin in the bloodstream, gradually replacing the oxygen. Its concentration is cumulative to the point that, when there is too little oxygen in the bloodstream, life will no longer be supported. Carbon monoxide especially affects fetuses, infants, and people with anemia or a history of heart disease. Low levels of exposure can cause fatigue and increased chest pain in people with chronic heart disease. Higher exposure levels may cause headaches, dizziness, and weakness in healthy people as well as sleepiness, nausea, vomiting, confusion, disorientation, loss of consciousness, and possibly death.

CO is very dangerous because it is colorless, odorless, tasteless, and nonirritating. It can only be measured with a testing device, **Figure 34.5**. However, alarms can be purchased that, if properly installed, will respond when CO levels become dangerous. CO detectors are presently required to "alarm" at CO levels set by the Underwriters Laboratory (UL Standard

Figure 34.5 A testing device that will measure ppm of carbon monoxide.

Courtesy Bacharach, Inc., Bacharach Institute of Technical Training

Figure 34.6 This chart indicates carbon monoxide concentrations and symptoms that may develop.

CO CONCENTRATIONS & SYMPTOMS DEVELOPED	
Concentrations of CO in the air	Inhalation time and toxic symptoms developed.
9 ppm (0.0009%)	The maximum allowable concentration for short-term exposure in a living area, according to ASHRAE.
50 ppm (0.0050%)	The maximum allowable concentration for continuous exposure in any 8-hour period, according to federal law.
200 ppm (0.02%)	Slight headache, tiredness, dizziness, and nausea after 2–3 hours.
400 ppm (0.04%)	Frontal headaches within 1–2 hours, life-threatening after 3 hours, also maximum parts per million in flue gas (on an air-free basis), according to EPA and AGA.
800 ppm (0.08%)	Dizziness, nausea, and convulsions within 45 minutes. Unconsciousness within 2 hours. Death within 2–3 hours.
1,600 ppm (0.16%)	Headache, dizziness, and nausea within 20 minutes. Death within 1 hour.
3,200 ppm (0.32%)	Headache, dizziness, and nausea within 5–10 minutes. Death within 30 minutes.
6,400 ppm (0.64%)	Headache, dizziness, and nausea within 1–2 minutes. Death within 10–15 minutes.
12,800 ppm (1.28%)	Death within 1–3 minutes.

Courtesy Bacharach, Inc., Bacharach Institute of Technical Training

2034). However, those who are sick or prone to illness, including infants and the aged, should use detectors that are designed to alarm at lower levels of carbon monoxide. Typically, lower-priced detectors initiate an alarm at higher levels of CO. Carbon monoxide in the ambient air is measured by the number of CO molecules present in a million molecules of air, referred to as parts per million (ppm). See **Figure 34.6** for concentrations and the symptoms they develop. Carbon monoxide monitors or alarms should be installed in all areas of a building where a combustion process is being used and in other parts of a building where CO may collect.

Auto exhaust is considered to be the leading cause of carbon monoxide alarm responses. When individuals let their cars warm up or otherwise let them run in a garage that is attached to or below the house, the CO may become trapped and infiltrate the living areas of the house, producing a dangerous condition and setting off the alarm. Unvented, poorly installed, and improperly maintained oil and gas appliances account for a large percentage of CO alarms.

Another frequent cause of CO alarms is the backdrafting of natural-draft combustion appliances. These backdrafts may be caused by blockages in the vent, or by pressure differences. As the exhaust systems in the bathrooms, kitchen, attic, and other areas of the house exhaust air from the structure, the house will have a net negative pressure with respect to the outside air. This tends to push vented air back into the house. **Figure 34.7** shows air being exhausted from within the house and other air returning through the venting or chimneys to make up for the exhausted air. This backdrafting air may contain carbon monoxide. Combustion appliances must be properly installed and adjusted, and a proper supply of fresh air, that includes oxygen, must be available. In all vented appliances a proper flue passageway must be available to vent the flue gases to the atmosphere.

The other pollutants released from combustion appliances include **nitrogen dioxide**, which causes irritation of the respiratory tract and can cause shortness of breath, **sulfur dioxide**, which can cause eye, nose, and respiratory tract irritation and breathing problems, and *particles from combustion*. These particles are suspended in the air and can cause eye, nose, throat, and lung irritation. Certain chemicals attached to the particles can cause lung cancer. All of these risks depend on the length of exposure, the size of the particles, and the chemical makeup of the contaminants. Wood smoke, for example, contains both polycyclic organic matter (POM) and non-polycyclic organic matter, both of which are considered to be health hazards, and are by-products of wood combustion.

It is important to keep wood stove emissions to a minimum and to make sure that stove doors close tightly. All joints in stove pipe and/or fittings should be tight or sealed. EPA-certified wood stoves should be used whenever possible. Central air-handling systems, including furnaces, flues, and chimneys, need to be inspected regularly. Cracked heat exchangers should be replaced immediately. Cracked or damaged flues and chimneys should be repaired. Ductwork in central air-conditioning and heating systems should be cleaned periodically (See Section 34.7, "Duct Cleaning.") Exhaust fans should be installed over all cooking

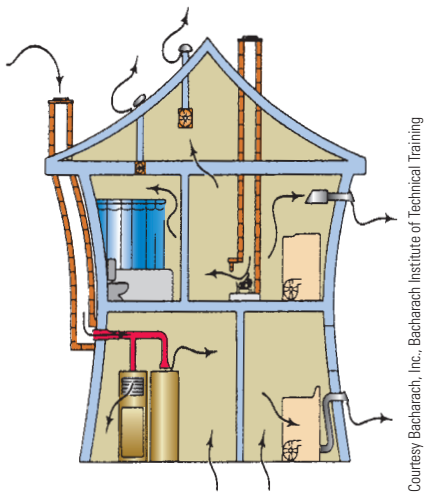
Figure 34.7 Air exhausted from a house causes a negative pressure within the house. This interferes with the venting of combustion appliances, causing a backdraft that forces some of the flue gases back down the chimneys and vents into the living areas.



stoves. These exhaust fans should be vented to a location outside the structure. Failure to do so would simply result in the moving of the cooking fumes from one location within the structure to another. This would be the same as sweeping dirt from one room of the house to another without picking it up.

HOUSEHOLD PRODUCTS CONTAINING ORGANIC CHEMICALS

Paints, varnishes, cleaning products, disinfecting and hobby products, and various fuels contain *organic chemicals*. The compounds from these products are released primarily when they are being used but may also be released if the products are not stored properly. Follow manufacturers' recommendations for proper use and storage of these household products, and use proper procedures when disposing of partially full containers when no longer needed. Always make certain that all containers are properly sealed before storing to minimize the potential for leakage and air contamination.

FORMALDEHYDE

Formaldehyde is a naturally found compound that is chemically known as methanal, CH_2O. Formaldehyde is commonly used in the manufacture of some building materials and certain household products. It is also contained in combustion gases and may exist in the gases from unvented fuel-burning appliances such as unvented gas stoves or kerosene space heaters. Pressed wood products that have adhesives containing urea-formaldehyde (UF) resins include particleboard, which may be used as subflooring and shelving, hardwood plywood paneling, medium-density fiberboard, cabinets, and some furniture tops. Pressed wood, such as softwood plywood and flake board, is intended for exterior use and contains phenolformaldehyde (PF) resin. Formaldehyde has a strong odor, can cause cancer, and can be fatal if ingested. Brief exposure to formaldehyde can be irritating to the eyes, nose, and throat.

PESTICIDES

Pesticides may be used in and/or around a residence to control insects, termites, rodents, or fungi. Most disinfectants contain pesticides. Weed killers, some pool chemicals, and kitchen sanitizers, for example, contain pesticides. Research has indicated that a high percentage of exposure to pesticides occurs indoors. Pesticides should only be used in accordance with the manufacturer's instructions. As with other household chemicals, make certain that all containers are properly sealed prior to storage. Since there are many different types of pesticides, the health effects due to exposure vary greatly. The mildest reactions to pesticide exposure include nose, throat, and eye irritation. Contact with pesticides can also result in more severe reactions and, depending on the exposure time, can cause various cancers and reproductive problems.

Under the Food Quality Protection Act (FQPA), the EPA is in charge of evaluating pesticide levels in food to ensure that the products are safe to consume. Many people assume that simply rinsing foods will wash the pesticides away, but this is not true. In order to minimize pesticide exposure from food, it is a good practice to wash, trim, and peel all food products that have been exposed to pesticides.

ASBESTOS

Asbestos is found in older homes and buildings. It is no longer used in many countries, as it has been proven to be a carcinogen. It may be found in pipe and furnace insulation materials, shingles, textured paints, and floor tiles. Concentrations of airborne asbestos can be found when asbestos-containing materials have been disturbed by cutting, sanding, or removal activities. The most dangerous asbestos fibers are too small to be seen, can accumulate in the lungs, and can cause lung cancer and other diseases. Before a renovation project is started, asbestos experts should be brought in to evaluate the construction materials used on the job to determine if asbestos is present. If its presence is detected, a qualified remediation crew will have to be hired to remove the contaminants. The process of removing asbestos is time-consuming and costly. **SAFETY PRECAUTION:** *If there is any possibility that deteriorating, damaged, or disturbed materials contain asbestos, they should be examined and tested by a person certified to do so. If the materials do contain asbestos, they must be removed by contractors licensed and equipped to do so. No other persons should handle the material.*•

LEAD

Humans may be exposed to *lead* through air, drinking water, food, contaminated soil, deteriorating paint, and dust.

Old lead-based paint is probably the greatest source of exposure. In 1978, lead paints were banned by the federal government. Lead particles can come from outdoor sources of lead dust and from indoor activities using lead solder. Lead pipes and soldering materials were used until the mid-1980s. The Safe Drinking Water Act, last updated in 2014, set new, stricter guidelines for the allowable lead content in piping materials. The new limit is 0.25%. **SAFETY PRECAUTION:** *Deteriorating, damaged, or disturbed materials that contain lead, particularly lead paint, should be removed by contractors licensed and equipped to do so. No other persons should handle the material.*•

34.4 DETECTING AND ELIMINATING THE SOURCE OF CONTAMINATION

Some types of contamination can be easily determined and steps can be taken to eliminate the source. Many types of indoor air-quality testing and monitoring instruments are available, **Figure 34.8**. Monitoring instruments can measure such materials as carbon dioxide, carbon monoxide, hydrogen sulfide, sulfur dioxide, chlorine, nitrogen dioxide, nitric oxide, hydrogen cyanide, ammonia, ethylene oxide, oxygen, hydrogen, hydrogen chloride, ozone, and others.

34.5 VENTILATION

Ventilation is the process of supplying air by natural or mechanical means to a space. Ventilation air is part of the air supplied from outdoors plus any recirculated air that has been cleaned or treated. Ventilation air should be supplied to the occupants' breathing space. Indoor air quality can be improved when proper ventilation procedures are followed. These procedures remove some of the polluted air and dilute the remaining pollutants with outside air. Outside air and/or cleaned filtered air does not benefit building occupants if it short-cycles from the supply diffuser immediately back to the return grille.

Ventilation has a negative effect on the efficiency of heating and cooling systems. The air that is brought in from the outside must be heated or cooled to maintain the desired temperature in the occupied space. See Unit 35, "Comfort and Psychrometrics," for how to calculate the heating or cooling capacity that must be added to account for outdoor air from ventilation. ASHRAE Standard 62 prescribes ventilation and other measures to ensure acceptable air quality.

Commercial buildings are often designed with the appropriate mechanical ventilation, which takes into account the expected number of occupants and any special requirements arising from the activities taking place in the building. Few homes, however, have heating, cooling, or ventilation systems that mechanically bring outside air inside. Therefore, opening windows and doors or operating window or attic fans becomes necessary. Bathroom or kitchen fans may be used to exhaust, or remove air from the structure, but this air must be replaced to prevent creating a negative pressure in the structure. This replacement air may infiltrate, or leak into, the house, or a door or window may be opened for short periods of time. Mechanical ventilation methods can also be used.

ENERGY RECOVERY VENTILATORS

Energy recovery ventilators (ERVs), **Figure 34.9**, are commonly used to reduce the negative effects on system efficiency by transferring heat between the entering and leaving air streams. *One design for mechanical equipment that provides air dilution consists of two insulated ducts run to an outside wall. One duct*

allows outside air to enter the building, and the other exhausts air to the outside. In one version of this design, the ventilation and exhaust ducts are configured to allow sensible heat to transfer between the two air streams. In addition, a desiccant-coated disc rotates between the two air-streams to allow for latent heat to transfer between them.

In the colder winter months, the ERV recovers both latent and sensible heat from the air stream being exhausted from the space. Consider the system shown in **Figure 34-10**. *The air in the occupied space is at a temperature of 70°F with 50% R.H. (1). The outside air is at a temperature of 20°F with 30% R.H. (2). The exhaust (red) air stream and the ventilation (blue) air stream are in contact with each other to allow for heat transfer. It can be seen that the temperature of the exhaust air has dropped from 70°F (1) to 40°F (3), while the temperature of the ventilation air has increased from 20°F (2) to 50°F (4). In addition, it can be seen that the relative humidity of the exhaust air stream has dropped, while the relative humidity of the ventilation air stream has increased. This latent heat transfer is a result of the rotating desiccant wheel between the two air streams. Were it not for the ERV, the ventilation air stream (2) would be brought directly into the structure and the heating equipment would have to treat this air, reducing the effectiveness and efficiency of the system. A similar situation arises in the warmer summer months. In the summer months, the exhausted cooler air is used to cool and dehumidify the ventilation air before it enters the structure.*

Other designs use different types of heat transfer systems. In most units, indoor humidity levels are prevented from becoming too moist or too dry. Another type of recovery ventilator, called a heat recovery ventilator (HRV), provides only sensible heat recovery. HRVs are used primarily in northern climates where cooling is not a major factor. This type of controlled ventilation may be designed to reduce pollen, dust, and other household pollutants, providing a healthier indoor environment.

SECURITY

Security is a relatively new topic for HVAC/R technicians and others as a result of events that have occurred during the past few years, including war, terrorism, accidents, and natural disasters. Building owners, managers, and technicians should meet and assess all risks and dangers that could possibly be present and develop a plan for each of these potential events. Universal plans are seldom useful due to the differences in building architecture, HVAC/R systems, and building occupancy and use.

Outdoor air intakes for buildings should be located away from public areas when possible. An elevated position or a roof location is the best in most instances. Under normal conditions these locations may also produce cleaner air. If an event does occur that results in an air pollutant, some recommend that ventilation systems not be shut down until the source of the pollutant is determined. Of course, the source should be determined as quickly as possible. If it is outside, the ventilation system should be shut down. If it is inside, the building will need all the outside ventilation it can get to dilute the pollutant. If the ventilation system is shut down, the outside louvres should be closed and sealed if they are movable.

Filtering systems with the highest physically and economically possible minimum efficiency reporting value (MERV) ratings should be used in buildings. MERV ratings range from 1 to 16, with the upper levels providing the most filtering. For example, a filter with a MERV rating of 7 is about 30% efficient, while a filter with a MERV rating of 13 is about 80% efficient. Filters should be chosen not only for their capacity to arrest particles but also according to the amount of pressure drop they would cause.

Higher efficiency filters will operate with larger pressure drops across them. Using filters that are too efficient, therefore, can result in improper airflow through the appliance. In air-conditioning systems, inadequate airflow can result in evaporator coil freeze-ups and liquid floodback to the system compressor. On heating systems, inadequate airflow through a furnace can cause excessively high temperature rises across furnaces, possibly leading to cracked heat exchangers and a dangerous carbon monoxide condition.

The filter retainer frame should be inspected regularly to ensure that it has not come loose or deteriorated. Clips should hold the frame tight. For the best seal, gaskets should be used. Considerable amounts of air can pass around the filter frames if they are not installed and maintained properly. Air filters are

Figure 34.10 Airflow patterns through an energy recovery ventilator.

only effective if air is directed through them. Filters should be sized so that they completely fill the opening in the duct or filter grill or rack. Under no circumstances should air be permitted to bypass the filter medium.

A qualified and knowledgeable technician can be very valuable in preparing a security plan and maintaining building equipment. The National Energy Management Institute (NEMI) has developed the Testing, Adjusting and Balancing Bureau (TABB) certification, which technicians can obtain.

34.6 AIR CLEANING

Along with source control and ventilation, air cleaning is another method of providing acceptable indoor quality. *There are four general types of air cleaners: mechanical filters, electronic air cleaners, ion generators, and ultraviolet-C light. Some systems are considered "hybrid" devices because they may contain two or more particle-removing devices. For instance, a mechanical filter may be combined with an electrostatic precipitator or an ion generator. Air cleaners may contain absorbent or adsorbent materials to remove gaseous materials. Absorption is the process of one substance being absorbed by another. For instance, carbon dioxide and carbon monoxide can be absorbed by either solid or liquid-spray filters. Adsorption occurs when a thin film of a liquid or gas adheres to the surface of a solid substance. Charcoal is used extensively as an adsorber.*

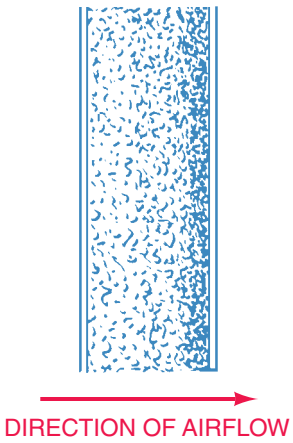
FILTERS

HIGH-LOFT POLYESTER FILTER MEDIA. These filters are spray-bonded and can be purchased in bulk, in media rolls, or in cut pads, **Figure 34.11**. Bonded filters are often made up of different layers of materials, each with a different medium concentration, making the filter more dense as air passes through them, **Figure 34.12**.

Figure 34.11 Filter media in rolls and pads.

Courtesy Aerostar Filtration Group

Figure 34.12 A section of fiberglass medium showing that the medium becomes denser as the air passes through it. This adds to the capacity of the filter to filter particles because the larger particles are filtered first in the less dense parts of the filter.



FIBERGLASS THROWAWAY FILTERS. These filters are constructed of continuous glass fibers bonded together with a thermosetting agent. They are coated with a dust-holding adhesive that helps prevent particulates from migrating downstream, **Figure 34.13**. The filter material is designed to get progressively denser as the air passes through it.

PLEATED FILTERS. Pleated filters have much more surface area than non-pleated filters and typically require less frequent changing. *These filters can accumulate heavier, more restrictive particles at the bottom of the pleats, leaving the sides open longer for effective filtration,* **Figure 34.14**.

CUBE FILTERS. *These filters have a very high dust-holding capacity and are designed to operate effectively in high humidity applications. Three filter layers are heat sealed together. The first layer acts as a high-porosity impingement filter, which captures*

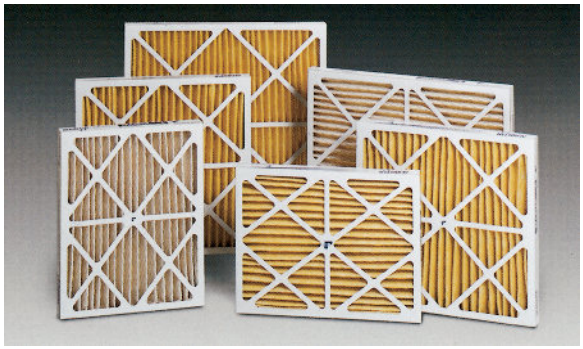
Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 34.14 *A pleated filter. These filters have more filter surface area per front area of the filter.*



Courtesy Aerostar Filtration Group

large particulate matter and helps prevent a condition known as face-loading. Face-loading occurs when the lead, or front, surface of the filter becomes clogged with dirt and prevents the smaller particulate matter from reaching the deeper, more dense, layers of the filter. The second and third layers of the filter capture smaller and smaller particulate matter. Cube filters, **Figure 34.15**, *are available in a number of configurations, including single, double, and triple pocket arrangements.*

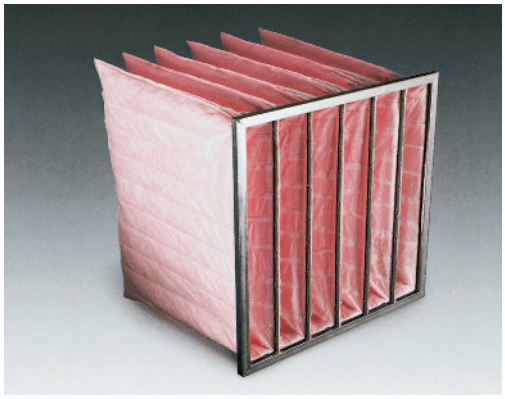
POCKET FILTERS. *Vertical separators for each pocket channel air throughout the medium to prevent turbulence and allow even contaminant loading,* **Figure 34.16**. *Pocket filters are often used as either a final air filter for commercial applications or as a prefilter to a High Efficiency Particulate Arrestor (HEPA filter) when used in sterile or hospital applications.*

HEPA FILTERS. *This type of filter is used where the highest degree of filtration is desired or required. Many dust particles are in the 20–30 micron (µm) size range. (The symbol µm stands for micrometer, often called a micron.) Other particles are much smaller and require a much more efficient filter. HEPA filters are highly efficient—they can capture particles down to 0.3 µm or*

Figure 34.15 *A cube filter. This filter has a lot of surface area and requires a deep filter case.*

Courtesy Aerostar Filtration Group

Figure 34.16 *A pocket filter.*



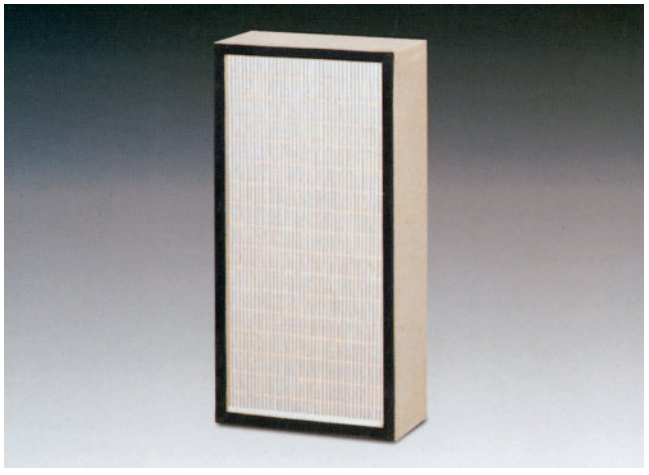
Courtesy Aerostar Filtration Group

smaller. These minute particles can contain mold, dust mites, bacteria, pollen, and other allergens that, if breathed in, may remain in the lungs.

Figure 34.17 *is an example of a HEPA filter. This particular filter can remove from the air 99.99% of particulates having a minimum size of 0.3 µm. Many HEPA filters remove 99.97% of particulates having a minimum size of 0.3 µm. For comparison, a human hair ranges from 70 to 100 µm in diameter, and an object 300 µm in diameter would fit easily through the eye of a sewing needle.*

SAFETY PRECAUTION (FILTER APPLICATION WARNING): *Common sense dictates that individuals would naturally want to use the most effective filtration system possible, but caution must be used when selecting a filter type or when changing from one filter type to another. Filter enclosures or racks have fixed dimensions, and the new filters are often selected based on the size and configuration of these racks. Should the filter configuration change, the racks would also need to be changed. If a technician replaces a low-efficiency or low-density filter a high-density filter, it is very likely that the airflow will be reduced. The blower*

Figure 34.17 *A HEPA filter.*



Courtesy Aerostar Filtration Group

will have more difficulty moving air through the higher density filter medium. If the airflow is reduced too much, there will be problems with the heat exchanger. In summer, there may be coil freezing problems. In winter, the heating system may overheat, so the technician must be aware of airflow requirements. Filters are rated in cfm at a prescribed pressure drop expressed in inches of water column. Be sure to match the new filter with the old filter airflow to reduce the chances of system performance problems.

ELECTROSTATIC PRECIPITATORS OR ELECTRONIC AIR CLEANERS

There are several types of **electrostatic precipitators**. *These cleaners are designed to be mounted (1) at the furnace, (2) within the throwaway filter frame, or (3) within duct systems. They may also be stand-alone portable systems.* **Figure 34.18a** *shows a duct-mounted electronic air cleaner. These systems generally have a prefilter section that filters out the larger airborne particles and an ionizing or charging section,* **Figure 34.18b**. *Some also have a charcoal filter,* **Figure 34.18c**. *The prefilter traps larger particles and airborne contaminants. In the ionizing or charging section, particles are charged with a positive charge. These particles then pass through a negatively charged collection plate. The positively charged contaminants are attracted to this collection plate. The air then passes through a charcoal filter, on those systems that have them, to remove many of the odors and gases by adsorption.*

ACTIVATED CHARCOAL AIR PURIFIER. *Activated charcoal, also called activated carbon, is manufactured in pellet form from coal or coconut shells. The material is treated during the manufacturing process so that the pellets produced have a very large internal surface area. Activated charcoal is especially effective when used to adsorb solvents, other organic materials, and odors. The purifier,* **Figure 34.19**, *is mounted in the return air duct of a heating and air-conditioning system. The velocity of the air within the duct forces the gaseous material to impinge on the activated charcoal, which is held in tubes suspended in the airstream. The gaseous material is attracted to the carbon particles, and eventually it condenses into a liquid and is held in place. These gases and/or odors are held in the carbon media. Periodically, the carbon media must be replaced. Some typical gases that can be removed by this type of purifier are*

- *compounds, such as alcohols, aldehydes, and acids from household products, construction materials, carpeting, furniture, or other household items.*
- *chlorinated hydrocarbons.*
- *inorganic compounds, such as halogens, phosgene, and sulfur compounds.*
- *a variety of odors from cooking, waste storage, pets, and humans.*

BI-POLAR IONIZATION AND POLARIZED FILTRATION

Ions are commonly found in clean environments, such as areas with low populations and low levels of industrial contamination. In overpopulated areas like city centers, ions are almost nonexistent. The concentration of ions is also very low in indoor environments. This is partially due to the fact that houses and other structures are being constructed more tightly, reducing the amount of entering natural ventilation. Ions help to reduce air contamination because they cause contaminants to bond to each other, making them heavier and larger. Larger particles are more likely to get trapped in filters and heavier particles are more likely to fall to the floor. Two technologies are being used as **ion generators**, which charge particles in the air to increase the number of ions and reduce air contamination levels.

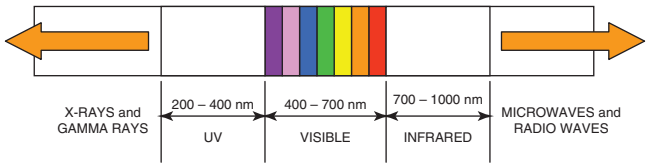
Polarized filtration uses a high voltage at low current to put an electric charge on both the filter media and the particles that are present in the air. This causes the particles to become attracted to the filter media since the charges on the filter and on the contaminants are opposite. Charging the particles also causes them to bond to each other, creating larger and heavier particles. These larger particles are more likely to get trapped by the charged filter.

Bi-polar ionization creates air ions but does not charge the filter media. The ions of contaminants such as mold and dust bond together and get trapped in the filter. One of the benefits of bi-polar ionization is that it does not require additional filtration, so the addition of this type of unit does not further restrict airflow. In addition, as in the case of polarized filtration, the heavier particles fall to the floor and pose less of a problem than do airborne contaminants.

ULTRAVIOLET LIGHT

The use of ultraviolet (UV) light for providing cleaner indoor air has been studied.

Figure 34.20 Diagram showing the wavelength of UV light with respect to that of visible light.



UV light occupies a specific range in the light spectrum. Its wavelength ranges from 200 to 400 nanometers (nm), a unit that represents a length equal to 0.000000001 (eight zeros) meter. Just below the UV range is the microwave portion of the spectrum (**Figure 34.20**); the visible light spectrum ranges from 400 nm to 700 nm, and the infrared spectrum starts at 700 nm and goes up from there. Within the UV range there are three frequency bands:

- Long wave: 315 to 400 nm
- Midrange: 280 to 315 nm
- Low range: 200 to 280 nm

The long wave band represents what is called UV-A and the midrange is referred to as UV-B. The lower end of the UV spectrum represents light waves referred to as UV-C waves, and it is these light waves that help clean the air in forced-air heating and cooling systems. The UV-C (germicidal) range has been studied for use in destroying microbes that may cause unhealthy air in homes, offices, or other buildings, including hospitals and schools. The UV-C light has the ability to penetrate the walls of microbes that can have negative effects on indoor air quality. Once penetrated, the UV-C light can damage the DNA of the microbe, killing smaller and weaker ones, and preventing larger ones from reproducing.

Ultraviolet air treatment systems (**Figure 34.21**) are used on forced-air conditioning or heating systems and

Figure 34.21 An ultraviolet air cleaner with a photocatalytic oxidation (PCO) filter.

are most effective when used in conjunction with high-efficiency air filtration media. These units are easily installed in duct systems in much the same way that electric duct heaters are installed. They can be part of a new installation or added to existing systems. The location of the UV light is very important and the manufacturer's guidelines should be followed. These devices are typically positioned either close to the air filter or the evaporator coil, as both of these are prime locations for microbes such as mold to accumulate. Some manufacturers recommend installing UV devices in both the supply and return ducts, depending on the needs of the system. Most UV systems are available in different sizes for residential, commercial and industrial installations.

UV bulbs contain mercury, which has the potential to cause health issues as well as environmental damage if not handled and disposed of properly.

Many UV air purifiers come equipped with a supplemental photocatalytic oxidation filter, commonly known as a PCO filter. These filters are coated with titanium oxide (TiO_2) to facilitate the photocatalytic oxidation process. This process creates hydroxyl radicals and superoxide ions, which are highly reactive electrons. These electrons combine with pollutants in the air, such as various forms of bacteria and volatile organic compounds, or VOCs, and break them down into carbon dioxide and water. (VOC is an umbrella term used to describe a wide range of substances, such as formaldehyde, acetaldehyde, ammonia, and various acids that are found in building materials and household cleaning products.)

It is important to select the right UV light for the system. If the airflow through the PCO filter is not sufficient, the process of breaking down the VOCs may not be completed, resulting in the possible formation of even more VOCs. The type of volatile organic compounds present also has an effect on the time needed by the air treatment system to break them down. For example, cigarette smoke contains hundreds of different chemicals. Laboratory studies have indicated that, when air that is heavily contaminated with cigarette smoke is treated with a PCO filter, formaldehyde is formed as a by-product of the process.

SAFETY PRECAUTION: *Although the UV light may not be visible, do not look at it when it is activated. The unit should be placed where technicians or building occupants will not be exposed to it accidentally. Other safety issues include:*

- *Do not turn the light on before installing it.*
- *Place warning signs for building occupants and future technicians.*
- *Check the duct for possible light leaks, and seal them if any are found.*
- *Turn off the light before performing any maintenance or service on the HVAC/R system.*
- *Replace the light element annually.*

34.7 DUCT CLEANING

Dirty air ducts may be a possible source of pollutants in homes. Homeowners should consider having the air ducts cleaned if

- there is visible mold growth present on hard-surface (sheet metal) ducts or on other components of the heating and cooling system.
- ducts are infested with vermin (rodents or insects).
- ducts are clogged with excessive amounts of dust and debris and/or particles are actually released into the home from supply registers.

Duct cleaning generally refers to the cleaning of the interior of ductwork and the cleaning of various heating and cooling system components of forced-air systems. This includes the supply and return air ducts and registers, grilles and diffusers, heat exchangers, heating and cooling coils, condensate drain pans, fan motor and fan housing, any humidification components within the system, and the air-handling unit housing. If the duct system is to be cleaned, all of the listed components should be cleaned. Failure to clean all units may result in recontamination of the entire system. If there is one inlet to the return duct system, having the filter placed there would help keep the return duct system clean.

SAFETY PRECAUTION: *The entire system should be inspected before cleaning to make sure that no asbestos-containing materials are in the heating and cooling system. If asbestos is found, specialized procedures are required. The asbestos should not be disturbed or removed except by specially trained and equipped contractors.*

The vacuum system used should exhaust particles outdoors or high-efficiency particle air-vacuuming equipment should be used if the exhaust is inside the building. All carpeting and household furnishings should be protected. To dislodge and contain dust and other particles, equipment that allows controlled brushing of duct surfaces and contact vacuuming should be used, **Figure 34.22**. Soft-bristled brushes should be used on fiberglass duct board and sheet metal ducts lined internally with fiberglass. Some newer duct-cleaning systems, like the one shown in **Figure 34.22**, are equipped with variable speed controls so low speed can be used on flexible duct runs and high speed can be used on rigid metal duct runs. When cleaning is completed, all access holes and/or access joints should be resealed and reinsulated, when appropriate, so that they are airtight. If moisture and/or mold are found, the source of this problem should be determined and the problem should be corrected, or it will reoccur.

Duct cleaning technicians should be familiar with and follow the National Air Duct Cleaning Association's standards, and if the ducts are constructed of flex duct, duct board, or lined with fiberglass, guidelines of the North American Insulation Manufacturers Association (NAIMA) should be followed.

34.8 AIR HUMIDIFICATION

In fall and winter, homes often feel dry because cold air from the outside infiltrates the conditioned space. The air in the home feels dry when it is heated because it expands, spreading out the moisture. The amount of moisture in the air is often expressed as **relative humidity**, which is the percentage of moisture in the air compared to the air's ability to hold moisture. In other words, if the relative humidity is 50%, each cubic foot of air is holding one-half the moisture it is capable of holding. The relative humidity of the air decreases as the temperature increases, because air with higher temperatures can hold more moisture. When a cubic foot of 20°F outside air at 50% relative humidity is heated to room temperature (75°F), the relative humidity of that air drops.

For comfort, the "dry" air should be replenished with moisture. The recommended relative humidity for a home is between 40% and 60%. When the relative humidity goes above these limits, bacteria, viruses, fungi, and other organisms become more active. In conditioned spaces with lower relative humidity, the dry warm air draws moisture from everything in the conditioned space, including carpets, furniture, woodwork, plants, and people. Furniture joints loosen, nasal and throat passages dry out, and skin becomes dry. Dry air causes more energy consumption than necessary because the air gets moisture from the human body through evaporation from the skin. The person then feels cold and sets the thermostat a few degrees higher to become comfortable. With more humidity in the air, a person can be more comfortable at a lower temperature. Static electricity is also much greater in dry air. A person also may receive a small electrical shock when touching something after having walked across the room.

Years ago people placed pans of water on radiators or on stoves. They even boiled water on the stove to make moisture available to the air. The water evaporated into the air and raised the relative humidity. Although this may still be done in some homes, efficient and effective humidifiers can produce this moisture and make it available to the air by evaporation. The evaporation process is speeded up by using power or heat or by passing air over large areas of water. The area of the water can be increased by spreading it over pads or by atomizing it.

HUMIDIFIERS

Evaporative humidifiers work on the principle of providing moisture to a surface called a medium and exposing it to the dry air. This is normally done by forcing the air through or around the medium; the air picks up the moisture from the medium as a vapor or a gas. There are several types of evaporative humidifiers.

The *bypass humidifier* relies on the difference in pressure between the supply (warm) side of the furnace and the return (cool) side. It may be mounted either on the supply plenum or duct or the cold air return plenum or duct. Piping must be run from the plenum or duct where the humidifier is mounted to the other plenum or duct. If mounted in the supply duct, piping must be run to the cold air return, **Figure 34.23**. The difference in pressure between the two plenums draws some heated air through the humidifier to the return duct.

The *plenum-mount humidifier* is mounted in the supply plenum or the return air plenum. The furnace blower forces heated air through the medium, where it picks up moisture. The air and moisture are then distributed throughout the conditioned space, **Figure 34.24**.

The *under-duct humidifier* is mounted on the underside of the supply duct so that the medium is extending into the heated airflow, where moisture is picked up in the airstream. **Figure 34.25** illustrates an under-duct humidifier.

HUMIDIFIER MEDIA

Humidifiers are available in several designs with various kinds of media. **Figure 34.25** is a photo of a humidifier with drum-shaped medium. A motor turns the drum, which picks up moisture from the reservoir.

The moisture then is evaporated from the drum into the moving airstream. The drums can be screens or sponges.

The screen-type humidifier medium resembles the drum medium but uses disc screens instead. The discs are mounted on a rotating shaft, causing the slanted discs to pick up moisture from the reservoir. The moisture is then evaporated into the moving airstream. The discs are separated to overcome electrolysis, which causes the minerals in the water to form on the medium. The wobble of the discs mounted at an angle washes the minerals off and into the reservoir. The minerals then can be drained from the bottom of the reservoir.

A plate- or pad-type medium is shown in **Figure 34.24.** The plates form a wick that absorbs water from the reservoir. The airstream in the duct or plenum causes the water to evaporate from the wicks or plates.

Figure 34.26 shows an electrically heated water humidifier. In electric furnace and heat pump installations, the temperature in the duct is not as high as in other types of hot-air furnaces. Media evaporation is not as easy as with lower temperatures. The electrically heated humidifier heats the water with an electric element, causing it to evaporate and be carried into the conditioned space by the airstream in the duct.

An *infrared humidifier* is shown in **Figure 34.27.** It is mounted in the duct and has infrared lamps with reflectors that reflect the infrared energy onto the water. The water thus evaporates rapidly into the duct airstream and is carried throughout the conditioned space. This is similar to the sun's rays shining on a lake and evaporating the water into the air. Both the electrical and the infrared types of humidifier use electrical energy.

Humidifiers are often controlled by a **humidistat**, **Figure 34.28.** The humidistat controls the motor and the heating elements and has a moisture-sensitive element, often made of hair or nylon ribbon. This material is wound around two or more bobbins and shrinks or expands, depending on the humidity. Dry air causes the element to shrink, which activates a snap-action switch and starts the humidifier. Many other control devices are used, including solid-state electronic components that vary in resistance with the humidity.

ATOMIZING HUMIDIFIERS

Atomizing humidifiers discharge tiny water droplets (mist) into the air, which evaporate very rapidly into the duct airstream or directly into the conditioned space, **Figure 34.29.**

Figure 34.29 An atomizing humidifier.

Source: AutoFlo Company

These humidifiers, which can be *spray-nozzle* or *centrifugal* types, should not be used with hard water because it contains minerals (lime, iron, etc.) that leave the water vapor as dust and will be distributed throughout the house or building. Eight to ten grains of water hardness is the maximum recommended for atomizing humidifiers. Some models are operated by a thermostat that controls a solenoid valve which turns the unit on and off. The furnace must be on and heating before this type will operate. Others, wired in parallel with the blower motor, operate when the blower motor operates. Most are also controlled with a humidistat.

The spray-nozzle humidifier sprays water through a metered bore of a nozzle into the duct airstream, where it is distributed to the occupied space. Another type sprays the water onto an evaporative media where it is absorbed by the airstream as a vapor. These humidifiers can be mounted in the plenum, under the duct, or on the side of the duct. It is generally recommended that atomizing humidifiers be mounted on the hot air or supply side of the furnace. The *centrifugal atomizing humidifier* uses an impeller or slinger to throw the water and break it into particles that are evaporated in the airstream, **Figure 34.30**. **SAFETY PRECAUTION:** *Atomizing humidifiers should operate only when the furnace is operating or moisture will accumulate and cause corrosion, mildew, and a major moisture problem where the humidifier is located.*•

SELF-CONTAINED HUMIDIFIERS

Many residences and light-commercial buildings do not have heating equipment with ductwork through which the heated air is distributed. Hydronic heating systems, electric baseboards, or unit heaters, for example, do not use ductwork.

To provide humidification in these systems, *self-contained humidifiers* may be installed. These generally operate in the same way as those used with forced-air furnaces, using the evaporative, atomizing, or infrared processes. They may include an electric heating device to heat the water, or the water may be distributed over an evaporative media. A fan must be incorporated in the unit to distribute the moisture throughout the room or area. **Figure 34.31** illustrates a drum-type self-contained humidifier. A design using steam is shown in **Figure 34.32**. In this system the electrodes heat the water, converting it to steam. The steam passes through a hose to a stainless steel duct. Steam humidification is also used in large industrial applications where steam boilers are available. The steam is distributed through a duct system or directly into the air.

PNEUMATIC ATOMIZING SYSTEMS. *Pneumatic atomizing* systems use air pressure to break up and disperse the water in a mist of tiny droplets. **SAFETY PRECAUTION:** *These systems as well as other atomizing systems should be installed only where the atmosphere does not have to be kept clean or where the water has a very low mineral content, because the minerals in the water are also dispersed in the mist throughout the air. The minerals fall out and accumulate on surfaces. These systems are often used in manufacturing establishments, such as textile mills.*•

34.9 SIZING HUMIDIFIERS

A humidifier of the proper size should be installed. This text emphasizes installation and service, so details for determining the size or capacity of humidifiers will not be covered. However, the technician should be aware of some general factors involved in the sizing process:

1. The number of cubic feet of space to be humidified. This is determined by taking the number of heated square feet of the building and multiplying it by the ceiling height. A 1500-ft^2 house with an 8-ft ceiling height would have 1500 ft^2 × 8 ft = 12,000 ft^3.
2. The construction of the building. This includes quality of insulation, storm windows, fireplaces, building "tightness," and so on.
3. The amount of air change per hour and the approximate lowest outdoor temperature.
4. The level of relative humidity desired.

34.10 INSTALLATION

Plan the installation carefully, including the location of the humidifier and the wiring and plumbing (with drain). A licensed electrician or plumber must provide these services where required by code or law. The most important facts to know about installing humidifiers are the manufacturer's instructions. Evaporative humidifiers often are operated independently of the furnace. It is normally recommended that they be controlled by a humidistat, but it does no real harm for them to operate continuously, even when the furnace is not operating. Atomizing humidifiers, however, should not operate when the furnace and blower are not. Moisture will accumulate in the duct if they are allowed to do so.

Particular attention should be given to clearances within the duct or plenum. The humidifier should not exhaust directly onto air-conditioning coils, air filters, electronic air cleaners, blowers, or turns in the duct. If mounting on a supply duct, choose one that serves the largest space in the house. The humid air will spread throughout the house, but the process will be more efficient when given the largest distribution possible.

34.11 SERVICE, TROUBLESHOOTING, AND PREVENTIVE MAINTENANCE

Proper service, troubleshooting, and preventive maintenance play a big part in keeping humidifying equipment operating efficiently. Cleaning the components that are in contact with the water is the most important factor. The frequency of cleaning depends on the hardness of the water: the harder the water, the more minerals in the water. In evaporative systems, these minerals collect on the media, on other moving parts, and in the reservoir. In addition, mold, algae, bacteria, and virus growth can cause problems, even to the extent of blocking the output of the humidifier. Algaecides can be used to help neutralize algae growth. The reservoir should be drained regularly if possible, and components, particularly the media, should be cleaned periodically.

Indoor air quality can be adversely affected by the humidifier because it uses water and any mold, mildew, or algae can be distributed by the moving airstream. Mold, mildew, or algae may cause allergic reactions or upper respiratory problems. One of the maintenance factors that must be attended to regularly is the cleanliness of the water reservoir and evaporative surface when an evaporative humidifier is used. These surfaces must be cleaned and sanitized on a regular basis to prevent mold and algae from accumulating. Some manufacturers have used UV lights to kill these growing molds and algae and to prevent them from contaminating the area. Follow the manufacturer's recommendations for cleaning a particular unit. If the humidifier is an atomizing type, look for mold or mildew in the duct downstream from the nozzle.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

HUMIDIFIER NOT RUNNING

When the humidifier does not run, the problem is usually electrical or a component is bound tight or locked due to a mineral buildup. A locked condition may cause a thermal overload protector to open. Using typical troubleshooting techniques, check overload protection, circuit breakers, humidistat, and low-voltage controls if there are any. Check the motor to see whether it is burned out. Clean all components and disinfect if appropriate.

EXCESSIVE DUST

If it is the humidifier that is causing excessive dust, the dust will be white due to mineral buildup on the media. Clean or replace the media. If excessive dust occurs in an atomizing humidifier, the wrong equipment has been installed.

WATER OVERFLOW

Water overflow indicates a defective float valve assembly. It may need cleaning, adjusting, or replacing.

MOISTURE IN OR AROUND DUCTS

It is primarily atomizing humidifiers that cause moisture in ducts. **Remember, this equipment should operate only when the furnace operates.** Check the control to see whether it operates at other times, such as in the COOL or FAN ON modes. A restricted airflow may also cause this problem.

LOW OR HIGH LEVELS OF HUMIDITY

If the humidity level is too high or too low, check the calibration of the humidistat by using a sling psychrometer. If it is out of calibration, it may be possible to adjust it. The humidistat may need to be relocated if it is too close to a window or door. Ensure that the humidifier is clean and operating properly.

34.12 DIAGNOSTIC CHART FOR FILTRATION AND HUMIDIFICATION SYSTEMS

All forced-air systems have a filtration system of some sort. These vary from the basic air filter to the more complex electronic air filter. Most of the problems with basic air filters are caused by reduced airflow due to lack of maintenance. The problems that occur with electronic air-filter systems are more complex.

Humidification systems all contain water, and water can cause problems if the system is not properly cared for. The following chart lists some of the common problems of filtration and humidification systems.

Problem	Possible Cause	Possible Repair
Filters, Media type		
Restricted	Filters are not changed often enough	Change on a more regular schedule.
Dust entering conditioned space, possibly caused by dirty evaporator coil and fan blades	Filter media too coarse	Change to finer filter media.
	Air bypassing filter	Install filters of the correct size.
Electronic Filter		
No power to filter	Filter interlock with fan	Establish correct fan interlock circuit.
Power to filter but filter not operating	Filter grounded in element	Clean filter.
	Contacts in filter element not making contact	Clean contacts and reassemble.
	Defective power assembly	Change power assembly.
Filter makes cracking sound too often	High dust content in air	Change to finer prefilter.
Humidifiers		
Unit not operating—depends on electricity	Faulty electrical circuits	Change fuse or reset breaker.
	Humidistat not calling for humidity	Repair faulty electrical circuits or connections.

Problem	Possible Cause	Possible Repair
	Interlock with fan circuit	Check humidistat calibration; adjust or change humidistat.
		Determine what type of interlock and correct.
Unit operating, but humidity is low	No water supply	Reestablish water supply.
	Defective float	Change float.
	Evaporation media saturated with minerals and will not absorb water	Change media.
	Power assembly that turns evaporation media not turning	Make sure that power is available; if it is, change unit.

SUMMARY

- Many modern homes and office buildings are being designed and constructed more tightly to keep air out in order to maximize heating and cooling efficiencies. This often results in the accumulation of air pollutants inside.
- Eliminating the source of indoor pollution should be the first step in improving indoor air quality.
- Mold growth indoors is a major problem with regards to indoor air quality.
- Indoor air quality can be improved through the use of ventilation, which dilutes the air and reduces the concentration of air pollutants.
- Cleaning air by filtering, absorption, and adsorption are other means by which indoor air quality can be improved.
- Ducts may be cleaned if there is significant evidence that contamination is a problem.
- In cool or cold weather, humidifiers may be needed for comfort and to protect furniture and other household materials from drying out.

REVIEW QUESTIONS

1. List five different sources of indoor air pollution.
2. ASHRAE Standard _____, "Ventilation for Acceptable Indoor Air Quality," is the standard generally used to determine acceptable indoor air quality.
3. Radon is a(n) _____, _____, and _____ gas.
4. Three different biological contaminants are _____, _____, and _____.
5. What are two substances molds need in order to grow?
6. Three methods of controlling indoor air contamination are _____, _____, and _____.
7. If radon gas is suspected, what should be done?
8. How does ventilation help to improve air quality?
9. Three general types of air cleaners are _____, _____, and _____.
10. True or False: Carbon monoxide is produced by mixing vapors from nitrogen dioxide and sulfur dioxide.
11. Describe the difference between absorption and adsorption.
12. True or False: Fiberglass filter media is generally coated with a special nondrying, nontoxic adhesive on each fiber.
13. An electrostatic precipitator is the same as
    A. an extended surface air filter.
    B. a fiberglass media filter.
    C. an electronic air cleaner.
    D. a washable steel air filter.
14. The purifier ingredient in an activated charcoal air purifier may be
    A. activated carbon.
    B. coconut shell pellets.
    C. manufactured from coal.
    D. any of the above.
15. Ion generators _____ particles in an area.
    A. disintegrate
    B. charge
    C. wash
    D. remove odors from
16. The relative humidity in heated homes is generally the _____ in the winter season.
    A. highest
    B. lowest

17. The recommended relative humidity for a home is between
    A. 50% and 70%.
    B. 20% and 40%.
    C. 30% and 50%.
    D. 40% and 60%.
18. True or False: Some humidifiers have their own water-heating devices.
19. Static electricity is more commonly a problem when the air is _____.
    A. dry
    B. moist
20. The plenum-mounted humidifier is installed in the _____ plenum.
    A. supply
    B. return
    C. supply or return
21. Describe the difference between an evaporative and an atomizing humidifier.
22. Why is it essential for the furnace to be operating when an atomizing humidifier is being used?

COMFORT AND PSYCHROMETRICS

OBJECTIVES

After studying this unit, you should be able to

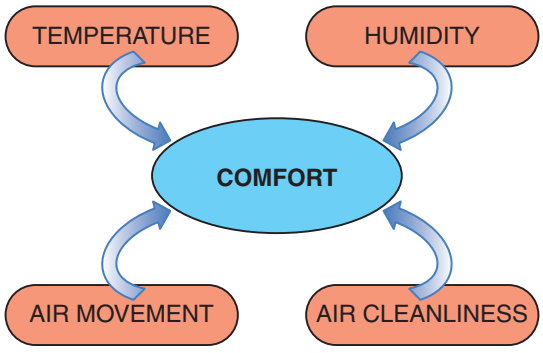
- recognize the four factors that affect comfort.
- explain the relationship between body temperature and room temperature.
- explain why one person might be comfortable when another is not.
- define psychrometrics.
- define wet-bulb and dry-bulb temperature.
- define dew point temperature.
- explain vapor pressure of water in air.
- describe humidity.
- plot air conditions on a psychrometric chart.
- plot an air-conditioning process on a psychrometric chart.

35.1 COMFORT

Comfort describes a delicate balance of pleasant feeling in the body. A comfortable atmosphere describes our surroundings when we are not aware of discomfort. Providing a comfortable atmosphere for people is the job of the heating and air-conditioning profession. Comfort involves four things: (1) temperature, (2) humidity, (3) air movement, and (4) air cleanliness, **Figure 35.1**.

The human body has a sophisticated control system for both protection and comfort. When we move from a warm house to the cold outdoors, the body begins to adjust to the changing conditions. If we move from a cool house to the warm outdoors on a hot summer day, the body will also adjust itself to keep comfortable and prevent us from overheating. Body adjustments are accomplished by the circulatory and respiratory systems. When the body gets too warm, the vessels next to the skin dilate to get the blood closer to the surrounding air in an effort to increase the heat exchange with the air. This is why you turn red when you become hot. If this does not cool the body, you will perspire. When the perspiration evaporates, it takes heat from the body and cools it. Excess perspiration in hot weather explains why you must drink more fluids.

Figure 35.1 Comfort is described as a balance of air temperature, humidity, air movement, and air cleanliness.



35.2 FOOD ENERGY AND THE BODY

The human body may be compared to a coal-burning boiler. Coal is burned in the boiler to create heat energy. Supplying food to the human body can be equated to adding coal to the boiler. When the coal is burned and converted to heat, some of this energy goes up the flue or chimney, some escapes to the surroundings, and some is carried away in the ashes. If fuel is added to the fire and the heat cannot be dissipated, the boiler will overheat.

The body uses food to produce energy. Some energy is stored as fatty tissue, some leaves as waste, some leaves as heat, and some is used as energy to keep the body functioning. If the body needs to dissipate some of its heat to the surroundings and cannot, it will overheat. The average core body temperature is 98.6°F. The surface temperature of the body, or the temperature of our skin, is considerably lower than 98.6°F and varies according to the temperature of its surroundings. So, if someone is standing outside in 100°F air, the body will not be able to reject heat to its surroundings, **Figure 35.2**. Instead, the body will actually absorb heat. When such is the case, the body's internal temperature-control system will cause perspiration to form on the surface of the skin in an attempt to cool the body. As the surrounding temperature drops, the body will reject heat naturally, as a warmer substance transfers heat to cooler ones, **Figure 35.3**. We are comfortable when our body transfers heat to its surroundings at the correct rate.

Figure 35.2 The body will absorb heat if the surroundings are warmer than the body.

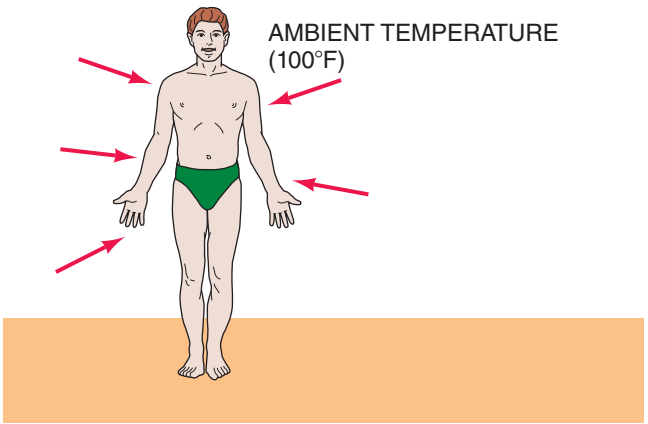


Figure 35.3 Average body temperature is 98.6°F.

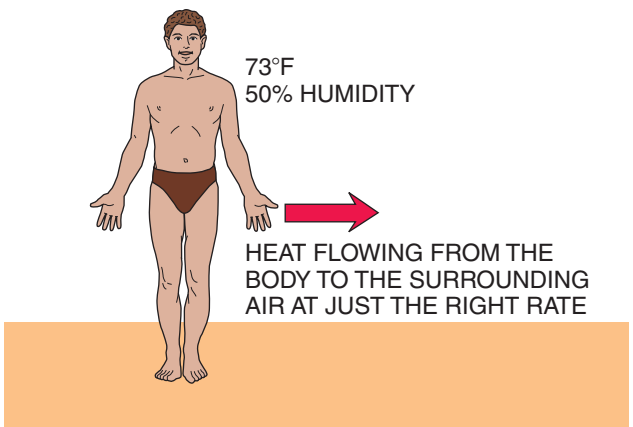

35.3 HEAT TRANSFER TO AND FROM THE BODY

The body gives off and absorbs heat by the three methods: conduction, convection, and radiation, **Figure 35.4**. The evaporation of perspiration could be considered a fourth way, **Figure 35.5**. When the surroundings are at a particular comfort condition, the body is giving up heat at a steady rate that is comfortable. The surroundings must be cooler than the body for the body to be comfortable. Typically, when the body is at rest (sitting) and in surroundings of 75°F and 50% humidity with a slight air movement, the body is close to being comfortable. In cooler weather, a different set of conditions applies (e.g., we wear more clothing). The following statements can be used as guidelines for comfort.

1. In winter:
   A. The effects of lower temperatures can be offset by a higher relative humidity.
   B. The lower the relative humidity is, the higher the temperature must be.
   C. Air movement is more noticeable.

Figure 35.4 The three direct ways the human body gives off heat. (A) Conduction. (B) Convection. (C) Radiation.

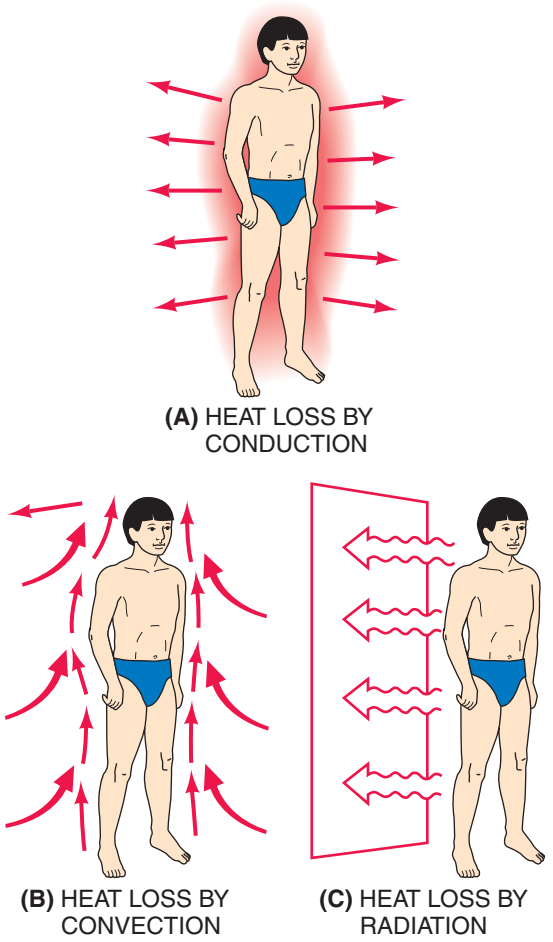

Figure 35.5 A fourth way the body gives off heat—the evaporation of perspiration.

Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

2. In summer:
   A. Air movement helps reduce the negative effects of high relative humidity.
   B. The effects of higher temperatures can be offset with a lower relative humidity.
3. The comfort conditions in winter and in summer are different.
4. Styles of clothes in different parts of the country make a difference in the conditioned space-temperature requirements for comfort. For example, in Maine, the clothing worn during the winter months would be warmer than the clothing worn during the winter in Georgia, so the temperatures of similar interior spaces in each location will be somewhat different.
5. Body metabolism varies from person to person, based on a number of factors including gender and age. Women, for example, are not as warm-bodied as men and, as a result, typically have less tolerance than men do for large temperature swings. The circulatory system generally does not function as well in older people as compared to younger people.

35.4 THE COMFORT CHART

The chart in **Figure 35.6**, often called a *generalized comfort chart*, can be used to compare one situation with another. **Figure 35.6(A)** represents the comfort chart for the summer months. In the center of this chart there is a bold rectangular area that represents the temperature and humidity combinations at which most people will be comfortable. The air temperatures are located along the bottom of the chart, and the (relative) humidity percentages are shown by the curved lines as indicated in **Figure 35.7**.

From the comfort chart for the summer months, it can be determined that the average individual will be comfortable if the surrounding air is 75°F with a relative humidity of 50%, **Figure 35.8**. This is because the 75°F line and the 50% relative-humidity line cross at a point that is located within the "comfort" zone. It can also be determined that the average person will *not* be comfortable if the surrounding air is 85°F and the relative humidity is 50%, **Figure 35.9**. This is because these two lines intersect at a point that is outside the comfort region. The same concept applies to the comfort chart for the winter months, as shown in **Figure 35.6(B)**.

A technician may use charts like those shown in **Figure 35.6** to plot and compare comfort conditions in an occupied space. In general, the closer the plot falls to the middle of the chart, the more people would be comfortable at those conditions. Notice that there is a different chart for summer and winter conditions. The charts shown in **Figure 35.8** and **Figure 35.9** show only the relationship between air temperature and relative humidity. There are many other properties of air that affect comfort levels. The complete graph is referred to as a **psychrometric chart** and compiles information about the following air characteristics:

- Dry-bulb temperature
- Wet-bulb temperature
- Relative humidity
- Specific volume
- Moisture content
- Heat content
- Dew point temperature

Each of these items will be discussed in more detail in this unit. Section 35.13, "Plotting on the Psychrometric Chart," will explain how to use the chart to determine the various characteristics of air at different sets of conditions.

35.5 PSYCHROMETRICS

The study of air and its properties is called **psychrometrics.** When we move through a room, we are not aware of the air inside the room, but the air has weight and occupies space like water in a swimming pool. The water in a swimming pool is more dense than the air in the room; it weighs more per unit of volume. Perfectly dry air weighs 0.075 lb/ft^3 at standard atmospheric pressure, **Figure 35.10**. The density of water is 62.4 lb/ft^3.

Air, like water, offers resistance to movement. To prove this, take a large piece of cardboard and try to swing it around with the flat side moving through the air, **Figure 35.11**. It is hard to do because of the resistance of the air. The larger the area of the cardboard, the more resistance there will be. For example, if you took a large piece of cardboard outside on a windy day, the wind will try to take the cardboard from you. The cardboard acts like a sail on a boat, **Figure 35.12**. Air not only offers resistance to movement, it also takes up space. If you invert an empty glass and push it down in water, you can observe that the air completely fills the glass and, by creating resistance, prevents the water from flowing into the glass, **Figure 35.13**.

The weight of air in a room can be calculated by multiplying the room volume by the weight of a cubic foot of air. In a room 10 ft × 10 ft × 10 ft, the volume is 1000 ft^3, so the room air weighs 1000 ft^3 × 0.075 lb/ft^3 = 75 lb, **Figure 35.14**. It is important to remember that the 0.075 lb/ft^3 that is used in this example assumes that the air is at standard atmospheric conditions and is *dry*. Deviations from these conditions will have an effect on the weight of the air. The number of cubic feet of air to make a pound of air can be obtained by taking the reciprocal of the density. The reciprocal of a number is 1 divided by that number. The reciprocal of the density of air from the previous example is 1 divided by 0.075, or 13.33 ft^3/lb of air, **Figure 35.15**. The reciprocal of density is known as the specific volume, or the volume that 1 lb of a substance occupies. Both density and specific volume values are used in many calculations.

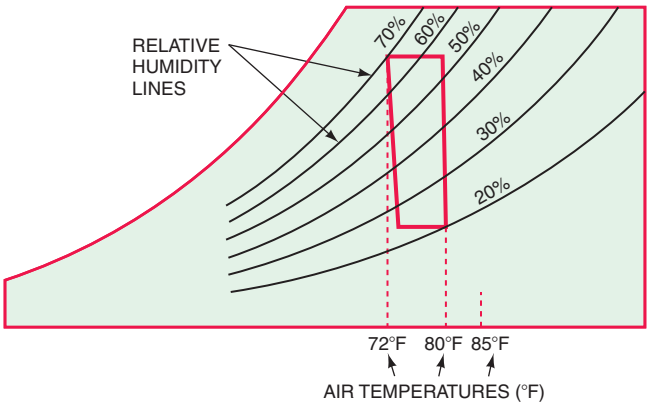

Figure 35.8 This combination of temperature and humidity lies within the boundaries of the comfort chart.

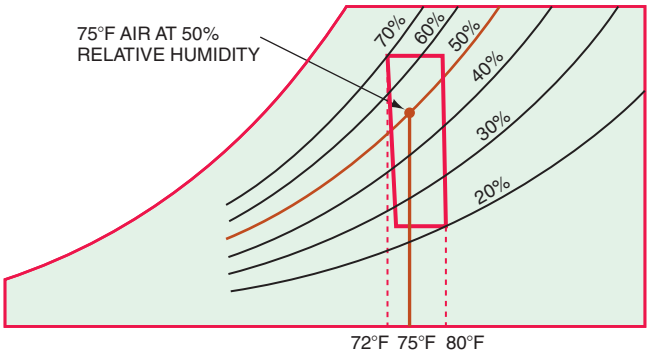

Figure 35.9 This combination of temperature and humidity lies outside the boundaries of the comfort chart.

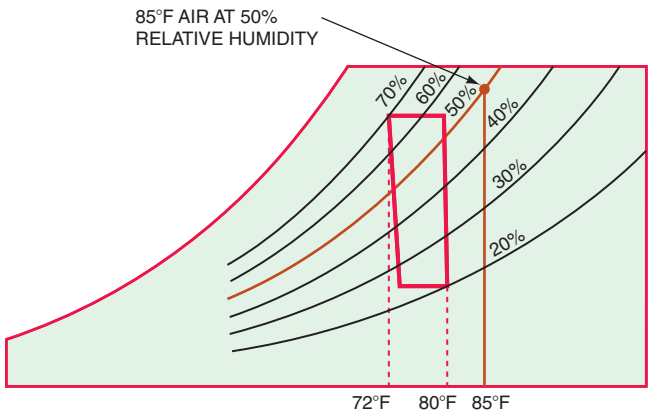

35.6 MOISTURE IN AIR

Air consists of approximately 78% nitrogen, 21% oxygen, and 1% other gases, **Figure 35.16**. But air is not totally dry. Surface water and rain keep moisture in the atmosphere everywhere at all times, even in a desert. Two-thirds of the

Figure 35.13 Air creating resistance that prevents water from entering the glass.

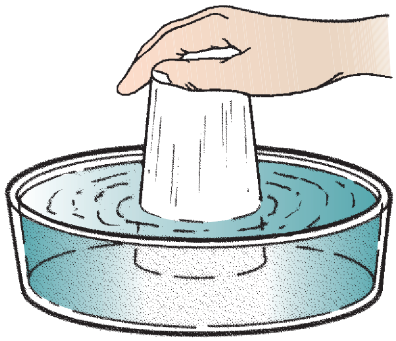

Figure 35.14 This room is 10 ft × 10 ft × 10 ft. The volume of the room is 1000 ft³ of air that weighs 0.075 lb/ft³. 1000 ft³ × 0.075 lb = 75 lb of air in the room.

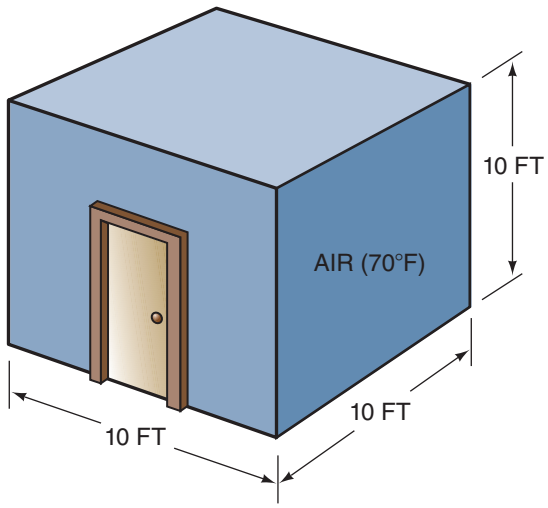

earth's surface is covered with water. Water, in the form of low-pressure vapor, is suspended in the air and is called *humidity,* **Figure 35.17.** Two types of humidity that are studied are absolute humidity and relative humidity.

35.7 ABSOLUTE AND RELATIVE HUMIDITY

The moisture content in air (humidity) is measured by weight and expressed in pounds or grains (7000 grains = 1 pound) per pound of air. Air can hold very little water vapor. Each pound of air at sea level (standard atmospheric pressure) at a temperature of 70°F can hold a maximum of 110.5 grains of moisture, or 0.01578 (110.5/7000) pounds of water. The amount of water vapor that an air sample can hold will change as the air conditions change. The actual amount of water vapor that is contained in an air sample is referred to

Figure 35.15 At standard atmospheric pressure, it will take 13.33 cubic feet of air to make up 1 lb of air.

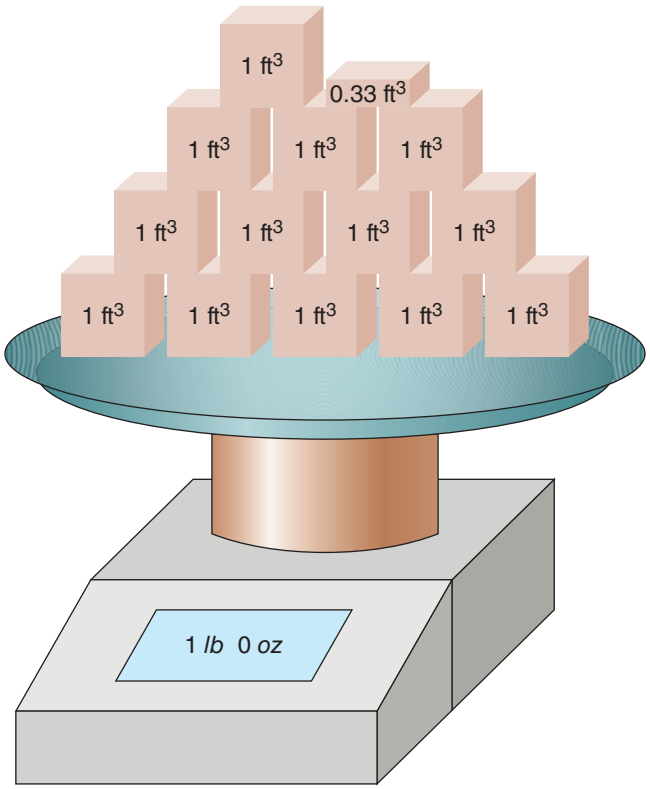

Figure 35.16 Substances that make up air.

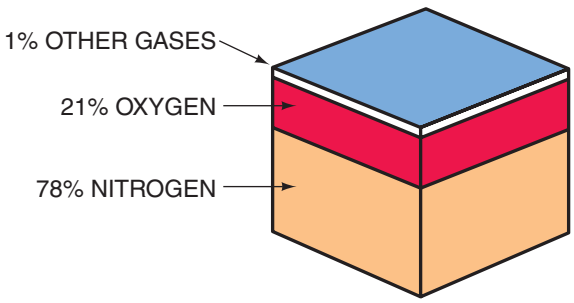

Figure 35.17 Moisture suspended in air.

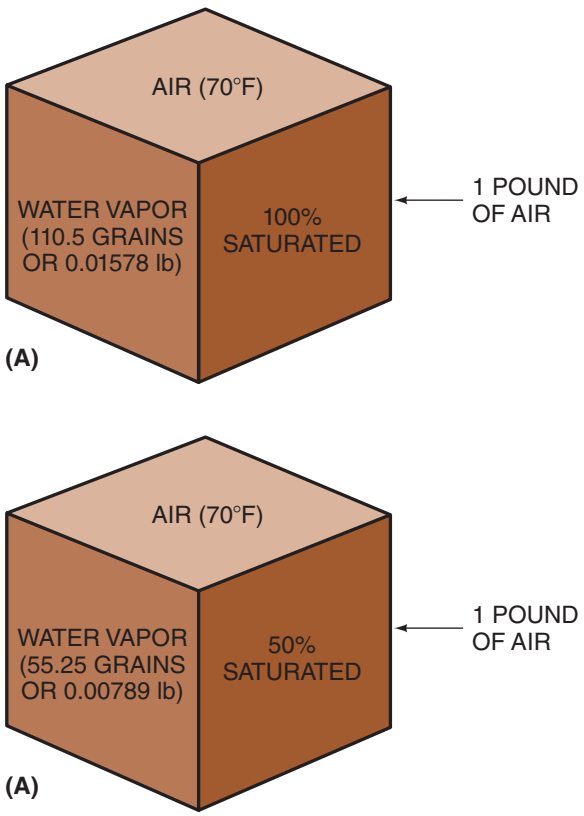
as the *absolute* humidity and is expressed in either grains per pound or pounds of water per pound of air. For example, a particular air sample that contains 10 grains of moisture per pound of air has an absolute humidity of 10 grains per pound. Absolute humidity is not commonly used for field calculations. Relative humidity, on the other hand, is very useful and is often used to determine air conditions and the operating effectiveness and efficiency of air-conditioning equipment.

Relative humidity is the relationship between the weight of water vapor in a pound of air compared to the weight of water vapor that a pound of air could hold at a 100% saturated condition, **Figure 35.18**. **Figure 35.18(A)** shows that 100% saturated air at 70°F holds 110.5 grains of moisture per pound, and **Figure 35.18(B)** shows that 50% saturated air will hold 55.25 grains at the same temperature. The air in **Figure 35.18(A)** has a relative humidity of 100%, while the air sample in **Figure 35.18(B)** has a relative humidity of 50%.

Large buildings typically have a set of specifications that tell the technician what the design conditions are for the occupied space. The HVAC system should be able to maintain these conditions when the system and controls are set and operating correctly. When there are complaints in certain areas of the building, the technician may be called on to determine whether these spaces are within the correct temperature and humidity ranges. Often, the only way to settle a dispute is to plot the air conditions on a comfort chart or compare the readings with the building's specifications. The technician must be prepared to accurately measure and record the conditions that are present in order to help determine what the problem is.

Although meteorologists talk about relative humidity, they do not like to use it for comparing conditions because as air temperature changes, the air's ability to hold moisture changes. Instead, meteorologists use dew point temperature to make comparisons. Dew point will be discussed in more detail later in this unit.

Figure 35.18 (A) This air sample is 100% saturated, so the relative humidity is 100%. (B) This air sample is 50% saturated, so the relative humidity is 50%.



35.8 SUPERHEATED GASES IN AIR

Because air is made up of several different gases, it is not a pure element or gas. As we have mentioned, air is made up of nitrogen (78%), oxygen (21%), and approximately 1% of other gases, **Figure 35.16**. These gases are highly superheated. Nitrogen, for instance, boils at −319°F, and oxygen boils at −297°F at atmospheric pressure, **Figure 35.19**. Hence, nitrogen and oxygen in the atmosphere are *superheated gases*—they are superheated several hundred degrees above absolute zero (0° Rankine). Each gas exerts pressure according to Dalton's law of partial pressures. This law states that each gas in a mixture of gases acts independently of the other gases and the total pressure of a gas mixture is the sum of the pressures of each gas in the mixture. More than one gas can occupy a space at the same time.

Water vapor suspended in air is a gas that exerts its own pressure and occupies space with the other gases. This pressure, known as the water vapor pressure, changes with temperature. As the temperature increases, the water vapor pressure increases. Consider the situation where a dish of water is resting on a table. If the water vapor pressure in the air is lower than the water vapor pressure in the dish, the

Figure 35.19 If you place a container of liquid nitrogen and a container of liquid oxygen in a room, the nitrogen and oxygen will start to evaporate or boil.

water in the dish will evaporate slowly to the lower pressure area of the water vapor in the air. Values for the vapor pressure of moisture in air can be found in some psychrometric charts and in saturated water tables. If the water vapor pressure in the dish is lower than the pressure of the vapor in the air, water vapor from the air will condense into the water in the dish. This can occur if the water in the dish has ice added to it and the vapor pressure is lowered as a result of the reduced water temperature.

When water vapor is suspended in the air, the air is sometimes called "wet air." If the air has a large amount of moisture, the moisture can be seen (e.g., fog or a cloud). Actually, the air is not wet because the moisture is suspended in the air. This could more accurately be called a nitrogen, oxygen, and water vapor mixture.

35.9 DRY-BULB AND WET-BULB TEMPERATURES

Up to this point in the unit, we have made several references to the temperature of air. When doing so, we have been referring to the level of heat intensity that is obtained when measured by a standard thermometer. In actuality, there are two types of temperature readings that are very useful to the field technician. These are the *dry-bulb* temperature and the *wet-bulb* temperature.

The moisture content of air can be checked by using a combination of dry-bulb and wet-bulb temperatures. *Dry-bulb* temperature is the sensible-heat level of air and is taken with an ordinary thermometer. Wet-bulb temperature is measured by a thermometer with a wick on the end that is soaked with distilled water, **Figure 35.20**. Both the wet-bulb and dry-bulb temperature readings are obtained at the same time by using an instrument referred to as a psychrometer. Some psychrometers are referred to as sling psychrometers, **Figure 35.21(A)**, that require that the thermometers be spun in an airstream. Newer generation digital or electronic psychrometers, **Figure 35.21(B)**, can be positioned in a moving airstream and do not need to be spun manually. The reading from a wet-bulb thermometer takes into account the moisture content of the air. It reflects the total heat content of air.

To take accurate wet- and dry-bulb temperature readings, the sling psychrometer is spun in the air, **Figure 35.22**. The wet-bulb thermometer will get cooler than the dry-bulb

Figure 35.20 Wet- and dry-bulb thermometer bulbs.

Figure 35.22 Technician spinning a sling psychrometer.

thermometer because of the evaporation of the distilled water. Distilled water is used because some water has undesirable mineral deposits. Some minerals will change the boiling temperature. The rate at which water will evaporate from the wick on the wet-bulb thermometer is determined by the moisture content of the surrounding air. If the surrounding air is very dry, the moisture will evaporate quickly, causing the wet-bulb temperature to drop lower. If the surrounding air is very wet (high relative humidity) the rate of evaporation will be very low and the wet-bulb temperature reading will be closer to the dry-bulb temperature reading. The closer the wet-bulb and dry-bulb temperatures are to each other, the higher the relative humidity. For example, if the wet-bulb and dry-bulb temperature readings are both 78°F, the relative humidity will be 100%. This is true because, if the air is saturated with moisture, no moisture can evaporate from the wetted wick on the wet-bulb thermometer and no reduction in wet-bulb temperature will result. The wet-bulb temperature can never be higher than the dry-bulb temperature. If it ever measures higher, there is a mistake.

The difference between the dry-bulb reading and the wet-bulb reading is called the *wet-bulb depression*. **Figure 35.23** shows a wet-bulb depression chart. As the amount of moisture suspended in the air decreases, moisture from the wet-bulb thermometer's wick will evaporate and the wet-bulb temperature reading will drop. This will cause the wet-bulb depression to increase. As the moisture content in the air increases, the rate of evaporation from the wick will decrease and the wet-bulb depression will be low. For example, a room with a dry-bulb temperature of 76°F and a wet-bulb temperature of 64°F has a wet-bulb depression of 12°F (76 degrees − 64 degrees) and a relative humidity of 52%. This is found by locating the point where the 76-degree dry-bulb temperature line (left side of the table in **Figure 35.23**) and the 12-degree wet-bulb depression line (across the top of the chart in **Figure 35.23**) cross. If the 76°F dry-bulb temperature is maintained and moisture is added to the room so that the wet-bulb temperature rises to 74°F, the relative humidity increases to 91% and the new wet-bulb depression is 2°F. If the wet-bulb depression is allowed to

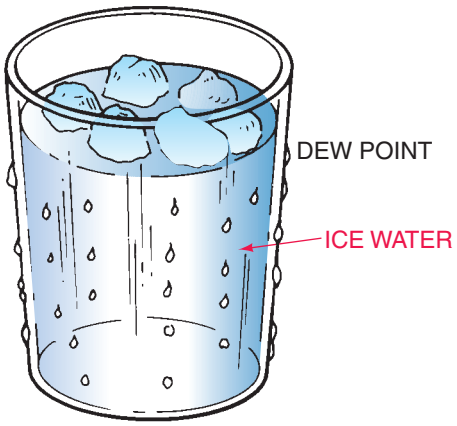
go to 0°F (e.g., 76°F dry bulb and 76°F wet bulb), the relative humidity will be 100%. The air is holding all of the moisture it can—it is *saturated* with moisture.

35.10 DEW POINT TEMPERATURE

The **dew point temperature** is the temperature at which moisture begins to condense out of the air. If a glass of ice water is placed on a table in a 75°F room that has a relative humidity of 50%, moisture will begin to form on the surface of the glass, **Figure 35.24**. Moisture from the room will also collect in the water in the glass and its level will begin to rise. It is left as a student exercise to verify, by using the psychrometric chart, that the dew point temperature of air at 75°F and 50% relative humidity is 55.5°F. Air can be dehumidified by passing it over a surface that is below its dew point temperature; moisture will collect on the cold surface, for example, an air-conditioning coil, **Figure 35.25**. The condensed moisture is drained, and this is the moisture that you see running out of the condensate line of an air conditioner, **Figure 35.26**.

Figure 35.24 The glass was gradually cooled until beads of water began to form on the outside of the glass.



35.11 ENTHALPY

As air is heated or cooled, the heat content of the air changes. When cooled, the air's heat content decreases, and when heated, the air's heat content increases. The enthalpy of air is the measure of heat content and is expressed in Btu per pound of air. Enthalpy is the total heat content of air and has both sensible- and latent-heat components.

Given the conditions of an air sample, the heat content of the sample can be determined by using the psychrometric chart, which will be discussed in the next section. If the conditions of an airstream are known both before and

Figure 35.26 The water dripping from the back of this window air conditioner is moisture that was collected from the room onto the cooling coil of the unit.

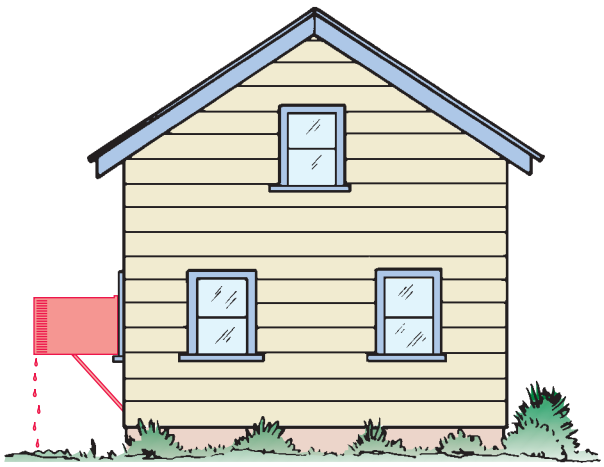


Figure 35.25 The cold surface of the evaporator coil causes moisture to condense from the air as the air passes over the surface of the coil.

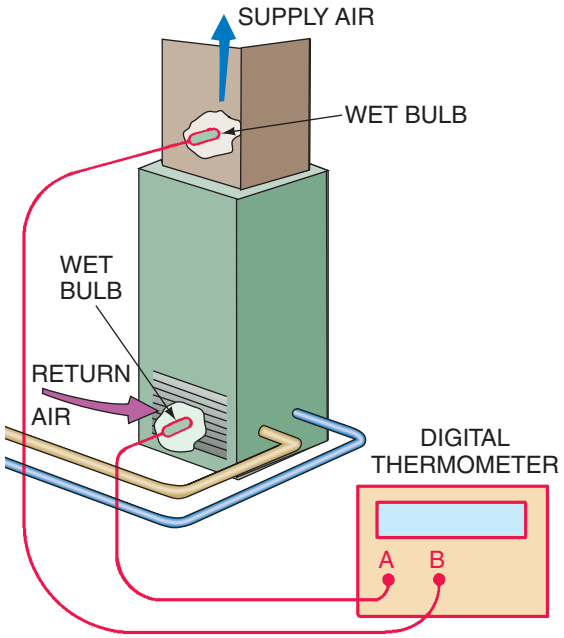
Figure 35.27 A wet-bulb reading can be taken on each side of a heat exchanger.



after the air passes through the heating or cooling equipment, we can easily determine how much heat has been either added or removed from the air as it passes through the heat-transfer surface. This information, together with some other basic calculations, will enable the service technician to verify the capacity and operating efficiency of the system. As we will soon see, enthalpy and wet-bulb temperatures are closely related. So, by measuring the wet-bulb temperature of the air before and after it moves through a heat exchanger, we can get a good idea of how much heat energy, in Btu/lb, is being transferred, **Figure 35.27**. If the amount of air moving through the heat exchanger, in cubic feet per minute, is known, we can formulate a fairly accurate estimate of the performance of the heat exchanger.

35.12 THE PSYCHROMETRIC CHART

All of the properties of air are compiled on the psychrometric chart, **Figure 35.28**. The bottom scales on the chart represent the sensible-heat portion, and the vertical scales on the right-hand side of the chart represent the latent-heat portion. Just to recap, sensible heat is the term used to describe a heat transfer that can be measured with a thermometer, while a latent-heat transfer is one that represents a change in state of a substance with no change in temperature. Since enthalpy is the total heat, the enthalpy scale, which is located on the curved top portion of the chart, is a combination of the latent-heat (vertical) and sensible-heat (horizontal) properties of the air. The chart looks complicated, but a clear plastic straightedge and a pencil will help you understand it.

The vertical lines extending from the bottom of the chart to the top represent lines of constant dry-bulb temperature, **Figure 35.29**. The dry-bulb temperature scale is found across the bottom of the chart. As a process moves up and down a dry-bulb temperature line, the dry-bulb temperature remains the same. Moving to the right indicates an increase in dry-bulb temperature, while moving to the left indicates a decrease in the dry-bulb temperature.

The wet-bulb temperature is represented by a set of gently sloped lines, as shown in **Figure 35.30**. The wet-bulb temperature values are read from the chart on the scale indicated along the left edge of the chart. The relative humidity is represented by the upward sloping lines within the chart, **Figure 35.31**. The bottom, horizontal line on the chart represents 0% relative humidity, while the left-hand border of the chart represents 100% relative humidity. Within the chart itself, there are nine other lines, each of which represents a 10% increment of relative humidity.

The moisture content, or absolute humidity, is represented by the horizontal lines on the chart, **Figure 35.32**. The absolute humidity can be read from the scales on the right side of the chart in either grains of moisture per pound of air or pounds of moisture per pound of air. The dew point temperature is also indicated by the horizontal lines, but the dew point temperature values are read from the same scale that is used to read the wet-bulb temperature.

The total heat, or enthalpy, of an air sample can be measured from the chart as well. The enthalpy scale is found above and to the left of the wet-bulb temperature scale, **Figure 35.33**. The lines of constant enthalpy are nearly identical to the lines of constant wet-bulb temperature. So, if the wet-bulb temperature of an air sample is known, the enthalpy of the air sample is also known.

The steeply sloped lines on the chart represent the specific volume of an air sample, **Figure 35.34**. These lines represent how many cubic feet of air will be needed to make up one pound. Remember, the specific volume is the inverse of density.

If you know any of the two conditions previously mentioned, you can easily determine any of the other conditions. The easiest conditions to determine from room air are the wet-bulb and the dry-bulb temperatures. For example, you can use an electronic thermometer as a wet-bulb thermometer if you do not have one. Take two leads and tape them together with one lead about 2 in. below the other, **Figure 35.35**. A simple wick can be made from a piece of white cotton. Wet the lower bulb (with the wick attached) with distilled water that is warmer than the room air. Tap water can be used but may result in slightly incorrect results due to the water's impurities. Hold the leads about 3 ft back from the element on the end and slowly spin them in the air. The wet lead will drop to a colder temperature than the dry lead. Keep spinning them until the lower lead stops dropping in temperature but is still damp.

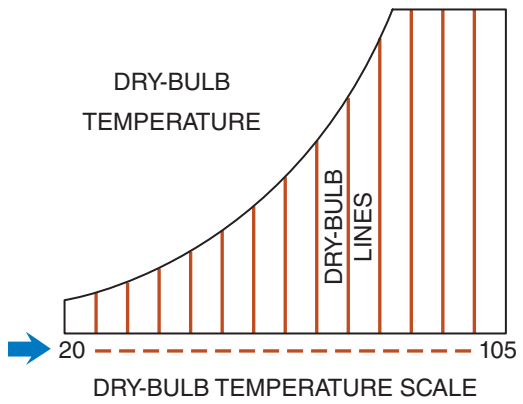

Figure 35.30 A skeleton chart showing the wet-bulb temperature.

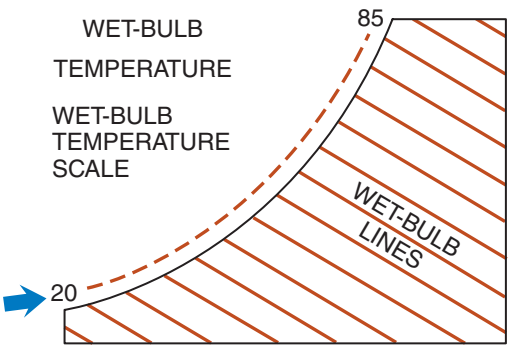

Figure 35.31 A skeleton chart showing the relative humidity lines.

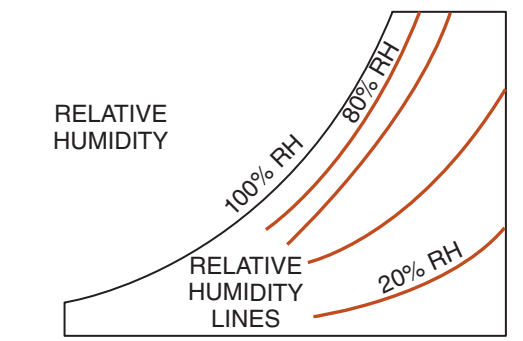

Figure 35.32 A skeleton chart showing the moisture content of air expressed in grains per pound of air.

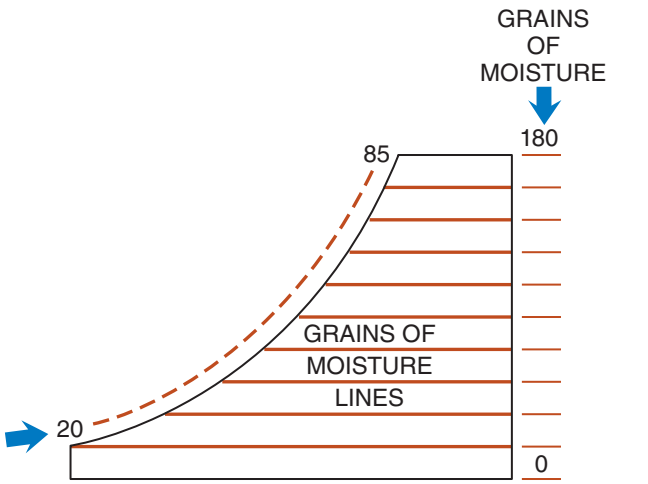

Figure 35.33 A skeleton chart showing the total heat content of the air in Btu/lb. These lines are almost parallel to the wet-bulb lines.

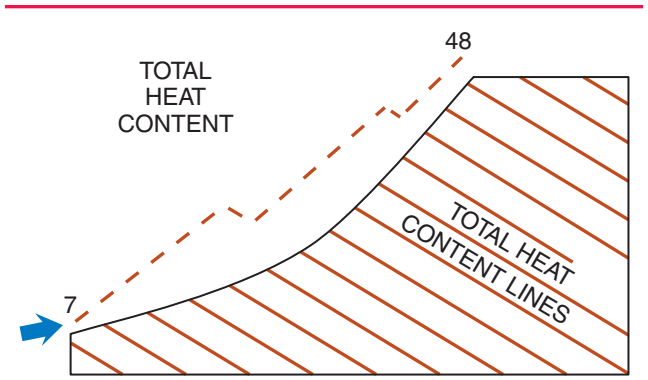

Quickly read the wet-bulb and dry-bulb temperatures without touching the bulbs. Suppose the reading is 75°F DB (dry bulb) and 62.5°F WB (wet bulb). Put your pencil point at this place on the psychrometric chart, **Figure 35.36**, and make a dot. Draw a light circle around it so you can find the dot again. The following information can be determined from this point:

1.	Dry-bulb temperature	**75°F**
2.	Wet-bulb temperature	**62.5°F**
3.	Dew point temperature	**55.5°F**
4.	Total heat content of 1 lb of air	**28.2 Btu**
5.	Moisture content of 1 lb of air	**65 gr**
6.	Relative humidity	**50%**
7.	Specific volume of air	**13.7 ft³/lb**

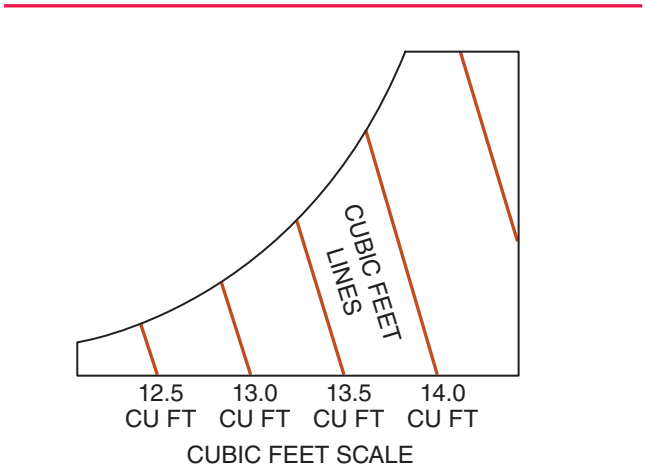

Figure 35.35 How to make a simple sling psychrometer.

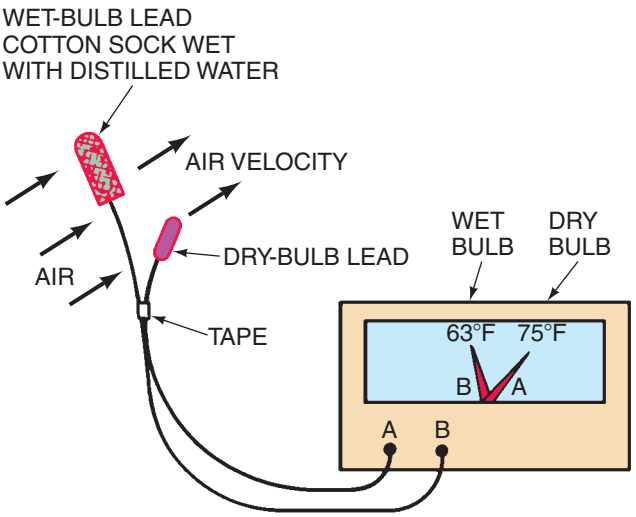

35.13 PLOTTING ON THE PSYCHROMETRIC CHART

The conditions of air can be plotted on the psychrometric chart as the air is being conditioned. The following examples show how different air-conditioning applications are plotted:

- Air is heated. It can be seen from this diagram that a heating-only process is indicated by an arrow moving in a horizontal direction from left to right, **Figure 35.37**. This indicates that the temperature of the air is increasing. This will also indicate an increase in enthalpy. Since there is no vertical movement on the system's process line, moisture is not being added or removed from the air, so there is no latent activity taking place. The absolute humidity will remain the same, but the relative humidity will decrease. This is because the air's ability to hold moisture increases as the temperature of the air increases.
- Air is cooled. A cooling-only process is indicated by a horizontal arrow moving from right to left, **Figure 35.38**. Since the air is not being humidified or dehumidified, there is no latent-heat activity in this process. The temperature of the air is dropping, so the enthalpy of the air is also dropping. In addition, the relative humidity of the air is increasing because, as air is cooled, its ability to hold moisture decreases.
- Air is humidified. When air is humidified, there is no change in the dry-bulb temperature of the air sample. The humidification process is indicated by an upward-pointing arrow, **Figure 35.39**. The enthalpy of the air sample will increase, along with the wet-bulb temperature of the air sample.
- Air is dehumidified. When air is dehumidified, there is no change in the dry-bulb temperature of the air sample. The dehumidification process is indicated by a downward-pointing arrow, **Figure 35.40**. The enthalpy of the air sample will decrease, along with the wet-bulb temperature of the air sample.
- Air is cooled and humidified using an evaporative cooler. During this process, the dry-bulb temperature decreases, while the relative humidity increases, **Figure 35.41**. This is popular in hot, dry climates.

When an airstream enters air-conditioning equipment, the airstream can be heated, cooled, humidified, or dehumidified, **Figure 35.42**. Some equipment will both add heat and moisture or cool and remove moisture. The following examples will show what happens in the most common heating and cooling systems:

- The most common winter application is to heat and humidify. This process will produce both a rise in temperature and an increase in moisture and dew point temperature, **Figure 35.43**.
- The most common summer application is to cool and dehumidify air. A decrease in temperature, moisture content, and dew point will occur, **Figure 35.44**.

35.14 FRESH AIR, INFILTRATION, AND VENTILATION

For us to be comfortable, the air that surrounds us has to be maintained at the correct conditions. The air in our homes is treated by heating it, cooling it, dehumidifying it, humidifying it, and cleaning it so that our bodies will give off the correct amount of heat for comfort. A small amount of air is induced from the outside into the conditioner to keep the air from becoming oxygen-starved and stagnant. This is called fresh air intake, or *ventilation*. If a system has no ventilation, it is relying on air infiltrating the structure around doors and windows.

Figure 35.37 Air passing through a sensible-heat exchange furnace.

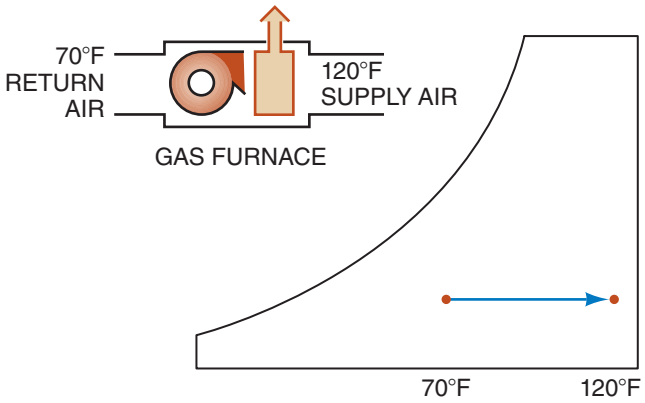

Figure 35.38 Air is cooled with a dry evaporator coil operating above the dew point temperature of the air. No moisture is removed. This is not a typical situation.

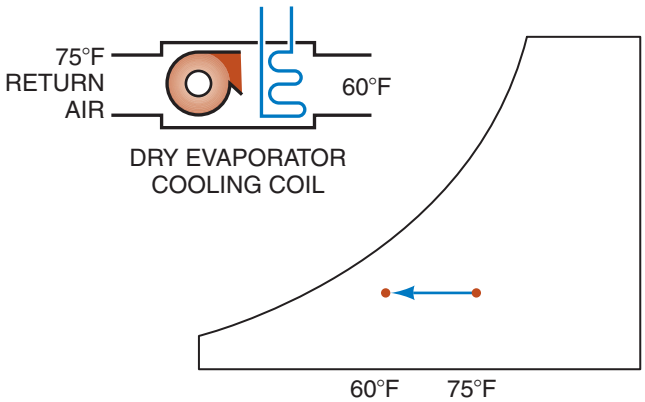

Figure 35.40 Moisture is removed from the air. This is not a typical application and is shown only as an example.

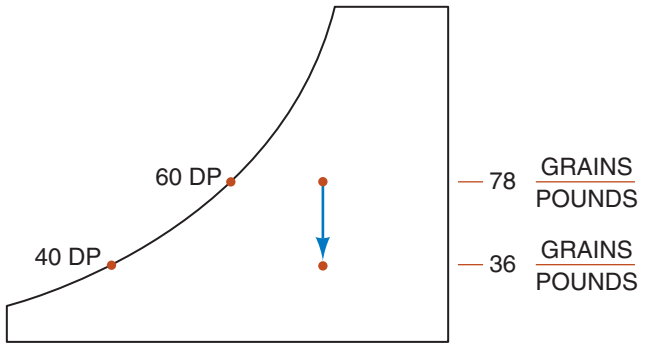

Figure 35.41 Hot, dry air passes through the water circuit of the evaporative cooler. Heat is given up to the cooler water, and the air entering the house is cooled and humidified; water evaporates to cool the air.

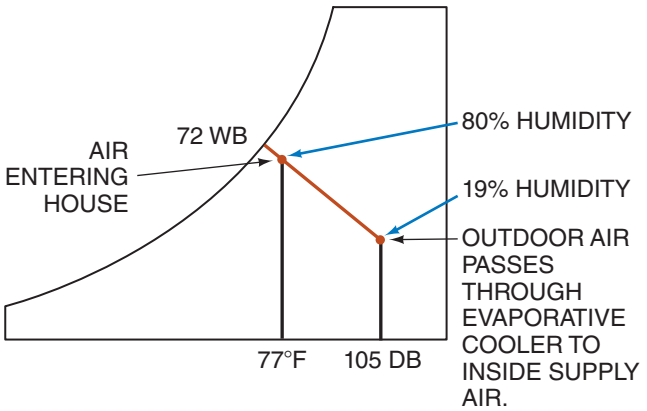

Figure 35.39 Spray atomizers are used to add moisture to the air. The dew point temperature and moisture content both increase.

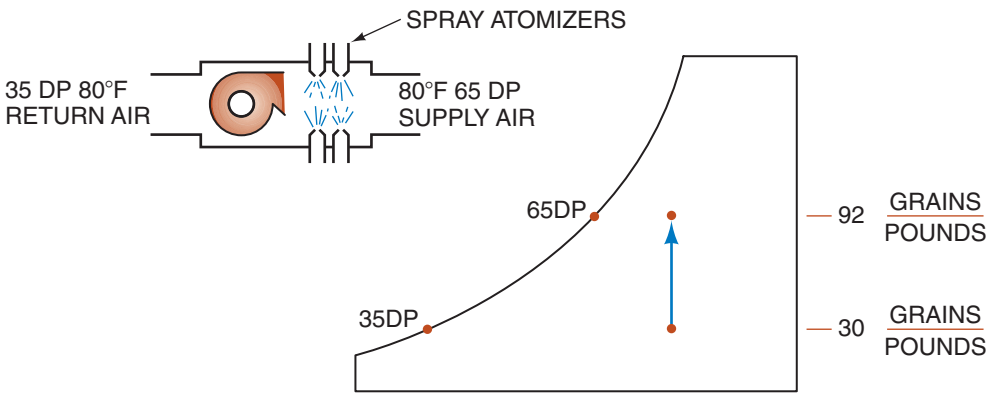

Modern energy-efficient homes can be built so tightly that infiltration does not provide enough fresh air. Recent studies indicate that indoor pollution in homes and buildings has increased as a result of an increase in energy conservation in heating and air-conditioning systems and the structures in which they are used. People are more energy conscious now than in the past, and modern buildings are constructed to allow much less air infiltration from the outside.

A typical homeowner may take the following measures to prevent outside air from entering the structure:

- Installing storm windows
- Installing storm doors
- Caulking around windows and doors
- Installing dampers on exhaust fans and dryer vents

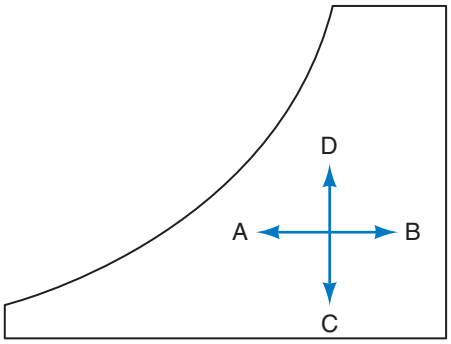
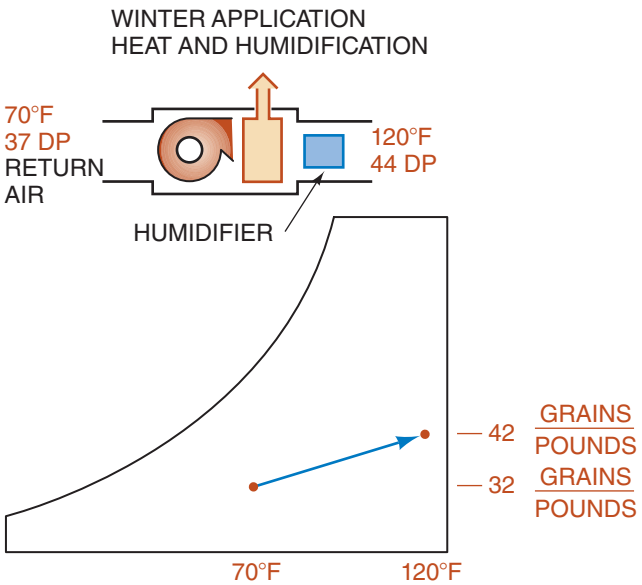
Figure 35.42 A summation of sensible and latent heat.



WHEN AIR IS CONDITIONED AND THE PLOT MOVES IN THE DIRECTION OF:

(A) SENSIBLE HEAT IS REMOVED.
(B) SENSIBLE HEAT IS ADDED.
(C) LATENT HEAT IS REMOVED, MOISTURE REMOVED.
(D) LATENT HEAT IS ADDED, MOISTURE ADDED.

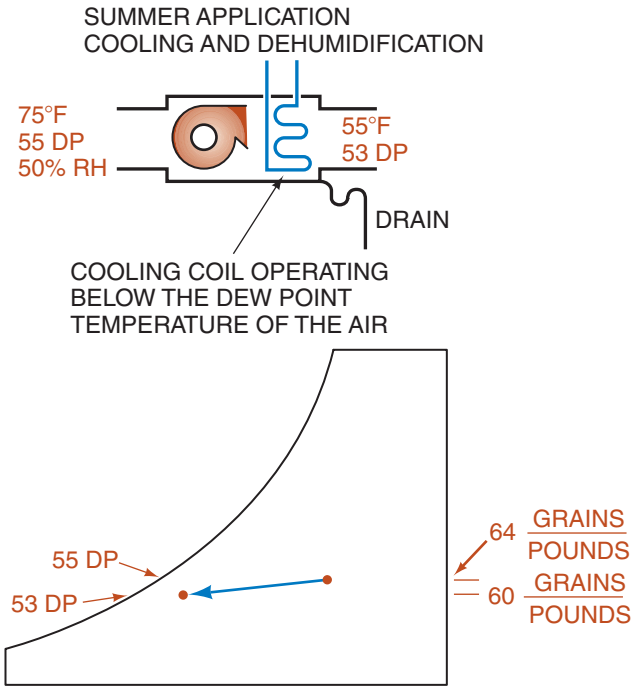
Figure 35.43 Sensible heat raises the temperature of the air from 70°F to 120°F. Moisture is evaporated, and latent heat is added to the air.



All of these will reduce the amount of outside air that leaks into the structure and will reduce energy costs. This may not be all good because of the following indoor pollution sources:

- Chemicals in new carpets, drapes, and upholstered furniture
- Cooking odors
- Vapors from cleaning chemicals
- Bathroom odors
- Vapors from freshly painted rooms
- Vapors from aerosol cans, hair sprays, and room deodorizers
- Vapors from particle-board epoxy resins
- Pets and their upkeep
- Radon gas leaking into the structure from the soil

Figure 35.44 Removal of sensible heat cools the air. Removal of latent heat removes moisture from the air.



These indoor pollutants may be diluted with outdoor air in the form of ventilation. *Infiltration* is the term used for random air that leaks into a structure; ventilation is planned, fresh air added to the structure. When air is introduced into the system before the heating or air-conditioning system, it is called ventilation. This may be accomplished by using a duct from the outside to the return-air side of the equipment, **Figure 35.45**.

There is some discussion as to how much ventilation air should be introduced to a residential structure, but it is generally agreed that changing the air in the space once every four hours or so is desirable. This means that 25% of the indoor air is pushed out by inducing air into the system. For example, suppose a 2000-ft² home with 8-ft ceilings needs ventilation because the home is very tight. How many cubic feet of air per minute must be introduced to change 25% of the air per hour?

$$2000\ \text{ft}^2 \times 8\text{-ft ceiling} \times 0.25 = 4000\ \text{ft}^3/\text{h}$$

$$\frac{4000\ \text{ft}^3/\text{h}}{60\ \text{min/h}} = 67\text{cfm}$$

This ventilation air has the potential to add a considerable load to the equipment. For example, suppose the house is located in Atlanta, Georgia, where the outdoor design temperature is 17°F in the winter. (See **Figure 36.13**, Design Dry-Bulb column 99%.) If the home is to be maintained at 70°F indoors when the outdoor temperature is 17°F, there is

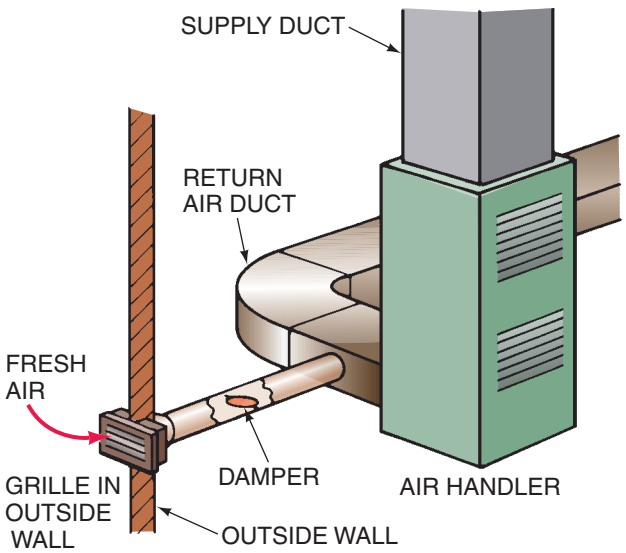
Figure 35.45 Fresh air is drawn into the return-air duct to improve air quality inside the house.



a 53°F temperature difference (TD). The load on the heating equipment due to ventilation alone will be

$$Q_s = 1.08 \times \text{cfm} \times \text{TD}$$
$$Q_s = 1.08 \times 67 \times 53$$
$$Q_s = 3835 \text{ Btu/h}$$

This formula is explained in detail in Unit 30, "Electric Heat." An outside temperature of 17°F is only for 1% of the year; the fresh air will be warmer than 17°F the other 99% of the year. This problem depicts the worst possible case. Many system designers will use the 97.5% column for designing a system and may select smaller equipment because of the warmer design temperatures. This may be taking a chance in the event of a cold winter.

The summertime calculation is made in much the same manner, except a different formula is used. Sensible and latent heat must be considered. In the summer, the design temperatures are 95°F dry-bulb and 74°F wet-bulb. The total heat formula may be used for this calculation:

$$Q_t = 4.5 \times \text{cfm} \times \Delta h$$

where Q_t = total heat
4.5 = a constant used to change pounds of air to cfm
Δh = difference in total heat (enthalpy) indoors and outdoors

To solve the problem of fresh air, plot the indoor air and the outdoor air on the psychrometric chart.

Outdoors: 95°F dry-bulb and 74°F wet-bulb = 37.68 Btu/lb
Indoors: 75°F dry-bulb and 50% relative humidity indoors = 28.2 Btu/lb, **Figure 35.46.**

Total heat difference = 37.68 − 28.2 = 9.48 Btu/lb

$$Q_t = 4.5 \times \text{cfm} \times \text{Total Heat Difference}$$
$$Q_t = 4.5 \times 67 \times 9.48$$
$$Q_t = 2858 \text{ Btu/h total heat added due to ventilation}$$

NOTE: *The 4.5 that is used in the total heat calculation is only an estimate and assumes that the average specific volume of the air is 13.33 ft³/lb. Since the conversion involves changing time units (hours to minutes) as well as taking the specific volume into account, the 60 min/h ÷ 13.33 ft³/lb calculation will yield a result of 4.5. However, if the average specific volume differs greatly from the 13.33 value, there will be small calculation errors down the road.*

System designers would require this total heat calculation to be broken down into the sensible-heat gain and the latent-heat gain. Equipment must be selected for the correct sensible- and latent-heat capacities or space humidity will not be correct. This calculation is done by using the sensible-heat and the latent-heat formulas as separate calculations. You will not arrive at the exact same total heat, because you cannot see the lines on the psychrometric chart closely enough for total accuracy. (In addition, refer to the calculation note above.)

$$Q_s = 1.08 \times \text{cfm} \times \text{TD}$$
plus
$$Q_l = 0.68 \times \text{cfm} \times \text{Grains Difference}$$

where Q_l = latent heat
0.68 = a constant used to change cfm to pounds of air and grains per pound
Grains difference = the difference in the grains per pound of air for the indoor air and the outdoor air

Example:

$$Q_s = 1.08 \times \text{cfm} \times \text{TD}$$
$$Q_s = 1.08 \times 67 \times 20$$
$$Q_s = 1447 \text{ Btu/h sensible heat}$$

From the psychrometric chart points plotted earlier, you will find that the outdoor air contains 92 gr/lb and the indoor air contains 64 gr/lb for a difference of 28 gr/lb of air.

$$Q_l = 0.68 \times \text{cfm} \times \text{grains difference}$$
$$Q_l = 0.68 \times 67 \times 28$$
$$Q_l = 1276$$
$$\text{Total Heat} = Q_s + Q_l$$
$$\text{Total Heat} = 1447 + 1276$$
$$\text{Total Heat} = 2723 \text{ Btu/h}$$

Notice the small difference between the 2858 Btu/h and the 2723 Btu/h results. This difference is not large enough to cause a problem in the evaluation of the total system performance.

Office buildings have the same pollution problems, except they have more sources of pollution because there are more people and different and varied activities. Office buildings have a tendency to be remodeled more often, which leads to more construction-type pollution. Also, copying machines that use liquid copy methods give off vapors, and there are more people per square foot in office buildings.

The national code requirements for fresh air in buildings where the public works are based on the number of people in the building and the type of use. Different buildings may have different indoor pollution rates because of the activity in the building. For example, buildings that have a lot of copying machines or blueprint machines may have more indoor pollution than ones with only electronic processors, such as computers. Department stores have different requirements than restaurants do. **Figure 35.47** shows some of the fresh-air requirements for different applications recommended by ASHRAE. These figures are constantly changing as new research is done and are for comparison only.

The design engineer is responsible for choosing the correct fresh-air makeup for a building, and the service technician is responsible for regulating the airflow in the field. The technician may be given a set of specifications for a building and told to regulate the outdoor air dampers to induce the correct amount of outdoor air into the building.

For the purpose of setting the outside air dampers, the mixed-air condition may be determined by calculation. The condition may be plotted on the psychrometric chart for ease of understanding. The dampers may then be adjusted for the correct conditions. For example, suppose a building with a return air condition of 73°F dry-bulb and 60°F wet-bulb is taking in and mixing air from the outside of 90°F dry-bulb and 75°F wet-bulb. When these two conditions are plotted on the psychrometric chart and a line is drawn between them, the condition of the mixture air will fall on the line, **Figure 35.48**. If the mixture were half outdoor air and half indoor air, the condition of the mixture air would be midway between points A and B.

Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

The point on the line between A and B may be calculated for any air mixture if the percentage of either air source, outdoor or indoor, is known. For example, when the point for 25% outdoor air and 75% indoor air mixture was calculated, the following calculation was used to find the dry-bulb point on the line. When the dry-bulb point is known and it falls on the line, you have a coordinate to find any other information for this air condition.

25% outdoor air: 0.25 × 90°F = 22.50°F
75% indoor air: 0.75 × 73°F = 54.75°F
The mixture (dry-bulb) = 77.25°F

When you look on the chart in **Figure 35.49**, you will find the point (C). Note that the point always falls closest to the air temperature with the highest percentage of air.

An actual problem may be something like the following:

BUILDING AIR-CONDITIONING SPECIFICATIONS

- Total building air = 50,000 cfm
- Recirculated air = 37,500 cfm, 75% return air
- Makeup air = 12,500 cfm, 25% outside air
- Indoor design temperature = 75°F dry-bulb, 50% relative humidity (62.5 wet-bulb)
- Outdoor design temperature (Atlanta, Georgia) = 94°F dry-bulb, 74°F wet-bulb

A technician checking the outdoor air percentage finds that the outdoor temperature is not at the design temperature. It is 93°F dry-bulb/75°F wet-bulb and the indoor conditions are 73°F dry-bulb/59°F wet-bulb. What should the mixture air temperature be?

A calculation for the mixture air is made. The actual conditions are plotted in **Figure 35.50**.

93°F × 0.25 = 23.25°F
73°F × 0.75 = 54.75°F

The mixture (dry-bulb) = 23.25°F + 54.75°F = 78°F

This calculation tells the technician that 25% of the mixed air dry-bulb temperature comes from the outside air, which is at 93°F, and therefore constitutes 23.25°F; 75% of the temperature is from the 73°F inside air dry-bulb temperature, which constitutes 54.75°F. Adding them together gives the mixed air dry-bulb temperature of 78°F (23.25 + 54.75 = 78). The technician can use dry-bulb temperatures alone to calculate air mixture percentages.

The technician would now check the mixture air temperature. If it is too high, he would slightly close the outdoor air dampers until the mixture air temperature stabilizes at the correct mixture temperature. If the mixture temperature is too low, he would slightly open the outdoor dampers until the mixture air temperature is stable and correct.

Figure 35.49 Mixture of different percentages of outside and inside air.

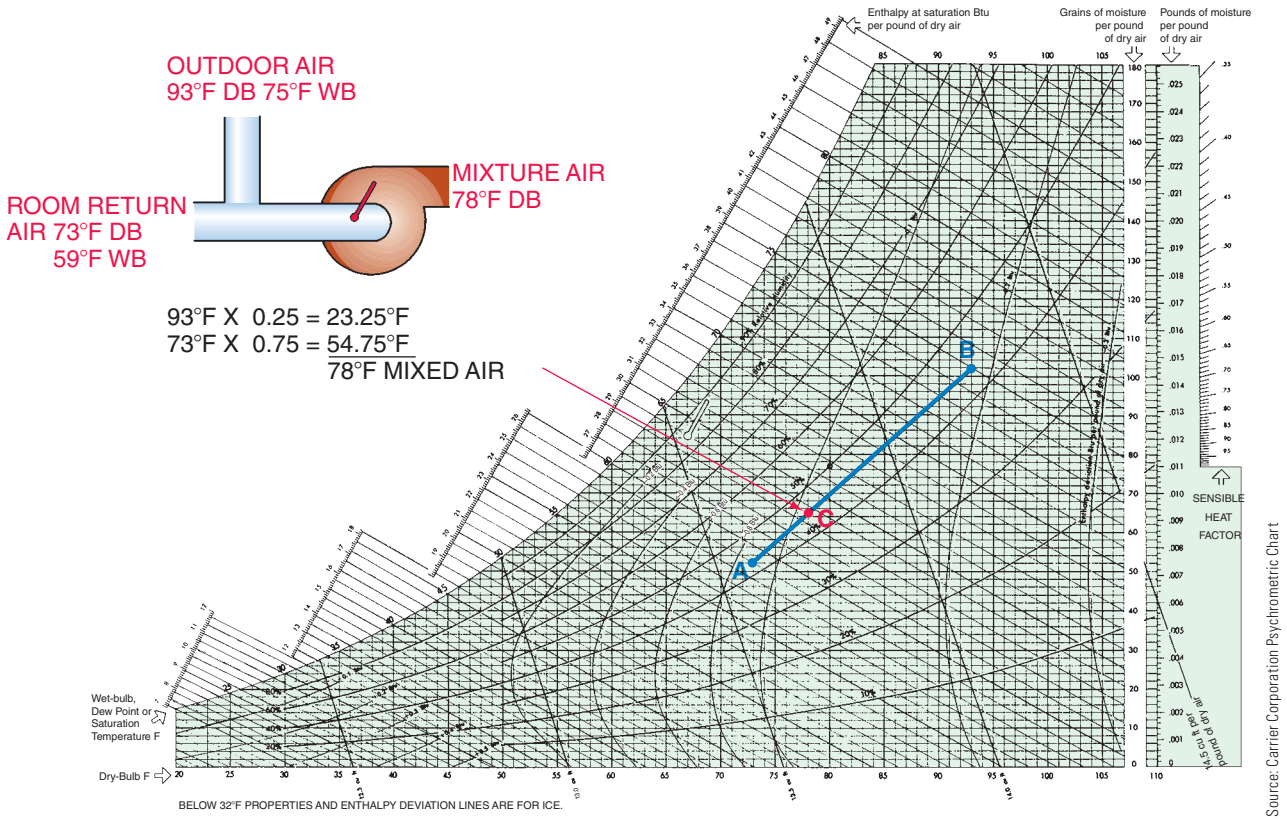
Figure 35.50 This practical problem of finding the mixed air condition is shown plotted on the chart. Point C is the mixed air point.



NOTE: *The outdoor and indoor conditions should be rechecked after adjustment because of changes in weather and indoor condition. These calculations and proper damper settings also depend on correct instrumentation while checking the air temperatures.*•

A technician may also use the psychrometric chart for field checking the capacity of a piece of air-conditioning equipment. For example, suppose the capacity of a 5-ton (60,000 Btu/h) unit is in question and the unit uses gas as the heat source. The heat source is used to determine the cfm of the equipment.

A technician may want to perform the cfm part of this problem first thing in the morning because it will involve operating the heating system long enough to arrive at the cfm. The unit heat is turned on and an accurate temperature rise across the gas heat exchanger is taken at 69.5°F. **NOTE:** *The technician was careful not to let radiant heat from the heat exchanger influence the thermometer lead.*•

The unit nameplate shows the unit to have 187,500 Btu/h input. The output would be 80% of the input, or 187,500 Btu/h × 0.80 = 150,000 Btu/h output to the airstream. The fan motor would add about 600 W × 3.431 Btuh/W = 2048 Btuh, for a total of 152,048 Btu/h. **NOTE:** *The blower is operated using the FAN ON position on the room thermostat. This ensures the same blower speed in heating and cooling.*•

Using the sensible-heat formula, the technician can find the cfm.

$$Q_s = 1.08 \times \text{cfm} \times \text{TD}$$

Solved for cfm:

$$\text{cfm} = \frac{Q_s}{1.08 \times \text{TD}}$$

$$\text{cfm} = \frac{152{,}048}{1.08 \times 69.5}$$

$$\text{cfm} = 2026 \text{ft}^3/\text{min}$$

The technician then would turn the unit to cooling and check the wet-bulb temperature in the entering and leaving airstream. Suppose that the entering wet-bulb is 62°F and the leaving wet-bulb is 53°F, **Figure 35.51**.

Total heat at 62°F wet-bulb is 27.85
Total heat at 53°F wet-bulb is 22.00
Total heat difference = 5.85 Btu/lb of air

Using the total heat formula:

$$Q_t = 4.5 \times \text{cfm} \times \text{Total Heat Difference}$$
$$Q_t = 4.5 \times 2026 \times 5.85$$
$$Q_t = 53{,}334 \text{ Btu/h Total Heat}$$

The unit has a capacity of 60,000 Btu/h, so it is operating very close to capacity. This is about as close as a technician can expect to get.

SUMMARY

- *Comfort* describes the delicate balance of physical well-being in relationship to our surroundings.
- The body stores energy, wastes it, consumes it in work, or gives heat off to its surroundings.
- For the body to be comfortable, it has to be warmer than its surroundings so that it can give up excess heat.
- Air contains 78% nitrogen, 21% oxygen, 1% other gases, and suspended water vapor.
- The specific volume of air is the reciprocal of the density: $1/0.075 = 13.33\ ft^3/lb$.
- The moisture content of air can vary the transfer of heat from the human body; therefore, different temperatures and moisture content can produce the same relative comfort level.
- Dry-bulb temperature is registered with a regular thermometer.
- Wet-bulb temperature is registered with a thermometer that has a wet wick. The wet-bulb thermometer lead gets colder than the dry-bulb thermometer lead because the moisture on the wick evaporates.
- The difference between the wet-bulb reading and the dry-bulb reading is the wet-bulb depression. It can be used to determine the relative humidity of a conditioned space.
- Water vapor in the air creates its own vapor pressure.
- The wet-bulb reading on a psychrometric chart shows the total heat content of a pound of air.
- When the cubic feet of air per minute is known, the wet-bulb reading in and out of an air exchanger can indicate the total heat being exchanged. This can be used in the field for calculating the capacity of a unit.

REVIEW QUESTIONS

1. Name the four comfort factors.
2. State three ways the body gives off heat.
3. Lower room temperatures can be offset in winter by
   A. lowering the relative humidity.
   B. being very still.
   C. activity.
   D. raising the relative humidity.
4. Perspiration cools the body by _____.
5. Relative humidity is measured using a
   A. thermotyporiter.
   B. sling psychrometer.
   C. dry-bulb thermometer.
   D. volt-ohmmeter.
6. Name the two unknowns that are easiest to obtain for making plots on the psychrometric chart.
7. Air that contains all of the moisture that it can hold is known as _____.
8. In order for an air-conditioning coil to remove moisture from the air, it must be below the _____ _____ temperature of the air.
9. For a room to be comfortable, the following conditions are considered average: _____°F dry-bulb and _____% relative humidity.
10. With a dry-bulb reading of 70°F and a wet-bulb reading of 61°F, the dew point temperature is _____°F.
11. Relative humidity in question 10 is _____%.
12. A gas furnace has an output of 60,000 Btu/h. The return air temperature is 72°F, and the temperature out of the furnace is 130°F. Disregarding the heat the fan motor may add to the airstream, how much air is the furnace handling?
13. A house has 3500 ft^2 of floor space and a 9-ft ceiling. What is the cubic volume of the house?
14. If the fresh-air requirements for the house in question 13 were to be 0.4 air changes per hour, how much fresh air must be taken in per minute?
15. If the outside fresh-air conditions were to be 93°F dry-bulb and 74°F wet-bulb, what would the total heat content of the air be?
16. If the air leaving the cooling coil were to be 55°F dry-bulb and 53°F wet-bulb, what would the total heat content of the air be?
17. Using the answers from questions 14, 15, and 16, what would be the total heat gain due to the fresh air for the house in question 13?
18. Describe why fresh air is important in a house.

UNIT 36

REFRIGERATION APPLIED TO AIR-CONDITIONING

OBJECTIVES

After studying this unit, you should be able to

- explain three ways in which heat transfers into a structure.
- state two ways that air is conditioned for cooling.
- explain refrigeration as applied to air-conditioning.
- describe an air-conditioning evaporator.
- list three types of compressors used in air-conditioning systems.
- describe an air-conditioning condenser.
- describe an air-conditioning metering device.
- list different types of evaporator coils.
- identify different types of condensers.
- explain how "high efficiency" is accomplished.
- describe package air-conditioning equipment.
- describe split-system equipment.
- list various ways to reduce solar heat gain on a structure.

SAFETYCHECKLIST

- ☑ Use caution when loading or unloading air-conditioning equipment from the truck. Wear an approved back brace when lifting and use your legs, keeping your back straight and upright. Trucks with lift gates may be used to lower the equipment to the ground.
- ☑ When installing equipment in attics and under buildings, be alert for stinging insects. Avoid being scratched or cut by exposed nails and other sharp objects in attics and in crawl spaces under buildings. Be sure to treat flesh wounds quickly to prevent infection.
- ☑ Wear goggles and gloves when installing charged line sets or gauges because escaping refrigerant can cause frostbite. Treat frostbite just like a burn. Warm the affected body part back to body temperature and apply burn ointments or creams to the affected areas.

36.1 REFRIGERATION

Air-conditioning (comfort cooling) is refrigeration applied to the space temperature of a building to cool it during the hot summer months. Air-conditioning is classified as high-temperature refrigeration. The air-conditioning system absorbs the heat that leaks into the structure and deposits it outside the structure where it originally came from. The basics of refrigeration and its components were discussed in Unit 3, "Refrigeration and Refrigerants". Some of the material is covered again here so that it will be readily available. As you study this unit, you will find that the major components used for refrigeration applied to air-conditioning are the same major components as used in commercial refrigeration equipment.

36.2 STRUCTURAL HEAT GAIN

Heat leaks into a structure by conduction, infiltration, and radiation (the sun's rays or solar load). In the northern hemisphere, the summer *solar load* on a structure is greater on the east and west sides of the structure. This is because the sun shines for longer periods of time on these parts of the structure, **Figure 36.1**. If a building has an attic, ventilating this space will help relieve the solar load on the ceiling, **Figures 36.2(A)** and **(B)**. There are three kinds of attic ventilation, power, natural, and solar powered. **Figure 36.2(A)** shows a power ventilator. It is a thermostatically controlled fan that cycles on when the attic temperature reaches a predetermined temperature, typically 85°F. This fan must have a high-limit control to shut the fan off in case of an attic fire. The power ventilator would just feed air to a fire. Solar-powered attic fans operate in the same manner as traditional electric-powered attic fans except solar-powered attic fans receive their power from photo-voltaic cells (solar panels) located on the roof. **Figure 36.2(B)** *shows a natural-draft ventilation system that is used more extensively. It is called a ridge vent system. The ridge vent is cut along the top of the entire roof ridge. Another vent, called a soffit vent, typically runs along the bottom of the roof overhang. These two vents create air circulation along the entire underside of the roof surface. Both systems are said to keep the roof shingles cooler and to prolong roof life. The power vent consumes some power and requires service when broken.*

If the structure has no attic, the roof of the house is also the ceiling of the living space. There should be sufficient insulation in the roof to minimize the heat gain in the occupied space, **Figure 36.3**.

Heat enters the structure through walls, closed windows, and closed doors by conduction. The rate of heat transfer into the structure depends on, among other things, the temperature difference between the inside and the outside

Figure 36.1 The solar load on a home.

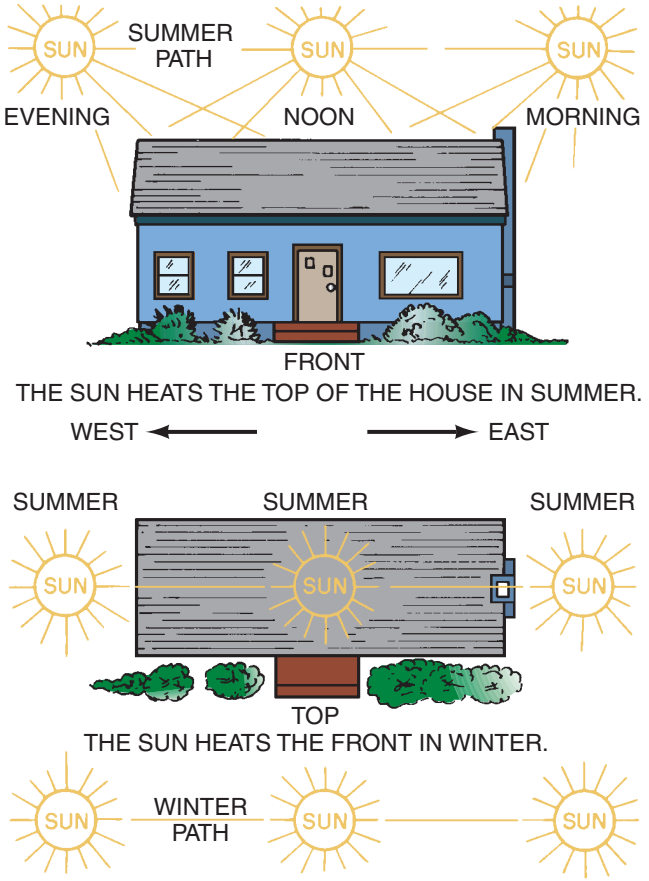

Figure 36.2 A ventilated attic helps keep the solar heat from the ceiling of the house.

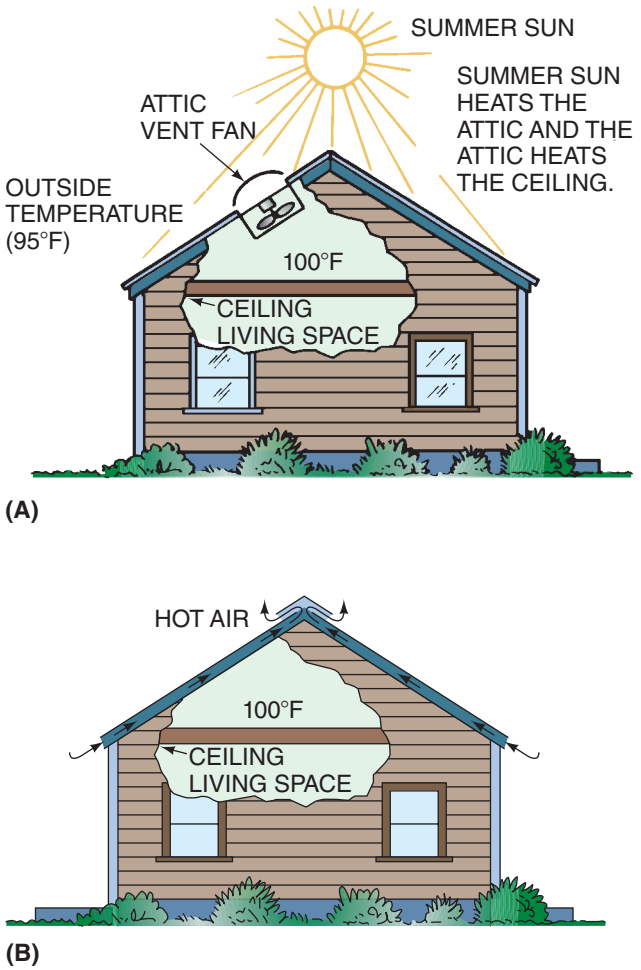

of the house, **Figure 36.4**. Some of the warm air that gets into the structure infiltrates through the cracks around the windows and doors. Air also leaks in when the doors or windows are opened. This infiltrated air has different characteristics in different parts of the country. Using the example in **Figure 36.4**, the typical design condition in Phoenix, Arizona, is 105°F dry-bulb and 71°F wet-bulb. In Augusta, Georgia, the air may be 90°F dry-bulb and 73°F wet-bulb. When the air leaks into a structure in Phoenix, it is cooled to the space temperature. This air contains a certain amount of moisture for each cubic foot of air that leaks in. This moisture is referred to as absolute humidity, and is measured in grains of moisture per pound of air. In Augusta, the infiltration air will have a higher moisture content (absolute humidity) than the infiltration air in Phoenix because Phoenix has a drier climate when compared to Augusta, Georgia.

The moisture content of the air in different locations must, therefore, be taken into account when selecting air-conditioning equipment. Equipment selected for parts of the country that are humid will have more capacity to remove moisture from the conditioned space. For this reason, used equipment cannot just be readily moved from one location to another.

Figure 36.3 This house has no attic. The sun shines directly on the ceiling of the living space.

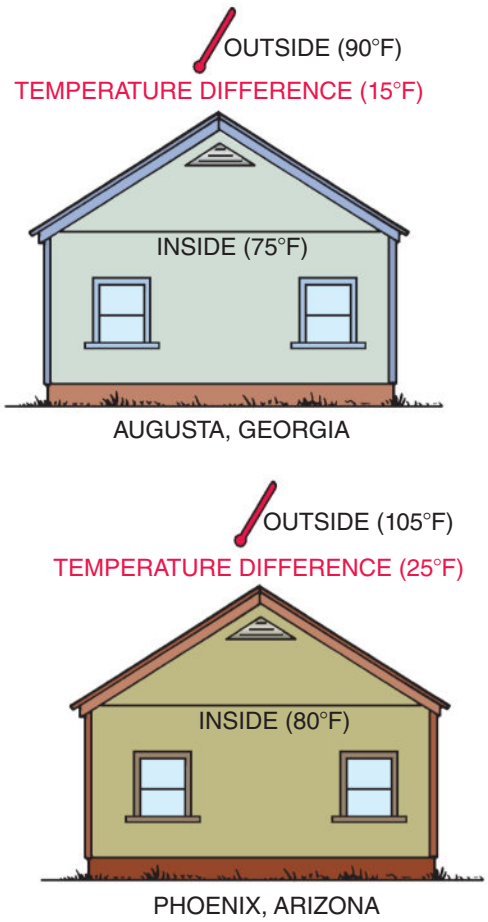
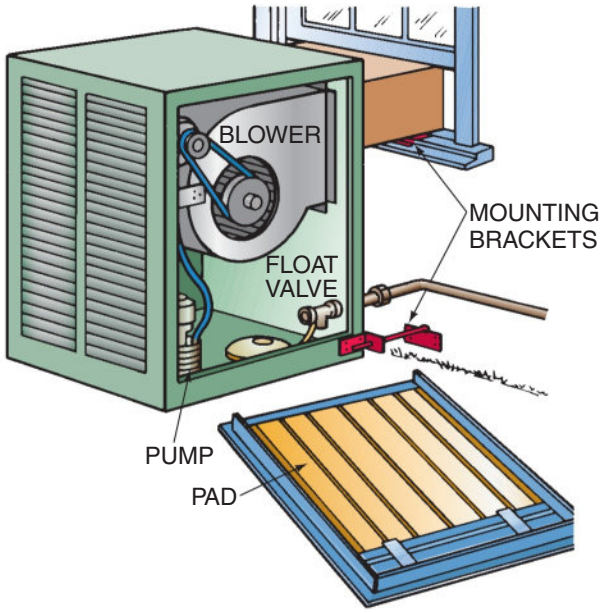
Figure 36.4 The difference between the inside and outside temperatures of a home in Augusta, Georgia, and a home in Phoenix, Arizona.



36.3 EVAPORATIVE COOLING

Air has been conditioned in more than one way to achieve comfort. In the climates where the humidity is low, a device called an **evaporative cooler**, **Figure 36.5**, *has been used for years.* Evaporative cooler are also commonly referred to as swamp coolers. *Water slowly running down the fiber mounted in a frame is the cooling media. Fresh air is drawn through the water-soaked fiber and cooled by evaporation to a point close to the wet-bulb temperature of the air. The air entering the structure is very humid but cooler than the dry-bulb temperature. For example, in Phoenix, Arizona, the design dry-bulb temperature in summer is 105°F. At the same time the dry-bulb is 105°F, the wet-bulb temperature may be 70°F. An evaporative cooler may lower the air temperature entering the room to 80°F dry-bulb, which is cool compared to 105°F, even if the humidity is high.*

Figure 36.5 *An evaporative cooler.*



Evaporative cooling units use 100% outdoor air. There must be an outlet through which the air that enters the structure can leave it. The conditioned air will have a tendency to move toward the outlet used to exhaust the air from the structure. Opening a window on the far side of the structure from where the air enters allows air to exit; otherwise, the structure will become pressurized by air that is being pushed in.

Evaporative coolers come in three common configurations: the drip-type swamp cooler, the spray or slinger-type swamp cooler, and the rotary-type swamp cooler. The drip-type evaporative cooler, **Figure 36.6(A)**, uses a pump to lift a column of water to the top of the evaporative pad, where the water drips down and wets the surface of the pad. As the hot, dry outside air passes through the wet pad, heat causes some of the moisture from the pad to evaporate. The evaporating moisture absorbs heat from the air stream passing through the pad, and the air stream is cooled. The spray or slinger-type evaporative cooler uses a pump to spray water onto the evaporative pad, **Figure 36.6(B)**. Just as with the drip-type swamp cooler, the moisture from the pad evaporates, cooling the airstream. The rotary-type evaporative cooler uses a motor to rotate the evaporative pad in the water sump, **Figure 36.6(C)**. As the pad rotates, it becomes wet and functions in a manner similar to the other two types just discussed.

36.4 REFRIGERATED COOLING OR AIR-CONDITIONING

Refrigerated air-conditioning is similar to commercial refrigeration because the same components are used to cool the air: (1) the evaporator, (2) the compressor, (3) the condenser, and (4) the metering device. The four components of refrigerated air-conditioning are assembled into two basic types of equipment for air-conditioning purposes: package equipment and split-system equipment. These components are assembled in several ways to accomplish the same goal—refrigerated air to dehumidifying by lower air temperature. Review Unit 3, "Refrigeration and Refrigerants," if you are not familiar with the basics of refrigeration.

PACKAGE AIR-CONDITIONING

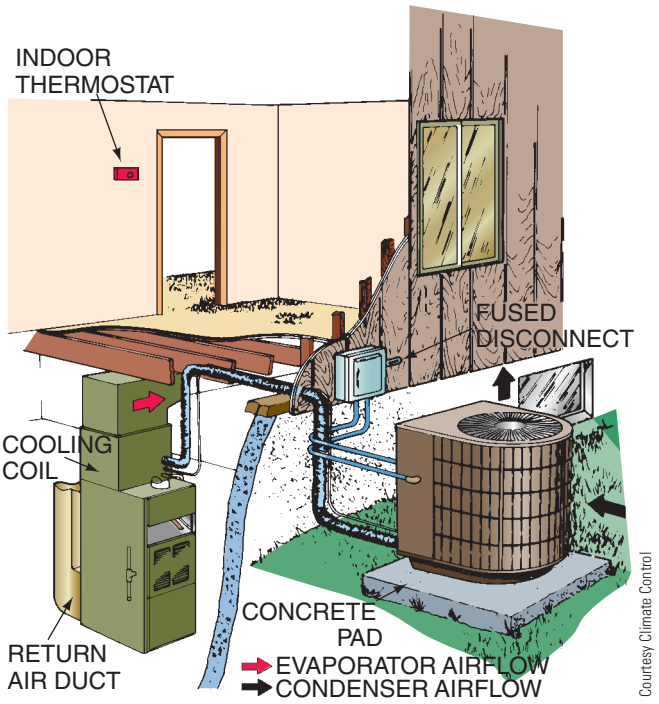
With **package equipment** all of the components are built into one cabinet much like a window unit. It is also called *self-contained* equipment. Air is ducted to and from the equipment. Package equipment may be located beside the structure or on top of it. In some instances, the heating equipment is built into the same cabinet. Package units have three main heating options: natural gas heating, electric heating, and heat pump—the latter using the reverse cycle of refrigeration absorbing heat from outdoors during winter and rejecting the heat to the conditioned space. Package units come in three styles: ground level, rooftop, and multi-position. Ground level package units are used when the roof cannot support the weight of the unit or when servicing the unit becomes a problem. Rooftop package units are the most common in the field. They provide safe operation away from the occupants while hiding the big bulky unit from sight. Rooftop units are the preferred method of installation due to location, which creates perfect conditions for optimum air circulation—hot air rising while cold air falls. Multi-position package units have the ability to be used for either rooftop application or ground level application, and can save storage space for a wholesaler or contractor. Package units will be discussed in greater detail in Unit 50, "Commercial, Packaged Rooftop, Variable Refrigerant Flow, and Variable Air Volume Systems."

SPLIT-SYSTEM AIR-CONDITIONING

In **split-system** air-conditioning, the condenser is located outside, remote from the evaporator, and uses interconnecting refrigerant lines known in the field as the line set. The evaporator may be located in the attic or a crawl space in the horizontal application, or a closet for upflow or downflow applications. The blower that moves air across the evaporator may be included in the furnace, or the air handler may be used for the air-conditioning system, **Figure 36.7**.

One type of split system that is becoming very popular is the ductless split system. Ductless split systems consist of

Figure 36.7 A split air-conditioning system.



a matching outdoor condensing unit, **Figure 36.8**, connected to one or more indoor fan coil units, **Figure 36.9**. Each room in the structure has its own indoor unit. They have grown in popularity in the United States over the last 30 years due to their many possible configurations, which require no ductwork and can achieve high seasonal energy efficiency ratings. Most ductless split systems are equipped with remote controls, some wired and some wireless, to give the equipment user the ability to control the operation of the unit from a distance.

Production of ductless split systems began in Japan in the early 1970s. The Japanese searched for a compact air-conditioning system that would be suitable for limited interior space buildings that were to be used in close proximity to one in other. They demanded these systems to operate quietly and be energy efficient. The ductless split system was their answer, making its way from Asia to Europe before making its way over to the United States in the early 1990s. Ever since then they have grown in popularity and options.

Ductless split systems come in many styles such as compact ceiling cassette, ceiling cassette, high wall, under ceiling, slim duct, and floor mounted. These systems are used in many residential applications such as additions, renovations, home preservation projects, garages, attic conversations, sun rooms, and finished basements. Commercial applications include computer rooms, churches, bars, and restaurants, to list a few.

The biggest advantage of the ductless split system over conventional split systems is the duct-free design. Conventional

Photo by Eugene Silberstein

split systems with ductwork have the potential, according to the DOE, to lose as much as 30% of their airflow due to air leaks; not so with ductless split systems.

Ductless split systems are able to achieve the desired space temperature faster with reduced air volume losses using VFD compressor capacity controls. Ductless split systems also offer smaller temperature swings in the conditioned space, making them a highly efficient option, while providing even heating and cooling in the occupied space. Moreover, individual room zoning provides the means for the homeowner to control the temperature in each and every room, via individual fan coil units. This zoning option allows for greater comfort and savings.

These systems can be installed in just about any application model where heating and cooling is desirable, which makes them extremely marketable options for both homeowners and contractors. Contractors are gravitating to ductless split systems for their clients due to their ease of installation.

Heat pump ductless split systems give the advantage of both heating and cooling throughout the year. The operation is similar to conventional heat pump systems, which absorb heat, both sensible and latent, from the conditioned space in the cooling mode, while rejecting heat into the conditioned space in the heating mode. This concept will be discussed later in Unit 43, "Air Source Heat Pumps". This feature makes ductless split-type heat pump systems a popular option for both residential and commercial applications.

Appearance is a major drawback with ductless systems, so manufacturers continue to seek other options. Many manufacturers of ductless systems have tried to improve their fan coil unit appearance by making them look less obtrusive in the living space. One manufacturer has even created a fan coil unit that looks like art on the wall. These systems require that precise heat gain and heat loss calculations be performed to ensure proper system sizing.

36.5 THE EVAPORATOR

The evaporator is the component that absorbs heat into the refrigeration system. It is a refrigeration coil made of aluminum or copper with aluminum fins attached to the coil of either type to give more surface area for better heat exchange. There are several designs for airflow through the evaporator coil and for draining the condensate water from the coil, depending on the installation. The different designs are known as the *A* coil, the *slant* coil, and the *H* coil.

THE A COIL

The *A coil* is used for upflow, downflow, and horizontal flow applications. It consists of two coils with side-by-side circuits that are spread apart at the bottom in the shape of the letter A, **Figure 36.10**. In upflow or downflow applications, the condensate pan is at the bottom of the A pattern. When used for horizontal flow, a pan is placed at the bottom of the coil and the coil is turned on its side. With the two coils in series the airflow in an A coil is through the core

Figure 36.10 An A coil. Notice that two coils are standing at an angle and touching at the top—shaped like an A.

of the coil; it cannot be from side to side. When horizontal airflow is required, slant or H coils may be more desirable.

THE SLANT COIL

The *slant coil* is a one-piece coil mounted in the duct on an angle (usually 60°), or slant, to give the coil more surface area. The slant of the coil causes the condensate water to drain to the condensate pan located at the bottom of the slant. The coil can be used for upflow, downflow, or horizontal flow when designed for these applications, **Figure 36.11**.

THE H COIL

The *H coil* is normally used in horizontal applications where space is limited, such as crawl space, attics, basements, and above drop ceilings. They can be adapted to vertical applications by using special drain pan configurations. The condensate drains are normally at the bottom of the H pattern, **Figure 36.12**, to allow for proper drainage.

Figure 36.11 A slant coil.

Courtesy BDP Company

Figure 36.12 An H coil.

COIL CIRCUITS

All of the aforementioned coils may have more than one refrigeration circuit for the refrigerant to travel. As was indicated in Unit 21, "Evaporators and the Refrigeration System," when a coil becomes too long and excessive pressure drop occurs, it is advisable to have more than one coil in parallel, **Figure 36.13**. The coil may have as many circuits as necessary to reduce the pressure drop through the coil while maintaining the proper amount of superheated vapor at the outlet of the evaporator. When there is more than one circuit, a distributor must be used to distribute the correct amount of refrigerant to the individual circuits, **Figure 36.14.** These circuits travel through the coil to the suction manifold, where superheated suction gas makes its way through the suction line.

MICROCHANNEL (FLAT-PLATE-AND-FIN) TECHNOLOGY

Efficient heat exchange between the refrigerant and air has been improved in the past few years by means of different coil designs. In the past, all coils have been copper or

Figure 36.13 A multicircuit coil. Notice that the expansion valve has four outlet tubes and that the suction line has four connections. There are four completely different circuits.

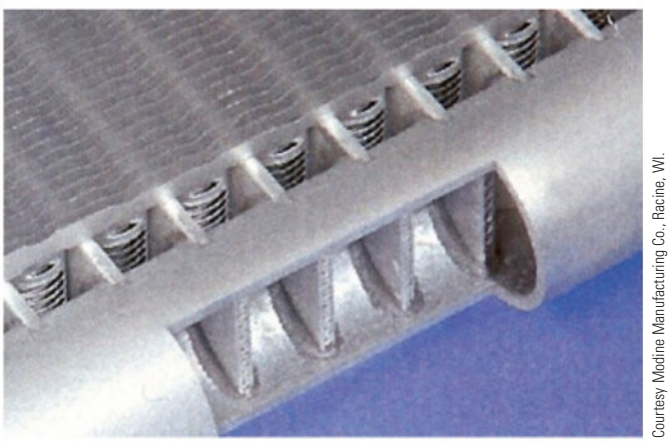
aluminum tubes with fins attached to the tubes. Coil sizes were limited to the tube sizes, typically 3/8" and 5/16". New coil designs have been developed that resemble automobile radiators, **Figure 36.15**. Small passages with fins, called microchannel or flat-plate-and-fin coils, have made it possible to build a smaller coil with more heat exchange surface that requires less refrigerant charge. Many manufacturers are using these coils for evaporators and condensers. Remember, when smaller, more efficient equipment can be built, it is a savings in materials, manufacturing time, storage space, and shipping costs and helps all the way from material purchasing to installation. These coils are discussed in detail in Unit 21, "Evaporators."

Figure 36.15 Cutaway of a microchannel coil.



36.6 THE FUNCTION OF THE EVAPORATOR

The evaporator is a heat exchanger that takes the heat from the room air and transfers it to the refrigerant. Two kinds of heat must be transferred: sensible heat and latent heat. Sensible heat lowers the air temperature, and latent heat changes the water vapor in the air to condensate. On average, three pints of condensate will be produced per ton of system capacity per hour. The condensate collects on the coil and runs through the drain pan to a p-trap (to stop air from pulling into the drain), and then it is normally piped to a drain.

Typically, room air may be 75°F dry-bulb and have a humidity of 50%, which is 62.5°F wet-bulb. The coil generally operates at a refrigerant temperature of about 40°F to remove the required amount of sensible heat (to lower the air temperature) and latent heat (to remove the correct amount of moisture). The air leaving the coil is approximately 55°F dry-bulb with a humidity of about 95%, which is 54°F wet-bulb. These points have been plotted on the psychrometric chart in **Figure 36.16**. The return air conditions have been plotted in red, while the supply air conditions have been plotted in blue. Notice that the relative humidity of the air leaving the cooling coil is much higher than the relative humidity of the return air. This is because the air has been cooled. However, the absolute humidity of the supply air is 60 grains per pound of air, as opposed to the absolute humidity of the return air, which is 65 grains per pound of air. The result is dehumidification. When the supply air mixes with the air in the room, it heats up and the relative humidity begins to drop.

These conditions are average for a climate with high humidity. If the humidity is very high, such as in coastal locations, the coil temperature may be a little lower to remove more humidity. If the system is in a locality where the humidity is very low, such as in desert areas, the coil temperature may be a little higher than 40°F. The coil temperature is controlled with the airflow across the evaporator coil. More airflow will cause higher coil temperatures, and less airflow will cause lower coil temperatures. The same equipment can be sold in all parts of the country because the airflow can be varied to accomplish the proper evaporator temperature for the proper humidity. Fin spacing on the evaporator may also affect the leaving air's humidity levels. Closer fin spacing will take more humidity out of the air. In an effort to provide greater comfort to the condition space, manufacturers are using variable frequency drive motors that modulate air volume to provide the greatest amount of evaporator efficiency.

36.7 DESIGN CONDITIONS

A house built in Augusta, Georgia, has a lower sensible-heat load and a higher latent-heat load than one constructed in Phoenix, Arizona. The designer or engineer must be familiar with local design practices, **Figure 36.17**. The airflow across the same coil in the two different parts of the country may be varied to accomplish different air conditions. People who choose equipment for conditioning homes and buildings either use the chart shown in **Figure 36.17** or some other chart that has been derived from this chart. The estimator, either a practical-design person or an engineer, will want the equipment to be sized for the best efficiency for the owner. The technician should also be familiar with this chart as a point of reference for understanding how designers choose equipment.

Using as a basis for comparison the summer conditions of the two cities Augusta, Georgia, and Phoenix, Arizona, let's explore the different possibilities. There are three columns for the design dry-bulb (DB) and wet-bulb (WB) conditions. The 1% column for Augusta lists 97 DB/77 WB. This means that, on average, from records taken over time, Augusta conditions will be at 97 DB/77 WB 1% of the time during the summer. The 2.5% column shows 95/76 and the 5% column shows 93/76. The person selecting the equipment may use any of these figures.

The equipment will perform at its best efficiency when running at full load. The starting and stopping of the system accounts for much of equipment inefficiency. Therefore, many designers try to select equipment to run as much as possible. If the equipment is selected for the 1% conditions, it will run at full load only 1% of the time. The rest of the time, it will be stopping and starting. If the equipment is selected for 5% conditions, it will be stopping and starting at conditions that fall below the 5% conditions. The problem with selecting equipment for 5% is that when the 1% conditions occur, the equipment will run all of the time and will not always maintain the conditions at a comfortable level for the occupants. This would also mean that the equipment would have no reserve capacity to lower the structure temperature in case of equipment downtime. For example, if the equipment is shut off for any reason for a period of time and the space conditions rise, it may not be able to reduce the space conditions until after an overnight run time. Suppose that a storm causes a power failure for several hours during the day—the unit will probably not catch up until the middle of the night when it can run at reduced load.

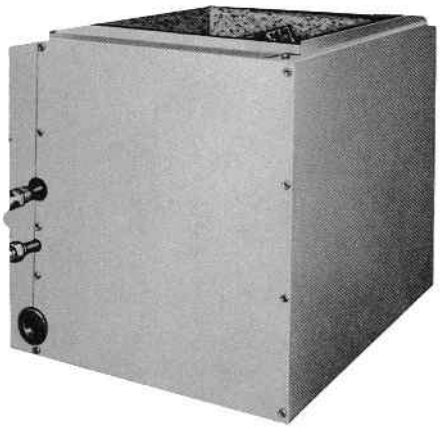
In order to alleviate difficulties such as this, many designers compromise by selecting equipment for the 2.5% conditions.

Another strategy that is becoming very popular to effectively match the system to the required capacity is to use variable refrigerant volume or variable refrigerant flow systems. Variable capacity equipment utilizes inverter-controlled compressor motors and fan motors to modulate both the flow of air and the flow of refrigerant through the system to adjust the capacity of the unit to fit the design conditions at the time. Variable refrigerant flow systems are discussed in Unit 50, "Commerical Packaged Rooftop, Variable Refrigerant Flow, and Variable Air Volume Systems." Variable-capacity compressors are discussed in Unit 23, "Compressors." Variable-speed motors are discussed in Unit 17, "Types of Electric Motors." The variable-capacity units all use some form of electronics to control capacity. They can control the space temperature and humidity, yet are designed so that you do not have to be an electronics technician to troubleshoot the systems.

Figure 36.18 An evaporator with a coil case.



Courtesy BDP Company.

36.8 EVAPORATOR APPLICATION

The evaporator may be installed in the airstream in several different ways. It may have a cased coil, **Figure 36.18**, or an uncased coil. Uncased coils do not include a casement, just a drain pan. Uncased coils are used mostly in areas where the cased coil will not fit properly. The coil must operate below the dew point temperature in order to remove humidity from the conditioned space. The cased coil should be insulated to keep it from absorbing heat from the surroundings. An insulated coil cabinet will not sweat on the outside, **Figure 36.19**. Many evaporators are built into the air handler by the manufacturer.

Figure 36.19 The operating conditions of an evaporator and a condenser. Notice that the cooling coil is in an enclosure to prevent sweating on the outside.

36.9 THE COMPRESSOR

The following types of compressors are used in air-conditioning systems: reciprocating, rotary, scroll, centrifugal, and screw. These are of the same design as similar types used in commercial refrigeration. The centrifugal and screw compressors, described briefly in Unit 23, "Compressors," are used primarily in large commercial and industrial applications and will be discussed further later in this text.

Compressors are vapor pumps that pump heat-laden refrigerant vapor from the low-pressure side of the system, the evaporator side, to the high-pressure, or condenser, side. To do this they compress the vapor from the low side, increasing the pressure and raising the temperature.

36.10 THE RECIPROCATING COMPRESSOR

The reciprocating compressors used for residential and light commercial air-conditioning are similar to those discussed in Unit 23, "Compressors." Reciprocating compressors used in air-conditioning are mainly cooled by suction gas and air passing over the shell of the compressor. If suction-gas-cooled, the suction line is piped to the motor end of the compressor, **Figure 36.20.** The maximum suction-gas temperature is usually about 70°F.

Reciprocating compressors in modern residential systems are usually the fully hermetic, suction-gas-cooled type, **Figure 36.21.** They are positive-displacement compressors using R-22, R-410A, or R-407C refrigerants. Some units built before 1970 may use R-12 or R-500. Because R-22 is an HCFC refrigerant, which contains chlorine, it was phased out for new equipment in 2010 and will be totally phased out of production in 2020. R-410A and R-407C are the two refrigerant blend replacements for R-22 in residential and commercial air-conditioning applications. R-410A is designed for new applications and R-407C can be used in new and retrofit applications. Refer to Unit 9, Section 9.11, "Refrigerant Blends," for more detailed information on R-410A and R-407C.

Figure 36.20 A serviceable hermetic compressor.

36.11 COMPRESSOR SPEEDS (RPM)

Older small and medium-size air-conditioning compressors were single-speed pumps and turned at the standard motor speeds of 3450 rpm or 1750 rpm. Early compressors were 1750 rpm, used R-12, and were large and heavy. Newer single-speed compressors operated at the faster speed and used more efficient refrigerants like R-22, R-410A, and R-407C. Most systems that are now being manufactured use variable-speed electronics to vary the compressor motor speed to control and adjust capacity. This is referred to as variable refrigerant flow technology. For more detailed information on variable refrigerant flow systems, refer to Unit 50, "Commerical Packaged Rooftop, Variable Refrigerant Flow, and Variable Air Volume Systems."

36.12 COOLING THE COMPRESSOR AND MOTOR

All compressors must be cooled because some of their mechanical energy converts to heat energy. Without cooling, the compressor motor would burn out and the oil would become hot enough to break down and form carbon. Hermetic

compressors have always been suction-gas-cooled. Rotary compressors are cooled with the discharge gas leaving the compressor. Discharge gas cools the compressor motor due to the fact the motor is much hotter than the discharge gas. However, the discharge gas temperature is influenced by the suction gas temperature. If the correct superheat is not maintained at the compressor, it will overheat because the discharge gas temperature will rise. So in the end the compressor motor temperature is still controlled by the suction gas temperature.

The newer compressor motors are able to run at higher temperatures because the motor windings are made of better materials and lubricating oils are of higher quality. Better insulation materials are used to help ensure that the windings will not overheat and break down while running under high-heat conditions. **NOTE:** *When dealing with a discharge-cooled compressor, the technician should determine that it is not running too hot.* The housing of a discharge-cooled compressor is hotter than that of a suction-cooled compressor. Checking the discharge line temperature is the sure test. Most manufacturers agree that the discharge line leaving the compressor should not exceed 225°F.

36.13 COMPRESSOR MOUNTINGS

Welded hermetic reciprocating compressors all have rubber mounting feet on the outside, and the compressor is mounted on springs inside the shell, **Figure 36.21**. New compressors have a vapor space between the motor and the shell, so the motor-temperature sensor must be on the inside to sense the motor temperature quickly. The suction gas dumps out into the shell, usually in the vicinity of the motor. Some compressors dump the suction gas directly into the rotor, where the turning rotor tends to dissipate any liquid drops in the return suction gas. The suction pickup tube for the compressor, which is inside the shell, is normally located in a high position so that liquid refrigerant or foaming oil cannot enter the compressor cylinders, **Figure 36.21**.

The compressor for air-conditioning equipment is normally located outside in the condensing unit. These hermetic compressors cannot be field serviced and often are not factory serviced. When one becomes defective, the manufacturer may authorize the technician to discard it or may require that it be returned to the factory to determine what made it fail. Due to the high number of compressor misdiagnoses in the field, manufacturers often require that the technician fully complete a compressor failure report detailing as much information as possible about the defective compressor, in effort to limit the amount of misdiagnoses.

36.14 THE ROTARY COMPRESSOR

The rotary compressor is small and light. It is sometimes cooled with compressor discharge gas, which makes the compressor appear to be running too hot. A warning about the hot temperature may be posted in the compressor compartment. The compressor and motor are pressed into the shell of a rotary compressor, and there is no vapor space between the compressor and the shell. This is another reason why the rotary compressor is smaller than a reciprocating compressor. The rotary compressor, which is used in small- to medium-sized systems, is more efficient than the reciprocating compressor, **Figure 36.22**. The primary reason the rotary compressor is highly efficient is that all the refrigerant that enters the intake port is discharged through the exhaust or discharge port. There is no clearance volume as there is in the reciprocating compressor. Rotary compressors are manufactured in two basic design types: the stationary vane and the rotary vane.

STATIONARY VANE ROTARY COMPRESSOR

The components of the stationary vane compressor are the housing, a blade or vane, a shaft with an off-center (eccentric) rotor, and a discharge valve. The shaft turns the off-center rotor so that it "rolls" around the cylinder, **Figure 36.23**. The blade or vane keeps the intake and compression chambers of the cylinder separate. The tolerances between the rotor and cylinder must be very close, and the vane must be machined so that gas does not escape from the discharge side to the intake. As the rotor turns, the vane slides in and out to remain tight against the rotor. The valve at the discharge keeps the compressed gas from leaking back into the chamber and into the suction side during the off cycle.

As the shaft turns, the rotor rolls around the cylinder, allowing suction gas to enter through the intake and compresses the gas on the compression side. This is a continuous process as long as the compressor is running. The results are similar to those with a reciprocating compressor. Low-pressure suction gas enters the cylinder, is compressed (which also causes its temperature to rise), and leaves through the discharge opening.

ROTARY VANE ROTARY COMPRESSOR

The rotary vane compressor has a rotor fitted to the center of the shaft, and the rotor and the shaft have the same center. The rotor has two or more vanes that slide in and out and trap and compress the gas, **Figure 36.24**. The shaft and rotor are positioned off-center in the cylinder. As a vane passes by the suction intake opening, low-pressure gas follows it. This gas continues to enter and is trapped by the next vane, which compresses it and pushes it out the discharge opening. Notice that the intake opening is much larger than the discharge opening. This is to allow the low-pressure gas to enter more readily. The process of intake and compression is continuous as long as the compressor is running.

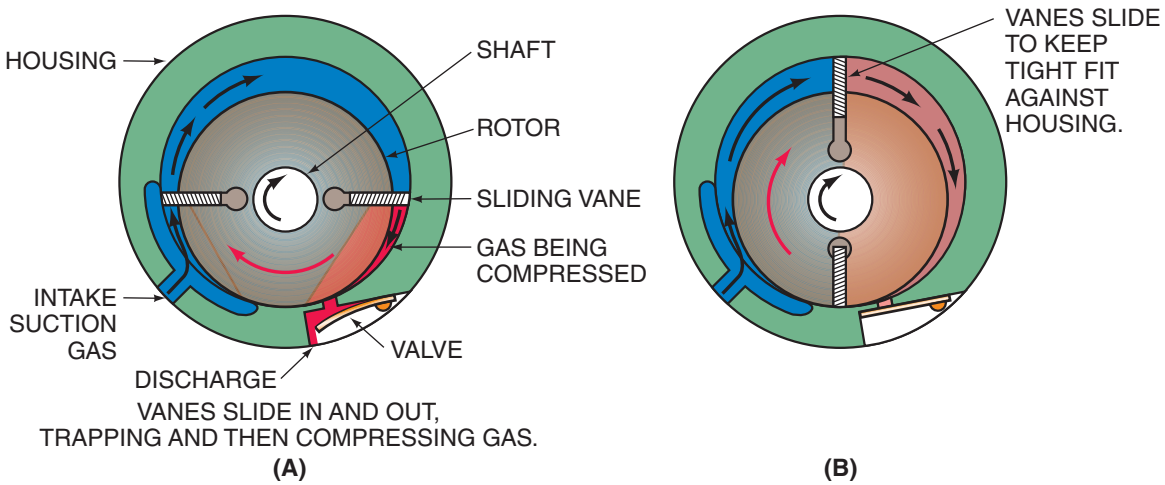
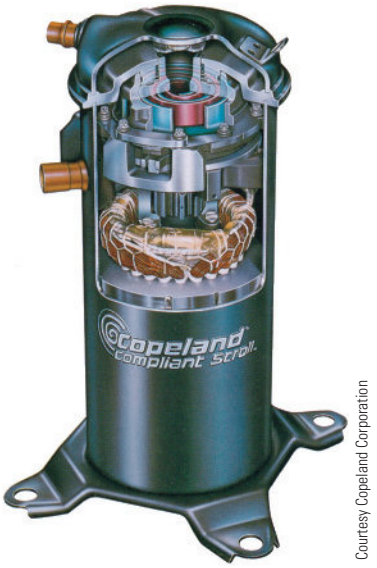
Figure 36.24 Operation of a rotary vane rotary compressor.



36.15 THE SCROLL COMPRESSOR

Compression in a scroll compressor, **Figure 36.25**, takes place between two spiral-shaped forms. One of these is stationary and the other operates with an orbiting action within it, **Figure 36.26**. The orbiting movement draws gas into a pocket between the two spirals. As this action continues, the gas opening is sealed off and the gas is forced into a smaller pocket at the center, **Figure 36.27**. The figure illustrates only one pocket of gas, but actually, most of the scroll or spiral is filled with gas and compression or "squeezing" occurs in all the pockets. Several stages of compression are occurring at the same time, which acts to balance the compression action.

Figure 36.25 A scroll compressor.



Courtesy Copeland Corporation

The scroll compressor is quiet compared to reciprocating compressors of the same size.

Contact between the spirals that seal off the pockets is achieved using centrifugal force. This minimizes gas leakage.

Figure 36.26 Orbiting action between the scrolls in a scroll compressor.

Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

Figure 36.27 Compression of one pocket of refrigerant in a scroll compressor.

Courtesy Copeland Corporation

However, should liquid refrigerant or debris be present in the system, the scrolls will separate without damage or stress to the compressor. The high performance of the scroll design depends on good axial and radial sealing. Axial sealing is usually accomplished with floating seals. Radial sealing is usually accomplished by only a thin film of oil. Therefore, there is little wear.

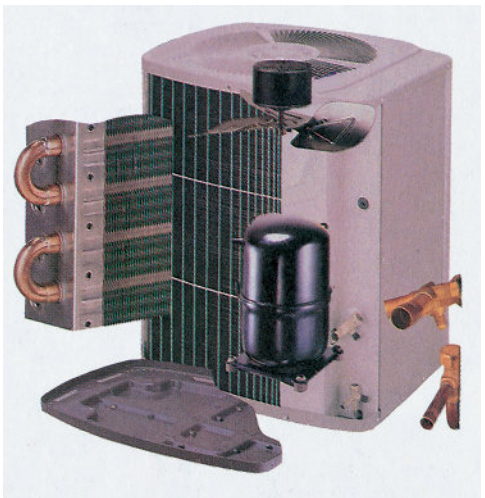
The scroll compressor is highly efficient due to the following factors:

- It requires no valves; consequently, there are no valve compression losses.
- The suction and discharge locations are separate, which reduces the heat transfer between the suction and discharge gas, so there is less difference in temperature between the various stages of compression occurring in the compressor.
- There is no clearance volume providing reexpansion gas as in a reciprocating compressor.

36.16 THE CONDENSER

In air-conditioning equipment the condenser is the component that rejects the heat from the system. Most equipment is air-cooled and rejects heat to the air. The coils are copper or aluminum and have aluminum fins to add to the heat exchange surface area, **Figure 36.28**. As mentioned earlier, new coil designs are being used for some condensers to make them smaller and more efficient. See Unit 21 "Evaporators and the Refrigeration System," for the details of coil design. The condenser is part of the condensing unit, which is the piece of equipment that contains the compressor, the condenser coil, the condenser fan, and the outdoor unit controls.

Figure 36.28 Condensers have either copper or aluminum tubes with aluminum fins.



Reproduced courtesy of Carrier Corporation

SIDE-AIR-DISCHARGE CONDENSING UNITS

Air-cooled condensers all discharge hot air, which contains heat absorbed from inside the structure. Early condensing units discharged the air out the side and were called side discharge units. The advantage of this equipment is that the fan and motor are located under the top panel, **Figure 36.29**. However, any noise generated inside the cabinet is discharged into the leaving airstream and may be clearly heard in a neighbor's yard. **NOTE:** *The heat from the condenser coil can be hot enough to kill plants that it blows on. These condensers are still in use.* Ductless split systems utilize side-discharge condensing units. The condensing unit shown in **Figure 36.29** is a side discharge unit. Since ductless split systems utilize inverter-controlled compressors and fan motors, the noise that is generated by these systems is very low.

TOP-AIR-DISCHARGE CONDENSERS

The most popular configuration for condensing units in residential equipment is the top-discharge design, **Figure 36.30**. In this type of unit, the hot air and noise are discharged from the top of the unit into the air. This is advantageous as far as air and noise are concerned, but because the fan and motor are on top, rain, snow, and leaves can fall directly into the unit. The fan motor needs to be protected with a rain shield,

Figure 36.29 The fan motor and all components are located under the top panel.

Figure 36.30 Equipment that discharges air from the top of the cabinet.

Courtesy York International Corporation

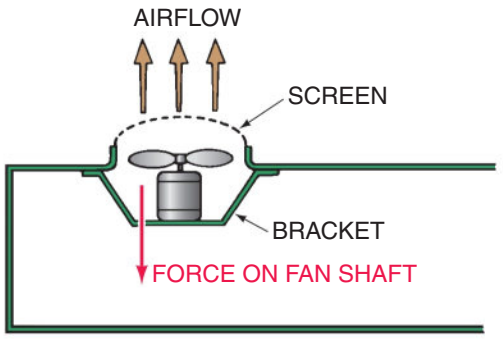
Figure 36.31. The fan motor bearings are in a vertical position, which means there is more thrust on the end of the bearing. In this type of application, therefore, the bearing needs a thrust surface, **Figure 36.32.**

CONDENSER COIL DESIGN

Some coil surfaces are positioned vertically, which allows grass and dirt to easily get into the bottom of the coil. Coils must be clean for the condenser to operate efficiently. Condenser coils should be cleaned every 3–5 years. Caution should be taken to read cleaning products' instructions carefully. Most coil cleaning products must be diluted with water for proper cleaning. Not all condenser coil chemicals can be used on every type of condenser coil. Improperly used chemicals can cause refrigerant leakages. *The bottom few rows of the coil in some equipment are used as a subcooling circuit to lower the condensed refrigerant temperature below the condensing temperature. It is common for the liquid line to be 10°F to 15°F cooler than the condensing temperature. Each degree of subcooling will add approximately 1% to the efficiency of the system. If the subcooling circuit is dirty, it could lower capacity by 10% to 15%.* If the equipment were sized too close to the design cooling load, the decreased capacity could mean the difference in a piece of equipment being able to cool a structure.

Figure 36.31 In units that discharge air from the top, the fan is usually on the top.

Figure 36.32 Top-air-discharge units place an additional load on the bearings. The fan is trying to fly down while it is running and pushing air out the top. During the starting and stopping of the fan, the fan blade and shaft rest on the bottom bearing. This bearing must have a thrust surface.



HIGH-EFFICIENCY CONDENSERS

Modern times and the federal government have demanded that air-conditioning equipment become more efficient. Probably the best way to improve efficiency is to lower the head pressure so that the compressor does not work as hard due to a lower compression ratio. More surface area in the condenser reduces the compressor head pressure even in the hottest weather. This means lower compressor current and less power consumed for the same amount of air-conditioning. Some oversized condensers are equipped with two-speed fans—one speed for mild weather, one for hot. Without two-speed fans the condensers would be too efficient in mild weather, causing the head pressure to be too low, which would starve the expansion device and result in less capacity, Inverter-controlled motors are also used. Refer to Unit 22, "Condensers," for more detailed information on high-efficiency condensers, condenser splitting, condenser fan cycling, variable-speed condenser fan controls, variable-frequency drives, and head pressure control devices.

Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

CONDENSER CABINET DESIGN

The condenser cabinet is usually located outside, so it needs to be weatherproof. Most cabinets are galvanized and painted to give them more years of life without rusting. Some cabinets are made of aluminum, which is lighter but may not last as long in a salty environment, such as coastal areas. Most small equipment is assembled with self-tapping sheet metal screws. These screws should be made of weather-resistant material that will last for years out in the weather. In the salt air of coastal areas, stainless steel is a good choice for sheet metal screws. When equipment that is assembled with drill screws is installed in the field, all of the screws should be fastened back into the cabinet tightly, or the unit may rattle. After being threaded many times, the screw holes may become oversized; if so, use the next half-size screw to tighten the cabinet panels.

36.17 EXPANSION DEVICES

The expansion device controls the flow of refrigerant into the evaporator. The TXV and the fixed-bore metering device (either a capillary tube or an orifice) are the types most often encountered on air-conditioning systems, but the TXV is almost exclusively used on all newly manufactured equipment. Electronic expansion valves (EEVs) are used on almost all ductless split systems. The TXVs are the same types as those described in Unit 24, "Expansion Devices," except that they have a different temperature range. Air-conditioning expansion devices are in the high-temperature range. TXVs are more efficient than fixed-bore devices because they allow the evaporator to reach peak performance faster. They allow more refrigerant into the evaporator coil during a hot pulldown—when the conditioned space is allowed to get too warm before the unit is started. Since the TXV maintains a constant evaporator superheat, an increase in system load will increase the evaporator superheat, causing the TXV to open.

With a TXV, the refrigerant pressures do not equalize during the off cycle unless the valve is equipped with a bleed port. When the pressures do not equalize during the off cycle, a compressor with a high-starting-torque motor must be used. This means that the compressor must have a start capacitor and starting relay for start-up after the system has been off. Some expansion valve manufacturers make a bleed port that always allows a small amount of refrigerant to bleed through. During the off cycle, this valve will allow pressures to equalize and so a compressor with a low-starting-torque motor can be used. Low-starting-torque motors are less expensive and have fewer parts that may malfunction.

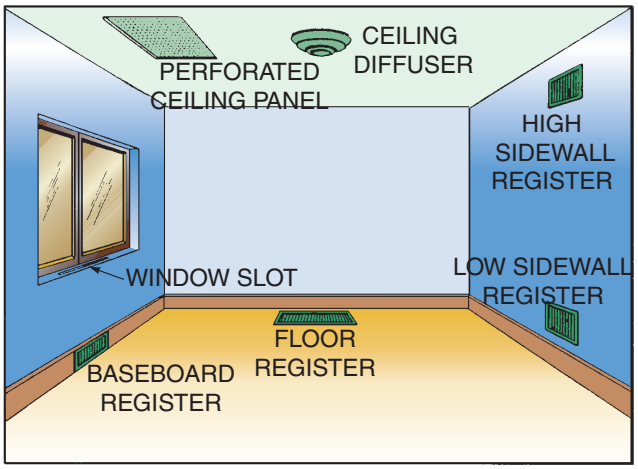
36.18 AIR-SIDE COMPONENTS

The air side of an air-conditioning system consists of the indoor blower as well as the supply air and the return air ducts. The airflow in an air-conditioning system is normally in the range of 400 cfm/ton in average humidity climates, but can vary significantly since many newer systems operate with variable speed blowers. A different airflow may be used for other climates. In humid coastal areas, airflow may be 350 cfm/ton, and 450 cfm/ton may be used in desert areas. The air leaving the air handler could be expected to be about 55°F in the average system. The ductwork carrying this air must be insulated when it runs through an unconditioned space or it will sweat and gain unwanted heat from the surroundings. In the case when the duct work carries heated air, uninsulated ducts will result in the transfer of heat from the air to the unconditioned air surrounding the ducts. The insulation should have a vapor barrier to prevent the moisture from penetrating and collecting on the metal duct. All seams in the insulation must be sealed securely.

The return air will normally be about 75°F. If the return air duct is run through an unconditioned space, it may not need insulation. Even if a small amount of heat did exchange, the cost of insulating versus allowing the small heat exchange should be evaluated to see which is more economical. If the duct is run through a hot attic, the duct must be insulated.

Cool air will distribute better from supply registers located high in the room. Ideally, the cool air will flow across the ceiling and then fall slowly through the room. The final distribution point is where the cool air is mixed with the room air to arrive at a comfort condition. **Figure 36.33** shows some examples of air-conditioning diffusers and registers.

Figure 36.33 The final task of the air-conditioning system is to get the refrigerated air properly distributed in the conditioned space.



36.19 INSTALLATION PROCEDURES

Package air-conditioning systems were described earlier as systems in which the entire air conditioner is built into one cabinet. A window unit is a package air conditioner designed to blow freely into the conditioned space. Most package air conditioners described in this text have two fan motors, one

for the evaporator and one for the condenser, **Figure 36.34**. A window unit, however, typically uses one fan motor with a double shaft that drives both fans. The outdoor fan is not designed to push air through a duct, but the indoor blower is. The package air conditioner has the advantage that all equipment is located outside the structure, so all service can be performed from outside the structure. *This equipment is more efficient than the split system because it is completely factory assembled and charged with refrigerant. The refrigerant lines are short, so there is less efficiency loss due to the refrigeration lines.*

The installation of a package system consists of mounting the unit on a firm foundation or roof curb, fastening the package unit to the ductwork, and connecting the electrical service to the unit. These units can be installed easily in some locations where the ductwork can be readily attached to the unit. Some common installation types are on the rooftop, ground level beside the structure, and in the eaves of structures, **Figure 36.35**.

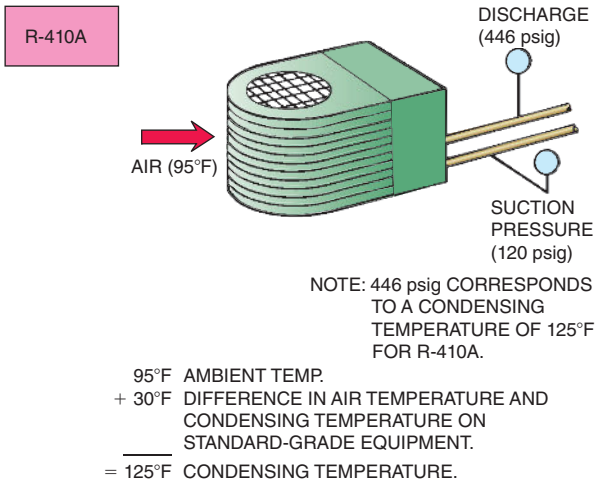
The split air-conditioning system is used when the condensing unit must be located away from the air handler. There must be interconnecting piping, often supplied in the form of a line set, which is furnished by the installing contractor or the equipment supplier. The condensing unit should be located as close as possible to the air handler to keep the line set as short as possible. The shorter the line set, the more efficient the system will operate. The tubing consists of a cool gas line and a liquid line. The cool gas line is insulated and is the larger of the two lines. The foam insulation on the suction line keeps unwanted heat from conducting into the line and keeps the line from sweating and dripping.

A typical installation and its pressures and temperatures are shown in **Figure 36.36**, which provides some guidelines about the operating characteristics of such a system. **SAFETY PRECAUTION:** *Installation of equipment may require the technician to unload the equipment from a truck or trailer and move it to various locations. The condensing unit may be located on the other side of the structure, far away from the driveway, or it may even be located on a rooftop. Proper care should be taken in handling the equipment. Lift-gate trucks may be used to set the equipment down to the ground.*

When installing the equipment, care should be taken while working under structures and in attics. Spiders and other types of stinging insects are often found in these places, and sharp objects such as nails are often left uncovered. When working in an attic, be careful not to step through a ceiling.

Figure 36.36 An installation showing the pressures and temperatures for a system in the humid southern part of the United States.



Care should also be taken while handling the line sets during connection if they contain refrigerant. Liquid R-22 boils at –41°F and R-410A boils at –60°F at atmospheric pressure and can inflict serious frostbite to the hands and eyes. Goggles and gloves must be worn when connecting line sets.

SUMMARY

- Evaporative cooling may be used in areas where the temperature is high and the humidity is low.
- High-temperature refrigeration, air-conditioning, or comfort cooling cools the air and removes moisture.
- Three common evaporator coil configurations are the A coil, slant coil, and H coil.
- Air-conditioning evaporators operate at about 40°F (at design conditions) and remove sensible heat and latent heat.
- Removal of sensible heat lowers the air temperature; removal of latent heat removes moisture.
- The compressor is the positive displacement pump that pumps the heat-laden vapor from the evaporator to the condenser.
- Condensers are located outside in order to reject the heat to the outside.
- Higher condenser efficiency is achieved by increasing the condenser surface area. Two-speed fans may be used—one speed for mild weather and the other for hot weather.
- Package air conditioners are installed through the roof or through the wall at the end of a structure, wherever the duct can be fastened.
- The package unit is charged at the factory and is factory assembled. Under similar conditions, it is more efficient than the split system.

REVIEW QUESTIONS

1. True or False: Evaporative air-conditioning will work in any climate.
2. What are the advantages of using refrigerated air-conditioning rather than evaporative conditioning?
3. The four major components of an air-conditioning system are the _____, _____, _____, and _____.

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

4. Most compressors are cooled using the _____ _____.
5. What advantage does a thermostatic expansion valve have over a capillary tube?
6. What advantage does a capillary tube have over a thermostatic expansion valve?
7. The _____ expansion device ordinarily must use a compressor with a high starting torque.
8. The most popular refrigerant used in the past for residential air-conditioning is R-_____.
9. What are two higher-efficiency refrigerant blends that can be used as long-term replacements for R-22 in residential and light-commercial air-conditioning applications?
10. What refrigerant blend can be used in retrofit applications as a long-term replacement for R-22 in residential and light-commercial air-conditioning applications?
11. What two types of heat are removed by the evaporator coil in the air-conditioning process?
12. The design boiling point for most evaporator coils in residential air-conditioning is _____°F.
13. What are the three most common types of compressors used in air-conditioning?
14. The large interconnecting line between the indoor and outdoor coil is the _____ line.
15. The small interconnecting line between the indoor and outdoor coil is the _____ line.
16. The outside design temperatures in the summer in Tucson, Arizona, for 2.5% of the time are _____°F dry-bulb and _____°F wet-bulb.
17. The dew point temperature tells you how much _____ is in the air.

UNIT 37

AIR DISTRIBUTION AND BALANCE

OBJECTIVES

After studying this unit, you should be able to

- describe characteristics of a propeller and a centrifugal blower.
- take basic air pressure measurements.
- measure air quantities.
- list the different types of air-measuring devices.
- describe the common types of motors and drives.
- describe various types of duct systems.
- explain what constitutes good airflow through a duct system.
- describe a return-air system.
- plot airflow conditions on the air friction chart.

SAFETYCHECKLIST

- ☑ Use a grounded, double-insulated, or cordless portable electric drill when installing or drilling into metal duct.
- ☑ Sheet metal can cause serious cuts. Wear gloves when installing or working with sheet metal.
- ☑ Wear goggles whenever working on ductwork if the system blower is operating.

37.1 CONDITIONING EQUIPMENT

Generally speaking, air has to be conditioned for people to be comfortable. One way to condition air is to use a blower to move the air through the conditioning equipment. This equipment may consist of a cooling coil, a heating device, a humidifier, or a device to clean the air. The forced-air system typically uses the same room air over and over again. Air from the room enters the system, is conditioned, and is returned to the room. Fresh air enters the structure either by infiltration around the windows and doors or by ventilation from a fresh-air inlet connected to the outside, **Figure 37.1**. Blower-assisted airflow is referred to as forced convection. Some specialized air-conditioning systems, such as those used in hospital operating rooms, are classified as 100% outside air systems. These systems do not recirculate the air from the occupied space back to the air-conditioning equipment. Instead, the air from the space is exhausted outdoors.

The forced-air system is different from a natural-draft system, where the air passes naturally over the conditioning equipment. Hot water baseboard heat is an example of natural-draft heat. The warmer water in the pipe heats the air in the vicinity of the pipe. The warmer air is less dense than cooler air, causing it to rise. New, cooler air from the floor takes the place of the heated air, **Figure 37.2**.

Figure 37.1 Ventilation using fresh air.

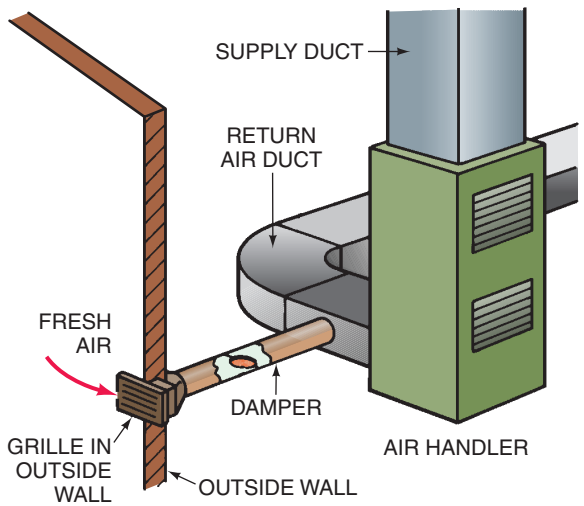

Figure 37.2 Air near the heated baseboard will become heated; it will expand and then rise.

Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

37.2 CORRECT AIR QUANTITY

The object of the forced-air system is to deliver the correct quantity of conditioned air to the occupied space. *When this occurs, the air mixes with the room air and creates a comfortable atmosphere in that space. Delivering the correct quantity of filtered air to the space also increases the efficiency of the system and overall indoor air quality.* Different spaces have different air quantity requirements, and the same structure may have several different cooling requirements. For example, a house has rooms of different sizes with different requirements. A bedroom requires less heat and cooling than does a large living room. Different amounts of air need to be delivered to these rooms to maintain comfortable conditions, **Figure 37.3** and **Figure 37.4**. Another example is a small office building with a high cooling requirement in the lobby and a low cooling requirement in the individual offices. One factor that is taken into account is the windows in each particular room or area in the structure. The number, type, and direction of the windows in the structure will have a significant effect on the amount of conditioned air that is required for each individual space. The correct amount of air must be delivered to each part of the building so that some areas will not be overcooled while other areas are undercooled.

37.3 THE FORCED-AIR SYSTEM

The components that make up the *forced-air system* are the *blower* (fan), the *air distribution system,* the *return-air system,* and the **grilles** and **registers** where the circulated air enters the room and returns to the conditioning equipment. See **Figure 37.5** for an example of duct fittings. When these components are chosen correctly, they work together as a system with the following characteristics:

1. No air movement will be felt in the conditioned space.
2. No air noise will be noticed in the conditioned space.
3. No temperature swings will be felt by the occupants.
4. The occupants will not be aware that the system is on or off unless it stops for a long time and the temperature changes.

To summarize, if the air-conditioning system is operating properly, the occupants of the space should not be aware of the system.

37.4 THE BLOWER

The *blower* provides the pressure difference needed to force the air into the duct system, through the heat-transfer surfaces in the conditioning equipment, through the grilles and registers, and into the room, **Figure 37.6.**

Figure 37.3 This floor plan has the heating and cooling requirements for each room indicated.

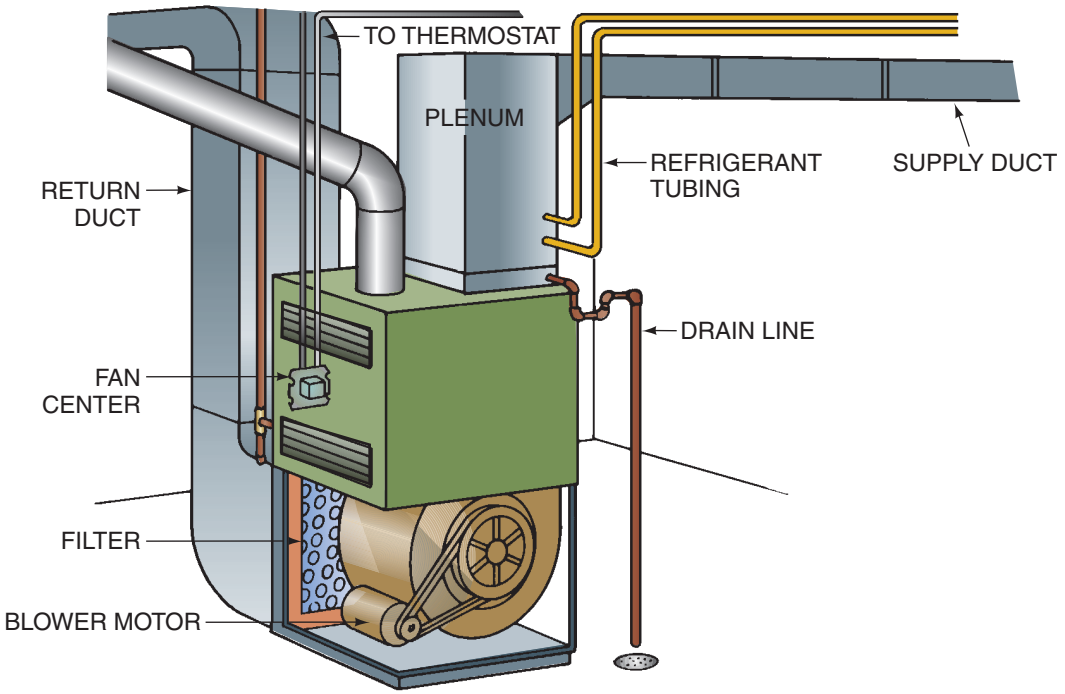
Figure 37.6 A blower and motor for moving air.



Air has weight and creates resistance to movement. This means that it takes energy to move the airstream to and from the conditioned space. If the blower on a 3-ton air-conditioning system is required to move 1200 cubic feet of air through the system per minute (400 cfm/ton), this is about 90 pounds of air moving through the system every minute (1200 ft^3/min × 0.075 lb/ft^3 = 90.02 lb/min). Ninety pounds of air moving through the system every minute equates to 5400 pounds of air every hour, or 129,600 pounds of per day. In order to move the required air quantities, the blower must overcome the resistance and friction created by other components located in the air distribution system: the return duct, the supply duct, the air filter, the cooling coil, the heat exchanger, the supply registers, and the return-air grilles.

The pressure in a duct system for a residence or a small office building is too small to be measured in psi. Instead, it is measured in units called inches of water column. Inches of water column is abbreviated as IWC or in. WC, where 27.7 IWC = 1 psi. Inches of water column was introduced earlier in the text in the gas heat unit where the operating pressures of natural gas and liquefied petroleum were discussed. A pressure of 1 in. WC is the pressure necessary to raise a column of water 1 in. Air pressure in a duct system is measured with a manometer, which is an instrument that accurately measures these very low pressures, **Figure 37.7**.

Since 1 psi = 27.7 inches, or 2.31 feet, as represented in **Figure 37.8**, we can conclude that, at standard conditions, atmospheric pressure will support a column of water

Figure 37.7 Digital electronic manometer.

Source: Ritchie Engineering Company, Inc.

approximately 34 feet high. This is because the atmosphere exerts a pressure of 14.696 psi at standard atmospheric conditions (2.31 × 14.696 = 34 feet). The average duct system will not exceed a pressure of 1 in. WC. A pressure of 0.05 psig

will support a column of water 1.39 in. high (27.7 × 0.05 = 1.39 in.). Airflow pressure in ductwork is measured in inches of water column.

37.5 SYSTEM PRESSURES

A duct system is pressurized by three pressures—**static pressure**, **velocity pressure**, and **total pressure**. Static pressure + velocity pressure = total pressure. Static pressure is the same as the pressure on an enclosed vessel and can be thought of as the pressure of the air pushing against the walls of the duct sections. This is like the pressure of the refrigerant in a cylinder that is pushing outward. The probe on the manometer is positioned perpendicular to the walls of the duct and therefore senses only the outward, or static pressure, in the duct, **Figure 37.9.**

The air moving in a duct system flows in a path that is parallel to the walls of the duct section. The velocity and weight of the air create what is called velocity pressure. **Figure 37.10** shows how a manometer is connected to measure velocity pressure in an air duct. Notice the position of the sensing probes. The air flows straight into the inlet of the probe, which registers both velocity and static pressure. The manometer determines the velocity pressure by canceling the static pressure with the second probe. We have velocity pressure and static pressure pushing on the left side of the manometer and only the static pressure pushing on the right side of the manometer.

The total pressure of a duct can be measured by using the manometer a little differently. In this case, only the probe that is placed in the airstream is needed, as it senses both the velocity and static pressures in the duct. This is the duct system's total pressure, **Figure 37.11.** The main difference between the manometer connections in **Figure 37.10** and in **Figure 37.11** is that there is no second connection to cancel out the static pressure from the measurement.

Figure 37.10 A manometer connected to measure the velocity pressure of the air moving in the duct.

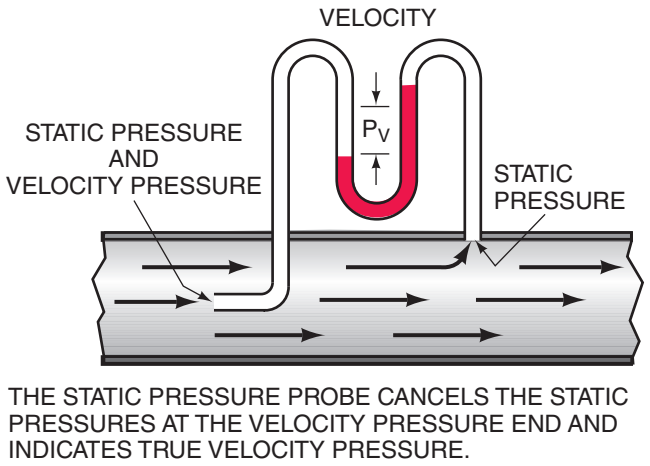

Figure 37.9 A manometer connected to measure the static pressure.

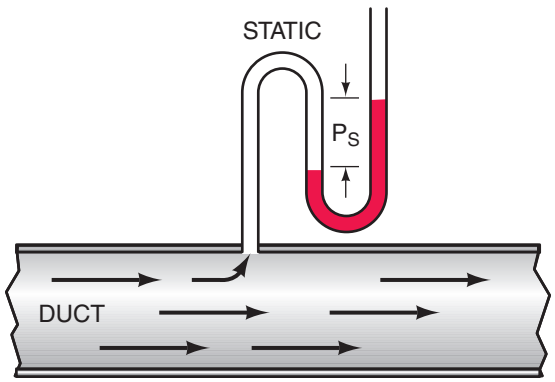

Figure 37.11 A manometer connected to measure the total air pressure in the duct.

37.6 AIR-MEASURING INSTRUMENTS FOR DUCT SYSTEMS

The manometer that was just discussed is an instrument that measures air pressure. An instrument that is commonly used on air distribution systems is the anemometer, or **velometer**, which is used to measure air velocity, or speed, **Figure 37.12**. The velometer measures how fast air is moving past a particular point in an air duct. Once the average air speed, in ft/min, has been determined using an instrument similar to that shown in **Figure 37.12**, the air volume that is moving in the duct can be easily determined, as long as the cross-sectional area of the duct section, in ft^2, is known. For example, if the average air speed through a 9″ × 8″ rectangular duct section is 700 ft/min, we can determine the air volume as follows:

$$\text{Air Volume (cfm)} = \text{Air Velocity (ft/min)} \times \text{Cross-sectional Area } (ft^2)$$
$$\text{Air Volume (cfm)} = 700 \text{ ft/min} \times [(9'' \times 8'') \div 144 \text{ in}^2/\text{ft}^2]$$
$$\text{Air Volume (cfm)} = 700 \text{ ft/min} \times (72 \text{ in}^2 \div 144 \text{ in}^2/\text{ft}^2)$$
$$\text{Air volume} = 350 \text{ cfm}$$

These calculations and concepts are covered in more detail in Section 37.19, "Measuring Air Movement for Balancing."

A number of additional functions have been incorporated into the design of new-generation air-measuring instruments. The instrument in **Figure 37.13**, for example, has the capability to measure the temperature, dew point temperature, wet-bulb temperature, and relative humidity of the air as it passes through the device. Other new-generation air-measuring instruments are wireless. The instrument shown in **Figure 37.14** has the ability to measure airflow, air velocity, and temperature, while the device in **Figure 37.15** can also measure humidity. These devices have the ability to communicate with electronic hand-held devices, such as smart phones, when

the appropriate application is installed, **Figure 37.16.** Some other instruments have a modified keypad so that the service technician can enter the duct measurements into the device. This enables the instrument to display the actual cfm of the air, saving the technician time on the job and reducing the number of manual calculations that need to be performed.

Figure 37.15 This device has the ability to measure relative humidity in addition to other airflow properties.

Figure 37.16 New-generation airflow instruments are wireless and have the ability to transmit data to technicians via their smart phones and other handheld electronic devices through proprietary applications.

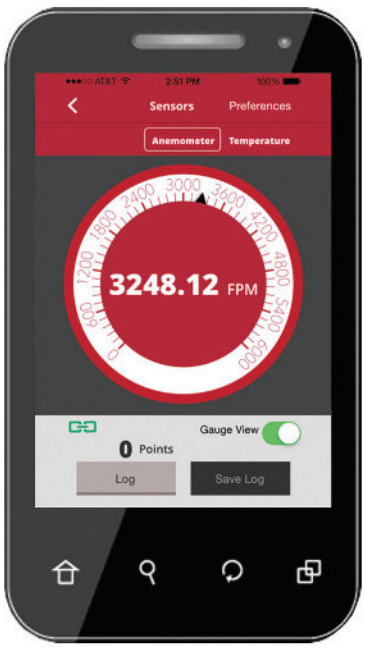

Figure 37.17 A telescopic pitot tube.

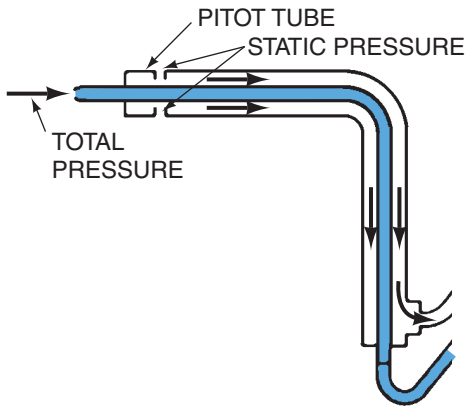
Figure 37.18 How a pitot tube arrangement is used to measure velocity pressure.



A special device called a **pitot tube**, developed many years ago, is used to check duct pressures, **Figure 37.17**. The pitot tube is constructed as two concentric tubes and is bent into a 90-degree angle. The pitot tube is inserted into the duct section and directed into the stream so the air flowing in the duct will enter the tube. The small holes in the outer tube are perpendicular to the airstream's direction of flow. The airflow into the center tube represents the total pressure, while the pressure at the perpendicular holes represents the static pressure, **Figure 37.18. Figure 37.19** shows such a setup, where PT is the total pressure, PV is the velocity pressure, and PS is the static pressure. The velocity pressure reading is obtained by subtracting the static pressure from the total pressure. Modules connected to the pitot tube sense both the static and velocity pressures and determine the pressure difference internally, **Figure 37.20**.

37.7 TYPES OF FANS AND BLOWERS

Fans and blowers are devices that are used to move air through, among other things, heat exchangers and duct systems. The two types of air-moving devices that are discussed in this

Figure 37.19 Pressures exerted on the pitot tube.

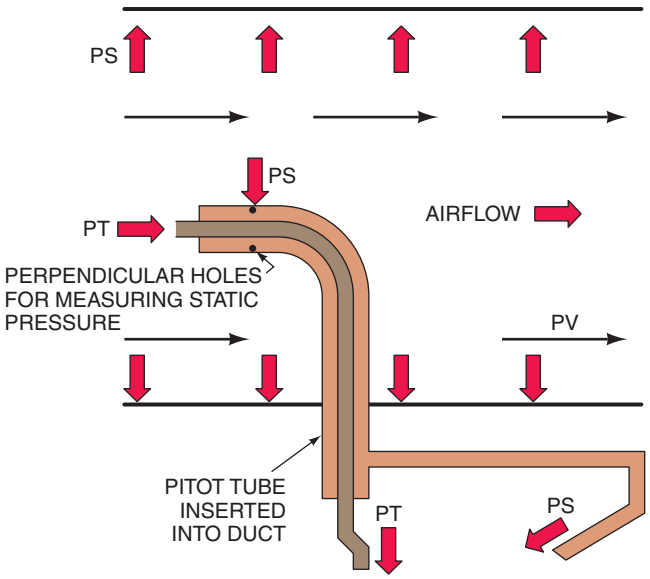

Figure 37.20 The pitot tube can connect to modules that determine the pressure differential automatically.

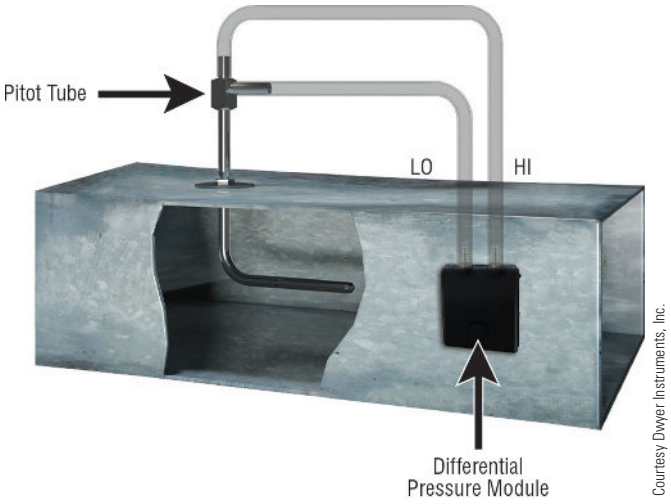
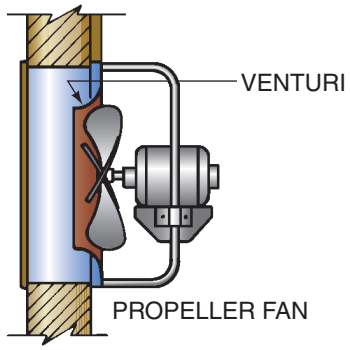


text are the **propeller fan** and the *forward curved centrifugal blower,* also called the **squirrel cage blower** or *blower wheel.*

The propeller-type fan is often used as an exhaust fan or a condenser fan. Propeller-type fans can move large volumes of air at low pressure differentials. The propeller can be cast iron, aluminum, or stamped steel and is set into a housing called a *venturi* to help ensure that air flows in a straight line from one side of the fan to the other, **Figure 37.21.** Propeller-type fans make more noise than centrifugal blowers so they are normally used where noise is not a factor.

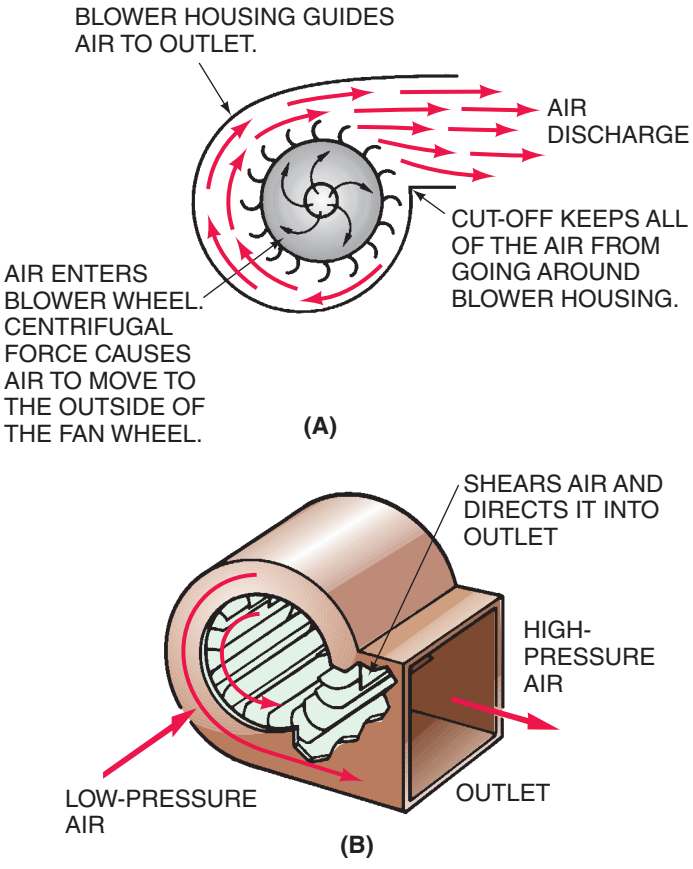
The squirrel cage or centrifugal blower creates more pressure from the inlet to the outlet and moves more air against more pressure. For this reason, these blowers are desirable

Figure 37.21 A propeller-type fan.



for use in ducted air distribution systems. This blower has a forward curved blade and a cutoff to prevent the air from spinning around the blower wheel within the housing. Air enters the blower from the center and is then thrown by centrifugal action to the outer perimeter of the blower housing. Some of the air would keep going around with the blower wheel if it were not for the shear that cuts off the air and sends it out the blower outlet, **Figure 37.22.** The centrifugal

Figure 37.22 A centrifugal blower.

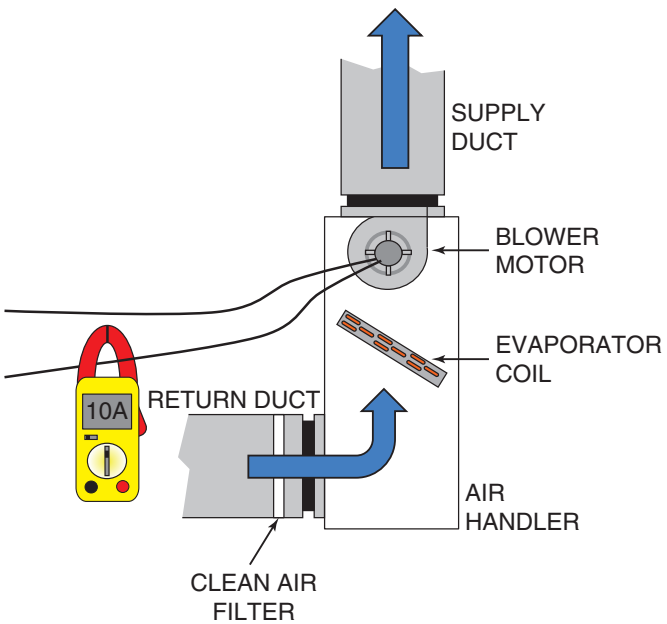


blower is very quiet when compared to the noise generated by propeller-type fans. It meets all the requirements for very large, high-pressure duct systems. High-pressure systems have pressures of 1 in. WC or higher. The rotation of a centrifugal blower is critical to its ability to move air. The rotation can be determined by looking at the blower from the side and finding the blower outlet. The blower wheel must turn so that the top of the wheel is rotating toward the blower outlet.

One characteristic that makes troubleshooting the centrifugal blower easier is the air volume-to-horsepower requirement. This blower uses energy at the rate at which it moves air through the ductwork. The current draw of the fan motor is proportional to the number of pounds of air it moves. For example, a fan motor that draws full-load amperage at the rated blower capacity will draw less than full-load amperage when operating under any conditions that are lower than the motor's maximum capacity. If the blower inlet is blocked, the suction side of the blower will be starved for air, and the current draw of the motor will go down. If the discharge side of the blower is blocked, the pressure will go up in the discharge side and the current draw will also go down because the blower is not moving as much air, **Figure 37.23**. The air is merely spinning around in the blower and housing and not being forced into the ductwork.

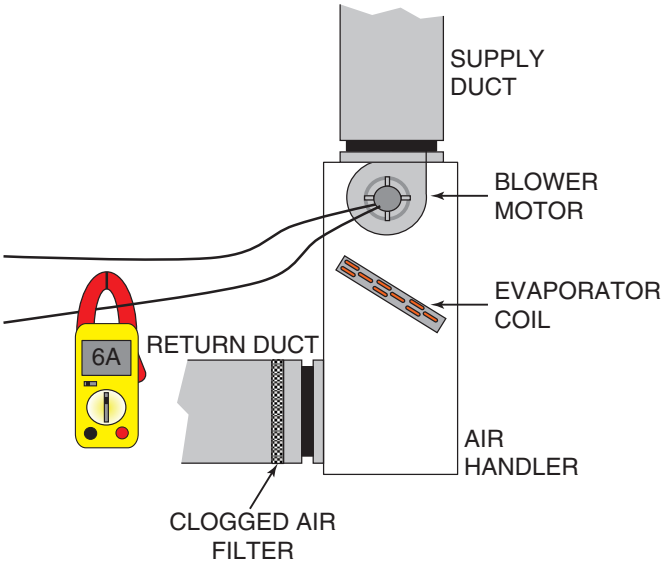
The airflow through this particular type of blower can be checked with an ammeter when making simple field measurements. If the airflow is reduced, the current draw will drop. If the airflow is increased, the current draw will increase. For example, if the door on the blower compartment is removed or not secured properly, the motor current will go up. This is

Figure 37.23 (A) When the airflow through the air handler is correct, the amperage draw of the motor will be correct as well. (*Continued*)

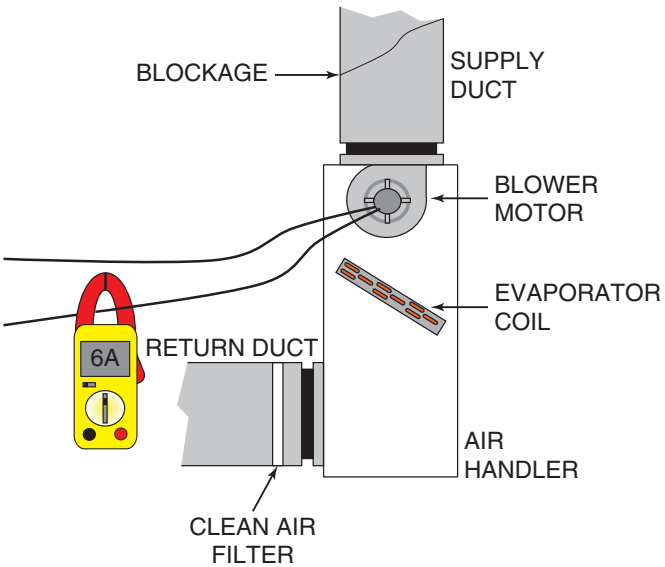


(A)

Figure 37.23 (*Continued*) (B) If the air filter is clogged, airflow will be reduced and the amperage draw of the motor will go down. (C) If the supply ductwork is restricted for any reason, airflow will be reduced and the amperage draw of the motor will go down.



(B)



(C)

because the restrictions created by the heat exchanger, return duct, and air filter have been removed and more air will be moved by the blower, **Figure 37.24**. In addition, the amperage reading can be a useful tool for properly setting up belt-driven blower assemblies. If the driven pulley is too small, the blower will turn too fast and the amperage draw of the motor will increase. The same condition will be present if the drive pulley is too large. This is a relatively common situation given that the drive pulley is often a variable-pitch component. Some technicians will use the variable-pitch feature on the drive pulley to adjust the tension on the belt. This practice

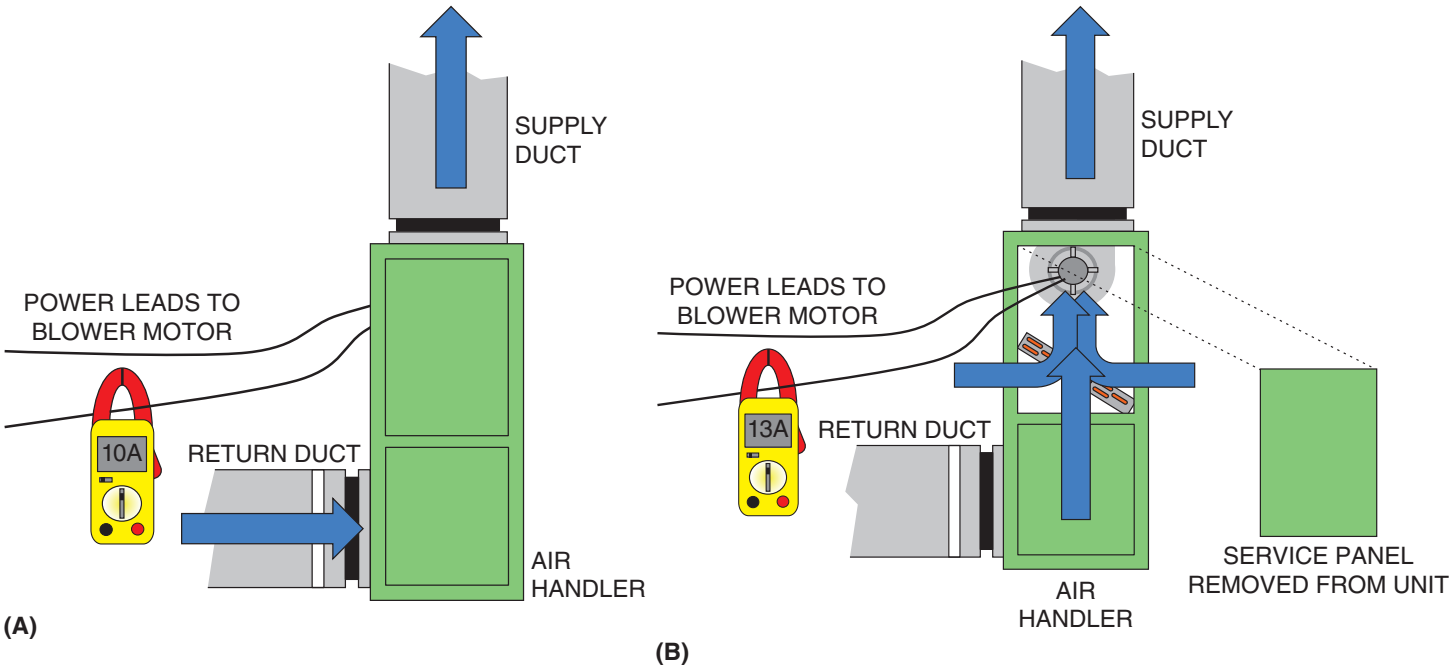
Figure 37.24 (A) When service panels are properly secured and the airflow through the air handler is correct, the amperage draw of the motor will be correct as well. (B) If the service panel is removed, airflow through the air handler will increase and the amperage draw of the motor will go up.



is not acceptable as doing so will alter the rate at which air is moving through the system and will also affect the amperage draw of the motor.

37.8 TYPES OF DRIVE ASSEMBLIES

There are two types of drive assemblies that are commonly used to turn fans and blowers: the belt drive and the direct drive.

Belt-driven assemblies have two bearings on the blower shaft and two bearings on the motor shaft. Sleeve bearings and resilient (rubber) mountings are used to keep bearing noise out of the blower section. Sometimes these bearings are permanently lubricated by the manufacturer, so a technician cannot oil them. The drive pulley on the motor, the driven pulley on the fan shaft, and the belt all must be maintained. Because the pulleys can be adjusted or changed to change the blower speed, this motor and blower combination has many uses, **Figure 37.25**.

The direct-drive blower assembly is commonly used on cooling equipment up to 5 tons. The motor is mounted directly to the blower housing, usually with rubber mounts, with the motor shaft extending into the blower wheel, **Figure 37.26**. The direct-drive blower is very quiet and does not have belts and pulleys that can wear out or need to be adjusted.

With direct-drive blower assemblies, the number of bearing surfaces is reduced from four to two. The bearings may be permanently lubricated at the factory. The front bearing, which is located inside the blower wheel, may be difficult to access for lubrication purposes if a special oil port is not furnished. With this type of blower assembly, the blower wheel turns at the same speed as the motor, so multispeed motors are often used. The volume of air moved by the blower may be adjusted by the different motor speeds instead of adjusting the pitch or size of the pulley. The motor may have up to four different speeds that can be changed by switching wires at the motor terminal box. Common speeds are from about 1500 rpm down to about 800 rpm. The motor, for example, can be

Figure 37.25 This blower is driven with a motor using a belt and two pulleys to transfer the motor energy to the fan wheel.

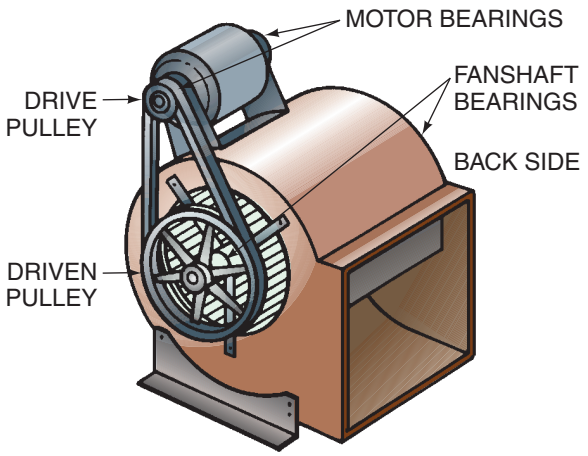


Figure 37.26 A direct-drive blower assembly.

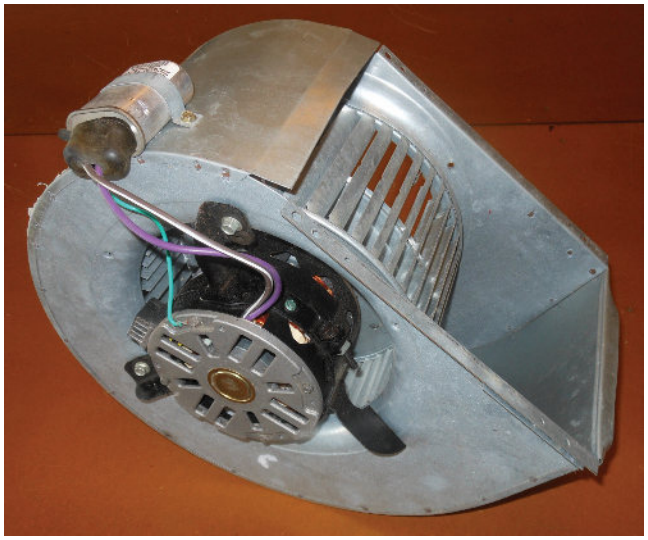

Photo by Eugene Silberstein

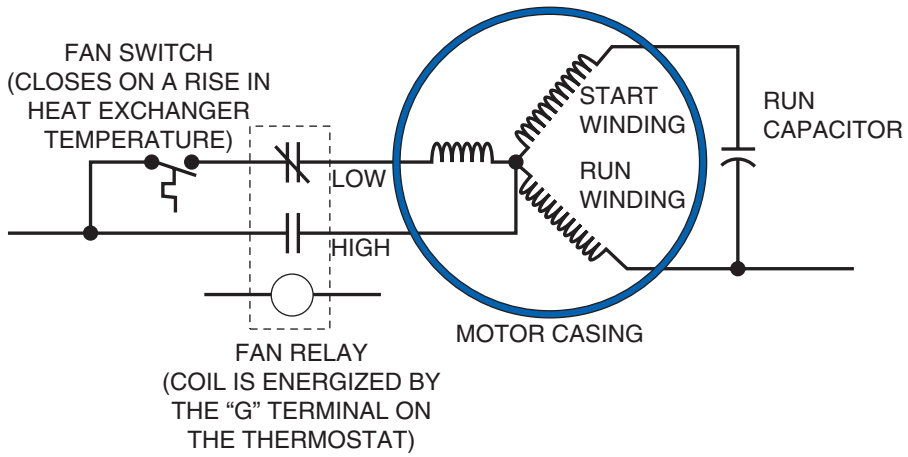
operated at a faster speed in the summer for more airflow in the cooling mode, **Figure 37.27**. The changing of the motor speed is accomplished by the fan relay as shown in the diagram. In the heating mode, the normally closed contacts on the fan relay allow the blower to operate at low speed when the heat exchanger is warm and the fan switch contacts are closed. In the cooling mode, the G terminal on the thermostat is powered, and the fan relay coil is energized. This closes the normally open contacts on the fan relay, allowing the motor to operate at high speed.

New-generation, high-end blower assemblies utilize electronically commutated motors (ECMs). These motors are programmed to deliver the desired amount of airflow under a wide range of conditions and do not require the use of multiple wire taps to adjust the speed of the motor.

Figure 37.27 The wiring diagram of a multiple-speed motor.



37.9 THE SUPPLY DUCT SYSTEM

The supply duct system distributes air to the terminal units, registers, grilles, or diffusers in the conditioned space. Starting at the blower outlet, the duct can be fastened to the blower or blower housing directly or by means of a fireproof vibration eliminator, **Figure 37.28**, between the blower and the ductwork. This vibration eliminator is often referred to as a canvas connector or collar, although these are very rarely made of canvas anymore. Flexible rubber or a similar material is more commonly used. The flexible rubber material is attached to two wide strips of sheet metal that ultimately connect to the duct system and the air handler, **Figure 37.29**. The vibration eliminator is recommended on all installations to prevent noise transmission through the duct system. Given the relatively low cost of the vibration eliminator material, it is wise to incorporate this component into all air distribution systems.

The supply duct system must be designed so that it allows the air to move toward the conditioned space as freely as possible. It must be sized properly: neither undersized nor

Figure 37.29 Material used to fabricate canvas connectors.

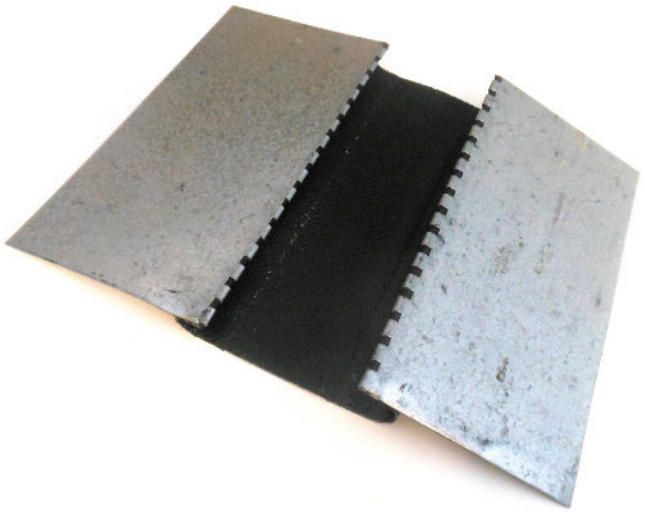

Photo by Eugene Silberstein

oversized. Oversized duct systems cost more to fabricate and install and will also result in the slowing of the air as it flows through the duct. Recall from earlier in this unit that the volume of airflow through a duct section is calculated by multiplying the velocity of the air by the cross-sectional area of the duct. Consider an air duct that is designed to move 350 cfm and has a cross-sectional area of one-half of a square foot (72 in^2). The velocity of the air is determined as follows:

$$\text{Air Volume (cfm)} = \text{Air Velocity (ft/min)} \times \text{Cross-sectional Area } (ft^2)$$
$$\text{Air Velocity (ft/min)} = \text{Air Volume (cfm)} \div \text{Cross-sectional Area } (ft^2)$$
$$\text{Air Velocity (ft/min)} = 350 \text{ cfm} \div 0.5 \text{ ft}^2$$
$$\text{Air Velocity (ft/min)} = 700 \text{ ft/min}$$

Let's now assume that the ductwork was oversized by 50% for this application. The desired airflow is still 350 cfm, but the cross-sectional area of the duct is now 0.75 ft^2. The velocity of the air is now as follows:

$$\text{Air Velocity (ft/min)} = \text{Air Volume (cfm)} \div \text{Cross-sectional Area } (ft^2)$$
$$\text{Air Velocity (ft/min)} = 350 \text{ cfm} \div 0.75 \text{ ft}^2$$
$$\text{Air Velocity (ft/min)} = 467 \text{ ft/min}$$

By reducing the velocity of the air, the path the air takes as it leaves the supply register will also be changed. The air will not come out with the force that was originally planned for at the design stage. In addition, undersizing a duct will result in excessive air velocity, which will increase the noise levels of the system and, once again, alter the desired air patterns.

Duct systems typically follow one of four common configurations. Duct systems can be **plenum**, *extended plenum, reducing plenum,* or *perimeter loop,* **Figure 37.30**. Each system has its advantages and disadvantages.

THE PLENUM SYSTEM

The plenum system is well suited for a job in which the room outlets are all close to the unit. This system is economical from a first-cost standpoint and can be installed easily by an installer with a minimum of training and experience.

Plenum systems work better with fossil-fuel (coal, oil, or gas) systems than with heat pumps because the leaving-air temperatures are much warmer in fossil-fuel systems. The plenum system is desirable when the duct runs are short, as in the case of apartment installations. The return-air system can be a single return located at the air handler, which makes materials economical. The single-return system will be discussed in more detail later. **Figure 37.31** shows an example of a plenum system with registers in the ceiling.

THE EXTENDED PLENUM SYSTEM

The extended plenum system is a popular choice for use in a long structure such as the ranch-style house. This system extends the main plenum closer to the farthest supply register. The extended plenum is called the *trunk duct* and can be round, square, or rectangular, **Figure 37.32**. Small ducts called *branches* complete the connection to the terminal units. These small ducts also can be round, square, or rectangular. Smaller branch ducts are usually round because round ducts in smaller diameters are relatively inexpensive, commercially available, and do not need to be specially fabricated for the project. Average homes typically use 6-in. round duct for the branches.

The main drawback of the extended plenum system is that the velocity of the air is lower as the air reaches the last takeoffs on the extended plenum. Consider the portion of the air distribution system shown in **Figure 37.33**. An airflow of 1000 cfm is moving through the duct at a velocity of 700 ft/min. It can be determined that the cross-sectional area of the duct is 1.43 ft^2 (1000 cfm ÷ 700 ft/min). After the first takeoff, where 200 cfm is directed to an area in the conditioned space, there are 800 cfm of air remaining. Because this duct system is an extended plenum system, the duct size remains the same. This means that the velocity of the air after the first 200-cfm takeoff will be only 560 ft/min (800 cfm ÷ 1.43 ft^2). After the second 200-cfm takeoff, the air velocity will be only 420 ft/min.

THE REDUCING PLENUM SYSTEM

The reducing plenum system reduces the size of the trunk duct as the volume of air in the duct decreases. This reduction in duct size is accomplished with duct fittings called transitions, **Figure 37.34**. Transitions are used to connect duct sections of different sizes, **Figure 37.35**. This system has the advantage of conserving materials and being able to maintain a constant air pressure and velocity from one end of the duct system to the other, when properly sized. This layout also ensures that approximately the same pressure and velocity are pushing air into each branch duct.

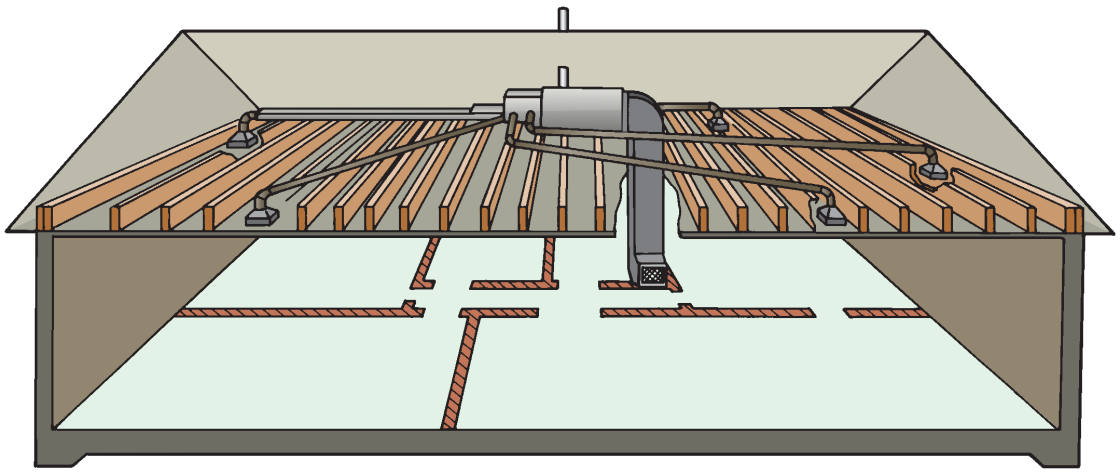
(D) PERIMETER LOOP SYSTEM WITH FEEDER AND LOOP DUCTS IN CONCRETE SLAB

Figure 37.31 A plenum system.



Let's take a look at the same duct system originally shown in **Figure 37.33**. That system will now be shown as a reducing plenum system, **Figure 37.36**. The initial volume of air is the same (1000 cfm) and the two takeoffs are still designed to carry 200 cfm each. The 1.43 ft^2 cross-sectional area is equivalent to a 14″ × 14″ square duct section. After the first takeoff, there are 800 cfm of air left in the main trunk line. To keep the velocity of the air the same, the cross-sectional area of the duct will have to be reduced to 1.14 ft^2 (800 cfm ÷ 700 ft/min). This is equivalent to a rectangular duct section that is about 14″ × 12″. After the second takeoff, there are 600 cfm of air left in the main trunk line. To keep the velocity of the air the same, the cross-sectional area of the duct will have to be reduced to 0.86 ft^2

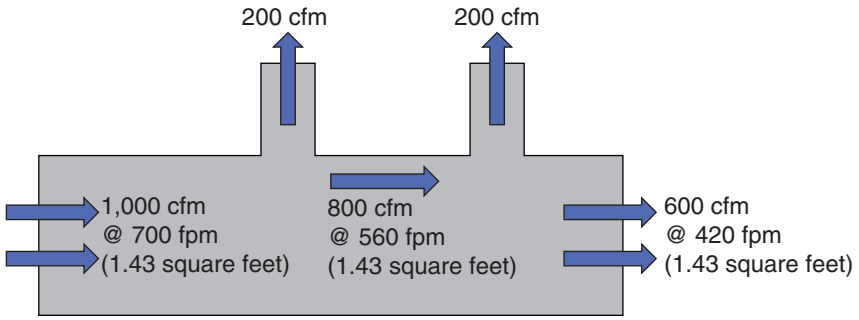

Figure 37.34 A transition fitting.

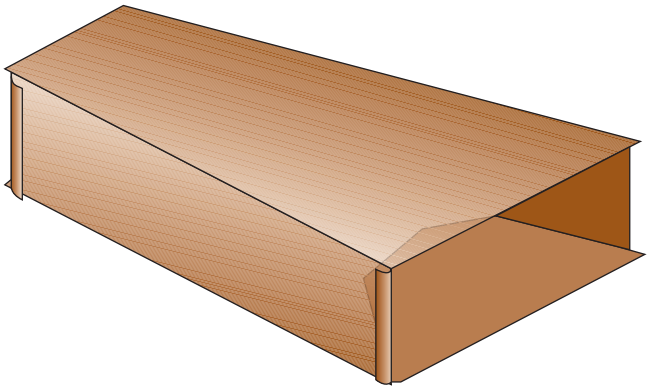

(600 cfm ÷ 700 ft/min). This last duct section is equivalent to a rectangular duct section that is 14″ × 9″.

Fabricating a 14″ × 9″ duct section will require less material than a 14″ × 14″ duct section. The same holds true for the 14″ × 12″ section. The main downside to this type of system, however, is the need for the transition duct sections, which are more difficult and expensive to fabricate than sections of straight duct. Most of the time, the air distribution system is designed so that the different-sized duct sections will have one measurement in common to make the fabrication of transition fittings easier. We can see from the previous example that the duct measurements changed from 14″ × 14″ to 14″ × 12″ to 14″ × 9″. To further ease the process, one side of the transition fitting is often at a 90-degree angle to the edges of the fitting, **Figure 37.37(A)**. When the air distribution system is located within the occupied space and is visible to the occupants—or for other design considerations—the transition fittings may have a symmetrical layout, **Figure 37.37(B)**. Laying out and fabricating symmetric transition fittings is more complicated than fabricating non-symmetric fittings.

THE PERIMETER LOOP SYSTEM

The perimeter loop duct system is particularly well suited for installation in a concrete floor in a colder climate. The loop can be run under the slab close to the outer walls with the outlets next to the wall. Warm air is in the whole loop when

Figure 37.35 A reducing plenum system.

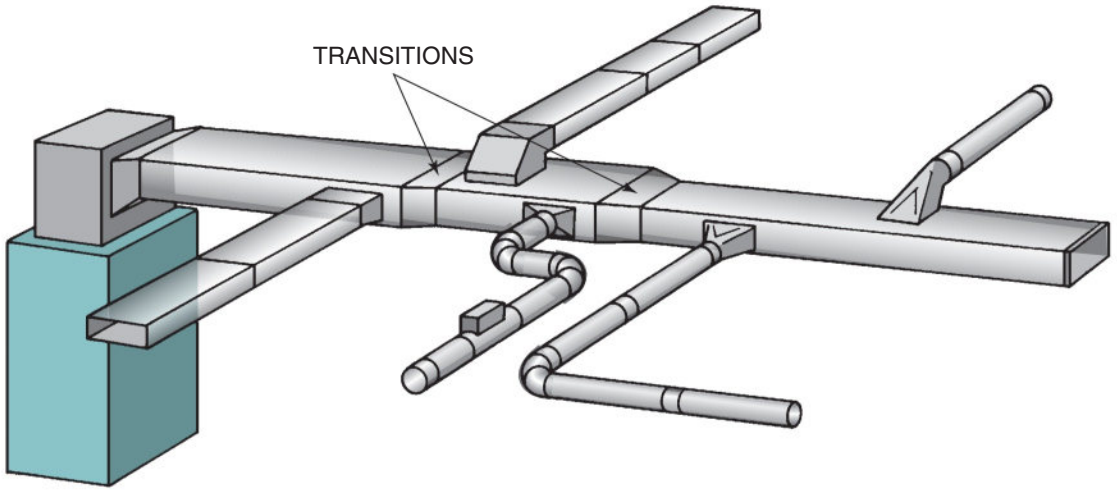

Figure 37.36 The velocity of the air that reaches the end of the trunk line can be maintained by reducing the size of the trunk line.

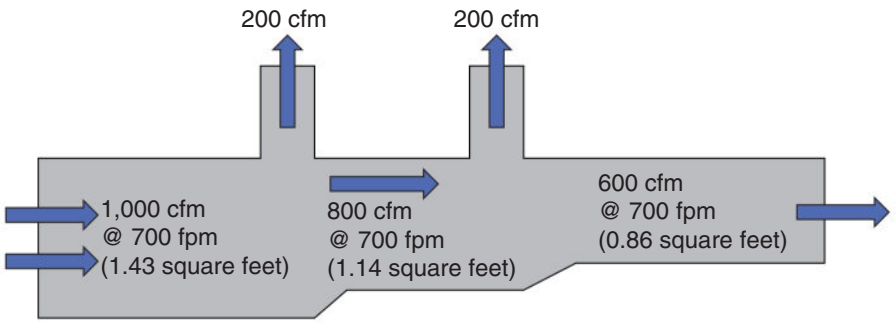

Figure 37.37 (A) Common transition fitting layout. (B) Symmetrical transition fitting.

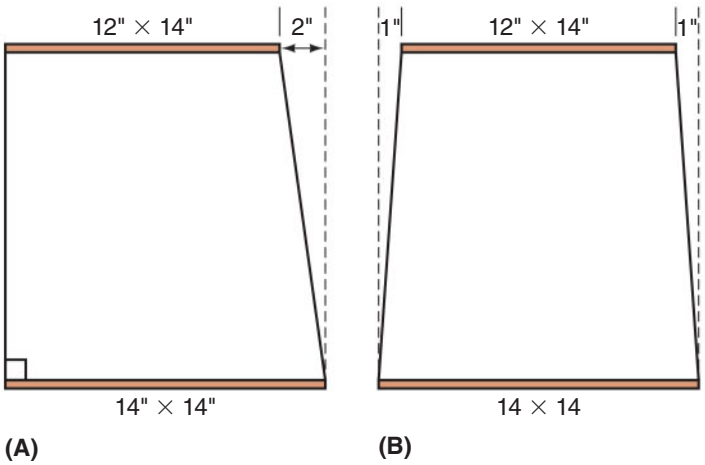

the furnace blower is running, and this keeps the slab at a more even temperature. The loop has a constant pressure around the system and provides the same pressure to all outlets, **Figure 37.38.**

37.10 DUCT SYSTEM STANDARDS

All localities should have some minimum standard for air-conditioning and heating systems. The regulating body might use a state standard, or it might set up a local standard. These standards are called codes. Many state and local codes adopt other known standards, such as those of the International Code Council (ICC). The ICC was formed in 1994 when the Building Officials and Code Administrators International (BOCA) and Southern Building Code Congress International (SBCCI) joined together. The International Fire Code Institute (IFCI) became part of the ICC in 2003. All technicians should become familiar with the local code requirements for their geographic region and follow them. Code requirements are not uniform across the country.

37.11 DUCT MATERIALS

The ductwork that carries the air from the blower to the conditioned space can be made of different materials. For many years galvanized sheet metal was used exclusively, but galvanized duct sections are expensive to fabricate and require

Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Figure 37.38 A perimeter loop system.

highly skilled individuals to properly install them. Galvanized metal is by far the most durable material. It can be used in walls where easy access for servicing cannot be made available. Aluminum, fiberglass ductboard, spiral metal duct, and flexible duct have also been used successfully. **SAFETY PRECAUTION:** *The duct material selected for a particular project must meet local building and fire protection codes.*•

GALVANIZED-STEEL DUCT

Aluminum duct follows the same guidelines and has the same characteristics as galvanized duct. The cost of aluminum prevents it from being used for many applications. Many air distribution systems are fabricated from a material known as galvanized-steel sheet metal. Galvanized steel is steel sheet metal that has been treated with zinc to form a coating on the surface of the metal. The zinc coating will ultimately form zinc carbonate on the surface of the metal, which acts to prevent corrosion of the steel underneath. Galvanized steel is easily identified by the crystal-like patterning on the surface of the metal, often referred to as spangle, **Figure 37.39**.

Galvanized sheet metal comes in several different thicknesses, called the *gauge* of the metal. As the gauge number gets larger, the thickness of the sheet metal gets thinner. For example, the thickness of 30-gauge galvanized sheet metal is 0.0157 in., while the thickness of 22-gauge galvanized sheet metal is 0.0336 in. Thus, 22-gauge galvanized sheet metal is about twice as thick as 30 gauge. **Figure 37.40** shows the thicknesses of some commonly used gauges of steel, galvanized-steel, and aluminum sheet metal.

Figure 37.39 Spangle on galvanized sheet metal.

The thickness of a section of sheet metal is directly related to its weight. The Manufacturer's Standard Gauge for Sheet Metal (sheet steel) is 41.82 lb/ft^2. This is a constant factor and, when multiplied by the thickness of the steel sheet metal, will provide the weight of 1 ft^2 of the material. For example, the thickness of 24-gauge sheet steel is 0.0239 in. (from **Figure 37.40**). The weight of 1 ft^2 of this material is 1 lb (0.0239 inches × 41.82 lb/ft^2). It is left as an exercise for the reader to confirm that 1 ft^2 of 30-gauge steel sheet metal weighs 0.5 lb. The thickness of the metal used to fabricate smaller duct sections can be thinner than the metal used to fabricate larger sections of ductwork. When the ductwork is larger, it must be more rigid or it will swell and make noises when the blower starts or stops. **Figure 37.41** shows a table to be used as a guideline for choosing duct metal thickness. Quite often the duct manufacturer will cross-break or make a slight bend from corner to corner on large fittings to make the duct more rigid, **Figure 37.42**.

Metal duct is normally fabricated in 4-foot lengths and can be round, square, or rectangular. Smaller round duct can be purchased in lengths up to 10 ft. Duct lengths can be fastened together with special fasteners (called S fasteners or slip fasteners) and drive cleats if the duct is square or rectangular, or fastened with self-tapping sheet metal screws if the duct is round. These fasteners make a secure connection, **Figure 37.43**. If there is any question of air leaking out, special tape or sealant can be applied to the connections. **Figure 37.44** shows a duct section being connected to a furnace using self-tapping sheet metal screws. **Figure 37.45** shows a connection that has been taped after being fastened. A special product called mastic is used to help make airtight duct connections. Mastic is a very thick, puttylike substance that is applied with a stiff bristle paintbrush, **Figure 37.46**. It dries to a very hard, but slightly flexible, sealant. Most mastics are water soluble, so they are easy to clean up after use. All duct systems should be properly sealed to minimize air leakage.

Figure 37.42 Cross-breaks on ductwork helps to keep the duct section rigid.

FIBERGLASS DUCT

Fiberglass duct is furnished in two styles: flat sheets for fabricating square and rectangular duct sections and round prefabricated duct sections, **Figure 37.47.** Fiberglass duct is normally 1 or 1½ in. thick with an aluminum foil backing, **Figure 37.48.** The foil backing contains fiber reinforcement to make it strong. When a duct is fabricated, portions of the fiberglass material is cut away, while the reinforced foil backing is left intact to support the connection and provide an air barrier, **Figure 37.49.** The duct sections are easily transported and connected in the field. The rough inside lining of fiberglass duct acts as a sound dampener. As a result, these systems are very quiet.

Figure 37.50 shows a layout of a fiberglass ductboard system. Main trunk lines, offsets, and takeoffs can be fabricated on the job. Special round takeoffs are available that can be inserted into the main trunk line and connected to prefabricated round duct sections for supplying air to the remote locations. One of the main benefits of using the fiberboard duct system is that the sections can be fabricated or modified on the job. In the event that a section has not been fabricated properly, the job can continue because the piece can be remade relatively quickly.

The ductboard can be made into duct in several different ways. Special knives that cut the board in such a manner

as to produce overlapping connections can be used in the field by placing the ductboard on any flat surface and using a straightedge to guide the knife, **Figure 37.51**. When fabricating a duct section, the fiberboard is positioned on the work surface with the fiberglass facing up and the foil backing against the work surface. Using the appropriate knife, cuts are made in the material, **Figure 37.49**. Notice that only the fiberglass is cut away and that the foil backing is left intact. Once all of the cuts have been made, the duct section is folded, **Figure 37.52(A)**. After folding, the flap of foil backing will serve as on overlap for completing the connection, **Figure 37.52(B)**. To finish the section, the flap is stapled and taped to seal the section, **Figure 37.52(C)**. When the duct is made in the shop, it can be cut and left flat and stored in the original boxes. This makes transportation easy. The pieces can be marked for easy assembly at the job site.

Figure 37.49 (A) Ductboard is positioned with the foil backing down. (B) Some of the fiberglass is cut away, leaving the foil backing in tact.

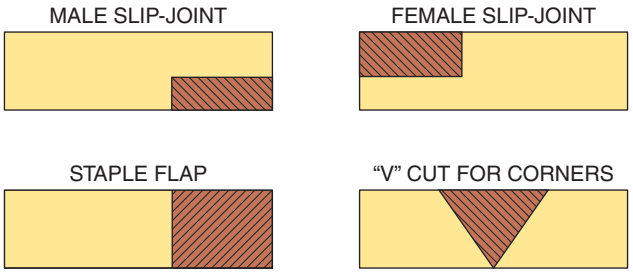
Figure 37.51 Special knives cut various shapes into the fiberboard panels for easy duct fabrication and assembly.



SPIRAL METAL DUCT

Spiral metal duct is more commonly found on larger systems. Spiral metal duct can be purchased in various diameters from 8 inches to over 36 inches, but can also be fabricated on the job site. On-site fabrication is expensive, as special machinery is required, but is a viable option for contractors that do a large amount of this type of work. The material used to fabricate these duct sections comes in rolls of flat, narrow metal. The machine winds the metal off the spool and folds a seam into it. One benefit of fabricating spiral metal duct sections on the job is that very long pieces of duct can be fabricated on site that would otherwise have to be made in much smaller lengths and then joined together.

FLEXIBLE DUCT

Flexible round duct, **Figure 37.53**, comes in sizes up to about 24 in. in diameter. Flexible duct material can be either insulated or uninsulated. Without the insulation, the duct looks like a coil spring wrapped with a flexible foil or plastic backing. Installing flexible duct is easy because the runs can be aligned fairly loosely, unlike rigid duct, which must be perfectly aligned.

Some flexible duct comes with vinyl or foil backing with insulation, in lengths of 25 ft to a box. One benefit of flexible duct material is that it is easy to route around corners or other obstructions. The duct runs should be kept as short as practical and not allowed to make tight turns that may cause the flexible duct to collapse. Flexible duct offers more friction to airflow than metal duct does, but it also serves as a sound attenuator that reduces the transmission

Figure 37.52 (A) Once the fiberglass material has been cut away, the duct section can be folded. (B) A flap of foil backing material is used to fold over the last corner. (C) The foil backing flap is then taped to complete the section.

of blower noise. For best airflow, flexible duct should be stretched as tightly as is practical, **Figure 37.54**, to reduce the resistance to airflow, and properly supported to prevent sagging.

Figure 37.53 Flexible duct.

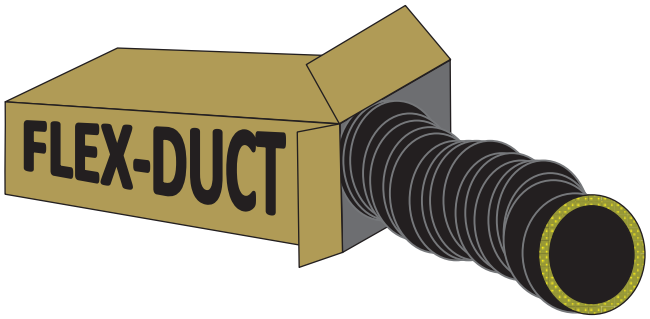

Figure 37.54 Flexible duct should be stretched for proper installation.

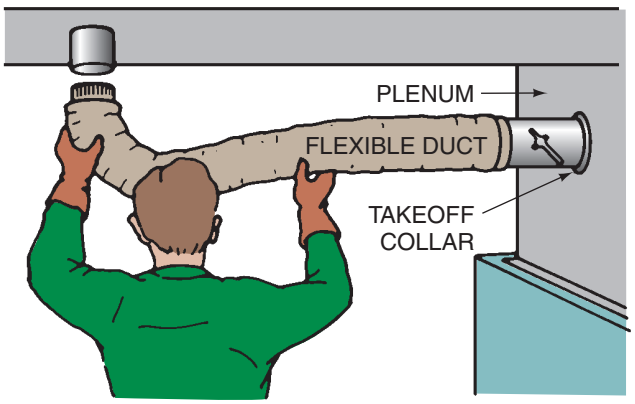

COMBINATION DUCT SYSTEMS

Duct systems can be combined in various ways. For example:

1. All square or rectangular metal duct, the trunk line, and the branches of the same shape, **Figure 37.55**
2. Metal trunk lines with round metal branch duct, **Figure 37.56**
3. Metal trunk lines with rigid round fiberglass branch duct, **Figure 37.57**
4. Metal trunk lines with flexible branch duct, **Figure 37.58**
5. Ductboard trunk lines with rigid round fiberglass branches, **Figure 37.59**
6. Ductboard trunk lines with round metal branches, **Figure 37.60**
7. Ductboard trunk lines with flexible branches, **Figure 37.61**
8. Round metal duct with round metal branch ducts, **Figure 37.62**
9. Round metal trunk lines with flexible branch ducts, **Figure 37.63**

37.12 DUCT AIR MOVEMENT

Special attention should be given to the point where the branch duct leaves the main trunk duct in order to get the correct amount of air into the branch duct. The branch duct must be fastened to the main trunk line with a *takeoff fitting*. The takeoff is the connecting point between the main trunk line and the branch duct. The connection at the main trunk line is the throat portion of the takeoff. The other side of the takeoff is connected to the runout, or branch, duct. Often, an air distribution system installation will utilize takeoffs that have the same throat and runout measurements, **Figure 37.64(A)**. Utilizing such takeoffs may very well not be the best option. The takeoff that has a larger throat area than the runout duct will allow the air to leave the trunk duct with a minimum of effort. This could be called a streamlined takeoff, **Figure 37.64(B)**. The streamlined takeoff encourages the air moving down the main duct to enter the takeoff to the branch duct.

Air moving in a duct has *inertia*—it wants to continue moving in a straight line. If sudden or sharp turns are made in the duct run, there will be a great deal of turbulence created, **Figure 37.65**. For example, a square-throated elbow offers more resistance to airflow than a round-throated elbow. If the duct is rectangular or square, turning vanes, **Figure 37.66**, will improve the airflow around a corner. The turning vanes separate the air into individual streams and direct them around the bend in a duct in a manner similar to the white dashed lines on a highway that help to keep vehicular traffic flowing properly around bends and turns in the road, **Figure 37.67**.

37.13 BALANCING DAMPERS

A well-designed system will have *balancing dampers*, **Figure 37.68**, in each of the branch ducts to balance the flow of air in the various parts of the system. Balancing the airflow with dampers enables the technician to direct the correct volume of air to each room or area for better temperature control. The dampers should be located as close as practical to the trunk line, with the damper handles accessible and uncovered if the duct is insulated. The best place at which to balance airflow is as close to the trunk as possible. This way, if there is any air velocity noise its effects will be minimized before the air enters the room. A damper consists of a piece of metal shaped like the inside of the duct with a handle protruding through the side of the duct to the outside. The handle allows the damper to be turned at an angle to the airstream to slow the air down. Damper handles are directional. When the handle is positioned perpendicular to the duct, the damper is closed, **Figure 37.69**. When the handle is positioned parallel to the direction of airflow, the damper is open, **Figure 37.70**.

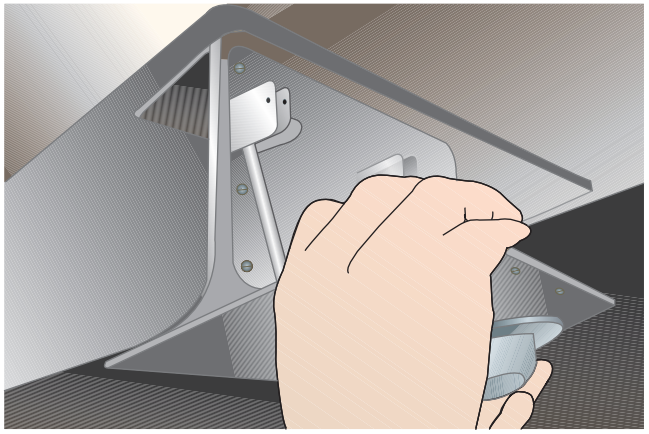
Figure 37.71 A zone damper.



37.14 ZONING

As we mentioned in the previous section, balancing dampers are used to ensure that the proper amount of air is delivered to each area in the conditioned space. Balancing the airflow in the system helps ensure that the space is heated and/or cooled evenly. Once the system is properly balanced, the balancing dampers should never have to be touched again. Another type of damper that is found in an air distribution system is the zone damper. Here are some characteristics that will differentiate between the two types:

- Balancing dampers are set to the desired position and locked in place at the time of initial system start-up or shortly thereafter.
- Zone dampers are opened and closed in response to changes in room temperature.
- Balancing dampers are manually opened and closed.
- Zone dampers open and close automatically in response to temperature changes. These dampers can be pneumatically (air) or electrically controlled.
- Balancing dampers are used to set airflow at some point between minimum and maximum on the basis of the size of the duct and the velocity of the air moving through the duct.
- Zone dampers will move from the fully open to the fully closed position depending on whether or not the temperature requirements for the zone are satisfied.

The zoning process utilizes zone dampers, **Figure 37.71**, *and enables a single forced-air heating and/or cooling system to maintain different temperatures in different rooms or areas of the conditioned space. By zoning a system, efficiency is increased.* Consider, for example, a single central air-conditioning system that is being used to cool a two-story house. Typically, the second floor of the structure will be considerably warmer than the lower level. This temperature difference can be as high as 10 degrees. If the thermostat is located on the lower level, the upper floor will never get cool. If the thermostat is located upstairs, the lower level will be too cool. The same condition can occur in some ranch-style homes. In this case, one side of the house may be warmer than the other. Depending on the location of the thermostat, one side of the home will be comfortable, while the other will be either too hot or too cold.

Zoning an air-conditioning system involves installing a thermostat and a zone damper for each room or zone in the structure. These thermostats and dampers are wired to a central control panel that will control the operation of the system on the basis of the actual conditions in the space. The complexity of these systems varies greatly depending on what features and tasks the system is able to perform.

A very basic zoning system is shown in **Figure 37.72**. This system has two separate zones, each with its own zone damper and thermostat. In a system similar to the one shown in this figure, it is easy to divide the structure into two separate areas, as the main plenum branches off in two distinct directions. For this example, we will assume that each of the two zones has the same airflow, cfm, and requirements. When configured in this manner (as two otherwise equal zones), the ductwork serving each zone should be oversized about 50%. If the total system were to provide 2000 cfm, this would mean that each trunk should be able to carry 1000 cfm of air. For zoning purposes, each trunk should be sized to carry approximately 1500 cfm, or 75%, of the total airflow requirement for the system. The wiring/control system for the zoned system shown in **Figure 37.72** is comprised of a central control panel, two damper motors, and two thermostats. One thermostat is centrally located in each of the two zones.

Of course there are more intricate and complicated zoning systems available. Typically, the two-zone system just discussed can set up zones in one of the following ways:

- Zone 1: upstairs; Zone 2: downstairs
- Zone 1: living room and kitchen; Zone 2: bedrooms and bathrooms

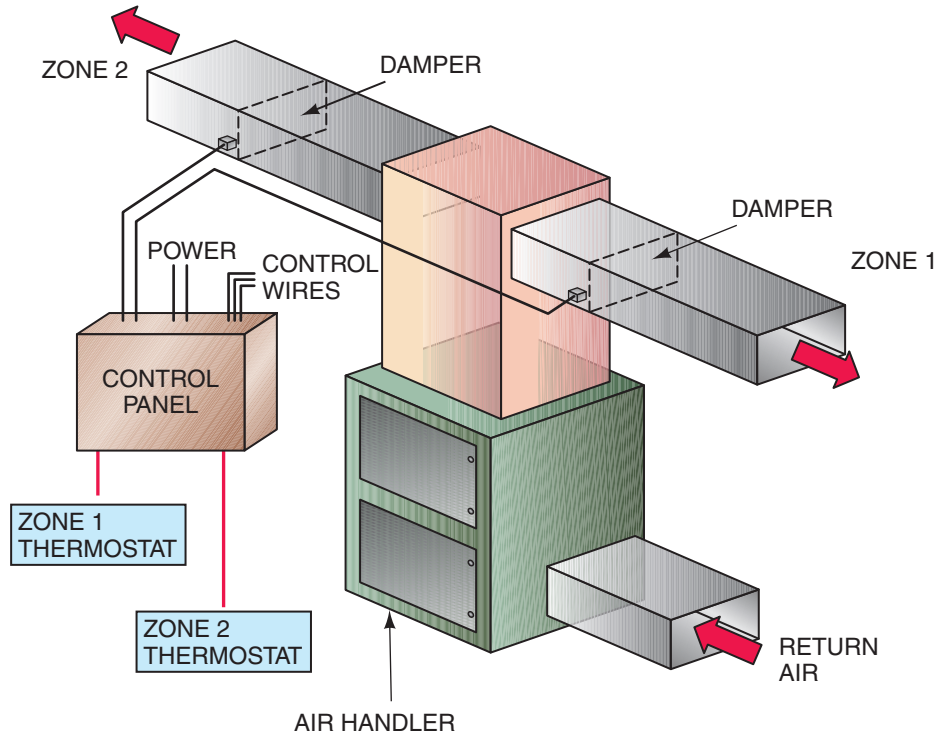
Figure 37.72 A common two-zone system layout.



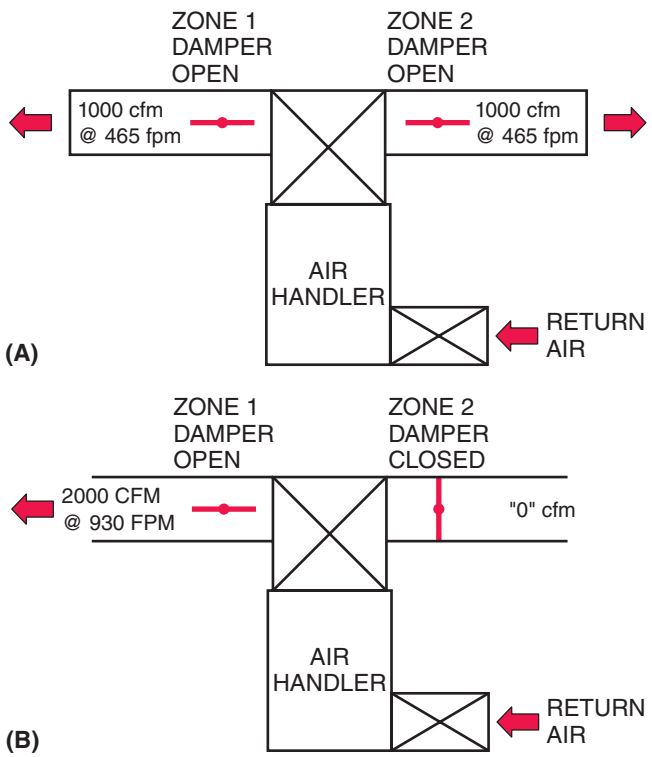
As homes get larger, the zoning requirements change as well. For example, the master bedroom suite in some higher-end homes has its own zone. The possibilities for zoning are limited only by the system designer's imagination. It is not unreasonable to have a separate zone for every room in a home. Obviously, systems like this are very costly to design and install and are more complicated to troubleshoot.

ZONING WITH A SINGLE-SPEED BLOWER MOTOR

The opening and closing of the zone dampers will have an effect on the velocity and volume of the air moving through the system. This is not an action that should be undertaken lightly, as a reduction in airflow through a cooling coil can, for example, cause the coil to freeze, further reducing airflow and causing a major reduction in cooling. In a two-zone system, as in the situation discussed in the previous section, oversizing the duct system by approximately 50% will, for the most part, alleviate this problem.

Let's take a closer look. If the system were designed to move 2000 cfm at a velocity of 700 ft/min, the supply plenum would have to have a cross-sectional area of 2.86 ft^2 (2000 cfm ÷ 700 ft/min). If the air is to be divided between the two zones as shown in **Figure 37.73**, each zone will have to carry 1000 cfm at the same 700 ft/min. This means that the cross-sectional

Figure 37.73 (A) Both zones are calling for cooling, so each zone is being supplied with 1000 cfm of cooled air. (B) Only Zone 1 is calling for cooling, so this zone is receiving all of the air.



Copyright 2017 Cengage Learning. All Rights Reserved. May not be copied, scanned, or duplicated, in whole or in part. Due to electronic rights, some third party content may be suppressed from the eBook and/or eChapter(s). Editorial review has deemed that any suppressed content does not materially affect the overall learning experience. Cengage Learning reserves the right to remove additional content at any time if subsequent rights restrictions require it.

area of the duct is going to be 1.43 ft². By oversizing this zone duct by 50%, the cross-sectional area will be increased to 2.15 ft². The duct will still be carrying the 1000 cfm, so the velocity of the air will be reduced to 465 ft/min (1000 cfm ÷ 2.15 ft²), which will be the velocity when both zones are calling for cooling, **Figure 37.73(A)**. When only one zone is calling for cooling, the entire 2000 cfm will flow through the duct feeding that zone. The speed of the air flowing through that duct will be 930 ft/min (2000 cfm ÷ 2.15 ft²), **Figure 37.73(B)**.

In systems with three or more zones, oversizing the duct to each zone by 50% is not practical. In such cases, oversizing the ducts by 10% to 15% will often suffice. In addition to this minimal oversizing of the duct, a bypass duct can be installed in the system, **Figure 37.74**. The bypass duct allows the blower to move the required amount of air even if a number of zones are not calling for conditioning. The bypass duct should be equipped with a damper so that the airflow can be adjusted. This damper can be manually or automatically controlled. When the damper is manual, it should be set for the "worst-case scenario," which is when only the smallest zone is calling for conditioning.

Consider the system shown in **Figure 37.75(A)**. This is an air-conditioning system with four zones. In this case, all four zones are calling for cooling, so there is no problem with excess or unwanted air volume. In **Figure 37.75(B)**, only the smallest zone is calling for cooling, so all zone dampers are closed with the exception of the one serving Zone 4. The blower will still deliver 2000 cfm, but only 400 cfm are needed. This is the worst-case scenario, as only the smallest zone is calling for cooling. The bypass duct should be sized to handle enough air for this condition, which, in this case, is 1600 cfm (2000 cfm − 400 cfm). When the damper in the bypass zone is controlled automatically, a pressure switch is often used to open and close the damper. The pressure switch senses the pressure in the duct and, as the pressure in the duct rises, causes the bypass damper to open.

When using the bypass-duct method, it is important to sense the temperature of the air as it moves through the system. By having conditioned air fed back through the system, the air can become overheated in the heating mode or overcooled in the cooling mode. This can damage the equipment. For example, if the return air is too cool, it may very well cause the evaporator coil to freeze. This can lead to liquid floodback to the compressor, resulting in major system damage. The sensor should send a signal to the central control panel to cycle the compressor off when such conditions are present. Different manufacturers tackle this situation differently, so be sure to follow the recommendations and instructions provided with each specific zoning product.

One alternative to using the bypass duct is to incorporate a dump zone into the system. Instead of recirculating the air back through the equipment, the excess air is directed to an area in the structure that does not have critical temperature

Figure 37.74 A bypass duct.

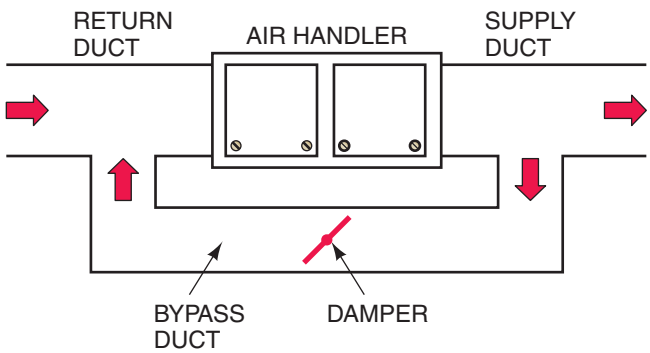


Figure 37.75 (A) All four zones are calling for system operation. (B) This is the worst-case scenario, as only the smallest zone is calling for system operation. The bypass damper must be able to handle enough air for this situation.

requirements. Such areas include basements, common hallways, or similar spaces. Since this may be objectionable to the occupants of the structure, options should be discussed prior to the design and installation stages of the job.

ZONING WITH A MULTISPEED COMPRESSOR AND VARIABLE-SPEED BLOWER

Some of the most desirable zoning systems utilize multispeed compressors and variable-speed blower motors. These systems use computer-controlled panels that store information regarding the air requirements for each zone. Some of these zoning systems use the following pieces of data:

- Return-air temperature
- Supply-air temperature
- Airflow requirements for each zone
- Percentage of airflow for each zone as a percentage of total system airflow

More advanced zoning systems have the ability to

- provide simultaneous heating and cooling by zone.
- provide continuous fan operation options by zone.
- control individual zone temperature.
- set heating or cooling priority by zone.

Consider the following system setup:

- Zone 1: 200 cfm—den and bedroom 4
- Zone 2: 450 cfm—bedrooms 2 and 3
- Zone 3: 500 cfm—master bedroom suite
- Zone 4: 450 cfm—living room and dining room area

The total cfm requirement for this home is 1600 cfm, so the percentage of air going to each zone is as follows:

- Zone 1 → (200 cfm ÷ 1600 cfm) × 100% = 13%
- Zone 2 → (450 cfm ÷ 1600 cfm) × 100% = 28%
- Zone 3 → (500 cfm ÷ 1600 cfm) × 100% = 31%
- Zone 4 → (450 cfm ÷ 1600 cfm) × 100% = 28%

Notice that the total air volume is equal to 100%. These air volume percentages are rounded off and will get programmed into the central control panel. The average air volumes for Zones 1 through 4 will then be estimated as 10%, 30%, 30%, and 30%, respectively. On the basis of this information and the zones that are calling for conditioning, the compressor and blower speeds will be selected automatically by the system. For example, if Zones 3 and 4 are calling for cooling, the blower will operate at a speed that will deliver 960 cfm of air (60% of 1600 cfm). The compressor speed will be selected on the basis of this airflow as well as the data gathered from the return- and/or supply-air sensors. If another zone now calls for cooling, the blower will ramp up its speed to deliver more air volume.

If the system is equipped to provide both heating and cooling, the zoning equipment may have the capability of selecting a priority mode of operation. For example, if a heating priority is programmed into the system and there are simultaneous calls for heating and cooling, the system will satisfy the heating demand first and then switch over to satisfy the cooling demand. Similarly, if there is a cooling priority programmed into the system, the system will satisfy the cooling demand first and then switch over to the heating mode for those zones that require it. There may also be a priority referred to as *zone priority*. Zone priority gives preference to whatever mode of operation is called for by the priority zone. For example, some homeowners set the master bedroom suite as the priority zone. So if that zone is calling for cooling and the rest of the home is calling for heating, the cooling demand will be satisfied first.

ADDING ZONING TO AN EXISTING SYSTEM

Although it is easier to zone a system when it is initially designed and installed, retrofitting existing systems has become a very popular option. With the new 13 SEER regulations in place as of January 2006, more and more attention is being put on energy efficiency and conservation. Since many of the 13 SEER units incorporate variable-speed blowers, adding some sort of zoning equipment seems to be a logical step toward increasing the operating efficiency of systems. Adding zones to an existing system has become an easier task as well. Compact, easy-to-install dampers are readily available in both round, square, and rectangular configurations to fit into existing duct sections. The manufacturers of these products provide templates along with their products to further ease the installation process. **Figure 37.76(A) – (D)** shows the installation of round and square zone dampers.

37.15 DUCT INSULATION

When ductwork passes through an unconditioned space, heat transfer may take place between the air in the duct and the air in the unconditioned space. If the heat exchange adds or removes very much heat from the conditioned air, insulation should be applied to the ductwork. A 15°F temperature difference from the inside to the outside of the duct is considered the maximum difference allowable before insulation is necessary.

Insulation is built into a fiberglass duct by the manufacturer. Metal duct can be insulated in two ways: on the outside or on the inside. When applied to the outside, the insulation is usually a foil- or vinyl-backed fiberglass. It comes in several thicknesses, with a 2-in. thickness the most common. The backing creates a moisture vapor barrier. This is important where the duct may operate below the dew point temperature of the surroundings and moisture would form on the duct. The insulation is joined by lapping and

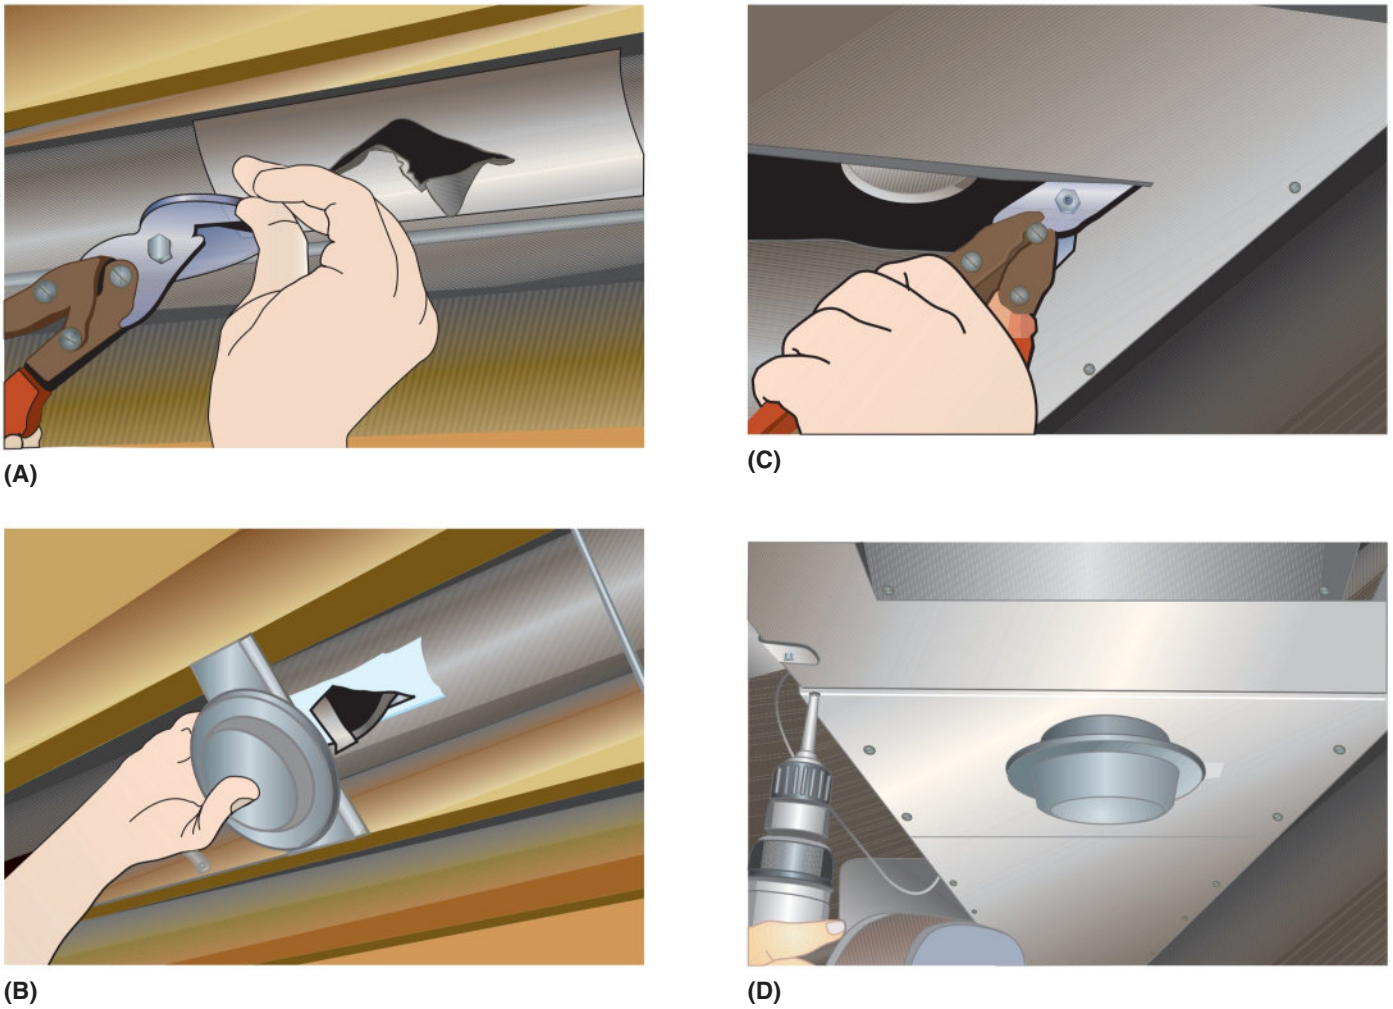
Figure 37.76 Installing a zone damper in a round duct (A)–(B). Installing a zone damper in a square duct (C)–(D).



stapling it. It is then taped to prevent moisture from entering the seams. External insulation can be added after the duct has been installed if the duct has enough clearance all around. When applied to the inside of the duct, the insulation is either glued or fastened to tabs mounted on the duct by spot weld or glue. This insulation must be applied when the duct is being manufactured.

37.16 BLENDING THE CONDITIONED AIR WITH ROOM AIR

When air reaches the conditioned space, it must be properly distributed into the room so that the room will be comfortable without anyone being aware that a conditioning system is operating. This means that the final components in the system must place the air in the proper area of the conditioned space for proper air blending. Following are guidelines that can be used for room air distribution.

1. When possible, air should be directed onto the walls. They are the load where the heat exchange occurs. For example, in winter air can be directed to the outside walls to cancel the load (cold wall) and keep the wall warmer. This will keep the wall from absorbing heat from the room air. In summer the same distribution will work; it will keep the wall cool and keep room air from absorbing heat from the wall. The **diffuser** spreads the air in the desired air pattern, **Figure 37.77**.
2. Warm air for heating distributes better from the floor because warm air tends to rise, **Figure 37.78**.
3. Cool air distributes better from the ceiling because cool air tends to fall, **Figure 37.79**.
4. The most modern concept for both heating and cooling is to place the diffusers next to the outside walls to accomplish this load-canceling effect.
5. The amount of throw (how far the air from the diffuser will blow into the room from the diffuser) depends on the air pressure behind the diffuser and the style of the diffuser blades. Air pressure in the duct behind the diffuser creates

37.17 THE RETURN-AIR DUCT SYSTEM

The return-air duct system is constructed in much the same manner as the supply duct system except that many installations utilize central returns instead of individual room returns. Individual return-air systems have a return-air grille in each room that has a supply diffuser (with the exception of bathrooms and kitchens). Individual return systems provide the best return air, but they are much more expensive to install when compared to similarly sized, central return air systems. The return-air duct normally has a slightly larger cross-sectional area than the supply duct, so there is less resistance to airflow in the return system. In addition, the air flowing though the larger return duct will be much quieter than if the return ducts were made smaller. (more details will be provided in the section on duct sizing). See **Figure 37.81** for an example of a system with individual room returns.

A central return system is usually satisfactory for a one-level residence. Larger return-air grilles are typically centrally located in a hallway so that air from the individual rooms can easily move back to the common return. In order for air to return to the central return, there must be a path, such as doors with grille work, open doorways, and undercut doors in common hallways. However, these open areas in the doors can reduce privacy. In a structure with more than one floor level, a return should be installed on each level. Remember, cold air is more dense than warmer air and moves downward. Warm air is less dense than colder air and tends to flow upward naturally. **Figure 37.82** illustrates air stratification in a two-level house.

A properly constructed central return air system helps eliminate blower noise in the conditioned space. The return-air grille should not be mounted directly to the furnace or air handler because the noise of the blower will be noticeable several feet away. There should be no line of sight between the return-air grille and the inlet of the blower. There should be at least one elbow or bend between the return-air grille and the blower to help keep noise levels low. If this cannot be done, the return-air plenum can be insulated on the inside to help deaden the blower noise. Return-air grilles are normally large and meant to be somewhat decorative. They do not have another function unless they house a filter. They are usually made of stamped metal or have a metal frame with grille work, **Figure 37.83**.

37.18 SIZING DUCT FOR MOVING AIR

To move air takes energy because (1) air has weight; (2) the air tumbles down the duct, rubbing against itself and the ductwork; and (3) fittings create resistance to the airflow.

Figure 37.80 Air registers and diffusers.

	FLOOR	BASEBOARD	LOW SIDEWALL	HIGH SIDEWALL	CEILING
COOLING PERFORMANCE	Excellent	Excellent if used with perimeter systems	Excellent if designed to discharge upward	Good	Good
HEATING PERFORMANCE	Excellent	Excellent if used with perimeter systems	Excellent if used with perimeter systems	Fair–should not be used to heat slab houses in northern climates	Good–should not be used to heat slab houses in northern climates
INTERFERENCE WITH DECOR	Easily concealed because it fits flush with the floor and can be painted to match	Not quite so easy to conceal because it projects from the baseboard	Hard to conceal because it is usually in a flat wall	Impossible to conceal because it is above furniture and in a flat wall	Impossible to conceal but special decorative types are available
INTERFERENCE WITH FURNITURE PLACEMENT	No interference–located at outside wall under a window	No interference–located at outside wall under a window	Can interfere because air discharge is not vertical	No interference	No interference
INTERFERENCE WITH FULL-LENGTH DRAPES	No interference–located 6 or 7 inches from the wall	When drapes are closed they will cover the outlet	When located under a window, drapes will close over it	No interference	No interference
INTERFERENCE WITH WALL-TO-WALL CARPETING	Carpeting must be cut	Carpeting must be notched	No interference	No interference	No interference
OUTLET COST	Low	Medium	Low to medium, depending on the type selected	Low	Low to high—wide variety of types are available
INSTALLATION COST	Low because the sill need not be cut	Low when fed from below–sill need not be cut	Medium–requires wall stack and cutting of plates	Low on furred-ceiling system; high when using under-floor system	High because attic ducts require insulation

Friction losses in ductwork are due to the actual rubbing action of the air against the side of the duct and the turbulence of the air rubbing against itself while moving down the duct. Friction due to air rubbing against the walls of the ductwork cannot be eliminated but can be minimized by good design practices. Proper duct sizing for the amount of airflow helps maximize system performance. The smoother the interior duct surface, the less friction there is. The slower the air is moving, the less friction there will be. Although it is beyond the scope of this text to go into details of duct design, the following information can be used as basic guidelines for a typical residential installation. Each foot of duct offers a known resistance to airflow. This is called **friction loss**. It can be determined from tables and special slide calculators designed for this purpose. The following example explains friction loss in a duct system, **Figure 37.84**.
