Preface

Because the field of science education had been developing and flourishing for over half a century, it was timely and fitting that the first *International Handbook of Science Education* was assembled in 1988 to synthesise and reconceptualise past research and theorising in science education, provide practical implications for improving science education, and suggest desirable ways to advance the field in the future.

This *Second International Handbook of Science Education* demonstrates just how much and how rapidly the field has evolved, expanded and diversified over the last decade or so. In providing a detailed and up-to-date overview of advanced international scholarship in science education, this two-volume, 96-chapter, 1,400+–page work is the largest and most comprehensive corpus of knowledge and resource ever produced in science education for use by researchers, teacher educators, policymakers, advisers, teachers and graduate students.

In structuring this *Handbook*, we divided the field of science education into the following 11 significant areas:
Sociocultural Perspectives and Urban Education

- Learning and Conceptual Change
- Teacher Education and Professional Development
- Equity and Social Justice
- Assessment Evaluation
- Curriculum and Reform
- Argumentation and Nature of Science
- Out-of-School Learning
- Learning Environments
- Literacy and Language
- Research Methods.

In designating this *Handbook* as ‘international’, we wanted to have a book that would have significance to readers from many countries. Consequently, authors have included research from a variety of countries and broad geographic coverage was considered when selecting authors. Altogether 172 authors from 20 countries were involved in producing this *Handbook*.

We especially would like to thank our chapter authors for being part of this enormous publishing enterprise and for being patient with us when we were unable to keep all the balls in the air at once. Also we are grateful to everyone at Springer and Curtin University who helped to bring this major task successfully to fruition.

Chapter 1
Sociocultural Perspectives on Science Education

Kenneth Tobin

After 36 years of studying the teaching and learning of science, it is clear to me that there are many ways to teach in order to produce success and just as many ways to teach to produce failure. Being an effective science teacher entails much more than changing one or two variables and maintaining high expectations for the achievement of youth. Instead, effective teaching is complex, necessitating that teachers enact successful chains of interactions, not just for one person, or even one person at a time, but for a social network, producing and sustaining learning environments built upon fluent transactions that facilitate collective and individual outcomes. Teaching science is collective, and it is important that all participants, teachers and students, have a sense of the game that affords forms of participation that are timely, appropriate, and anticipatory. Central to productive learning environments are individuals who act not only for themselves, but also for the collective; that is, they enact practices not only intended to promote their own achievement but also to expand the agency and learning of others. Accordingly, each learning practice also becomes a teaching practice and teaching and learning are regarded as dialectical constituents of a learning environment. The essences of a dialectical relationship are irreducibility and copresence, each entity presupposing the existence of the other. I employ dialectical theory to avoid the creation of binaries and the use of either/or logic and I depict dialectical relationships using the following convention, teaching | learning, in which the vertical stroke is indicative of a dialectical relationship between the adjacent constructs.

Illuminating Science Education with Sociocultural Theory

Making Sense of What Happens in Science Classes

I adopt an ontological stance that theory illuminates experience, affording participants making sense of their social lives. This stance is salient because in the everyday unfolding of events participants do what they do without epistemological engagement and it is only when there is a breach in the flow of interactions, when the unexpected occurs, that actors take stock of what has happened and reflect on action. On such occasions those actions deemed to have salience become epistemic objects and can be examined in terms of a theoretical standpoint. Because so much of what happens in social life happens without conscious awareness, reflexivity is important for actors, such as science teachers and their students, so that they can identify aspects of their practices and their supporting rationale, changing them as desirable to benefit the collective. Thinking back on what happened during a science lesson with the purpose of identifying desirable changes necessitates evaluations being made about what is and is not working for the benefit of the teachers and students. Reflecting on practice is a recursive activity in which a theoretical standpoint illuminates experience and affords goals such as identifying roles and associated practices that can be changed for the purpose of improving learning environments. The standpoint used to identify salient roles and practices is also an object for potential change. Since the use of different theoretical lenses can lead to different events being considered salient, it is important for teachers and learners to become aware of and understand the theoretical standpoints they use to make sense of learning environments. Also, participants in a field should be willing to understand others' standpoints and consider their viability. Hence, when teachers and students consider changes to learning environments, it is not just roles and practices that are objects for change, but also the participants' standpoints, which give meaning to questions such as what happened, what should happen, and what is of value?

My Framework

I examine science education through the lenses of social and cultural theory, adopting a standpoint that considers science as cultural enactment. When science is done (i.e., enacted), like other forms of culture it can be considered as a dialectical relationship between production and creation. I use dialectically related constructs for enactment involving agency (i.e., production) and passivity (i.e., creation), constituents of a whole that do not exist independently. Cultural production involves agency, is goal oriented and intentional, and occurs when actors consciously appropriate structures (e.g., a student responds to a teacher question about an oscillating pendulum gradually losing its energy). Simultaneously, cultural creation occurs passively and may be unrelated to goals even though an actor is aware of culture being created over which she/he does not have complete control (e.g., creation of negatively valenced emotions while balancing equations). Accordingly, cultural enactment involves agency and passivity, which are dialectically related to one another and to the extant structures.

Most models for learning science have emphasized agency and focused on the learning of individuals (Roth 2007). From a sociocultural perspective, however, individuals are dialectically related to collectives, and agency cannot exist independently of structures or passivity. Hence, agency is both individual and collective and is reliant on a dynamic structural flux that characterizes social fields. Roth and Calabrese Barton (2004) discussed scientific literacy as collective and provided compelling accounts of the ways in which collective goals (hereafter motives) are accomplished when individuals agree on and enact a division of labor that includes coordinated action toward the agreed motives. That is, the goals of an individual are dialectically related to the collective's motives. For most educators, thinking of the outcomes of science in collective as well as individual terms is a novel experience that points to a need for different forms of activity, such as cogenerative dialogue (hereafter cogen), which is considered later in this chapter as a means of establishing productive dialogues between teachers and students in which all participants learn from one another. As Michel Juffé (2003) notes, passivity can be thought of as receptivity to learn from others. Being-in-with others is a sufficient condition for learning passively as science is enacted in a field (including a science classroom or informal learning institution such as a museum). Hence, science learning occurs even when participants do not have the goal of learning science and when they are unaware that they have learned. Reflexive practices at a later time can reveal what has been learned (i.e., awareness and potential worth of what has been learned).

Many scholars totally misunderstand the nature of passivity, thinking of it in behavioral terms. That is, they think of passivity as not being overtly involved in an activity. On the contrary, a person who is agentic simultaneously learns passively. Based on our research in urban schools, the factors that seem most salient to receptivity to learn are: being-in-with others doing science (i.e., physical proximity); solidarity with others; cosmopolitanism that unites subgroups based on differences within and between social categories; possessing a science-related identity; having positive emotions toward science and doing science; recent success in science; and willingness to invest the emotional energy needed to initiate and sustain participation. When the emotional energy of a field is positively valenced all participants have opportunities to create a shared mood that is positively valenced, contributing to receptivity to learn and possibly expanding agency as well.

Structures as Affordances for Enactment

I use social field in much the same way a physicist might use magnetic, electric, and gravitational fields. A social field is a site for cultural enactment and is constituted by structures, which are resources that afford cultural production and creation. Because they are unbounded, fields are uncontained by space and time, which are considered as structures. Examples of other structures include individuals and their characteristics, equipment and materials, goals and schemas, and social categories such as age, gender, race, ethnicity, religion, and class. Participants' practices, which are simultaneously structured and structuring, are an integral part of a dynamic structural flux that characterizes a field and affords enactment through agency and passivity. Because the structural flux is indeterminate, agency is expanded by the possibilities afforded by the unfolding enactments of social life. Of course, to the extent that similar structures have been encountered previously, aspects of the structural flux can be anticipated and appropriate knowledge can come to hand just as it is needed (i.e., structural resonance or entrainment occurs). In such circumstances cultural fluency is afforded and it is only when unexpected structures arise that fluency is breached (e.g., when anticipated structures are not available in time and/or when unanticipated structures emerge). Accordingly, participants in a field might find it beneficial to participate in reflexive activities (e.g., cogen) in which they take stock of what is happening – identify what is working satisfactorily, what changes are desirable, what is possible, and what has been accomplished.

When it comes to applying the idea of a field, the decision of where to focus depends on the purposes of a study and what is usefully regarded as a field. For example, choices to examine science education within a school, or a class within a school, are convenient but arbitrary and are analogous to using a zoom lens in microscopy. If a researcher's gaze focuses on a science class, then field can be a useful theoretical entity to illuminate what is happening in the class. If the gaze moves to the participation and learning of Black females, for example, then the field can be considered in terms of those participants and their activity. The scope of a social field can vary from the global (e.g., including macrostructures such as neoliberalism) to the molecular level involved in neural processing and all magnitudes in between. Similarly, time can vary from exceptionally long to extremely short, reflecting the purposes of a study and the tools used to support inquiry. From an analytical standpoint, it is important to remember that structures interpenetrate all fields of an individual's lifeworld, thereby mediating activity (i.e., the enactment of culture). Because of the agency | passivity dialectic, what happens in a field is afforded by structures, not determined by them (i.e., individuals always are agentic while being passive with respect to a dynamic flux of structures).

When participants enact culture in a field, there is a tendency to reproduce culture that is similar to what has been produced in the field historically. For this reason, an investigation might productively examine cultural enactment as a function of time, identifying patterns over long and short periods of time. Some structures in the field of science education are relatively stable. For example, despite an exponential increase in the production of science knowledge, the K–12 curriculum has been little changed in a half a century. Also, looking at patterns over a shorter time span, the science subject matter taught varied from day to day. Similarly, teacher and student roles and practices vary when viewed from minute to minute, however, when viewed from week to week, or month to month, discernible patterns are similar to those I described in the 1980s (e.g., Tobin 1987).

In fields in which science education is enacted, it is important to explore the implications of individual | collective relationships and examine the roles of individuals in relation to their goals and motives. A division of labor can be considered with the motive of expanding collective agency – that is, individuals acting for the benefit of others. In order to do this, it is important to embrace a value of supporting others' agency and assuming co-responsibility for facilitating others' goals. If this occurs, a likely outcome would be solidarity; based on a heightened sense of belonging to a collective and the desirability of creating coalitions that bring together subgroups that might be defined by social categories, such as race, gender, class, and native language. A form of solidarity that transcends subgroups is cosmopolitanism (e.g., Appiah 2006), regarded as a vital outcome of science education as it is enacted in diverse social settings (i.e., in fields in which there are numerous salient social categories associated with participants such as native language, gender, and ethnicity).

Solidarity and Science Education

Solidarity is a form of symbolic capital, a sense of belonging to a social category, such as youth having an interest in science. For example, in a high school science class in the Bronx, a central feature of students' identity might be defined in terms of the poles of a binary – speakers and nonspeakers of Spanish. The symbol of speaking or not speaking Spanish can thus become an identity marker and a form of capital used in creating social bonds and networks. That is, speaking Spanish can become a social category that affords solidarity and the co-emergence of two groups. This might manifest in participants' preferences for selecting those with whom they prefer to work and be seated. Similarly, social categories such as gender, race, and class can act alone or in combination to afford solidarity among clusters of participants within a field. In such circumstances, cosmopolitanism, the creation of solidarity across clusters, is a desirable outcome.

Scholars such as Jonathan Turner (2002) and Randall Collins (2004) have undertaken work in the sociology of emotions that is central to the creation of solidarity and cosmopolitanism in science education.

Cosmopolitanism

Turner researched the evolution of human emotions in terms of theory that includes primary, secondary, and higher-order emotions. He posited four primary emotions, three negatively valenced (fear, anger, sadness) and one positively valenced (happiness).

As social life is enacted, emotions are produced continuously, contributing to a valenced emotional climate. Turner referred to this using the analogy of emotional energy (EE). As a structure, EE serves the production and creation of culture. Usually I consider EE as positive, neutral, and negative. Empirically, it makes sense to look for spikes in the EE spectrum, that is, when emotions are strongly positive and negative, and the culture associated with them.

The school in which our research is situated in New York City draws on youth from a densely populated neighborhood. Through immigration and recent ancestry, these youth are associated with several ethnic groups including Puerto Rican, Dominican Republic, African-American, and Caribbean. In this instance, ethnicity can be a kernel for producing solidarity, as is Spanish, the native language most students speak. Within most classes it is not uncommon to find youth sitting in ethnic groups or native language groups. Social categories such as these can serve as bases for spending time together and being with others who are similar. That is, categories of difference can draw similar others into proximate space–time, allowing them to identify with one another and experience feelings of solidarity, based on their affiliation with a group.

Groups form within science classes and youth tend to identify with those groups. Since there are multiple groups, students can create, sustain, and reinforce multiple identities in a science class – identities that have little or nothing to do with science. Of course, this can be an advantage, because the identities that develop in conjunction with factors such as native language, ethnicity, and gender can be tied to science. However, this may take a conscious effort (i.e., agency), on the part of all participants, and adherence to science-related motives. The creation of a science identity that transcends multiple identities associated with other social categories requires a form of solidarity that brings together subgroups that are akin to diasporas (Hall 1990), or homes away from home. Kwami Appiah (2006) refers to this superordinate form of solidarity as cosmopolitanism, a topic that was studied by the ancient Greeks and consistently from then on (e.g., Parsons et al. 2007). The key idea in science education is to consider cosmopolitanism as a goal when other criteria are continuously reinforcing identities associated with difference, such as those I have discussed already. Jacques Derrida wrote an essay on the creation of cities of refuge; cities where refugees were welcome to come, not just to visit, but also to reside (Derrida 2006). A defining criterion for these cities was that each citizen needed to embrace the goal of affording community life while retaining the right to be different. Differences were seen as resources to allow the city to flourish. Therefore, the challenge was to find divisions of labor in order to take advantage of what different citizens within the city could do and accomplish, and ensure there was an alignment of what different collections of individuals did and motives for the city. The glue that held together different constellations of difference was a value for the right to be different and a sense that difference was a resource that could benefit the collective. Establishing cosmopolitanism in science education might fruitfully be considered analogously to cities of refuge.

In a science class, cosmopolitanism is not an end state, but is constantly being built as interactions unfold during science classes. The accomplishment of cosmopolitanism necessitates awareness and a continuous investment of EE. A tendency to fragment is likely to always be present and it is important that students are reflexive about cosmopolitanism and make serious efforts to nurture it. One of the most important outcomes deriving from cosmopolitanism, is the production | creation of science-related identities. If a science class can establish and maintain science-related identities, then participants can work together to produce higher levels of achievement and ultimately forms of success that are negotiable in the community at large. However, the challenges are many in urban schools such as those in New York City. It is not only students that differ in terms of social categories such as those I have mentioned but also teachers. For example, although Reynaldo Llena, a Filipino chemistry teacher, speaks Spanish, it is not his native language. Ethnicity and native language are social categories with the potential to set such teachers apart from their students (Tobin and Llena 2010). Accordingly, Llena embarked on a multiyear project in which he used cogen as a means of producing solidarity and cosmopolitanism, not just as outcomes but also as processes that needed constant attention. In the next section I address the nature and application of cogen as activities and methodologies, not just in research, but also for learning to teach, curriculum development and enactment, and learning to learn.

Cogenerative Dialogue

For the past 6 years we have been using cogen in ongoing research in New York City. This research builds on an earlier program that is ongoing in Philadelphia. The production of cosmopolitanism has been an important focus, not just as an outcome but also as a process that was closely linked to other valued outcomes such as increasing achievement on the State Regents examinations. One of the sites for this research was New York High where Llena, the chemistry teacher referred to above, was a central figure as a teacher researcher (e.g., Tobin and Llena 2010).

Cogen involves more than discussions among representatives of the key stakeholder groups in a school, science department, or class. Representation is an important criterion and so too is participation in an ongoing dialogue in which attentive listening is a valued component. The number of participants should afford ample opportunities for speaking, listening, and being reflexive about what has been happening. If speaking is to structure everybody's participation, then it needs to be external to the individual; that is, it cannot be inner speech only. This criterion often limits the number of participants in cogen. Our experience is that somewhere in the vicinity of five to nine participants is ideal, allowing for differences to be represented in a variety of social categories and, in approximately 45 min, ensuring that all participants have turns at talk and opportunities to listen and learn from others as they speak.

When we first established cogen, we focused on selecting participants who were different from one another. We wanted to obtain diverse perspectives on what was happening in a shared classroom experience and to do our best to learn from those perspectives. We were not interested in finding out what happened on the average; we wanted to know how individuals experienced the class, what was common, and what was idiosyncratic. Initially, we started with two to three students and any teachers who had been teaching in the class. Since we planned cogen in conjunction with coteaching, it was frequently the case that cogen also included two to three coteachers who, with the students, participated in a dialogue over shared experiences.

The dialogue focused on improving learning environments and facilitating success for all participants. It soon became apparent that there was little point in participants blaming one another for identified problems. If something was not working there was shared responsibility for making things work in ways the group endorsed. Hence, there was an initial priority to accept shared responsibility to enact in the classroom what was agreed to in cogen. Not surprisingly, this led to students taking a more active role in teaching science. If participants accepted responsibility for enacting what they agreed to, it seemed reasonable that they would get up from their seats during class to ensure that their peers' actions aligned with the motives of the class, use the chalkboard to clarify aspects of the science content that needed to be elaborated or clarified, and generally circulate to ensure that any peer in need of assistance could obtain it. Accordingly, one of the first changes we noticed in classes that incorporated cogen was that students got involved as peer teachers, that is, they became coteachers. In so doing changes were noticed in the ways in which spaces and other natural resources were utilized by teachers and students. For example, students often moved freely about the classroom and worked at the chalkboard.

Speaking for Others

In cogen, one of the rules is to share the turns at talk. All participants need to agree to a rule that the distribution of talk is equitable. Our research suggests that participants speak for approximately the same amount of time and have approximately the same number of turns at talk (e.g., Tobin 2006). In fact if this is not the case, there is shared responsibility to talk in ways that encourage those who are silent to speak. Accordingly, students who often said very little in class began to speak more; other participants listened to them, and what they said clearly made a difference to negotiated outcomes. Participants in cogen realized that they could have a voice and what they had to say could make a difference. Participants learned to talk in ways that would produce agreed-to outcomes and, importantly, talk in ways that would benefit others in cogen (e.g., expand their agency). Speakers were talking for the other. That is, when a person speaks, he or she contributes in ways that expand the agency of other participants, not only speaking for the purposes of the talker, but also to benefit others in cogen. Speaking for the other is a desired outcome that is accomplished more often than not in cogen.

Maintaining Focus

Establishing and maintaining shared focus also was a rule of cogen. We expected participants to listen attentively to what was said and only to speak in relation to what was said previously. Speakers were not encouraged to change the topic unless there was agreement that a change of topic was to occur. In this way the dialogue stayed focused on the matter at hand until a resolution was reached (i.e., a cogenerated outcome). All participants were encouraged to ask what have we cogenerated? By keeping this issue on the table, the talk tended to be focused and synchrony occurred in terms of what was said and what happened next. Widespread synchrony within cogen, referred to as entrainment, is a precursor to solidarity, a shared mood, and frequently collective effervescence such as laughter, clapping, and overlapping speech (Collins 2004). We began to see examples of participants becoming like the other, presumably afforded by mutual focus established and maintained by the rule structure of cogen. By retaining focus, synchrony was a common phenomenon, producing entrainment, which often comprised sets of similar actions distributed broadly across a social network.

Radical Listening

Productive cogen necessitated careful listening of all participants. One person spoke at a time, and the others listened attentively. However, there is more to it than just listening attentively. Radical listening requires participants to understand what is being said, consider the associated standpoint, and understand the implications of what is being said for practices in the classroom (Tobin 2009). (Joe Kincheloe introduced this idea to me in an unpublished manuscript.) Radical listening requires each participant to understand the standpoint of others, figure out how to adopt those standpoints, consider implications of adopting them, and in ways that are reminiscent of thought experiment, consider implications of adopting practices that are consistent with others' standpoints. Rather than immediately searching for the shortcomings of a particular standpoint, radical listening necessitates the identification of its inherent strengths. The listener is required to understand and apply someone else's standpoint and carefully consider plausible outcomes and their viability for this collective – in this case a science class.

Expanding Participants' Roles

In order to reap the potential of cogen it is necessary for participants to produce and create new culture that is then potentially available to be enacted in other fields of the participants' lifeworlds, including the science classroom. Creating new culture that affords success is an outcome of cogen that opens up possibilities that have profound implications for the way that education is conducted in schools around the world.

A goal of cogen is the production of new roles focused on improving the quality of learning environments. There was evidence that the new culture produced in cogen was subsequently enacted in the science class (e.g., Tobin and Llena 2010). That is, cogen was a seedbed for the creation and production of new culture that could be used subsequently to improve the quality of learning environments. Participants were encouraged to bring artifacts from the class to cogen so that they could be used to focus the unfolding conversation. Accordingly, students and teachers brought work from the class, digital images of inscriptions from the chalkboard, evidence of students' participation in science tasks and off-task conduct, textbook pages, and other resources used in the class as aids to learning. A significant moment in the evolution of cogen was the use of digital video to capture what was happening in the class. Students and teachers found it useful to digitally record the lesson and then at a later time analyze what was happening by replaying and editing to capture vignettes deemed to have salience. Subsequently, these vignettes were brought to cogen and focused participants' interactions. Microanalysis was used to examine the quality of interactions and especially the way individuals spoke to one another, reacted to what was said, and acted for the other. Having video as a point of reference, has greatly enhanced the quality of dialogue and moved it toward evidence-based arguments, conversations, and resolutions.

Teachers and students in cogen became researchers of their own practices and shared the goals of finding out what was happening and figuring out why what happened did happen. There was a need to adopt different standpoints to make sense of their experiences and before long participants were willing to learn and apply new theories in a quest for understanding what was happening in their classroom. Accordingly, participants became interested in issues such as whether or not mutual focus occurred and was sustained, whether there was synchrony, entrainment, shared mood, collective effervescence, and solidarity.

Curriculum Change

Many good ideas for changing the enacted curriculum arose from cogen. For example, in one cogen students felt that the class lacked variety and interest. They proposed that the teacher use a game format during the next class and she willingly agreed to plan a lesson around a quiz show called *Jeopardy*. The teacher enacted this plan in a review lesson on genetics, and the students enjoyed the format and agreed that it could be used at least once a week to increase their levels of interest in what was happening in the class. This is one example of how a cogenerated idea led to changes in the enacted curriculum. Another example, also in genetics, involved students using video and their video editing skills to produce Podcasts that could teach peers in that class some aspect of genetics. This too was implemented and students learned by producing teaching resources for peers and also by using the resources that others produced. The students in cogen thereby became curriculum developers; using skills they developed for research to produce curriculum resources used to improve learning environments. A final example involved the use of hip-hop. The youth involved in cogen had an avid interest in hip-hop and many of them were interested in writing lyrics that incorporated the science they were learning. Other students were good at creating a beat to coordinate with the lyrics and worked collaboratively to produce a rap that could then be performed in the class as an example of what others could do in their quest to learn science. In this way rap was incorporated into many science lessons with some students working together in small groups to produce lyrics while others prepared beats to synchronize with the lyrics, thereby producing a rap that everybody could learn and perform.

Llena had an idea that youth participants in cogen could serve as mentors for others in their class and in other sections of the course he was teaching (in this case living environment). He developed a buddy system, in which each youth participant in cogen identified at least one buddy for whom she/he would become teachers and "buddies." The youth would ensure their buddies were ready for school, did their homework, arrived on time, came to class, and stayed engaged during each lesson. If a buddy experienced difficulties in class, the youth mentor would teach her/him about the subject matter of the lesson. Llena adjusted the assessment system so that those who accepted a mentoring role would earn credit if their buddies increased their achievement. The more the buddy increased her/his achievement the higher the grade of the mentor. The buddy system was a great success and it was not uncommon to see participants from cogen actively teaching their buddies during class time.

Cross-Field Production and Creation of Culture

Students were encouraged, developed confidence, and were aware that adults could and would listen to them and act on what they had to say. It was not surprising, therefore, that once students discovered they had a voice that could make a positive difference they spoke up in other fields, in and out of school. For example, youth involved in cogen not only cotaught but they also approached school administrators to make other changes to school structures (Bayne 2009). These included suggestions that other students should use cogen too, not only in science, but also in their other subjects. In one school this resulted in cogen being used in the middle grades so that students would develop more school spirit, and school-related identities. This suggestion was made by one of the participants from the high school, who had done cogen for 3 years and realized widespread benefits. Many of the youth who participated in cogen became involved in student government, several becoming chair of the school council.

At New York High, a group that had experienced cogen for 4 years suggested a series of turnkey activities involving grade 12 students teaching students from grade 9, and their teachers, how to enact cogen. Grade 12 students told students from other year groups about the benefits of cogen and encouraged their teachers to use them (Tobin and Llena 2010). Some of the teachers were reticent to do this and many students doubted that the teachers would listen to them. Clearly there was a lack of trust. However, the youth persevered and several years later there is evidence that even the most skeptical teachers adopted and successfully used cogen to improve the quality of learning. Evidence of success includes increased performance of students on statewide, standardized tests. Although we did not actively pursue this goal as a research group, performance on high-stakes tests is a gold standard in New York City, and it was a plus that cogen produced higher achievement scores on highly valued assessments. It is also noteworthy that students who often dropped out of high school participated in cogen, achieved success in their high school studies, and made the decision to go on to university. Hence, participation in cogen was an activity that produced success, changed identities, and produced forms of practice that transformed and expanded the possibilities of urban youth.

Prosody and Emotions

Participants in cogen became aware of the centrality of emotions in all interactions and events that occurred in the science class. As our research expanded and we became interested in the emotional content of talk, students and teachers also were interested in prosody and students from one class drew attention to the anger their teacher displayed as he taught. They drew his attention to features of his speech they interpreted as anger. The teacher assured them he was not angry, that he was interested in their learning, and would attend to what they had told him about the way he spoke. Apparently, differences in ethnicity between the students and the teacher led to misunderstandings about the emotional content of interactions and these misunderstandings mediated the creation of emotions, in this case creating negative emotions such as frustration and anger on the part of the students who perceived the teacher as angry with them for no good reason. Building trust, respect, and tolerance were outcomes of cogen – not just for students, but also for the teacher. Hence, the production of success in cogen created social bonds associated with affection between participants, increasing solidarity with the potential to translate to cosmopolitanism in the science class.

Emotions are a central part of action; that is, when we act our emotions are put on display in how we move and use our bodies, including gestures, facial expressions, head movements, and speech. For example, when we are excited, those who are in sync with us experience our excitement as we interact with them. High-energy teachers, for example, communicate their emotions to a class in the ways they coordinate their bodily actions and characteristics of their speech. Similarly, if a person is angry, others having a history of interacting with that person can "read" the anger, because it is visible in the person's actions. Humans who have intense and prolonged experiences with others can quickly pick up their emotions based on just a small number of encounters – "Oh, she is in a bad mood, I should avoid her for a while!" Or, "he is angry, I should let him sort this out before I raise these issues with him." These are just two examples of the kinds of thoughts I have when I approach people that I know and quickly size up their emotions prior to commencing my interactions with them. In our research we have begun to zero in on ways to measure the emotional content of actions.

During a routine set of classroom interactions, prosody analysis usually reveals numerous alignments in terms of pacing, pitch, and intensity. Synchrony also was found in terms of intonation, with successive speakers inflecting utterances as evidence of a shared mood. Research on these alignments and synchronies must take account of natural variations in the voices of adults and children, males and females, for example. We have seen examples of science teachers intentionally producing misalignments in an endeavor to change the emotional climate in the classroom. For example, high-energy teaching might involve exaggerated body movements, including verve, and prosodic features that are loud, unusually contoured in regard to frequency and intonation, and energy laden (i.e., high intensity in the higher-order formants). If participants become like the other by being with the other then students in the class of a high-energy teacher might begin to interact in high-energy ways simply by being in the classroom with the teacher. Of course symmetry can be anticipated and a loud and noisy class creates a structural milieu to afford loud and noisy teaching. My point is that misalignments or asynchronies can be intentional, the purpose being to alter the emotional climate and create a shared mood of a particular nature.

Misalignments can also cause trouble. We have experienced classroom climates that have spiraled out of control as successive speakers infused high-energy emotions into their speech. We called this heating up the climate. We noticed in the same classes, that when students spoke after one of their peers had made an angry utterance, their speech contained less emotional energy than that of the angry speaker (Roth and Tobin 2009). That is, they spoke "under" the previous speaker. Speaking over or speaking under is equivalent to heating up or cooling down the climate, respectively. When participants know the culture of the other, it seems they can anticipate what is to come based on what they have experienced so far, and they can act accordingly in ways that do not produce trouble. That is, they act appropriately to reproduce cultural fluency, thereby affording outcomes that align with the motives.

Potential for Change

More than a decade of research in science education employing a sociocultural framework has illuminated the folly of policies grounded in the macrostructures of neoliberalism, meritocracy, and accountability systems that focus on individuals' efforts and accomplishments. At the very least, our project suggests that it is time to step back and critique the assumptions and practices that have produced and reproduced what are euphemistically referred to as failing schools. Predictably, schools that fail are associated with lower levels of per capita student funding, race, ethnicity, and English proficiency. Use of a sociocultural framework provides windows into the practice of science achievement that afford explanations for the gaps we have experienced in science education and for the myriad tests of international comparison that show the USA lagging behind its economic competitors. Furthermore, the sociocultural framework illuminates an array of alternatives that promise to redress the ongoing and pervasive inequities that characterize science education.

The first tip I can remember receiving about being a good teacher resonates in my mind: "As they walk in the door on the first day, identify the biggest male student and politely request that he pick up a piece of paper from the floor. Show the class that you are in control." The advice made sense because it aligned with my experiences as a schoolboy – my best teachers all had quiet and busy classes in which students were highly involved. I accepted the viability of the assertion that environments like this were established and maintained by teachers exercising control over their students – they kept them quiet and productively engaged. School leaders and other judges of good teaching even maintained that they could assess good teaching by simply listening at a window or from behind a closed door. The ultimate test was that the noise level would not increase when the teacher left the room.

Sociocultural perspectives (e.g., associated with social class and race) highlight the salience for teachers and students of collaborating to produce and sustain productive learning environments. From this standpoint it makes no sense to regard teaching as the responsibility of just one person – teaching is radically collective. Accordingly, there are many implications across myriad domains of education policy and practice. Also, in teacher education and credentialing there are crucial implications that must be addressed. What is teacher knowledge? To what extent does teacher knowledge learned in one field transfer to other fields? Are there appropriate ways to assess the quality of teaching and make choices about which teachers are optimal for particular schools and classes? When it comes to teaching science, what is the appropriate balance between knowledge of science and knowledge of teaching science? Who should make the decisions about which teachers to hire and which teachers to assign to particular classes? And when it comes to doing research on teaching, who are the most appropriate researchers and how will they collaborate to produce viable outcomes? Also, to what extent is the purpose of research to produce new theory and to what extent is it to produce improved practices and policies? These are just a few of the many questions that warrant our attention; questions that produce answers with implications that may not have been considered from the different theoretical standpoints that have been traditionally adopted. Rather than addressing issues such as teacher education, research in classrooms, science curriculum development and enactment, and formulating policies to afford urban science education, I simply note here that it is past time for educational researchers to be reflexive about what they do and where they are going, using sociocultural lenses to augment those that have been used traditionally. It must be clear to all that the tried and tested methods have failed, and will continue to do so for as long as scholars and policy makers consider individuals in isolation from associated collectives and insist on accountability models that embrace individualism and meritocracy. It is no longer a question of trying to improve what we do, it is time to question what we do and seek alternatives, including the use of different rationale for identifying priorities and selecting among alternative pathways. The moment for change is now.

Chapter 2
Understanding Engagement in Science Education: The Psychological and the Social

Stacy Olitsky and Catherine Milne

It is a prevalent understanding among teachers, curriculum writers and education researchers that students need to be engaged in order to learn science. Empirical studies in education indicate the importance of student engagement for effective teaching and learning (e.g. Ainley et al. 2002). Many teacher education programmes advocate a focus on engagement when they promote pedagogical strategies based on constructivist views of education. Such programmes encourage teachers to provide opportunities for students to build their own meanings in science through direct experience, rather than the more traditional transmission models of teaching (e.g. Duckworth 1987). Pedagogy based on a constructivist approach implies student engagement in that the students need to be active, making sense of their world through integrating their new experiences with their prior experiences, beliefs and knowledge (Driver et al. 1994). One example of an approach to science teaching developed in accordance with constructivist thought is the 5E instructional model, which consists of the following phases: Engagement, Exploration, Explanation, Elaboration and Evaluation (Bybee 1997). According to this model, the first phase, student engagement, can be fulfilled through some type of short experience that is designed to access prior knowledge and stimulate curiosity. Similarly, in many teacher education programmes, teachers are encouraged to engage students by designing lessons with some kind of a 'hook' that is supposed to gain students' attention and pull them into the subject matter.

Constructivist perspectives, both personal and social, primarily focus on the cognitive aspects of engagement, in that the emphasis is on cognitive tasks such as questioning prior beliefs or building on prior knowledge. However, in order to

implement pedagogical strategies based on constructivism, engagement on an emotional level is crucial. For example, students need to be excited by the 'hook', or have positive emotional tone associated with the process of questioning their ideas in order for such strategies to be effective. Paul Pintrich, Ronald Marx and Robert Boyle (1993) were critical of models for student learning that focused only on 'cold' cognition, ignoring the role of student engagement in classroom activities. Further, empirical research has also affirmed the importance of engaging students on an emotional level (Alsop and Watts 2003). Mike Watts and Steve Alsop (1997) argued that theories, such as conceptual change, need to take into account the emotions behind actions if learning in science is the final goal of developing such theories. If we assume an active learner, an agent, then it makes sense to acknowledge the role of emotions in engagement. However, in order to do that, we need to develop a richer understanding of the nature and role of engagement in classroom contexts.

Such clarification is important, because the everyday use of the term 'engagement' among teachers emphasises the slipperiness of this idea as it currently emerges in discussions about pedagogy. For some teachers, engagement is an individual construct evidenced when they talk of a student who is 'disengaged'. This places an attribute, and perhaps responsibility, on that student. Sometimes teachers describe how they did not sufficiently 'engage the students', which then places the focus and the responsibility on the individual teacher. For others, engagement is collective, with teachers describing how students and teacher become so caught up in a lesson that they are surprised when the end of class is signalled.

In this chapter, we examine new research in which engagement is posited as emerging from collectively generated emotions, which then has implications for both cognition and behaviour. This social and emotional view of engagement does not mean that individuals' actions are thought to be irrelevant. Rather, attention to the collective aspects of engagement means that an individual's actions are not understood as a product of some kind of inclination or personality trait (e.g. this child is disengaged or shy). Instead, we follow the sociologist Randall Collins in viewing individuals as products of social situations, and argue for a dialectical relationship between the social and the individual.

We develop, illustrate and support our view of engagement by describing outcomes of our research that illustrate how collectively generated emotions led to changes in both behaviour and cognition within two science classrooms in Philadelphia. Similar findings about the results of engagement from two very different schools support the primacy of the social and emotional aspects of engagement in influencing other dimensions of engagement, and have implications for paths that teachers can take in order to implement positive classroom changes.

Conceptions of Engagement

Much of the research that informs current understanding of engagement in science education comes from behavioural or cognitive studies. Jennifer Fredricks, Phyllis Blumenfeld and Alison Paris (2004) proposed a multifaceted model that consisted of behavioural, emotional and cognitive engagement. They identified *behavioural engagement* as engagement associated with a range of actions from students' classroom behaviours, including on-task behaviour and participation in extracurricular activities. *Emotional engagement* is associated with students' attitudes, interests and values as identified in a student's reactions to peers, teachers, the curriculum content and school. *Cognitive engagement* is associated with motivational and self-regulated learning. Cognitive engagement could be identified from students' willingness to 'exert the effort' that was required to understand 'complex ideas and master difficult skills' (Fredricks et al. 2004, p. 60). The authors argued for the importance of thinking of engagement as a mega-construct that was composed of interrelated aspects of behaviour, emotion and cognition and for understanding engagement in each construct as existing on a continuum. They acknowledged the limitations of single variables for characterising the responses of children to specific tasks or activities and argued for the fusion of behaviour, emotion and cognition under the concept of engagement. Further, they identified engagement as a malleable construct that was open to changes in the context. While their review was helpful because it synthesised extant research on engagement, we do not think that the model of three separate continua is the most accurate perspective, because it begs the question of the complex relationship *between* cognition, emotion and behaviour. However, as we argue later in the chapter, social theory provides strategies for understanding this relationship.

If we look at research on engagement conducted over the past 20 years, we find that many studies adopt a focus on individual engagement. For example, in science education, consistent with the prevailing learning theories, early studies of engagement focused on individual students and measures such as 'time on task' as indicators of engagement (e.g. Tobin and Capie 1982). Even now, while researchers investigating engagement might acknowledge the importance of the social, they still rely on research methods such as interviews and surveys that seek individual measures of engagement. For example, acknowledging the limitations of a purely behaviourist approach to understanding engagement, Daniel Hickey and Steven Zuiker (2005) adopt a different approach using situated cognition to define engagement as *engaged participation*. They postulate engagement as a dialectic between participation and non-participation with students involved in negotiating their identity based on the extent to which they become involved in meaningful practices within specific knowledge communities. They argue that, rather than a focus on individuals, their unit of analysis is 'domain knowledge practices' associated with the curriculum. However, typical of previous studies, Hickey and Zuiker used individual sources of data such as student assessments to develop their model of engaged participation.

Two other studies of note inform our understanding of engagement as social. Leslie Herrenkhol and Maria Guerra (1998) used a design to try to move science education away from a transmission model of teaching and learning. They argued that: 'Transforming constructivist models into viable classroom practices has proven to be a significant challenge' (p. 467). They defined engagement as 'discourse practices that extend beyond the behaviour of individual students and involve social and cognitive activity' (p. 439). Working with 4th graders, they compared a classroom where students were assigned intellectual roles and a classroom where students were assigned both intellectual and audience roles. The results of their study indicated that both audience and activity was necessary for engagement. However, they did not speculate about why this might be so and their study was conducted not in a 'typical' class, but in two classes that were specifically set up for the study. In later sections of this chapter, we argue that sociology of emotions provides a framework for making sense of their findings.

Randi Engle and Faith Conant (2002) also used a situated cognition model to frame engagement as disciplinary, based on creating learning environments that support (1) problematising subject matter, (2) student agency to address these issues, (3) accountability for appropriate norms of behaviour, and (4) availability of resources. Engle and Conant identified observable connections between the discipline's discourse, in this case science, and students' actions and argued that if students make intellectual progress, this engagement is productive. They called their measure *productive disciplinary engagement*, a concept also promoted in the National Research Council's (2007) publication, *Taking Science to School*. Engle and Conant recognised the role of emotion and used observations from videotape data to identify some of the behaviours that we also associated with engagement. We agree with them that greater engagement can be inferred both from the level of substantive contributions that students make when a topic is under discussion and the ways in which students attend to each other. We argue that the sociology of emotions provides a framework for this analysis.

Moving from the Individual to the Collective: Emotional Engagement as Social and Temporal

Historically, emotional engagement has been measured using survey or self-report instruments and has been mainly associated with interest. For example, Connell et al. (1995) used self-reports to identify self-perceptions of perceived competence, autonomy and relatedness that were hypothesised to affect student engagement. While these measures can serve to identify aspects of individual student engagement, it could be hard to draw implications that could guide changes in teacher practices for several reasons. One issue is that these types of measures address aspects of a student's engagement at the particular point in time when the survey was administered, rather than averaging out the fluctuation in emotional engagement through sequences of events in the classroom. Therefore, it is difficult to pinpoint causes of either engagement or lack of engagement.

In addition, by focusing on individual students' self-perceptions, the relationship between collective engagement to individual levels of engagement is not sufficiently addressed. On a practical level, efforts to improve individuals' levels of engagement without accounting for the group interactions can be counterproductive. One example of this phenomenon comes from our own research in an urban school, City Magnet. The students described how, when the teacher tried to promote a sense of competence by assigning tasks that were easily accomplished, students would become embarrassed because everyone knew which questions were easy (Olitsky 2005). Just surveying the students' emotional engagement at a single point in time would be misleading, because the same student might report low emotional engagement after being given an easy question, yet high emotional engagement after successfully explaining a new concept to a peer. Self-reports could therefore be faulty measures because any student's sense of competence, autonomy or relatedness is deeply embedded in the day-to-day context of classroom interactions and their implications for emotions. An alternative approach to surveys would be to attempt to understand the contextual variables that inform fluctuations over time in the levels of engagement of both the individual and collective.

A recent study did address the temporal nature of engagement, investigating how emotional engagement varied with activity structure (Uekawa et al. 2007). Study methods included classroom observations, focus groups and the Experience Sampling Method (ESM), based on Mihaly Csikszentmihalyi's (1990) *flow* theory of engagement, to measure engagement in real time as students were asked to record their cognitive and affective responses at specific times. We find this work resonated with our view, because it acknowledges that levels of engagement change depending on context.

We have worked to develop research methods that can help us to investigate the role of classroom interactions in providing the context that informs student engagement. Following Erving Goffman (1959), we understand an interaction to be an act between members of a social group. A focus on interactions allowed us to identify segments of lesson sequences when engagement was a more obvious feature of the classroom. In addition, we situated classroom interactions within events over a longer timescale. In this chapter, we draw on examples from studies that we conducted to illustrate the importance of examining the social aspects of engagement over time, with an understanding of the ethnographic context. Both of the class contexts that we describe in this chapter are unusual in that students were more engaged than had been observed previously as demonstrated by changes in student participation, including their use of canonical science language.

An example of a change in student action that could only be recognised because of prolonged involvement of the researchers with the classroom context involved Sherez, an African American student. She was a significant player in the presentation of a series of science demonstrations designed to show that air was made of molecules that had volume even though these molecules could not be directly observed (Milne and Otieno 2007). In the first instance, when Sherez came to the front of the room to carry out a demonstration, she took 6.5 seconds to reach the front of the room where the demonstration was to be performed. In the demonstration, Sherez inverted a cup containing a scrunched-up piece of paper at its bottom under water and the paper stayed dry.

Sherez's actions were significant, not just for her, but also for the other students in the class. From previous observations of class interactions, we knew that, up to that point, Sherez had not been able to identify much chemistry that was of interest to her. At first, her participation in the first inverted cup demonstration was almost a risk-taking behaviour because she had to weigh any possible loss of social capital with other students against participation in the demonstration. Thus, her initial movement was measured, as demonstrated by her slow movement, providing a space for her to assess how other members of the class interpreted her involvement. Equally, her decision to participate became a resource for other class participants. Although we did not realise it at the time, these actions contributed to the emerging collective positive emotional energy of the class. The second time when there was a need for someone to conduct a modified version of the demonstration, following a rich discussion about the observations that could be made from the first demonstration, Sherez volunteered with alacrity and took less than a second to move to the front of the room to perform the new demonstration.

If Sharez had taken a self-report survey of emotional engagement at some point during the class session, the results would be misleading, and the important role of collective emotional engagement could be missed. If taken towards the beginning of the period, her answers might indicate that she was disengaged and, if taken towards the end of the period, her answers might indicate engagement. However, the answer to such questions would not tell us how engagement-related behaviours, such as the speed at which she came to the front and her verbal participation, changed over time depending on the overall levels of engagement of the class or how these actions became a resource for other students. Through observing interactions, it became apparent that, as students became emotionally absorbed in an activity, like the demonstration and the ensuing discussion, Sharez's behaviour changed. Without a focus on collective engagement, the significance of these separate observations would not be recognised.

Another example for the need for long-term study of classroom interactions involves Carla, a student at City Magnet school, who usually did not volunteer to participate in whole-class discussions and describes herself as not being good at science. However, when watching her peers at the board complete problems involving the balancing of chemical equations, she frequently offered helpful comments to them. Like other students in the classroom, she described the activity of balancing equations as 'fun'. This student might score as disengaged on a general self-report survey but, based on her behaviour and on interviews, her levels of engagement in the classroom varied with the activity and changed throughout the year.

In closely analysing both transcripts and videotapes, it became apparent that her participation changed in response to the collective mood of the class. There was a general pattern in which, following a series of interactions when students supported each other's work and there was a sense of solidarity and common rhythm, she was more likely to participate, sometimes using canonical science language. Following a series of interactions when students were not collectively engaged, or when students made negative comments about each other's attempts at participation, she was often either silent or made off-task comments. In studying this classroom over the course of a year, it became clear that her engagement was contingent on her level of confidence which, in turn, emerged from collective emotional experience. Without long-term observation of participation in the classroom, it would be difficult to discern these types of patterns.

As these two examples illustrate, it is crucial to focus on how engagement evolves over time within the social setting of the classroom in order to understand individual students' engagement-related behaviour, affect and cognition. In this chapter, we discuss how studying social interaction can tell us why and how student levels of engagement change. We argue that a social perspective is important in order to plan for positive changes that will result in the engagement of more students in science classrooms.

The Primacy of Emotional Engagement: Theoretical Perspectives

In this section, we delve more into social theory and recent studies in order to understand the relationship between collective and individual engagement. We attempt to formulate a perspective that can account for changes in engagement over time, address the dialectical relationship between the individual and the collective, and elucidate the interrelationship between different dimensions of engagement. We argue that emotional energy (Collins 2004) is a necessary ingredient for engagement, and that its presence within classroom interactions supports student learning and participation.

Some recent studies aimed at understanding inequalities in schools emphasise the importance of a social perspective on emotional engagement, and the impact of emotions on student behaviours. For example, Rowhea Elmesky (2001) and Gale Seiler (2002) found that when students' cultural capital is not valued in science classrooms, students perceive strong boundaries between their own knowledge, values and dispositions and the cultural enactment of school science. Negative emotions ensue when this occurs, and this interferes with learning. They recommend that science curricula be changed in order to be more relevant to the interests of students in low-income urban areas. In other words, rather than focusing on why an individual student is disengaged, efforts should be made to engage the class as a whole using knowledge of students' culture in order to increase curricular relevance and encourage expression of cultural dispositions. In doing so, students begin to feel more positively about their participation in science, with the implication that positive emotions lead to greater cognitive and behavioural engagement. In another study, Elmesky and Seiler (2007) found that interest in science among urban African American students increased due to collectively generated emotions resulting from science activities that facilitated students' enacting their cultural dispositions towards movement expressiveness.

In the sociology literature, the term 'engagement' is less common than in the education research literature, but there are other concepts that have a close correspondence. Mihaly Csikszentmihalyi's (1990) concept of 'flow' is used to explain when students are caught up in an activity, absorbed and engaged. He writes that students experience flow when there is a match-up of the level of skill and the type of task, so that students are challenged enough to find the task interesting, but not so challenged that the task seems impossible and they become frustrated. Engagement is relevant here, as one of the crucial aspects of flow is the emotions that students experience during a particular task (e.g. whether they are frustrated or confident). Flow, however, as it has commonly been applied, retains an individual focus in science education research studies even though we are of the opinion that flow can also be experienced collectively. In the classrooms in which we worked, we found that students were more willing to engage with a difficult task if they were involved in a collective experience that generated positive emotions, and less likely to engage with an appropriate task if the collective emotional engagement was absent.

We also find that the concept of flow offers only a partial approach to understanding when and how students become engaged, because there are many activities that offer a particular student a level of challenge that is appropriate to his/her skill. Appropriate challenge can be a precondition for engagement, but a theory of engagement also needs to account for why a student would become absorbed in one appropriately designed activity rather than another. Based on our research, we have come to see the role that collective emotional engagement plays in influencing students' becoming cognitively engaged in particular science-related topics or tasks.

In working to understand collective engagement, we draw on the concept of *emotional energy* (EE) and interaction ritual (IR). Collins (2004) explains that EE is the basis of why people engage in particular activities, join particular groups or develop particular identities. He argues that people are EE seekers, choosing courses of action based on their anticipation of the emotional pay-off from participation in solidarity-building interaction rituals. Collins' work emerged from Émile Durkheim's (1965) writings regarding how interaction rituals solidify group ties. He describes ritual as 'a mechanism of mutually focused emotion and attention, producing a momentarily shared reality, which thereby generates solidarity and symbols of group membership' (2004, p. 7). IRs are characterised by bodily co-presence, a build-up of mutual focus, the development of a common mood, an 'entrainment', or coordination, of body movements and speech, shared experience between participants on both an emotional and cognitive level, and boundaries to outsiders.

Apart from feelings of solidarity and an increase in positive feelings associated with the group, successful IRs also support focus on the symbols that circulated in the interaction. Symbols that are both exchanged and created become invested with emotional energy, and can be used later to generate successful IRs with others who find these symbols similarly charged. For example, after a rousing political speech, when attendees get caught up in coordinated cheering, the participants can become energised, be more likely to display signs in favour of the candidate, and be more likely to participate in the campaign. Another way to put this is that they become engaged in the political process.

Like symbols, concepts and knowledge can become invested with EE through being invoked in successful IRs. These include the ideas, concepts and language that circulate in science classrooms. The implication is that, if classroom interactions are characterised by solidarity, emotional energy will become invested in the science-related symbols and participants will be drawn to talking about science with teachers and peers. In other words, whether students choose to come to the front of the board to do a problem or carry out a demonstration depends on their anticipation of emotional pay-off for doing these things – whether they believe that the interactions will result in high levels of EE. Kenneth Tobin (2005) argued that head nodding, humour, eye contact, body orientation, overlapping speech and the completion of each other's sentences are behaviours associated with synchrony that support the emergence of emotional engagement. While acknowledging the cultural nature of some of these behaviours, our classroom experience indicated the veracity of Tobin's general argument. From this stance, emotional engagement is primary, and informs the behavioural and cognitive aspects of engagement, rather than three separate continua.

We have been critical of methods of data-gathering that rely primarily on self-reports. Collins' theoretical work suggests that engagement is to be understood as a social occurrence embedded within interactions. Taking this view, a person's engagement in an activity needs to be understood as the culmination of both short-term and long-term previous interactions with the symbols and groups that are relevant to that activity, illustrating the limitations of time-static measures, such as self-reports which do not address how individuals are the outcomes of situations.

The Role of Collective Emotional Engagement in the Emotional, Behavioural and Cognitive Engagement of Individuals

Collins (2004) describes how EE is not only invested in symbols, but also resides in individuals who have different levels of EE that they bring to interactions. These levels of EE are expressed as pride, confidence, shame, shyness or other characteristics related to how a person approaches others. Yet these characteristics are not 'personality traits' that are static, but instead they fluctuate from situation to situation based on each person's prior experiences with IRs in particular contexts. Collins explains: 'Pride is the emotion attached to a self energized by the group; shame is the emotion of a self depleted by exclusion … nonverbal and paralinguistic measures of pride and shame can be useful as measures of high and low EE' (p. 120).

An implication of this perspective on the transferability of EE from IRs to individuals is that socially shared emotion influences individual engagement. After successful IRs that result in participants leaving with high levels of EE, these participants are likely to approach similar situations in the future with greater levels of confidence. Confidence can be seen as an indirect measure of individual emotional engagement, as it is similar to the 'perceived competence' that is used in self-report measures in other studies of engagement. This emotional engagement in turn affects behavioural and cognitive engagement in that people who are confident in a specific situation are more likely to participate actively (behavioural engagement) and engage with the content (cognitive engagement).

Collins (2004) provides an example that can illustrate the relationship between the three dimensions of engagement in his discussion of why people sometimes choose not to speak in public forums. He describes how sometimes, in academic lectures, there is a long pause before the audience offers any questions:

> The subjective experience of members in the audience at that moment is that they can think of nothing to say. Yet if the pause is broken – usually by the highest-status member of the audience asking a question – multiple hands go up. This shows that the audience was not lacking in symbolic capital, in things to talk about, but in emotional energy, the confidence to think and speak about these ideas … not that they had nothing to say, but that they could not think of it until the group attention shifted to the audience. (p. 72)

This 'group attention' changes the focus of the IR, so that the audience becomes more central, which raises participants' EE levels and therefore their confidence to speak.

In Collins' example, as well as in our own observations of science classrooms, a multidimensional model of engagement with three separate continua is not sufficient for understanding how people become engaged. Instead, we believe that collective emotional experience is primary. Our studies show that high levels of EE lead to confidence and other expressions of emotional engagement such as pride, which then support students' active participation through activities such as volunteering to help with a demonstration or using canonical science language in developing an explanation.

In applying these ideas to science classrooms, a student's demonstration of science knowledge might not be a result of students' personality traits, general interest in science, or knowledge of the material. We argue that instead, the participation is an outcome of collective emotion generated in IRs. One relevant factor, similar to Collins' example of the academic lecture, is whether the focus of group attention is on the teacher or on the 'audience' – the students. Referring to the earlier example of Carla who participated more frequently during the unit in balancing equations, her increased participation was not because, in some abstract way, she believed that she was better at balancing equations than she was at other tasks in science. Instead, it was because, during interaction rituals associated with balancing equations, there was a shift in attention from the teacher to the students when the students solved problems at the board with the support of their peers (Olitsky 2007). The collective emotional experience generated when students helped each other during balancing equations IRs contributed to increases in levels of confidence for many students, and therefore their willingness to engage with the material on a cognitive level.

An important feature of this situation is that the teacher's efforts to help her students learn the material were effective because she provided a structure with the goal of establishing a positive emotional starting point, an essential ingredient for student success. According to Collins (2004), part of this emotional experience involves the establishment of a context that is well bounded and has a mutual focus that effectively secures the group's attention. Balancing chemistry equations, science demonstrations or any shared experience can provide such a starting point. The initial question that can frame planning for such an IR is not a cognitive one (e.g. 'What is the prior knowledge that students bring to a learning context and how can

I access this knowledge when teaching this material?'), but an emotional one ('How can I try to optimise the initial emotional experience for students when introducing this material?').

Certainly Ms Loman's providing students with an effective method for approaching problems involving balancing equations was essential for the IR to take place, as it would not have occurred if the students had no idea how to approach such problems. We are not arguing that these skills are unnecessary, and that it is only the emotional component that matters. Instead, we are arguing for the complementarity of emotion and skills in order for the instruction to be effective. In teacher education programmes, attention is often given to assessing student knowledge and drawing on this knowledge in order to design instruction. Our research suggests that, in the beginning of a school year or a unit in which new material is introduced, it is also vital to provide initial emotionally engaging experiences that establish boundaries around the class as a group.

In Tracey's classroom, the shared observational experience of students in the class as they participated in the science demonstrations about the gas laws allowed them to feel confident that each of them had access to the same experiences and therefore could make equally valid observations. Even if a specific student was not one of those to propose an explanation of the observed phenomenon using molecules and atoms, he/she felt more confident about his/her ability to make connections between the explanations and these shared observations (Milne and Otieno 2007). Science demonstrations are focused whole-class interactions that are constitutive of a fluid type of ritual that exists on a continuum between social situations and formal rituals. They are structured by some ritual elements, such as mutual focus, group assembly, barriers to outsiders and shared mood, but the application of these elements depends very much on the context and on the actions of agents including students and the teacher. Through use, demonstrations became ritualised as IRs and help to build student expectations that something interesting or contradictory was going to happen and contribute further to positive emotions in the classroom.

We have described IRs that are solidarity producing. However, other rituals, such as the 'order giving' rituals of some typical classrooms, can support a gain in EE for the order giver and a loss for the order taker, without actually increasing feelings of group membership (Collins 2004). One example would be a lecture or reprimand by a supervisor. After experiencing such a loss of EE and, therefore, shame, individuals might shy away from these groups and the use of symbols invoked during those interactions. A student who experiences science classrooms as order-giving rituals, in that teachers or other students do not accept her/his contributions as worthwhile, can carry low levels of EE into future interactions involving science. An apparent lack of confidence or interest can present as an 'individual' characteristic, but it is a product of the situation (i.e. an outcome of low levels of EE generated in previous interactions). Another route to an individual's loss of confidence is feeling excluded from an IR in which most of the participants experience solidarity and raised levels of EE. Participation in a dynamic conversation in which one does not know anything about the topic could result in this type of EE loss, thus highlighting the importance of science demonstrations as a shared experience in Milne and Otieno's (2007) study.

From the teacher's perspective, the confident student who is charged with EE appears to be more engaged. That student will freely inject his/her contributions with the expectation of solidarity, which Collins (2004) describes as 'smooth flowing rhythmic coordination in the micro rhythms of the conversational interaction; it gives the feeling of confidence that what one is doing, the rewarding experience that one's freely expressed impulses are being followed, are resonated and amplified by the other people present' (2004). Similarly, if the whole class, or even most of the class, is feeling high levels of EE and is confident in that setting, then it would seem to a teacher that the class is collectively engaged. When teachers describe a 'good discussion', in which most of the students provide contributions, take risks with their comments, ask questions and develop explanations, it is likely that most of the students anticipate high levels of EE in these interactions and so are more willing to speak. Other contexts in which we have observed this happening include students giving each other high-fives when they successfully complete a complex task, such as working out the chemical formula for a compound or completing a half-life problem (Milne and Ma 2008). The primacy of collective emotional experience and the power of confidence can be used to help in understanding the differences in engagement that were observed by the researchers conducting these studies.

An assumption that underlies some of the previous research on engagement is that past experiences of success at an activity will lead to a person's confidence in his or her abilities. The implication is that confidence emerging from success will contribute to the student being willing to verbally participate in class discussions, come to the front of the class to use the chalkboard or demonstration, use science language, or exert effort on a test. Yet our research has shown that prior success might not be sufficient for the emergence of either collective or individual engagement. Rather, the accompanying emotions are more predictive of engagement. Positive emotions can accompany actual success, but not always. For example, in City Magnet during the balancing equations, it was the harder problems at which students were initially *unsuccessful* that elicited student cooperation and positive emotions, rather than the easier problems that students solved successfully (Olitsky 2007).

Interaction Rituals and Engagement: Implications

Our studies have shown how collective emotions generated through successful IRs have transferred to individuals' increased confidence and pride, and have led to changes in different dimensions of student engagement within two science classrooms in Philadelphia. An implication of this research is that collective emotions can have a powerful impact on collective engagement and on individual identity, class participation and learning. Conversely, when individuals develop increased pride and confidence related to science participation, IRs in class have a greater chance of success. The similar findings about engagement from two very different schools, one selective and the other an urban neighbourhood school, support the primacy of the social and emotional aspects of engagement in influencing what has typically been described in previous research as cognitive engagement.

For teachers wishing to foster positive classroom changes, these studies suggest the need to provide a shared experience that is available to all within a context that has clear boundaries and excludes outsiders. Establishing this type of situation allows the development of group co-presence that supports students in monitoring each other's emotional states. From this structure, it is possible to build an intensity of group emotion evidenced by synchronous shared observations and explanations, students completing each other's sentences, overlapping or latched speech between participants and shared excitement. In a classroom, positive emotional energy builds from successful interactions into interaction ritual chains that support cognitive and behavioural aspects of engagement. This energy is available to everyone in the class who becomes caught up in the collective emotional experience.

Evidence of student engagement can include actions such as eye gaze, overlapping speech, entrainment in conversation and shared action. Cognitive aspects of interactions indicative of engagement can include participation in the use of language associated with science knowledge, an interest in asking questions, a willingness to focus on observation as well as explanation, and a desire to work together to construct science understanding. Emotions are experienced internally and exhibited so that they are available to others. We have argued that establishing collective engagement requires specific classroom structures. However, the agents of teacher and students are central to the establishment of interaction ritual chains and emotional energy that are essential for the expression of collective and individual student engagement.

Going back to Herrenkhol and Guerra's (1998) study, their definition of engagement was based primarily on cognitive types of actions that involve 'monitoring one's own comprehension of another's ideas, coordinating theories with existing evidence, and challenging the claims put forth by others' (p. 441). Participation in these types of tasks requires risk-taking in that students need to be willing to share their own conceptions and ideas. They, therefore, require some level of confidence in engaging in science discourse. We argue that it is the collective emotional experience that leads to individual student confidence, thereby making cognitive engagement possible. The link between confidence and these higher-level cognitive tasks further lends support to our argument that emotional energy provides the basis for cognition and should be the initial focus of educational practice.

Additionally, the view of engagement as stemming from collective emotions can add an important piece to perspectives of engagement that portray it as integrally tied to an individuals' participation within collective, goal-oriented activity, such as Engle and Conant's (2002) *productive disciplinary engagement.* An individual's participation within a discipline, which is a similar conception to the 'community of practice' that Jean Lave and Etienne Wenger (1991) describe, requires not only skill, but also the desire to be part of the group and manipulate its symbols, the confidence that one can participate in this group, and an identity associated with this group. All of these are outcomes of high levels of EE. An individual, therefore, needs to have participated in previous solidarity-producing interactions in order to be imbued with the EE that is a necessary precondition for productive disciplinary engagement. Similarly, Palincsar, Anderson and David (1993) describe the importance of flexibly adapting intellectual roles so that students do not apply science knowledge in a rote manner. Rather, students need to appropriate the science-related symbols and tools for their own use and develop fluency with them. This deep level of participation necessitates positive emotions, as high levels of confidence are necessary in order to take the risk of manipulating symbols in creative ways.

Overall, we argue that collectively generated emotions are a precondition to the different dimensions of engagement required for effective science teaching and learning. These emotions affect individual levels of EE, which have implications for student confidence and, therefore, learning. Conversely, when individuals emerge from IRs with high levels of EE, they can help initiate or participate in future solidarity-building IRs related to science. Assumptions that sometimes permeate some academic and non-academic discourse include views of individual students as either 'engaged' or 'disengaged', and views of subject matter as either interesting/relevant or uninteresting/irrelevant. In contrast, our research supports a focus on interactional situations and how EE transfers between the individual and the collective.

We argue that attention to emotion-related outcomes needs to inform all aspects of instruction. Individuals who emerge from series of solidarity-producing classroom interaction rituals will develop the confidence, desire and energy to expend the effort in order to engage with science content and to participate in communities centred on science.

Chapter 3
Identity-Based Research in Science Education

Yew-Jin Lee

Introduction

As one of the fastest growing areas in the social sciences, identity-based research has likewise begun to make its presence felt in science education. Because of its philosophical richness, the concept of identity, as well as closely related notions of subjectivity, self, and selfhood has generated a diverse and typically puzzling array of studies for the newcomer. Identity-based research is nonetheless exciting for it is associated with agent-centered development, a sense of belonging and affiliation, and engagement in learning, which are all right in the middle of what we hold dear in education. Identity is, as Anna Sfard and Anna Prusak (2005), p. 15) put it, the "perfect candidate for the role of 'the missing link' in the … complex dialectic between learning and its sociocultural context." This chapter does not seek closure but, instead, attempts to provide a rough guide of the terrain by examining some of the theoretical roots of identity and how it has energized science educators in recent years. Specifically, through the lens of identity, we better appreciate learning from a sociocultural perspective and the contingent processes of making different kinds of people and places.

An accessible vantage point for unraveling identity is to consider how it has been handled in psychology and sociology. Risking oversimplification, the former has generally emphasized internal or essentialist aspects of identity as characteristics of individuals, whereas the latter has understood it to be a collective property of people engaged in social interaction (Côté 2006). Based on these dichotomies, there emerge various epistemological and methodological conundrums, including to what extent identity is reflexively constituted by agents or their social groups and in what manner (e.g., biology, talk, rules, schema), whether the linguistic/postmodern turn holds any implications for determining identity (e.g., changeable, multiple, or indexical selves), and the salience of our

abstract theoretical models of identity vis-à-vis lived experience across time and space (Hammersley and Treseder 2007). Indeed, when temporality is factored in, it adds yet another layer of complexity as different aspects of identity formation seem to run at different speeds while other aspects remain invariant (Lemke 2000).

Some authors have understandably grown disdainful of identity-based research because of the sheer multiplicity of meanings and cognate terms, which allegedly has resulted in fuzzy thinking. The term "identity" is absent from the indices of the first *Handbook* in this series published over 10 years ago, as well as those by Sandra Abell and Norman Lederman (2007) and Dorothy Gabel (2004). Most educators, however, are comfortable with taking identity as being a subjective sense or definition of oneself, and the corresponding recognition of being a particular kind of person, an intersubjective component. Again, the degree to which one's identity changes with respect to the social situation and how much an individual is defined by the latter depends on one's starting assumptions about the mutual constitution of agency and structure.

Without trivializing these problems, it might be fruitful to heed Gilles Deleuze's adage and question about what identity can "do" rather than attempting to define what it "is." Besides proposing a popular composite model of identity that mixes four essentialist and nonessentialist dimensions, Gee (2000–2001) explains that using identity as an analytic lens can help shed light on critical issues of fairness and access in education. Scholars concerned with gender disparities and inequalities in science have thus not been slow to pick up on the theme of identity (Brotman and Moore 2008). Building upon James Gee's (2000–2001) fundamentally sociocultural model, anyone possessing a *science identity* would signal (1) competence, (2) performance, and (3) recognition (Carlone and Johnson 2007). Allied to this and a recurring motif in this chapter, it is evident that if teachers can support student science discourse (i.e., talk and behavior) use in classrooms, this assists in developing their *academic identities* in science and mastery of scientific literacy (Reveles and Brown 2008). This presupposes teachers identifying themselves as science teachers who are competent and like science in the first instance (Helms 1998; Luehmann 2007). Insofar as identity issues are implicated during personal meaning-making, success, and emotional energy in science learning (Olitsky 2007), having any identity that is valued or powerful in official school contexts is contingently shaped by other meta-factors such as race, class, and gender. Schools do provide a significant sense of place and resources for (science) identity development among students, although this transformation need not necessarily be affirming or positive over the short or long term. Other activities and locations are similarly pivotal sites for identity formation among youth, which science educators can co-opt for planning better learning experiences and engagement with science (Eisenhart and Edwards 2004; Rahm and Ash 2008).

Theoretical Frameworks in Identity Research

Because ontologies of difference are normative when thinking about science education in the twenty-first century, we ought to expect nothing less when undertaking identity-based research (Roth 2008). Compared to earlier times when identity-based research in science education was closely aligned with investigating student motivation, learning, and achievement from more psychological perspectives (Roeser et al. 2006), the focus has gradually shifted toward adopting sociocultural modes of inquiry because of an increasing acceptance of interpretative paradigms. What perhaps unites sociocultural viewpoints that are myriad within themselves is the denial of "mind" as the pure cogito: ability is better considered as a skillful coordination of people and objects in specific social settings – "knowing" is a performance. Being knowledgeable (or not) is thus equivalent to assuming an identity that is recognized by other members of a community. A review of salient literature from the last decade has shown that the three theoretical frameworks below have been among the most favorably received among science educators.

Figured Worlds and Practice Theories

A remarkable piece of anthropological scholarship, *Identity and Agency in Cultural Worlds* by Dorothy Holland, William Lachicotte, Debra Skinner, and Carole Cain (1998), continues and will continue to exert a powerful influence on identity-based research in science education. The book, almost single-handedly, has developed a model of identity development – *identity-in-practice* – that accounts for both free will and structural constraints at the intersection of shifting social contexts and individual circumstances. Besides stressing how identities are situated achievements, it directs one's attention to how identity is also a verb, something that requires action/work from self and others. A lynchpin in this argument lies in what is called *figured worlds* – "*historical* subjectivities, consciousness and agency, persons (and collective agents) forming in practice" (Holland et al., pp. 41–42). As imagined or "as if" locales that have recognizable social architectures (e.g., teenage romances), figured worlds motivate people to action, existing in a dynamic interplay with identities and human agency. They are populated with their typical agents (e.g., the science geek), appropriate ways of behavior and attached values, which then become heuristics for developing into certain kinds of people. Figured worlds permit or at least inspire a modicum of agency and control in situations that at first sight deny all such privileges. One quickly acknowledges their utility for science educators as tools for redesigning culturally sensitive learning environments with which students desire connecting and that they deem to be integral for their lifeworlds (Kozoll and Osborne 2004). If figured worlds are a generative unit of analysis, how large or encompassing should they be? It would seem that a science classroom can be decomposed into smaller figured worlds, such as individual work, group activities, and whole-class instruction (Tan and Barton 2008). It is not denied that figured worlds seem to be a convenient metaphor or that they overlap with culture (Brickhouse et al. 2006) and communities of practice (Barton et al. 2008), although these questions await final answers. At present, figured worlds have been used extensively by (science) educators who embrace the critical tradition, especially those who work in urban areas (Urrieta 2007).

The social theorists to whom *Identity and Agency* frequently refers range from Pierre Bourdieu and Mikhail Bakhtin to Lev Vygotsky and, above all, George

Herbert Mead. The authors take a middle stance between what they call culturalist (i.e., more structural, anthropological) and social constructivist, for which identity is solely constituted in interaction, in the *positionings* (see Holland et al. 1998, pp. 271–272) involving power, privilege, and rank. Identity is thus viewed as multiple and fluid though not entirely free and unbounded. Identity change both occurs in and is a by-product of the dialectic of past histories (and material circumstances) and the present semiotic signs that people improvise or resist. Sometimes these temporal and contextual *spaces of authoring* are said to occur within a lifetime and might become the next generation's new habitus or cultural artifacts. At this point, identity-in-practice appears to overlap with *practice theories*, which likewise emphasize the dialectic of structure and agency – that tango of interpellation which supports social others/culture/institutions at the same time as its remakes and the parallel manufacture of subjectivities. One can certainly orient toward and pursue certain goals though the outcomes are never guaranteed (Levinson and Holland 1996). For instance, in the process of creating a culture of academic success in an urban Magnet school, both individuals and institutions changed, alienating some players though ultimately achieving a niche for success in science and mathematics (Buxton 2005). Likewise, teachers who are caught up in reform movements face complex positioning and shifting subjectivities as they attempt to fulfill their objectives (Enyedy et al. 2006). Metaphors used here to (partially) capture how the social and personal are integrated have included habitus, history-in-person (Holland and Lave 2001), and lamination (Holland and Leander 2004). Key issues that are now being addressed are whether there are focal or anchoring practices that spawn other practices and social rules, and a call for more fine-grained empirical analyses of the actual mechanisms of practices (Swidler 2001).

Discursive Stances

Language, as preeminent social practice, is inseparable from identity. We use talk to do things and bring all manner of objects, including ourselves and others, into being. At other times, it seems as though the reverse is equally true. Physical objects and phenomena, mental states and identities are spoken into existence by prevailing discourses, which underscores that facet of subjectivity in identity as one being fitted into a mold or social position (Bucholtz and Hall 2005). This dual role of language with respect to identity is what Gee (2005) refers to as the mutuality of "D" and "d" discourses, which finds no conflict with structure/agency frameworks. Defined by immense heterogeneity rather than commonality in theory and methods, identity-based research that relies on discursive stances draws upon a long, albeit kaleidoscopic, record of use in the social sciences.

Whether talk is better regarded as a *resource* or carrier of knowledge and identity labels, as opposed to it being the *topic* of scrutiny itself, it is a useful analytic distinction. Researchers interested in knowing *what* was articulated and the meanings associated with these identity classifications would analyze narratives as a resource, as content to be mined at various levels of organization, such as clusters of science sense-making by students in Bryan Brown (2006) or stories of kids negotiating discrimination, poverty, and science in Angela Calabrese Barton (2003). Those who make thematic discourse as a topic accordingly follow an opposite track by examining *how* people present themselves and make sense of each other and of the rhetorical devices that they (un)consciously use to accomplish these tasks (e.g., constructing expertise during science discussions in Alandeom Oliveira et al. (2007) or signaling science discourse identities in Brown et al. (2006). Thankfully there is no necessity for taking sides because each approach has been very productive. It ultimately depends on the preferences for top-down or bottom-up contextual influences. In the real world of research, there is often an amalgam of these stances mentioned above, such as when grounded theory is used in conjunction with established sociological themes to trace a science teacher candidate's identity changes (Rivera Maulucci 2008) or when elements of narrative theory and discursive psychology explain the life-history accounting of a scientist (Lee and Roth 2004). One fascinating study of nerd girls used communities of practice derived from practice theories and sociolinguistics to show how "nerdiness" was a contested domain and that this identity depended upon linguistic and social factors (Bucholtz 1999). Compared with the other two theoretical frameworks in this section, discursive stances (e.g., those using conversation analysis) enjoy the advantage of being the most empirically founded (i.e.. open to verification by readers as well as being potentially closer to participants' concerns).

Activity Theory

Cultural-historical activity theory, or activity theory, furnishes a substantial set of principles for analyzing social action in everyday life (Roth and Lee 2007). Subjects (those whose perspective are taken) are always understood as motivated toward some Object (that which is to be acted upon). When Objects are absent, there is no societally relevant activity or motive of which to speak. Identity, rather than being an innate property of individuals, is thus an outcome of dialectically engaging in practical activity (Roth 2007a), which has much affinity with practice as *the* unifying methodological element (Cole 1996) and, by extension, identity-in-practice (Wenger 1998). Further, identity development is above all purposeful, a meaningful life project – though not always in favorable settings – that simultaneously is determined by and contributes to social life. Even though leading educators have endorsed activity theory as a means of understanding learning holistically (Kelly 2008), it remains a recent and daunting framework of choice for identity-based researchers in science education. For instance, Wolff-Michael Roth et al. (2004) explained how identities changed as people crossed from one activity system to another, while Roth (2007b) argued that efforts to inculcate scientific literacy and identities without taking into account the emotional-volitional and ethico-moral aspects were doomed. Outside science education, Kevin Leander (2002) showed how classroom artifacts as significant mediators of action served to stabilize one girl's identity as "ghetto." It is also surprising to note how welfare shelters could still afford positive sites for identity formation among homeless youth (Penuel and Davey 1999). Cognizant that some of these studies were performed in challenging urban environments, activity theory offers hope for the future. Being historically created institutions, these too are amendable to the transformative effects of human agency.

Identity-Based Studies in Science Education

In what follows, summaries of three recent identity-based studies give a sampling of the kinds of theories used to uncover identity and some substantive areas of concern among science educators.

Global Identities Among Immigrant Students

Katherine Bruna and Roberta Vann (2007) used critical discourse analysis and a "practice of science" (Barton 2003) perspective to ask how ready science teachers in the USA were to build spaces of hope for all learners. From their ethnographic results, they feared that educators were largely unprepared to draw on their students' funds of knowledge and were also restricted in granting students' control over their learning. Borderland identities in science were not celebrated (Brickhouse and Potter 2001). Seen through a critical episode – a classroom dissection of a fetal pig – this seemingly mundane science experiment took on greater significance as the students came from Mexican immigrant families in the town whose economic wealth depended on the alienating forms of labor supplied by these same meat-packing workers. As much as Linda (the science teacher in the study) showed genuine care, she could not escape positioning her English Language science students as future unskilled laborers for that was the socioeconomic structure (and identities) with which she was most familiar. The science lesson thus became metonymic of global capitalism and privilege, whose uneven effects were filtering down to classrooms and the kinds of people that the students were now, and could be later. In common with the increasingly loud calls for social justice, access, equity, and quality in science education, issues of identity formation among youth were central here and were used as weapons of critique, exposing the underbelly of educational systems (Brown 2004; Tobin et al. 2005).

Positional Identity and Science Teacher Professional Development

Positional identity or positionality (Holland et al. 1998) is the sense of one's relative place in the world shot through with power, privilege, access, and constraints that have historically stemmed from various social markers such as race, gender, ethnicity, age, and economic status. While it is acknowledged that these cultural worlds influence how a person views the world and is defined by others, we do not fully comprehend how they shape teachers in terms of their everyday classroom decision-making, their sense-making of life experiences, and their professional learning and career goals, which is the subject of a study by Felicia Moore (2008). Drawing on a sample of three African-American secondary science teachers in a rural district, Moore (2008, p. 685) examined how positional identity could open our minds to understand "teachers on a personal level, their classroom practices on a practical level, and their professional development on a professional level." Aligned with critical feminist thought, there was no single positionality expressed by these teachers, even though they came from rather similar social backgrounds and ethnicity. Cultural-historical worlds collide, overlap, and intercept in diverse, random ways. In terms of teacher professional development implications, accounting for positional identity, with its focus on sense-making across one's past experiences, nurtures sensitive and personal ways of teaching and relating to students, especially those who are marginalized (Proweller and Mitchener 2004).

Differential Identities from a Common Curriculum

Researching the experienced curriculum involves asking what it is like to learn in *this* environment and it foregrounds the feelings of teachers and students in their learning journey. With regard to gender differences in science learning (Brickhouse et al. 2000), these questions of meaning have been examined using concepts from cultural anthropology by Heidi Carlone (2004). Part of an ethnographic study of a reform-based physics curriculum, the author takes pains to show that just as some embraced the new pedagogies, some female students contested the associated science identities that it promoted. Replacing the identity of "listener, memorizer, and recipient of knowledge" (p. 404) with that of problem-solver, hard-worker, and generator of knowledge was simply too great a loss of identity (c.f. Black honors students acting White in Andrew Gilbert and Randy Yerrick (2001)). This resistance is unusual as the students were largely White, upper-middle-class teenagers whom we would expect to subscribe to student-centered teaching. But we are told that there was a culture of achievement in their community that narrowly defined success in terms of academic performance. This ideology, of course, conflicted with the inquiry goals of the physics curriculum, which eschewed didactic teaching and instead encouraged open-ended experiments by student groups. In the end, the report card for this curriculum here was mixed: some girls did not contest the circulating cultural myths in which science was seen as difficult or that scientists were superintelligent males. Yet, other girls responded to the new ways of learning and crafted new science identities for themselves. The power of this micro–macro approach in practice theory is that it offers reasons for the differential choosing or refutation of identities and learning trajectories by agents. For the science educator, it demonstrates how both reform and implementation processes are fraught with unintended responses, which truly "complicates our quest for gender-fair science" (Carlone 2004, p. 392).

Conclusions

For decision-makers in education, identity-based research of the kind articulated here presents frustratingly little in terms of "hard data" from longitudinal or large-scale studies to guide change. The uncertainties surrounding the theories of identity are legion and present further obstacles for policy and concrete translation into curriculum or programs (Brotman and Moore 2008). We are still unsure if it is necessary to change identities in order to learn science, the affordances that science practices allow for person-making, and the real, material consequences of identity as a construct (see Moje et al. 2007). So what does the crystal ball augur for identity-based research in science education? A decade ago, Barton sensitized educators to the situated nature of *all* pedagogy, how it was located within historical and sociopolitical currents that made "representation in science (what science is made to be) and identity in science (who we think we must be to engage in that science)…central" (Barton 1998, p. 380). This observation is still pertinent and it is clear that identity-based research is suited for interrogating these problems for it refuses to dichotomize the making of people from their learning and milieu. The concept of identity places tremendous power in the hands of science educators for it encapsulates within itself literally life-changing educational means and ends. Identity as being inveighs against deficit philosophies of learning that devalue differences, whereas identity as becoming invigorates our struggle for a better world that is not unattainable. Starting from our current troubled (and troubling) spaces called classrooms, where we literally coerce youth to occupy, identity-based research can help us to transform them into places that youth want to inhabit for the long term and in which they invest their talents in science.

Chapter 4
Diverse Urban Youth's Learning of Science Outside School in University Outreach and Community Science Programs

Jrène Rahm

To fully grasp students' scientific literacy development, we have to better understand the range and repertoires of cultural practices they participate in (Kris Gutiérrez and Barbara Rogoff 2003). These include, for example, afterschool science programs, science leisure activities, museums, summer science camps, science activities in community youth programs, in their families, and in school. Yet, Robert Halpern (2006) makes the point that to date few studies have explored children's and youth's navigations and learning trajectories within and across such practices, in part due to the complexity of children's out-of-school lives' development, and the difficulty in establishing how participation in diverse science activities adds up and contributes to students' scientific literacy.

As the matter currently stands, we know that engagement with science in such settings and practices makes a difference in terms of youth's academic standing and leads to increases in their levels of scientific literacy as reported by Mary Atwater, John Colson, and Ronald Simpson (1999), while Kathleen Fadigan and Penny Hammrich (2004) document positive effects in terms of an interest, positive attitudes, and confidence in science, as well as higher chances of pursuing career trajectories within the sciences. Similarly, Lisa Bouillion and Louis Gomez (2001) assert that university-based outreach science programs show positive outcomes in terms of students' understanding of the nature of science and scientific inquiry, while also opening up participants' eyes to science career possibilities (Bell et al. 2003). Furthermore, community science programs that respect youth for who they are play a crucial role in youth's identity work as potential insiders to science, offering them with opportunities to co-construct science and become agents of science (Angela Calabrese Barton 2007, 1998). To use science as a means to an end rather than an end in itself is what often distinguishes such programs from school science. Yet, Patricia McClure and Alberto Rodriguez (2007) argue that still more needs to be known about why, how and for

whom such programs make a difference, and in turn, how they constitute scientific literacy development of our students and may inform current practice.

In this chapter, I follow-up on that question through a brief exploration of a university outreach program and a number of community science programs driven by youth science. Grounded in sociocultural theory, I summarize briefly youth's forms of engagement but also identity work and positioning within science in these settings. Yet, I first step back in time and offer a brief historical account of informal science practices.

A Brief Historical Account of Informal Science Practices

The landscape of informal science practices has become extremely complex and the use of the term informal science itself problematic. I invoke it here in reference to Valerie Crane's discussion of it in one of the first books on the issue, offering an overview of the field when it was in its infancy (Crane 1994). At the time, informal science learning referred to learning activities that happened outside of school and that were not driven by an academic focus per se, that were voluntarily sought out, and that competed with other leisure activities that the children and youth could engage in during nonschool hours.

Heather Johnston Nicholson, Faedra Lazar Weiss, and Patricia Campbell's (1994) overview of community-based programs suggests that these institutions included math and science activities for a long time, typically in an unself-conscious way. In other instances, the poor quality of school science instruction led to a conscious effort to eventually make science the primary objective of such programs. Table 4.1 offers a typology of programs, which the authors suggest is still useful today. Science discovery programs are the ones meant to offer hands-on science activities to children, youth, and sometimes their families.

Through engagement in science activities, such programs aim to influence the participants' attitudes toward science and to increase their self-confidence as learners of science while also attempting to make science accessible. The overall message "science is play" unifies these programs (Nicholson et al. 1994, p. 119). In contrast, science camps that are part of the college and university outreach fabric or run by businesses and sometimes also community organizations, tend to recruit academically strong students for the science pipeline. Their message differs somewhat and may be summarized as follows: "[S]cience or math is work but you can be good at it and enjoy it" (Nicholson et al. 1994, p. 139). It is assumed that through engagement in intellectually challenging and authentic science, in some cases at the elbows of scientists and their graduate students, the participants' confidence in school science will increase and the youth can come to see themselves as potential insiders to the world of science. In turn, the career programs ensure that the now interested student stays in the scientific pipeline. In addition to opportunities to engage with science, such programs often also entail a mentorship component to ensure progress along a learning trajectory in science. Hence, such programs are typically extensive and offer some form of support over longer periods of time than science discovery programs and science camps (Table 4.1).

Table 4.1 Typology of informal science programs

Types of programs	Goals of programs	Examples
Science Discovery	To offer practical, hands-on science experiences to children, youth and their families that are enjoyable. Message: "science is play."	– Hands-On Science Outreach – Operation SMART (for girls only) – Linkages for the Future – 4-H Series (Science Experiences and Resources for Informal Educational Settings)
Science Camps (Associated with Community Organizations, College and University Outreach, Businesses, etc.)	An intensive encounter with science that will increase participants' confidence that they can succeed in science in school and become insiders to the world of science. Message: "science or mathematics is work but you can be good at it and enjoy it."	– EUREKA! (for girls of color only) – TERC Environment Network Project – Mathematics & Science Upward Bound Programs
Career Programs	Multifaceted support systems designed to ensure that students stay in the scientific pipeline. Extensive programs, support, and guidance offered over time.	– Project Interface – MESA (Mathematics, Engineering, Science Achievement Program) – Science Skills Center – Project SEED (Summer Educational Experiences for the Disadvantaged)

Adapted from Nicholson et al. (1994)

Ideally, all children and youth, irrespective of who they are, should have access to these three kinds of programs over the course of their childhood. Yet, accessibility to that infrastructure poses a serious challenge for diverse youth living in poverty, translating into the persistence of negative attitudes and low achievement scores in science as well as the underrepresentation of them in science (Calabrese Barton 2007). A study that gathered African-American parents' perspectives on informal science education further confirms that even when informal science practices are available in the community and part of the communities' infrastructure, they can remain inaccessible due to racial oppression. In the case examined by Jamila Simpson and Eileen Carlton Parsons (2009), the program relied on schools for advertisement, yet their calls for participants did not reach all students. Instead, many families heard about the program from other parents, coworkers, and children who convinced them of its value. When examining what the parents were hoping to find in such a program, it went beyond hands-on science that was related to real life and their community. They valued opportunities that nurtured their children's identity as African-American youth, such as the exposure to African-American role models in mathematics and science, to give one example.

Melvin Delgado (2002) identified four elements of accessibility that need to be considered when exploring the new frontier settings of science and youth development, as he termed them at the time, namely: (1) geographical, (2) psychological, (3) cultural, and (4) operational accessibility. Operational and geographical accessibility pose barriers more often for girls than boys, preventing their participation when their safety is questioned due to the timing of the program (returning in the dark) or due to the physical location of the program (Froschl et al. 2003). Simpson and Parsons (2009) describe issues related to psychological accessibility such as feeling accepted, respected, and physically safe in a setting. In addition, the study speaks to the importance of cultural accessibility in that the parents were searching for experiences that validated and nurtured their children's ethnic, racial, social, class, and gendered identity.

Clearly, much work remains to be done to better understand the many dimensions of accessibility to the informal educational infrastructure. At the same time, some examples exist of programs that have been successful in bringing outsiders in and that are worth exploring in detail. The first kind of program I examine is a Math and Science Upward Bound Program, one form of university outreach that has existed in the USA since 1990 (Olsen et al. 2007). Such programs, by definition, purposefully target diverse youth living in poverty and/or being first-generation college bound. Community science programs make up my second case, programs that start with youth rather than science and that consciously and continuously attempt to bridge the worlds of youth and science.

Two Kinds of Programs: Outreach and Youth Centered Programs

I begin with a look at identity work and learning trajectories in a university outreach program and underline the contradictions participants experienced over time as they engaged in science. I then explore what it means to engage in meaningful science in a number of community programs and how such may translate into more expansive and inclusive notions of science that challenge our long-held notions and practice of elite science. The two sections then lead to a discussion of issues that need to be taken serious in an era defined by a proliferation of informal science programming yet also disillusionment with science education.

Programs Reaching Out to Youth: The Case of Math and Science Upward Bound

University outreach programs can be roughly divided into two kinds: (1) those that offer authentic science activities to academically strong students and focus on helping them understand the true nature of science through engagement in authentic science at the elbows of scientists; and (2), those that aim to increase ethnic diversity on university campuses through enrichment programs for diverse elementary and high school students, sometimes in combination with prep work for college (Rodriguez et al. 2004). I focus here on a Math and Science Upward Bound program that did both. As summarized by Edward McElroy and Maria Armesto (1998):

> Upward Bound intervenes in the lives of underachieving low-income high school students by uplifting and developing their academic and sociocultural weaknesses. (p. 379)

This was also the case for COSMOS. As a Math and Science Upward Bound Program, its primary goal entailed strengthening the mathematics and science skills of the students who met the eligibility criteria such as being first-generation college bound, low income, having at least a 2.5 cumulative grade point average in high school, being in 9th or 10th grade at the time of application and showing an interest in math and science. Yet, in the eyes of the participating youth, the program was seen primarily as a gateway into college:

> What I like best about COSMOS is that there are people that really care and that are here to help you out, because obviously, we are low income students, we're gonna be first generation college students, we all have the potential to be something bigger and better, you know, but we just need that extra push, and so all our main staff and even our aides are here to help us and they care about it. [Youth Participant]

Participation was about confidence building and the learning of having a "right for a college education" (Assistant Director) irrespective of one's background. Further, the residence component of the program was particularly powerful in acculturating the youth to an institution they would have not had access to otherwise:

> I hope that through their exposure to our program and too, being on campus, that they learn that they have every right in the world to be here. Because they think with first generation kids, they're not sure they have the right. They know they're smart enough, but they don't know they have the right to be here, so maybe we can show them that. [Assistant Director]

To experience the right to be in college but also in science was crucial. The latter was achieved through involvement in hands-on science activities over sustained periods of time. In the first year, youth pursued a science project given to them while in the second year, the science project evolved from their own interest tied to the scientific theme they explored at that moment – the physics of sports – leading to projects on the physics of skateboarding, soccer, and golfing. In the third year, youth had an opportunity to engage in science at the elbows of scientists. They became members of a science community contributing to projects in biochemistry, ecology, and physics. Through scientific presentations, they shared their learning with their peers, parents, and all program staff at the end of each program year. Throughout the school year, they received some guidance by the staff through monthly school visits. They also received help preparing for college entrance exams, college applications, and in their search for scholarships for college. Clearly, the designated identity of the program was a youth that was an insider to science and that would pursue a career in science (Anna Sfard and Anna Prusak 2005). Interestingly, but maybe not surprisingly, such a designated identity became a handicap for many. Take the example of Brian, who was convinced that the program "helped and molded me into college-bound material," attesting to much self-confidence in "making it" in the system. Yet, after engagement in science in college and failure in biology, he let go of the science part in attempts to stay in college and save face: "I didn't care what it was going to take to stay in school, I was going to do it." While he had dreamt about studying at the Massachusetts Institute of Technology (MIT) "since I was eight years old," and later often referred to a career in engineering or possibly working at the Navy Intelligence Department, he eventually switched major, and dropped out of science altogether, pursuing a triple major in International Business, History, and Construction Management, hoping there would be a job one day in that field. He certainly valued becoming educated and had enjoyed science and had an opportunity to develop a vaster vision of science due to his participation in the program. Yet, in terms of the outcome, the program failed in making him a literal insider to science.

In contrast, Hannah entered the program with a strong interest in science that aligned itself well with the designated identity of COSMOS. In fact, the program made visible to her a means whereby she could combine mathematics and science, her two favorite school subjects, by eventually pursuing a career in engineering. The designated program identity aligned well with who she wanted to become and was becoming. Two years past participation, Hannah proudly shared her college experience with me:

> College has been very kind to me. My grades are great and I ended up landing a full ride at the engineering school. I'm enrolled in a 5-year degree program. At the end of the program I will have a BS in Engineering Physics and a MS in Electrical Engineering. [Email exchange, October 2003]

Hannah often referred to her parents and the manner her mother supported her by taking money out of her retirement fund to pay for school: "[T]hey wanted to see me fulfill what I have always wanted to do." She referred to COSMOS as "awesome" and as having helped her considerably, giving her the social capital needed to make it into college. Further, she received three credits for the algebra course she completed in the last program year. Her high school did not offer any upper-level science or math classes that could have prepared her in terms of the disciplinary knowledge, making such course credit particularly valuable. Later she added: "[I]f it wasn't for COMSOS I don't think I would be in the position I am in right now." When asked about her future, Hannah was unsure, but she certainly wanted to work in her field: "Physics, I might as well use the physics if I have to go through the excruciating pain of learning [it], relativity and quantum mechanics is not all that easy." Later she talked about NASA and how she would possibly move out of state for a job with them. Hannah had clearly appropriated an identity as an insider to science and may be considered the kind of youth such outreach programs aim for and hope to support. Most important, the case underlines clearly that access to other practices also mattered – such as quality school science experiences, family support, and now, access to meaningful and challenging science activities and practices, something that the engineering school could offer.

Such was not the case for Edric, who also entered COSMOS with a strong interest in science and by working at the elbows of scientists in the biochemistry lab appropriated and made his own the designated identity of COSMOS, positioning himself as an insider to science. It made him sign up for a bachelor degree with a major in science at the same University that housed the program. Yet to our surprise, Edric graduated 3 years later with a Bachelor of Arts with a major in communication studies. He described COSMOS as "a once in a lifetime opportunity, and I would not take it for granted," recognizing it as his "ticket" into the college pipeline, given his position as a first-generation Latino immigrant. Working on a drug compound that could be used one day to replace morphine in a research team of COSMOS, he could talk at length about the value he saw in such work: "I'm working with a new drug that, that may make it out into the market one day, that would be cool, if it comes out one day, you know, I worked on that drug, bragging rights, that would be cool." When we talked in his second year in College, Edric was frustrated about the fact that he could not get into more science courses at the University. His focus changed: "I just want to get out quick and start earning money, you've got to pay bills and stuff like that. … I want to do something in the medicine field still, I just don't see myself going for another 12 years after my college, right now, my biggest concern is getting out quick and start earning."

As for many other youth in similar economic positions, the pursuit of a long education became an ongoing economic challenge. Moreover, it made Edric pursue an education in an institution with fewer resources, further challenging his position as an insider to science. His case illustrates in interesting ways how COSMOS offered him with opportunities to appropriate the social capital needed to pursue an education, yet such social capital did not automatically translate into economic capital. The gendered, racial, and class-divided nature of science and higher education played out against Edric. He was not able to use his insider identity to science in transformative ways to persist in science or to break down some of the class-related barriers to science. He argued he could not, as is, persist in science, due to the economic demands and subsequent demands on his time, underlining the manner he lived the contradiction between his lived insider and outsider status. To graduate with a bachelor in the arts, majoring in communication studies was "both an act of self-preservation and an act of defiance" (Calabrese Barton 2007, p. 338), as it has also been described in lived contradictions in school science for marginalized youth (Angela Calabrese Barton and Kimberley Yang 2000). Yet, his case, along with the others, does not point to the failure of University outreach programs with a focus on science, technology, engineering, and mathematics (STEM), in bringing outsiders into science. Instead, they underline well how elusive such a task is as long as the structural features of the system remain unquestioned. As long as the structures that frame marginalized youth's experiences with science are left unquestioned, the reproduction of elite scientists will continue. The gatekeeping devices currently in place will keep most diverse urban youth out, while possibly leaving just enough room for occasional success stories such as Hannah to filter through to ensure, maybe, the unquestioned sustainability of such structures.

Youth-Driven Community Science Programs: Some Examples

Some researchers have started to take seriously the premise that children and youth come into contact with science in a variety of contexts irrespective of who they are and, hence, have a rich history of engaging in and with science in diverse ways over time, yet ways that may fall outside of the borders of science as currently defined. It led to community science programs in which science is co-constructed among the participating members and hence, is defined by the participants' lived experiences, worlds, and histories. An example is the science practice that came to define a group of youth in a homeless shelter, a project initiated by Barton and colleagues (1998, 2003). The mixed feelings about living in a homeless shelter and the need to come to own a space within such a place of contradiction between safety and a highly regulated, structured, and political place, led to a project on pollution in the community. It made the youth explore their neighborhood, eventually turning it into a place they were proud to live in and feel good about. Their negative emotions about living in such a place became the driving force behind their explorations of the science behind pollution and the actions they were ready to take to make an environmentally safer place out of their community, and to come to own a piece of it. Other activities that came to define that program were food experiments. Given the regimented eating schedule at the shelter, many children struggled with hunger at night, making food an important part of their daily struggles and, hence, a potentially interesting bridge into science too. Examples of activities are the edible play dough project and pizza experimentations – activities that took over the agenda at many occasions. In both instances, the youth put science to use in the context of their lived challenges – living in a shelter or often being hungry. As such, the intellectual, the emotional, and the physical constituted the science that emerged.

The pursuit of science fair projects on a question of concern to youth is another form of engagement that gives voice to students as my observations in an after-school science program for "girls only" suggest (Jrene Rahm 2010). One girl described the program as:

> It is about being with my friends, and to work on something I like doing, there is nobody here who says 'you have to do this or that', they let us choose our projects and then it is our responsibility to get them done.

Samira, another participating youth described her engagement in science fair projects:

> The first year, I think I did a project on optical illusions and I remember that there are people who take drugs that are called "hallucinogenic" and they have illusions. The second year, I did a project on rockets and learned that when the rocket takes off into space, there are two parts of the rocket that fall in the water and that are then picked up. And this year, I found out that thanks to fiber optics the voice can be transferred from one phone to another.

Samira participated in the science fair project component of the program for 3 consecutive years and posed questions on topics of interest to her and tied to her everyday experiences. Yet, what made the program special to her was also its psychological accessibility; it was a place she felt safe. As she explained: "I am Muslim and am not really allowed to be in contact with boys, in my religion it is like that." Since the program offered science activities to girls only, her parents did not oppose participation and it became a psychologically and culturally safe place for her to play with an insider identity to science.

That program shares many components with others that have attempted to tap into youth's cultures and histories as a means into science (see Margaret Eisenhart 2008). These examples underline the ways science is co-constructed and the manner interaction patterns behind such work differ drastically from those observed in other settings. The youth's questions drive the curriculum and offer opportunities for them to integrate different ways of knowing science and validate the links they make. Discourse analysis of science in such programs underlines too that youth have much to say about science and "know more about it than they are usually given credit for or allowed to express" (Eisenhart 2008, p. 91). That such is the case comes through also in science video documentaries youth had an opportunity to construct in yet another community science program. Melina Furman and Angela Calabrese Barton (2006) argue that an examination of how youth use their voice in the context of such a project can be particularly revealing for our understanding of youth's participation in vast repertoires of science practices and their scientific literacy development, and the work that goes into solidifying their identity as knowledgeable and capable of science. It suggests that community science programs may be safe spaces to show and act upon an interest in science, whereas in school, such may have to remain hidden so as not to jeopardize ones popularity among peers. Finding ways to deal with such contradictions, two girls in a garden program I studied simply identified themselves as environmental activists; something they argued had nothing to do with science, which they judged as boring anyway. By distancing themselves from science in that manner, they protected themselves yet could be engaged in environmental activism in their free time.

In summary, studies of community science programs that have youth at the center not only offer key insights into the role such contexts play for the development of scientific literacy and identity as an insider to science, but point to the many dimensions that need to be explored if we are to ever understand and in turn support, the making and becoming of youth in science.

Discussion

Scientific literacy development remains problematic for many low- and moderate-income children and youth, and not surprisingly, afterschool, community, and university outreach programs have been solicited to help with the task. It is as if informal science and out-of-school (OST) learning has been discovered as a potential quick fix to an ever-increasing problem of scientific illiteracy in North America. Yet, as my first example underlines well, quality out-of-school science programs, while important, cannot be held responsible for a system that excludes and is driven by an elitist and narrow notion of science and what engagement in and with science entails. I described programs that adhere to broader notions of science and that offer youth with opportunities to become agents of science and their own selves in science. I also discussed community programs that incorporate the concept of student voice, which Melina Furman and Angela Calabrese Barton (2006) take to entail the students' perspectives and, hence, their opinions of problems and potential solutions to making science inclusive of who they are and are becoming. Most importantly, the programs I explored are illustrative of science practices where youth can come to see themselves as "potent actors in their worlds" and develop an agentive sense of self in relation to education, science, and science careers (Glynda Hull 2008, p. xv). In these programs, youth have the opportunity to narrate a place of self in science in relation to who they are and are becoming, as well as in relation to their past and current trajectories within and among the diverse science practices that are and have been accessible to them over time. The descriptions underline well that learning trajectories and identities like engagement with and in science need to be understood as taking on many forms, as being continuously in the making, and as being defined and constituted by participation in vast repertoires of practices. If such were to be accepted, engagement in science outside of school would no longer be silenced next to elite or school science – the science of power. It would make possible a move beyond the dichotomy of "'inside/outside' of school which has fueled the 'culture of power' in science education" and the practice of excluding (Calabrese Barton and Yang 2000, p. 876). Youth's engagement in and with science in programs such as COSMOS or the afterschool science program for girls only described earlier would be understood as assets toward a trajectory in elite institutions. As is, COSMOS youth were shortchanged by the system given their position in society as diverse youth living in poverty and at-risk and, hence, in need of being fixed. Their academic potential and actual contributions to the making of science were spatially marked and recognized and supported in COSMOS but less clearly so beyond that space and time.

Conclusion

> You know, science is just getting out there and learning about the world around us, whether you know its reactions in chemistry or the butterflies outside, you know, the mountains, the ocean, it's everywhere, you can't get away from science. [COSMOS Youth]

As suggested by the quote, becoming an insider to science entails, in the words of Dawn Currie, Kelly Deirdre, and Shauna Pomerantz (2007), the "negotiation of a multitude of competing and contradictory discourses" (p. 381). It translates into a research focus that also needs to explore the diversity of science practices that the youth engage in and in relation to which they continuously redefine themselves. While many COSMOS youth could not realize the designated program identities of becoming scientists, the science they engaged in due to program participation still constituted who they were becoming as adults and the form their scientific literacy took, over time. What they had learned in COSMOS or the science club became interspatially linked with other science practices they engaged in. Their affiliation and engagement with science in COSMOS, the club, and other community programs I touched upon, made accessible to them heterogeneous sets of cultural knowledge that then constituted their future learning trajectories in important ways. Yet, ironically, such forms of engagement in and with science are still too often ignored and rarely considered as assets when marginalized youth attempt to enter the world of science and its pipelines.

Given our lives in an evermore complex global world filled with challenges and contradictions that can only be solved through diverse and challenging collaborative actions, we can no longer afford to lose the voices of youth. As long as we do not move beyond the era of positivist science, and the dominant discourse of physics as the ideal model, and do not make room for competing discourses and positions within science as the ones I described in this chapter, many youth will remain positioned as outsider of science. Gwyneth Hughes (2001) says it well, "science needs reforming, not its students" (p. 288).

This chapter suggests that a reformulation of scientific literacy development as constituted by youth's participation in a vast range of repertoires of cultural practices and official acceptance of those ways of knowing and engaging in science as tools for action in the future would bring to a halt the current disillusionment with science in education. Studies as the ones summarized here can teach us much about what a more inclusive notion of science and science practice may entail. Now it is up to us to listen and in turn challenge the power differentials that keep marginalizing such ways of conceptualizing, engaging, and being in science.

Chapter 5
Reality Pedagogy and Urban Science Education: Towards a Comprehensive Understanding of the Urban Science Classroom

Christopher Emdin

Problematising Science Education for Urban Students of Colour

Science education is traditionally framed as a field of study that focuses on the teaching and learning of science across the educational spectrum (Cheung and Keeves 1998). It also encompasses all fields of study that are related to the education of students in the sciences (DeBoer 1991; Duschl 1998), Consequently, it has a broad scope and functions to meet the needs of all students in all science classrooms through a variety of means. While this broadly defined definition of science education serves to address the needs of the various constituencies within the field of science education, it does not provide enough focus on the needs of specific populations who have traditionally been marginalised from success in the sciences. In particular, students of colour in urban settings who have been reported to not be as successful in the sciences as their counterparts of other racial and ethnic backgrounds, and in other settings, have not had their particular needs addressed in science education (Norman et al. 2001; Tate 2001). This is not to say that science educators do not discuss the teaching and learning of urban youth of colour in urban setting. In fact, researchers who consider these issues are scattered across the landscape of science education. However, a specific focus on the needs of these students is not a prevalent strand of the research. I argue that this issue persists because of the lack of a concerted effort to specifically address the needs of urban youth of colour in science classrooms. Efforts to specifically address the needs of these populations and other progressive approaches to research and practice are slow to becoming accepted within traditional science education and the preparation of science education researchers (Jablon 2002). I argue that this is neither a reflection of blatant disinterest in the needs of urban

youth of colour nor a conscious bias against these students. However, it is a reflection of a combination of a deep-seeded disinterest, pre-existent, under-explored and institutional biases, and an inability of the field of science education to evolve quickly enough to meet the needs of a growing and significant component of the constituency in schools.

The Silencing of Urban Youth Voice in Urban Science Education

In accordance with existent approaches to science education, researchers opt to engage in studies that align with the more dominant paradigm of studies which focus on more 'familiar science education topics' that require embedding in multicultural issues in order to be truly effective (Aikenhead 1993). Important approaches to science education – such as constructivism, the nature of science and pedagogical content knowledge – can be ineffective in urban classrooms without a specific focus on the needs of the most marginalised students within urban science classrooms and how they make sense of, or can benefit from, the use of these topics. Compounding the aforementioned issues are challenges such as the historically scattered nature of urban youth attendance in schools (Steward 2008), the impact of larger societal issues such as globalisation and gentrification of urban education (Lipman 2004) and, that within the spaces urban youth of colour inhabit, student voices are not heard and therefore do not inform educators and researchers about the types of approaches to teaching/learning that best serve them (Cook-Sather 2002). The above phenomena point to the fact that students of various ethnic and racial backgrounds across many urban contexts endure a plethora of issues that function to silence them in science classrooms, with science education as a discipline reaffirming this silencing.

This phenomenon (the silencing of the urban students) is often swept under the rug through a focus on broad-based approaches to science education that focus on initiatives that rightfully push for, among other things, an effort to provide all students, across backgrounds, with the same resources (Bybee 1995). The thinking behind this approach is that the equitable distribution of resources and instructional strategies across contexts will allow for some equal focus on the needs of students whether they have traditionally been marginalised from attainment in science or not. The strength in this approach is that it stands as an effort to reverse historical practices that have removed resources from youth of colour because of their societal positioning as not having the ability to be successful in challenging subject areas like the sciences. The weakness in these types of proposals is that this effort becomes ineffective because the provision of equal resources for all students at this point in time in science education necessarily maintains existent achievement gaps and the effects of inequitable practices.

Urban Science Education

The Needs of Urban Youth in an Urbanised World

Urban science education research, which in its true form focuses substantially on the needs of urban students thorough an understanding of their realities both within and outside the classroom, breaks from the traditional paradigm and focuses explicitly on what can be gained from the teaching and learning of science from the urban student's perspective. In efforts to focus on and consider the information for science teaching and learning that comes with this perspective, particular attention must be placed on the societal positioning of marginalised populations across the globe and the negative associations that comes with this labelling.

The current and ever-growing rise of globalisation and urbanisation serve as a charger of sorts for a focus on the experiences of the marginalised in urban settings and the reform of their schools (Lipman 2004). The effects of globalisation on the demographics of urban areas across the world has been described as particularly problematic for researchers in fields such as urban planning and economics, where the sheer numbers of people within urban settings and the creation of new urban settings where they have never before existed, has become overwhelming (MacLeod 2002). In fact, researchers have reported that, in 2009, more than 3.3 billion of the Earth's 6.6 billion people will be urbanised, rising to 5 billion in 2030 (UNFPA 2008).

While this research is often accompanied by how these demographics directly relate to the rise of slums, poverty and violence, I argue that science education is positioned to consider the positive effects of this urbanisation on the concentration of people who have been marginalised from, among other things, the learning of science. For example, immigrant families from certain Latin American countries, who travel to the USA and quickly become a high percentage of an urban neighbourhood, can be viewed as contributors to a lower socio-economic standing of a neighbourhood or can be seen as resources for shaping a more multilingual and inclusive science classroom. Students in a rural context who quickly become classified as urban students because of a sharp spike in population can be perceived as underprepared for using science to meet the job needs of an evolving and more technical society or can be utilised as resources for gaining insight into how science plays a role in shaping students' perceptions of self in an ever-evolving society. In the highly organic and continually changing urban spaces, progressive urban science educators can focus on initiatives that empower a large number of students to be full participants in science more than ever because of the high populations of the marginalised and socio-economically deprived who have become localised to urban areas. Globalisation, and the accompanying urbanisation of certain areas, can then be viewed as strengths that allow more complex and important work in science education.

Science Education in Urban Settings or Urban Science Education

Perceptions of urban students of colour as dangerous, uncivil and disinterested in school (Davis 1995), combined with the fact that youth of colour in these settings have traditionally not done well in science compared to their peers (NCES 2006), has caused urban science education to gain much popularity among certain scholars. While it is not necessarily supported as a field of study in its own right within science education, it is often fetishised and perceived as cutting edge or part of a new wave of research. Consequently, it has caught the attention of many scholars that position themselves as progressive. It also results in the advent of research that has a focus on studies in science education that exploit the recent intrigue in science education within urban contexts and utilise these contexts as a backdrop to their research that could have otherwise been omitted from the study. While a majority of these studies are intellectually sound and contribute to scholarship within the larger science education community, I argue that the continued pursuit of the urban context as backdrop or insignificant component of science education research could diminish the necessary attention to academic work within the discipline that exclusively focuses on a deep interrogation of contexts and the establishment of research that is undertaken to specifically address the needs of urban minoritised youth within urban contexts.

Context here refers not just to physical spaces beyond the classroom, but also to various interrelated phenomena such as cultural traditions, ways of knowing and being, and general sensibilities that are specifically urban. Understanding context in this sense lends to the understanding that ‘scientists and non-scientists benefit by recognizing that attempts at mutual influence, multiple frames of reference, and “objective” information in science communication are not neutral but evaluated with other social influences’ (Weber and Word 2001, p. 487), and that these influences impact on the ways in which conversations between students and teachers occur in the classroom. The interplay between ‘Westernized’ culture of science and the more communal ways of being of students in urban settings become glowingly apparent when research studies that are presented as urban science education do not thoroughly consider the contexts of urban settings. In fact, these studies only serve to affirm the established misconception held among students, teachers and academics that being of colour and urban are different from being able to be successful in school or science.

Moving Towards a Focus on Reality

Science educators who have begun to move beyond the use of the urban context as just a backdrop to their work, have began to uncover aspects of science teaching and learning that directly speak to the urban experience. These scholars have began to focus on sociolinguistic issues and ethnicity (Rodriguez 2003), socio-cultural dynamics within the urban context (Roth et al. in press), developing democracy in urban science classrooms (Basu 2008), and addressing specifically urban issues such as homelessness (Barton 1998), socio-political action (Hodson 1999) and hip-hop culture (Emdin 2009). These studies move beyond *science education in urban contexts* to *urban science education* as a distinct field of study that is particularly focused on context and providing equity to urban students. In these studies, science teaching and learning and other foci of traditional science education studies, such as professional development or science curricula, serve as an adjoining focus to a thorough consideration of context. With this approach, the goal of developing mechanisms for improving science education is so intertwined with addressing the specific needs of urban populations that they cannot be teased out within an academic study. These types of studies consider the nuances of context through an understanding and exploration of the realities of the urban student experience.

Searle (1995) describes the concept of reality as an agreed-upon outlook on or about social life, based on how it is perceived or created by a particular group of people. He argues that reality is essentially based on 'facts relative to a system of values that we hold' (p. 15). Therefore, if urban contexts hold diverse populations who have shared understandings based on their various experiences, these populations can be said to have certain realities. These shared realities provide information about not only the influence of the contexts of urban areas on their experiences in classrooms, but provide information about how students react to the teaching and learning of science.

From Pedagogy of Poverty to Reality Pedagogy

A focus on students' realities in research is directly related to a brand of pedagogy that also considers context and student experiences as the point from which effective teaching begins. I argue that if research and theory are to genuinely impact practice, then a focus on context and student realities within these contexts should match a reality-based pedagogy that it informs and that informs it. Reality pedagogy is an approach to teaching that begins with student realities and functions to utilise the tools derived from an understanding of these realities to teach science. Hodson (1999) provides a fertile ground for reality pedagogy in his questioning of urban schooling and questions such as: Whose view of reality is being promoted? Whose voices are heard? And why? He then ties this line of questioning to realities in urban science classrooms in later work when he states: 'In most classrooms, there is a conscious or unconscious reflection of middle class values and aspirations that serves to promote opportunity for middle class children and to exclude children of ethnic minorities and low socio-economic status, who quickly learn that their voices and cultures are not valued' (p. 790). Therefore, in order to answer these questions in ways that allow the voices of urban youth of a lower socio-economic status answer to the questions that Hodson posed, a move beyond the established approaches to pedagogy in urban settings is necessary.

This established approach to pedagogy found in urban settings is described by Haberman (1991) as a 'pedagogy of poverty' which emphasises certain types of practices which breed a certain reality in the classroom that causes students not to see the science classroom as a space of which they are a part. This type of pedagogy promotes a particular focus on basic skills and factual knowledge in science, provides little to no room for cultural relevance, and foregoes culturally sensitive pedagogy that promotes science language skills (Ladson-Billings 1995; Pomeroy 1994).

Defining Reality Pedagogy

Reality pedagogy acknowledges non-dominant standpoints of students and the nuances of their experiences outside of the classroom and utilises their position as 'other' as the point from which pedagogy is birthed. It considers the process of transitioning from a student's life world to the science classroom as a cross-cultural experience (Aikenhead and Jegede 1999) for which the culture of the student is significant in the classroom. When reality pedagogy is developed, transformative teaching is enacted and, consequently, research in science education within classrooms becomes informed by approaches to instruction that consider new approaches developed specifically for students in particular urban classrooms. Students define what effective instruction is and discuss how it is enacted in the classroom. This approach begins from the point where there is a consideration for what Cobern (1996) describes as the consideration of different cultural contexts that produce different sets of beliefs and realities. Cobern argues that these realities predispose individuals to feel, think and act in particular ways. I argue that an understanding of these realities, or efforts to understand them through research, provide information about what types of activities cause students to feel, think and act in ways that are conducive to learning science or that alienate them from it. When student perspectives on issues, such as ways to engage in certain activities in the classroom, ways to communicate with students, and means for enacting effective instruction are considered, feeling, thought and action that support science are enacted by students.

The goal here is not to change science or re-establish what topics are a part of the curriculum (which might be a necessary goal for some science education researchers), but rather an understanding of how the ways in which the specific science topics in the classroom are being delivered causes urban youth to feel, think or act in ways that are not conducive to their success in the classroom. Through reality pedagogy, the existing classroom reality, which might inhibit students from conceptualising and investigating the natural world, is questioned and a more comprehensive understanding of the inner workings of teaching and learning and their effect on urban youth are addressed. The outcomes of this questioning can be a challenge to what the teacher considers to be science and or science teaching and the distinctive ways in which it is traditionally delivered. However, through this questioning, success, participation and effective teaching and learning are redefined in ways that allow students to feel as if they can attain them.

Enacting Reality Pedagogy

Enacting reality pedagogy requires an understanding of the student's communities and the use of this understanding to positively affect the teaching and learning of science. The goal for the teacher who enacts this pedagogical approach is to immerse himself or herself so deeply in student culture that it becomes second nature to find ways to develop student interest in, and natural affinity for, science. Embarking on the journey towards enacting this pedagogy is an opportunity for science education to bear witness to the realities of those within urban settings.

Bearing witness is connecting to the ways in which individuals are denied full participation in society, as well as being able to identify and make connections with these individuals' experiences, despite the fact that one might not have physically experienced or seen all of the same things (Oliver 2000). Reality pedagogy is teaching based on witnessing and acknowledging that traditional science education and structures both within and beyond the classroom have negatively affected the ability of urban students of various racial, ethnic and cultural backgrounds to connect to science. Therefore, a pedagogical approach that has components both within and outside of the classroom is necessary for connecting urban youth to science.

> In order to meet this challenge [increasing racial, cultural, ethnic diversity among the populations attending urban schools] teachers must acquire the cultural competency for creating productive and inclusive learning environments, building academic capability among all students, and forging solid relationships with students' families and communities… (Murrell 2006, p. 81)

In my work with beginning teachers who work in urban schools, I have been able to guide them towards enacting reality pedagogy by incorporating certain practices into pre-service coursework and guiding them to utilise the information from these activities in the classroom when they begin teaching. While this is not a complete protocol or an outline of what should be the steps taken to enact reality pedagogy, it is a set of steps that I have implemented and found successful in helping teachers to move towards its implementation.

Steps Towards Reality Pedagogy in the Classroom

Teachers can visit student neighbourhoods/physical contexts once a week and communicate with people in neighbourhoods, such as store owners. Teachers can observe and take notes on phenomena in the neighbourhood and work towards using them as examples and analogies that relate to the science curriculum. Teachers can spend time listening, observing and participating in artifacts from student culture (including music, specific types of dialogue and other activities). Also teachers can verify the accuracy or effectiveness of their notes, observations, examples and analogies with students in structured dialogues and discuss how these artifacts can be used in the science classroom with students.

The teacher can deliver the lesson based on studies of notes, observations, examples and analogies discussed with students in structured dialogues. Teachers can videotape the classroom when these artifacts are used as part of the pedagogy as they can invite students into dialogues and uses the videotape of the classroom as a jumping-off point for discussion. (Participants in the dialogue view the videotape of the classroom, identify part of the lesson that needs to be improved and develop plans of action for improving the lesson.) Teachers and students can return to the classroom to implement the plans of action discussed in the dialogues.

A Focus on the Three Cs: Co-generative Dialogues, Co-teaching and Cosmopolitanism

In the steps to enacting reality pedagogy mentioned above, one of the most important steps is the first C (co-generative dialogues). These are the structured dialogues mentioned above that occur among students and their science teacher at least once a week for discussing what goes on in the classroom (Tobin et al. 2003). In groups of four to six students, participants engage in dialogues, sometimes based on video from the classroom, and discuss student perspectives on what is going on in the classroom. Through the enactment of this practice, student realities are investigated and issues that they have with the classroom are allowed to be brought to light and addressed in the classroom.

In conjunction with co-generative dialogues, co-teaching (the second of the three Cs) is a practice that allows both students and teachers to take on the role of teacher. In this process, students and their teacher return to the classroom to implement plans of action from co-generative dialogues. This step fits in with the final step in the in-school rituals listed above. In its enactment, it allows the student to take on responsibilities traditionally reserved for the teacher and allows the teacher to learn about student realities. Furthermore, it allows the student to take on the traditional co-teacher role by assisting the teacher in teaching science. In other words, the implementation of plans of actions from co-generative dialogues necessitates that students who are involved in the dialogues begin to share responsibility for the classroom through co-teaching. The last C (cosmopolitanism) is a philosophical tenet that is evident in the classroom when a co-responsibility for one another and a valuing for each other's realities is part of everyday experiences in the classroom. When cosmopolitanism is enacted, there are multiple co-generative dialogues being enacted, endless instances in which co-teaching with students are in place, and connections between the teacher and students and students with each other are more of the norm than the exception.

Conclusions

The goals of this chapter are to present how urban science education requires a thorough understanding of student realities that go beyond what is available through conventional approaches to science education and to articulate the need to focus on context through a valuing of students' reality. The chapter shows that the combination of a constantly renewed awareness of the role of context in urban science education, a focus on the realities of the urban student experience that is often masked in science education, and a thorough focus on practical steps that can be taken to begin moving teachers towards reality pedagogy provide new approaches to researching and teaching in urban science classrooms. The combination of the approaches to science education, the challenges to the field of study, and the tools for enacting research and pedagogy presented throughout this chapter move science education towards a more comprehensive view of the urban science classroom in the sense that it exposes aspects of the classroom that are not traditionally prominent and guides the field towards new approaches and new discoveries. Focusing on the contexts surrounding the urban science classroom through student realities presents an approach to science education that opens up new ways for understanding what has worked for urban students in science classrooms and what has not, while concurrently allowing teachers and researchers to uncover approaches to improving urban youth experiences in science classrooms that exist, but have not been given an opportunity to work.

Chapter 6
Learning Science Through Real-World Contexts

Donna King and Stephen M. Ritchie

A significant global challenge for a future dependent on science and technology is to engage students in science programmes that are relevant for the knowledge society. Many current science programmes privilege de-contextualised conceptual learning, often limited by a narrow selection of pedagogies that too often ignore the realities of students' own lives and interests (e.g., Tytler 2007). The context-based approach is an initiative in chemistry education that adopts an alternative rationale for learning experiences for students compared to traditional or conceptually focused programmes. While context-based programmes generally aim to improve student engagement by situating the learning of science in contexts that are meaningful to students, there is a lack of conformity about the meaning of 'context-based'. This chapter begins by reviewing literature relating to context-based approaches to learning, focusing on international trends in curricular development. Following this, outcomes from context-based interventions are examined. These include student interest, attitudes and motivation, as well as perceived relevance and conceptual understanding. Finally, the chapter culminates with a proposed meaning for context-based approaches that might be adopted internationally.

Use of Context in Science Education

The context-based movement finds its place among a large number of developments such as project-based learning (PBL) or inquiry-based science education as well as science–technology–society (STS) approaches that attempt to make the learning of science more meaningful for students. These curricular developments generally strive to achieve an in-depth understanding of a few key ideas instead of the conventional coverage of scientific content, and attempt to enhance learning, improve the

relevance of the science being taught and the engagement of students, as well as increase personal satisfaction for participating students. Both PBL and STS approaches have been reviewed extensively, the former by David Boud and Grahame Feletti (1998), and the latter by Judith Bennett, Frod Lubben, Sylora Hogarth (2007). While they share common features with the context-based approach, they will not be part of this review.

John Gilbert (2006, p. 960) defines the term 'context' with reference to its Latin derivatives: the verb 'contexere' means 'to weave together', and the noun 'contextus' expresses 'coherence', 'connection' and/or 'relationship'. Thus, the function of context is to describe such circumstances that give meaning to words, phrases, and sentences. In other words, a context should provide a coherent structural meaning for something new that is set within a broader perspective. These descriptions are consistent with the function of the use of contexts (p. 960) in chemical education: students should be able to provide meaning to the learning of chemistry; they should experience their learning as relevant to some aspect of their lives and be able to construct coherent 'mental maps' of the subject (Gilbert 2006).

However, there appears to be comparatively little debate in the literature about the meanings of context-based approaches as applied to science education. Elizabeth Whitelegg and Malcolm Parry (1999) suggest that context-based learning could have several meanings:

> [A]t its broadest it means the social and cultural environment in which the student, teacher and institution are situated. A narrower view of context focuses on a specific application of a theory, for example, application of physics theory for the purposes of illumination and reinforcement. (p. 68)

Yet, applications of science to the real-world features prominently in discussions on context-based teaching and, therefore, will be further explored.

An important part of learning in science is to link contrived classroom activities to events in the real world, usually with reference to a resource (e.g., artefact). The teacher and students can best utilise this resource if the topic is taught in context; that is, it is taught through addressing relevant societal issues or phenomena (Sutman and Bruce 1992). In other words, an authentic context for learning science can facilitate the development of desirable scientific practices (Ritchie and Rigano 1996). When students use ideas in familiar situations and consolidate relationships between science concepts and these experiences, their confidence with the topic can be enhanced.

While real-world application appears to be inherent in the use of context-based approaches in science education, there are different views about how this should be applied in the classroom (e.g., King 2007). Despite these differences, context-based programmes show promise in effecting favourable learning outcomes.

Outcomes from International Studies on Context-Based Approaches

Five international context-based chemistry programmes that were highlighted by Albert Pilot and Astrid Bulte (2006) are included in this review. The five programmes are: Chemistry in Context in the USA (American Chemical Society [ACS] (2001), Salters in the UK (University of York Science Education Group [UYSEG] 2000), Industrial Science in Israel (Hofstein and Kesner 2006), Chemie im Kontext in Germany (Parchmann et al. 2006) and Chemistry in Practice in The Netherlands (Bulte et al. 2006). We have also incorporated in the review, research that was conducted in the 1970s and 1980s for physics that provides further evidence of positive outcomes for context-based learning (i.e., PLON, Physics Curriculum Development Project, Eijekelhof and Kortland 1988). Common themes emerged from the literature on the six projects which fall into three key areas: relevance, interest and deeper understanding.

Relevance

Context-based education helps students see and appreciate more clearly links between the science they studied and their everyday lives (e.g., Hofstein et al. 2000). The Industrial Chemistry project in Israel, focused on how learning industrial chemistry case studies affected students' perceptions of their classroom learning environment. Three groups of Grade 12 high school students majoring in chemistry were selected for the study. Two of the groups (Groups 1 and 2) were exposed to an industrial chemistry case study whereas the third group of students, a control group, were not. The analysis revealed that Group 1 students outperformed the other two groups of students regarding their perceptions of the relevance of their chemistry studies. In addition, they achieved higher awareness of the social implications of their chemistry studies, for example, they found that their chemistry studies better prepared them to become future citizens and informed them about occupational possibilities (Hofstein et al. 2000).

A second study that investigated the relevance to students' lives of a context-based curriculum occurred during the evaluation of The PLON project. This project began in 1973 as a physics curriculum development project for general secondary education in The Netherlands. Contexts such as Working with Water, Living in Air and Energy in our Homes structured the PLON curriculum. One particular study of the project investigated the reality-centredness and activity-centredness of the curriculum materials. Activity-centredness referred to activity learning where the students performed a learning task in an independent and autonomous way rather than being guided and controlled by the teacher. Reality-centredness referred to the extent to which the subject of physics was presented explicitly in relation to everyday life and to students' out-of-school experiences (Wierstra and Wubbels 1992, 1994). The two groups of students that were selected for the study included a PLON group of students and a control group. The control group of students were from classrooms taught with a more traditional textbook. Student perceptions of the classroom environment (reality- and activity-centredness) were measured by a classroom environment survey administered after a mechanics lesson from the context of Traffic. Statistical analysis of the results revealed that the PLON students experienced the lessons of the context-based unit Traffic as more reality- and activity-centred than students in the traditional course (Wierstra and Wubbels 1994). Furthermore, other evaluation studies of the PLON project confirmed this result and showed that in most cases reality-centredness also promoted student appreciation of physics lessons (Wierstra 1990).

Interest/Attitude/Motivation

Students' interests in and enjoyment of their science lessons are generally increased when they engage in context-based courses (e.g., Ramsden 1992, 1994, 1997). Research from three international context-based programmes: Salters, ChemConnections and Chemie im Kontext revealed that most students had a positive experience in context-based courses.

The key principle that underpins the Salters approach is that the ideas and concepts selected and the contexts within which they are studied, should enhance the appreciation of students of how science contributes to their lives (Ramsden 1997). The main concepts are introduced in a drip-feed manner throughout the course and once introduced are constantly reinforced in different ways (Barber 2000, p. 11). The course makes use of a wide range of learning strategies; for example, group discussion, problem-solving exercise, role play and creative writing (Ramsden 1992).

Mary Barber (2000) compared students' learning in a traditional syllabus (i.e., with a strong emphasis on chemical facts, theory and concepts) with the Salters context-based course. She found that the Salters course was perceived as more interesting and varied (Barber 2000), however, the less able students in the Salters course found it difficult coping with the lack of routine and the applied nature of the questions (Barber 2000).

Judith Ramsden (1997) compared the performance of students on a range of diagnostic instruments following both a context-based approach (Salters) and a more traditional approach to high-school chemistry. The study showed there was little difference in levels of understanding, but there appeared to be some benefits associated with a context-based approach in terms of stimulating students' interests in science.

Joshua Gutwill-Wise (2001) investigated the impact of context-based learning in introductory chemistry courses, in particular ChemConnections modular materials, in two universities – a small university and a large university. The modular approach was very similar to the context-based approach since it involved a change in the content and pedagogy of the chemistry classroom. The shift in content emphasised chemistry as real-life problems such as building a better automobile air-bag system, investigating global warming, and understanding atmospheric ozone depletion. Modular classrooms consisted of new pedagogical approaches such as group work, discussion and the use of multimedia. Students in the context-based class at the small university showed more positive attitudes than their traditional counterparts, but the reverse was found at the larger university. When the course was taught for a second time at the larger university using only modules that had undergone rigorous editing, the surveys found these students more positive than students from the previous study. Therefore, some of the problems were resolved in subsequent courses.

Chemie im Kontext (ChiK) is a context-based project in Germany that is modelled on the ideas of the Salters courses. Since 2002, outcomes from ChiK have been investigated in several research projects (Parchmann et al. 2006). For example, a comparison between the motivation to learn chemistry of ChiK students and students learning within a conventional curriculum showed that the motivation of students following a conventional curriculum decreased significantly compared with the ChiK group (Parchmann et al. 2006). Furthermore, after 2 years of the project more than 60% of the ChiK students at the end of Grade 10 and Grade 11 stated that they wanted to choose chemistry in the upper secondary level. Ilka Parchmann et al. also found that the application of knowledge, the perceived personal relevance of chemistry and the influence of the teacher were important for the positive development of students' interests in chemistry.

Deeper Understanding

The earliest research study that investigated the relative merits of a context-based programme on students' conceptual understanding was conducted in the 1980s on the Dutch Physics programme PLON. The research revealed that PLON students did not achieve better results on traditional high school examination questions compared to students studying the traditional physics course (Wierstra 1984). However, Harrie Eijekelhof and Piet Lijnse (1988) argued that traditional education was fully aimed at these examinations and hence the conclusion could be made that PLON students were at least not harmed in their preparation for further studies through a context-based approach. Furthermore, Harrie Eijekelhof and Piet Lijnse (1988) rationalised that differences between curricula are often reflected first in the learning environment, and it is only later and in moderated form that these changes show in student-learning outcomes.

The ChemCom course was developed for upper secondary students in response to a need for a course which prepared students for effective resolution of science-related issues in the real world through a knowledge and interest in chemistry (Sutman and Bruce 1992). The results of the testing programme that assessed both chemistry learned and applications of chemistry, indicated that students completing the entire year-long ChemCom course significantly outperformed students completing more traditional college prep chemistry on test items designed by ChemCom writers (Sutman and Bruce 1992). Also, a second study found that minority students learned more when using ChemCom compared with a more traditional approach (Winther and Volk 1994).

Two similar studies comparing the understanding of chemical ideas between context-based (Salters) chemistry students and traditional chemistry students occurred in England. Firstly, Vanessa Barker and Robin Millar (2000) undertook a large-scale, comparative, longitudinal study of 400 upper secondary level students at 36 schools in England following A Level chemistry courses, including Salters Advanced Chemistry. The study employed a series of diagnostic questions on key areas of chemical understanding, administered at three points over an 18-month period, and showed comparable levels of understanding across all courses. In particular, they found that students who experienced a gradual introduction and revisiting of ideas in different contexts at several points during the Salters course appeared to develop better understanding of these ideas than students following more conventional courses (Barker and Millar 2000). Secondly, interesting data came from a study by Mary Barber (2000), who used a range of performance indicators to compare predicted and actual grades in Advanced level Chemistry examinations for Salters Advanced Chemistry with a group studying a more conventional course. Her study indicated that there was no particular disadvantage or advantage to students in either course in terms of the final examination grade they achieved. Although students took different examination papers, all examinations had to meet externally imposed standards, so the study provided additional evidence that the learning by students on context-based courses is comparable with that of students on more conventional courses (Bennett and Lubben 2006).

In another comparative study of Chemie im Kontext (ChiK), Gabriele Lange and Ilka Parchmann (2003) found slightly better results (significant, but low effect) for ChiK classes, compared to other classes who were taught a traditional unit in acids and bases (Lange and Parchmann 2003).

Recent Developments in Australia

In Australia there is a small body of research on context-based teaching from two states, Victoria and Queensland. In Victoria, this approach has been adopted in the Victorian Certificate of Education (VCE) syllabuses for physics and chemistry with some claims to success. Unlike Victoria, Queensland does not have external examinations; hence, teachers are able to offer more flexible opportunities for the introduction and success of a context-based approach in the teaching of chemistry and physics.

Context-based teaching in a new physics course for senior high school students was implemented in Victoria in the early 1990s (Hart 1997). Research conducted on the success of this course confirmed the prior research on international context-based approaches that many students perceived greater relevance of physics to real life and expressed an increase in motivation (Vignouli et al. 2002).

In Queensland, the context-based chemistry syllabus has been on trial in schools since 2002. Despite personal feelings of anxiety (Beasley and Butler 2002), some teachers who had been using this approach reported an increase in student motivation and enjoyment. However, there was a clear lack of independent research to support these statements (Lucas 2002). Research on both the VCE physics course and the Queensland context-based chemistry course revealed some new findings that have not been discussed in the literature so far.

Research by Vincent Vignouli et al. (2002) and John Wilkinson (1999) showed teachers were concerned that teaching physics in context resulted in the inability of students to transfer their learning and apply concepts in situations outside the context in which they were learned. Consequently, they feared that students would be unable to appreciate the general applicability of the physics principles. Unsurprisingly, concerns about transfer are not unique to a context-based course. Traditional physics courses are still implicitly based in an abstract, idealised context, and assume that the student will be able to transfer their learning to a range of real-world situations. Furthermore, past research has demonstrated that students do not generally transfer their learning (e.g., Pfundt and Duit 1997).

These findings contrast with a more recent study (King et al. 2008) in Queensland where a student who had completed 1 year of a traditional chemistry course and then repeated the year in a context-based chemistry course, demonstrated connections between concepts and contexts. In an interview after the completion of both courses, she made a purposeful connection between a chemical concept and the context of water quality. On this occasion, the student explicitly abstracted principles from the solubility rule that all nitrates are soluble, learnt in the traditional chemistry course, to the presence of insoluble materials in water, when she explained an experiment she had completed in the context-based unit on water quality.

The programme of research into context-based approaches to chemistry has been continued by the authors in a further study. A context-based unit on water quality structured the teaching and learning of a study in a year 11 chemistry classroom in a private boys' school in Queensland. In this study, the teacher designed a sequence of lessons where the real-life application (context) was central to the teaching and content was primarily taught in response to the students' need to know. However, the implemented pedagogy of the teachers changed during the unit due to her perceived constraints of time to complete the planned curriculum and opportunity for students to demonstrate the level of conceptual understanding she had anticipated. Even though the teacher was committed to implementing pedagogical change that prioritised student–student interactions over teacher-led content coverage, she was unable to maintain this for the whole duration of the unit. The study found that the paradigm shift or 180 degree change in student and teacher behaviour (Beasley and Butler 2002, p. 2) that was the intention of the new context-based syllabus, was too extreme even for a reflective, competent and willing chemistry teacher.

Further research from the same study revealed insights into how students learn in a context-based chemistry classroom. We used the metaphor of fluid transitions, which originated from the work by King Beach (2003) on collateral transitions, to refer to instances where the students' discourse moved back and forth between the chemistry concepts learnt in the classroom and the real-world context. The study investigated the structures that afforded students agency for fluid transitions to occur.

Structures are enacted by what Giddens calls 'knowledgeable' human agents (i.e. people who know what they are doing and how they do it), and agents act by putting into practice their necessarily structured knowledge (Sewell 1992). So structures make no sense apart from agency: what salient structure is depends on the participants in a situation (the students), their past experiences and the rules or schemas that have been developed in the classroom. Thus, because agency and structure are co-dependent and mutually presupposing concepts, they exist in a dialectical relationship represented as agency|structure.

The study found that students exercised their agency differentially depending on the resources to which they had access. In other words, successful learning in a context-based classroom was dependent on students accessing resources such as content knowledge, prior academic achievement in science and sound English literacy skills to achieve fluid transitions between sanctioned chemistry concepts and real-world contexts. Furthermore, the study showed that fluid transitions were realised in the written activities and student–student interactions where students made connections between concepts and contexts (King 2008).

The Search for a Unified Meaning of Context

Context-based approaches have attempted to make the meaning of science concepts more relevant to students through the application of canonical knowledge to the real world. We would argue that context-based teaching is more than transfer or application of concepts to the real world. Rather, context-based teaching embodies a need-to-know principle: the context must legitimise the learning of concepts from the students' perspectives, which is more likely to make their learning intrinsically meaningful. Following on from more recent research, the question then arises: How can classrooms afford students the opportunity for fluid transitions?

Pierre Bourdieu (1990) viewed the world as 'socially produced', in and by 'a collective work of construction of social reality' (Grenfell 2007, p. 54). He employed his own scientific (sociological) concepts such as a *field* to explain the dynamic relationships between structures and the people who occupy them. A field is 'a structured social space based on the objective relations formed between those who occupy it, and hence the configuration of positions they hold' (Grenfell 2007, p. 55). This notion of field enables the study of related social spaces at the macro (e.g. education), meso (e.g. school) and micro (e.g. classroom) levels – fields within fields (Grenfell 2007).

The recent study conducted in a year 11 chemistry classroom in Queensland (King 2008) revealed that fluid transitions occurred when the students used the discourse of science to explain water pollution in the local creek. That is, in their classroom conversations, the students were moving to and fro between the canonical science and the water quality of the local creek. Fluid transitions occurred when the students' transactions overlapped two or more fields simultaneously; that is, the field of the local community and their problem with the pollution in the local creek, and the classroom field. Even though the students did not appreciate fully that the creek was situated in the broader context/field of the local community, their classroom conversations showed evidence of merging discourses from each field. This perspective is helpful in identifying further opportunities to enhance fluid transitions.

A study by Angela Calabrese Barton et al. (2007) found that the connections between science and student worlds were not just there ready to be revealed in the classroom. On the contrary, they were successfully created when they took students into the field of their local community to learn about the science of fresh produce. The students actively found connections by engaging in conversations with community representatives (in this case a farmer and local produce manager) so that the community issues became integrated into the students' everyday lives. Calabrese Barton et al. (2007) also found that the students were not only seeing scientific topics in their everyday lives but also using science to make choices and influence other people's actions.

In relation to the study of the water quality of a local creek, further opportunities for enhancing fluid transitions might be realised by visiting the sites from which the water samples were taken; that is, the local yacht club, the sewage treatment plant, as well as observing the community use of the creek over a period of time, talking to local residents and visiting the local council office to discuss water treatment practices and storm water drainage systems. After the students have been immersed fully in the real-world field, it is possible that the toing and froing or fluid transitions may be replaced with a blending of the canonical science and the real-world context where the distinction between the two is indefinite. We define this blending of discourse as resonance.

Fluid transitions between the sanctioned science content of school curriculum and student worlds can be realised when students actively engage in fields that contextualise inquiry and give purpose for learning. Furthermore, if teachers employ pedagogical approaches that encourage diffusion through the porous boundaries of the fields, they open up possibilities for the merging of students' everyday literacies with the canonical science.

Chapter 7
Collaborative Research Models for Transforming Teaching and Learning Experiences

Rowhea Elmesky

> *As I reflect back on my first few months of teaching at CHS, I recall some fleeting moments that gave me the satisfaction of being a teacher. Sadly, many days …I came home and wondered: "Am I a failure as a teacher?" … The greatest challenge that I faced was to be accepted by them as their teacher. I wanted my students to know and understand that I was there to help them and not to punish them with detentions and suspensions. … Their academic level was well below grade level, and the word "science" was enough to repel them from doing any productive work in the classroom. In my entire life, I always tried to do the "right" things, but here I was sitting in a high school classroom without knowing how to do anything right. I was frustrated, but I promised myself that I would work to make things better. (p. 49)*

Apparent in this quote from an autobiographical reflection in Anita Abraham's dissertation, satisfaction and feelings of worth as a science teacher are connected to the type of classroom community that forms and to the nature of the interrelationships arising among students and with their teacher (Abraham 2007). For many teachers in urban schools, it is a daily struggle to teach science. They often experience frustration or failure in building classroom communities where they are able to successfully connect with or be "accepted by" their students. In fact, Anita's experiences of dissatisfaction and frustration as a new science teacher in an inner city school are indicative of the experiences of many new (and experienced) teachers in urban schools.

In studies by researchers such as Richard Ingersoll (2000), analyses of the Schools and Staffing Survey (SASS) and the Teacher Follow-up Survey (TFS) reveal that the retention of teachers, and particularly mathematics and science teachers, is directly linked to factors which include dissatisfaction. In fact, 40% of mathematics and science teachers who depart from the field cite their dissatisfaction as stemming from sources that cause them to feel disempowered. Specifically, two of

the major causes of displeasure for teachers who decide to eventually leave the profession are student discipline problems and perceptions of minimal student motivation. I suggest that these teachers, similar to Anita, may feel stripped of *agency*. According to William Sewell (1992), agency infers that one has the power or capability to shape the social relations in which one is embedded, "which in turn implies the ability to transform those social relations to some degree" (p. 20). Teachers wish to experience a sense of empowerment within the classroom and specifically in their interactions with students, thus, pointing to the fact that addressing the challenges of teacher retention and satisfaction requires attention to classroom dynamics, and specifically to the strengthening of social relationships with students.

This chapter shares a narrative of one immigrant science teacher's (Anita Abraham) experiences while working in a comprehensive neighborhood school with students from different social, cultural and economical backgrounds than herself. Further, the chapter provides images of how classroom experiences can become better understood from multiple vantage points when collaborative research is incorporated into the classroom, during and outside of class time, as occurred during the critical ethnographic study that Anita was conducting, with me, under an NSF-funded grant. The grant invoked a model of collaborative research (utilizing a "research with" rather than "research on" methodology), and teams were created at every school site to consist of two teacher-researchers from each participating urban school, at least two student-researchers from each focal class, and university researchers such as myself. Specifically, the chapter emphasizes how introducing researcher roles into the classroom helps to strengthen weak relationships between teacher and students, encourages the development of new teaching and learning roles, and improves the critical consciousness of both teacher and students.

Anita's Story

Although she held a bachelor's degree in Chemical Engineering from India, Anita decided to go back to school to become a teacher when she immigrated to the USA. Even before she finished student teaching, she was offered her first teaching job at City High School (CHS), a large Northeastern urban school with a nearly 99% African-American population, the majority of whom were from the surrounding low socioeconomic neighborhoods. CHS lacked human and material resources; with its concrete walls and heavy metal double doors, it looked more like a correctional school than a high school. During her first year, teaching at CHS was overwhelming. Anita found that many CHS students had lost hope and interest in school as a means to acquiring a viable education. Many students did not have access to resources like pens or paper. In general, students did not express interest in doing class work, and questioned the relevance of Anita's teaching by asking questions such as "Why do I need to learn this?" or "Where am I going to use it?" For the majority of the time, Anita felt that her primary job as a teacher was to work on classroom management issues rather than to teach. In an autobiographical reflective piece, she wrote: "I had no clue how to respond or what to do, and my inability to control the class and influence their attitudes haunted me day and night; I went to bed late thinking about the unpleasant events that I had experienced in the classroom." Anita felt that the students did not respect or acknowledge her as their teacher, and instead, were considering her as an outsider or someone who did not belong in their community because of her ethnicity and accent. Questions such as "Why are you here?" or "Why is everybody coming to our country?" made Anita feel disempowered. She wondered how to respond or what to do. The students' statements seemed to communicate that she was an intruder, making her first year of teaching painful and disappointing.

Even beyond that first year of teaching, the social, cultural, racial, and economic divide between Anita and her students was complex and daunting. As stated in the quote opening the chapter, Anita believed that "her greatest challenge was to be accepted by them as their teacher." Year after year, she tried an array of "quick fix" strategies, yet eventually she realized that she needed to develop meaningful relationships with the students. Becoming a teacher-researcher helped pave such a pathway, and Anita's case provides support for advocating the use of collaborative research models in science classrooms.

Collaborative Research in the Science Classroom

> Anita: As a science teacher at City High School, I had seen university researchers walking down the halls, in classrooms and also in the principal's office. Most of the teachers were suspicious about the university researchers. They tried to avoid them, were apprehensive about being interviewed by them, and afraid that they might accidentally say something that might put them in "trouble." In those days, I wasn't sure what the ongoing research was about, and I didn't make any effort to know either. Things started to change when our vice principal, a former science department head, asked me to join the Master's in Chemistry Education (MCE) program offered at the same nearby university. At the same time, Dr. Kenneth Tobin, the main university researcher from the Graduate School of Education, asked me if I would be interested in joining the research group already working at City High School. He further explained to me that, as a part of the research team, university researchers would have access to my classroom and I also would be participating in the research as a teacher-researcher. As a regular classroom teacher, I didn't consider myself a researcher and didn't know what qualifications were expected for a researcher. Moreover I wasn't comfortable letting a university researcher into my classroom. I was worried that, if things went out of control, those events would become the focus of their research findings. When I shared this information with one of my coworkers, Ms. Cloud, a 30-year veteran teacher, her reactions were negative, mainly because in her opinion educational researchers always concluded their findings without any input from the classroom teacher or students. However, I anticipated that my situation would be different because I would act as a teacher-researcher and my students would also become a part of the research team as student-researchers. Although I was still slightly apprehensive, I agreed to be a part of the research team, excited that my voice and my students' voices would also be heard during the research process.

These reflections shared by Anita, following the completion of the study, illuminate the mixture of emotion arising when teachers are asked to incorporate *research* into the classroom context. The remainder of the chapter describes some aspects of the research process in which Anita, student-researchers, and I collaborated during 2002 in her 11th grade Chemistry class and supplementary laboratory at City High School.

Critical Collaborative Research as a Tool for Daily Classroom Change

Urban schools, such as City High School where Anita taught, are marked by inequalities – visible in school staffing, funding, courses offered, and the resources available. The schools are often oppressive to students who are labeled as "resistant" or "unmotivated" and classrooms become grounds for conflict, disconnect, and struggle. However, critical ethnographic methodology and methods are tools for shifting classroom dynamics from "control over" to "collaboration with." That is, when participatory critique is encouraged, transformation in the classroom occurs and schooling can become a less oppressive experience and more rewarding for both the students and their teachers.

When Angela Calabrese Barton (2001) discusses critical ethnography, she describes the research process as a "dialectical theory- and practice-building process in which practice and research shape each other in an endless cycle" (p. 907). Thus, critical ethnography calls for identifying the problems and asks for transformation by connecting theory and practice. This dialectical relationship between practice, theory, and research triggers local transformation of the structure by providing tools for all participants to act in new ways as the findings from the research constantly inform participants of their practices and vice versa. Moreover, critical ethnographic methods increase the agency of the participants through methods that are inclusive of all of the stakeholders involved. Collaboration is key and necessitates that teachers and students take on researcher roles that allow them to draw strength from the research findings. Thus, both the research process and the associated findings serve as catalysts for growth and transformation.

Students as Researchers

Kenneth Tobin (2006) has conducted educational research that involves students as researchers and found that this type of model "provides a way to obtain their [the students'] perspectives on what is salient in terms of school, teaching, learning, and myriad other issues" (p. 27). That is, when student-researchers are included in salient ways in research studies, teachers are afforded greater opportunity to understand their perspectives on what is occurring in the school or neighborhood fields and, importantly, "why." Through the new role of "researcher," they significantly contribute to identifying patterns of coherence (as well as contradictions) within their classrooms, in relation to the teaching and learning they experience.

In Anita's classroom study, student-researchers engaged in activities such as the review and analysis of videotapes, interviewing each other and fellow classmates, transcribing such interviews, writing reflective journal entries, and developing video ethnographies that captured salient aspects of their lifeworlds outside of school. Weekly, the researchers ate lunch together, during which time they watched videotapes from class time and from within the laboratory. They were asked to identify video vignettes of salient events that were taking place, and these video vignettes then became focal points for discussion. In addition, a selection of video vignettes was shared with students who were participants within a captured video clip, in order to obtain their perspectives and to preserve and privilege their voices.

When Students Speak

With the introduction of a research design in Anita's classroom that employed students as researchers, the students quickly learned that their perspectives were valued and that it was acceptable to be critical of classroom practices. For example, in the following entry from one student-researcher's (Deidre's) journal, she highlighted a major issue present in schools like CHS where there is a culture of distrust of students in laboratory settings.

> I think Mrs Abraham should trust us and plus the burner, she gotta go to group to group, lightning it and its gonna take a long time and we wanna do our lab real quick and by her keep goin to group to group she just need to give us like some matches or a lighter so we can [light the] burner our own? Burner is easy to use. (2/02)

These types of reflections were useful in helping Anita to identify how her teaching practices afforded and truncated students' performance within the laboratory setting in a school where deficit perspectives of the students were the norm. In fact, for years, most students at CHS did not receive opportunities to participate in a science laboratory setting and, specifically, Biology students had been prevented from performing dissections due to the teachers and administration's fear that they would harm each other with scalpel blades. Accordingly, although some teachers like Anita eventually decided to incorporate a lab section into their science classes, there was still a tendency to enact control tactics that truncated student agency. Therefore, laboratory equipment like the Bunsen burner could only be lit by Anita, and this was not received well by students who found themselves waiting on one teacher during the tight slot of time designated for laboratory completion. Through the avenue of research, students like Deidre were able to bring to the surface how such teaching practices could be experienced as inefficient ("she gotta go to group to group") and as disrespectful of their abilities ("burner is easy to use"). Moreover, Deidre was able to represent student interests in having access to a greater range of resources; she was also able to provide concrete suggestions of how the students could experience greater autonomy ("she just need to give us like some matches or a lighter").

Contradictions are a normal part of social realms and to be expected within classroom cultures. Research designs that privilege multiple voices encourage the study of such contradictions rather than the search for patterns of coherence alone. In Anita's classroom, the involvement of multiple student-researchers allowed for various perspectives to emerge. For instance, while Deidre was quick to point out that the students in her class were quite capable (e.g., of lighting a Bunsen burner), another student-researcher (Maria) held a different view. Since the majority of the students in the class lacked previous experience in a science laboratory setting, Maria felt that Anita's assistance was necessary and perhaps even insufficient to meet all of the students' needs. In a conversation with me, she expressed:

> This is our first time for doing something. This is our first time being in the lab. It is our first time all this stuff. It is the first time. But I think she can get more help somewhere else too. She needs to find some more help. (2/02)

Maria's remarks and associated suggestions communicate frustration with schooling structures that have limited her and her peers' modes of participation in science. In the previous science class that Maria and her peers had completed at CHS, the curriculum had consisted of bookwork and lacked any laboratory component. Hence, when the students were in the chemistry laboratory, it was the first time for most of them and there were constant requests for Anita's assistance. She continuously circled the classroom throughout the duration of the laboratory activity, moving from group to group. The demands became strenuous for Anita and a source of negative emotion for both her and the students. Maria noted this in another research meeting:

> She [Anita] teaches but she still needs to be a little more patient with us also. … I think our group was asking for something. She was doing something else and she got like real mad like "I WILL BE THERE IN ONE SECOND!" And I understand that you [Anita] are only one person but we need help also.

Through the student-researchers' perspectives, it is evident that Anita's decision to simply add a laboratory component to her chemistry class did not magically rectify the years of inequitable science learning environments that students like Deidre and Maria had been experiencing. Instead, Anita needed opportunities to consider what resources afforded her students to experience success. Such considerations are fostered through incorporating a research worldview into the classroom where students (i.e., student-researchers) can take a proactive role to support their learning. While it is natural that the students may initially focus mainly on recognizing aspects of the environment that are unfavorable and engage in a process of sharing their frustrations, they will also come to simultaneously recognize teaching practices that foster success, respect, and autonomy. These occurred in Anita's classroom, as the student-researchers evaluated their classroom experiences. For example, although Deidre had been quick to point out that Anita did not allow the students to light the Bunsen burner, she recognized that Anita promoted student autonomy in other ways. For example, Deidre spoke about Anita's practice of encouraging the students to select their own laboratory groups – contrary to other teachers at CHS, stating:

> When we are in the laboratory [in Anita's classroom] and we have to pick who we are in the group with, and you work with people you are already familiar with – some teachers just put you with anybody. If you don't like that person and you are not familiar with that person, you are not going to work because you don't know anything about them. So [in Anita's classroom] you work with your friends and like we have the lab [Rate of Reaction], and we had to mix the chemicals, look at the color change, and time it for one second or two second. It was fun.

Students like Deidre viewed this opportunity for group self-selection as beneficial on multiple levels. Evident in her comments, Deidre recognized that working with familiar peers assisted in the process of carrying out experiments smoothly and in an enjoyable manner ("it was fun"). She also pointed out that rapport and comfort level with one's peers assisted in the completion of lab requirements such as the mixing of reactants, timing the experiment, and recording observations.

In fact, over the course of the semester, video data of the lab showed how the students often took responsibility for their own and each other's practices in the lab. That is, students kept an eye on their group members and on other groups to make sure that they were following procedures correctly. They often provided information by answering questions, sharing techniques, talking through the process and modeling for each other. For example, during a laboratory activity on physical and chemical changes, one group wanted to finish the activity quickly and decided to put the baking powder directly into the vinegar without first wrapping the powder inside a paper towel, as the procedure required them to do. However, this did not go unnoticed by a member in a different group who reacted quickly, by shouting, "Stevenson you wrong! Don't take it out! You wrong." Such interactions indicate that the students were acting with independence and as resources for each other within the laboratory, illustrating a spirit of collective responsibility.

Thus, throughout the research process, students had the opportunity to become more conscious of how their peers were functioning as science learners and to recognize shifts in their peers' practices and identities. That is, the student-researchers seemed to develop insights into what was needed to become successful science learners. In a written entry that was recorded in response to watching videotapes of the students in the chemistry laboratory, another student-researcher, Sasin, wrote:

> I think that the labs are the best part of this chemistry class. We have fun with it. I think we get a better explanation by seeing and doing these labs instead of a lecture. … I think we have grown as little scientist[s]. We look more familiar within videos with the equipment. Everyone seems to enjoy the lab. We all like to work in groups.

On a different occasion, as the student-researchers watched some video footage of their chemistry laboratory, they observed and discussed different students' practices and related aspects of the learning environment. For example, while watching a videotape of the students engaged in the Flame Test Laboratory Activity, Maria provided understandings regarding one student's engagement in the classroom. She commented:

> But at 11:07 [AM] we seem like we all were writing down our observation and getting along well. Look at Earl. Earl the type of person that doesn't do any work. He the one that copy and stuff like that. But he not dumb! Earl ain't dumb! He smart he just don't wanna do it … He don't wanna seem like he smart.

Earl was considered to be a troublesome student by many of his teachers, including Anita. During classroom instruction, instead of paying attention and writing notes, he usually put his head down. However, during the laboratory component of Anita's class, Earl began engaging in different practices as a science learner, and this attracted Maria's attention while viewing the video footage. Maria recognized a shift in his practices from someone who "doesn't do any work" and "copy and stuff like that" to someone who was writing down scientific observations and "getting along well." Her summative perspective (i.e., "He don't wanna seem like he smart") was insightful and catalytic. Anita became interested in understanding him better, for example, making efforts to learn more about his home life and experiences in other classrooms. Through her researcher role, Maria helped Anita to focus upon a student whom she had previously somewhat ignored. Thus, I argue, incorporating a collaborative research model into the science classroom assists in deeply interrogating how it may become a space where all students are central and have the opportunity to associate positive emotions and respect with the doing of science.

Sharing Responsibility for Success

> I learned a lot from research. We sit in groups and talk about class an[d] stuff. [Before] I never thought about the other kids and how they feel. I learned how Ms. A [Anita] cares about us. She taught us to help other people in class. I get good grades. Class is just a big group of helpers for everybody.

This chapter does not intend to set up an argument for linear, causal relationships between research and improved social relationships in the classroom; however, I do maintain that collaborative research models introduce dynamic and transformative structures into the classroom that encourage the building of a caring community where shared responsibility is key ("just a big group of helpers for everybody"). Structures, as discussed by Sewell in his article on agency, can be both material resources as well as virtual ones like rules, ideology and schema. For example, evident in Nisha's journal entry above, in Anita's class, becoming involved in research encouraged schema that valued nontraditional teaching and learning roles – where students take responsibility for their own and their peers' learning and where the teacher is someone who genuinely "cares." That is, collaborating in the doing of research encouraged the emergence of a community where students began to think about one another's perspectives ("how they feel"). The students were also able to see Anita as someone who was concerned about their well-being. Moreover, the introduction of research into the classroom helped to create spaces for authentic conversation, for instance, through the use of resources like group "talk." In a school where the students are silenced on a regular basis, the opportunity to *speak* is essential to promoting positive emotional energy in the classroom. In fact, the students in Anita's classroom were quick to share their experiences with research with other teachers. Maria related: "We told Ms Morris [the English teacher] about the research in your [Anita's] class and how we talk about what we like and what we don't and all. She liked it. She said that she might try it."

Reflection in Isolation No More

Many times, teachers make sincere efforts to engage in successful practices and to regularly reflect upon their teaching. As stated by Anita: "Everyday I tried to spend a couple of minutes reflecting on my actions, and at times asking the following question to myself – if I were a student, would I want me as a teacher?" However, arguably, when reflection occurs in an isolated context where the teacher is alone in developing her perceptions, it is difficult to identify and determine why particular practices are successful or not in promoting a positive classroom environment.

There is, however, much to be learned from students' contributions as researchers. The student-researchers' perspectives provide important dimensions for better understanding the classroom than would have been achieved if Anita reflected alone. The students provided important information about how responsibility and respect are aligned, helping Anita to recognize a wide spectrum of student perceptions of her actions; for example, her "helpful" practice of lighting Bunsen burners communicated distrust to some students, and for others, she was not be perceived as being "helpful" enough. She also was able to learn that an unpopular teaching practice (at CHS) of allowing students to work with "your friends" could help students generate positive feelings about science as an enjoyable subject area. The student-researchers additionally helped Anita to perceive the generation of positive emotional energy as central to encouraging a positive atmosphere for learning, where students can grow as "little scientist[s]."

School and classroom structures can be transformed to afford the learning of students in the classroom. Sonya Martin (2004) posits that "only by *collectively* [emphasis added] seeking to expose and examine the structures associated with the process of teaching and learning can contradictions be resolved to afford greater agency for all classroom participants" (p. 203). I suggest that teachers should jointly and regularly reflect with students on classroom practices, and collaborative research models pave out a space for hearing the students' voices. In the case of Anita, working with coresearchers enabled her to become more aware of how her practices were being interpreted and shaping the emotional status of the classroom. Although educational research findings are intended to improve teaching and learning in a classroom, the reality is that traditional research dynamics do not afford the immediate participants of a study with opportunities to reap the benefits; rather the implications of the research findings are for future classrooms. A research "with" methodology empowers students and teachers during the research process. That is, the model of critical research discussed in this chapter introduces a view where research is utilized as a tool that is immediately effective and designed to encourage a sense of empowerment. In this manner, teams of university teacher- and student-researchers become integrated and natural parts of a classroom routine where the learning environment is characterized by an openness to examining practices and taking responsibility for one's own actions.

Acknowledgment The research in this chapter was supported in part by the National Science Foundation under Grant No. REC-0107022. Any opinions, findings, and conclusions or recommendations expressed herein are those of the author and do not necessarily reflect the views of the National Science Foundation.

Chapter 8
Science Learning in Urban Elementary School Classrooms: Liberatory Education and Issues of Access, Participation and Achievement

Maria Varelas, Justine M. Kane, Eli Tucker-Raymond, and Christine C. Pappas

Paulo Freire, in his book *Pedagogy of Hope* (1992/1994), recounting part of his life and his work, wrote that it was important for him to 'connect recollections, recognise facts, deeds, and gestures, fuse pieces of knowledge, solder moments, *re*-cognize in order to *cognize*, to know, better' (p. 11) to form his ideas, understandings and practice. We believe that this is what needs to happen at two levels in science education: (a) in classrooms, as children engage with and attempt to learn science–figure out what it is, who does science, in what ways, and for what reasons, as well as what, how and why they study it themselves, including whether they can see themselves becoming scientists; and (b) in science education research, as we theorise and analyse data from school classrooms in attempts to learn about teaching and learning of science, especially of children of colour in urban classrooms who are often cheated of just opportunities for science education.

In this chapter, we 'fuse pieces of knowledge' published in major journals of science education (*Cultural Studies of Science Education*, *Journal of Research in Science Teaching*, *Research in Science Education*, and *Science Education*) and of educational research in general (*American Educational Research Journal*, Anthropology *and Education Quarterly*, *Cognition and Instruction*, *Curriculum Inquiry*, *Educational Action Research*, *Harvard Educational Review*, *Journal of Early Childhood Literacy*, *Journal of the Learning Sciences*, *Linguistics and*

Education, *Mind, Culture, and Activity*, and *Urban Education*) about the science learning of students of colour in urban elementary school classrooms in the USA. These students might be in ethnically homogeneous classrooms, or could be a significant part of racially diverse and ethnically diverse classrooms. We focus only on studies conducted in US classrooms because minority status and context matter in achievement, learning, identity development and engagement (Ogbu and Simons 1998). Furthermore, we focus on the last decade (1998–2008), as there was not much research in science education with students of colour before this time. In fact, in our literature review, we noticed an exponential increase in the number of studies as the decade unfolded, with the majority of the studies appearing in the last 2–3 years. Additionally, we 'solder moments' from our own Integrated Science-Literacy Enactments (ISLE) research programme that has been ongoing for several years now and in which we try to understand the urban classroom as a space for thinking, sharing and challenging, as we explore sciencing (i.e. science in the making) and its products. Here, along with references to published ISLE studies, we also share a few vignettes that have not been published elsewhere, exploring the orchestration of primary grade classroom communities and children's multi-modal engagement with each other, their teacher, materials and science ideas.

Like William Tate (2001), we consider science education as a civil rights issue. That is, children in low-income families, who are members of ethno-linguistic and racial groups that have faced discrimination in various forms, need to have similar opportunities to those that Jean Anyon's (1981) 'executive' class has enjoyed. Such opportunities embrace various important dimensions of the pedagogy of hope, including access, participation and achievement (Freire 1992/1994). However, as Lynne Bryan and Mary Atwater (2002) have documented, many teachers of urban classrooms see their students as less capable, leading to lower expectations, even if their performance is equivalent to students from higher socio-economic backgrounds. Many believe that their students lack motivation and self-control, and failure is inevitable for some low-income students. Being 'fair' meant treating everyone 'the same', ignoring differences and, thus, failing to recognise not only that some children are privileged while others are disadvantaged, but also that children's personal and cultural resources are often aligned with science in complex ways. For example, Josiane Hudicourt-Barnes (2003) challenged claims that Haitian children are non-verbal and unable to actively engage in science classrooms by showing that these children were able to employ the Haitian cultural practice of *bay odyans*, a form of discourse that is similar to scientific inquiry.

Discourses and Identity

In *Pedagogy of the Oppressed* (1970/1990), Paulo Freire juxtaposed the 'banking concept of education' – a prevalent form of education in which students are receptacles, waiting for knowledge to be deposited in their heads – to 'liberatory education'. Practising liberatory education requires a multifaceted approach. Topics must be relevant to children's lives. Children should engage in interesting, hands-on explorations that motivate them. Connections should be built with their own experiences. But, also, teachers need to approach such inquiries in a way that gives children a voice and a role to play in their classrooms, communities and beyond. It is not so much what the activity looks like or what it is to others, but what it is to the children in the classrooms, how they find a place in it, and how science becomes a possibility for them, not as a career down the road, but as a way of thinking about the world right now.

Enacting liberatory education is challenging. Even teachers who attempt to go against the grain by implementing culturally relevant practice often fall victim to creating participant structures that characterise a banking approach. For example, the study by Terry Patchen and Anne Cox-Petersen (2008) focused on two teachers, of Latino/a and African American students in a 4th grade and 2nd/3rd multi-age class in South Central Los Angeles, whose intent to teach in a culturally relevant way was not realised because their practice turned out not to 'match the weight of their culturally connected theory' (p. 1007). Questions shared in these classrooms showed evidence of rebalancing authority between teacher and students and encouraging student interaction. However, shifts in authority were manifested on conceptual, but not structural, levels. Moreover, although the teachers recognised students' prior knowledge, this knowledge 'was not necessarily extended in ways that… [would] actually exhibit a more profound valuing for what students bring into the classroom' (p. 1004), and connections that students were making between their personal experiences and scientific concepts were not determined by themselves but by their teachers. Recognising and considering power relationships was missing, albeit needed. Everyday and science Discourses – with capital 'D' to signify Gee's (1996) recognisable coordinations of people, places, objects and ways of speaking, listening, writing, reading, valuing, feeling and believing – were not integrated.

Bridging together everyday and science Discourses in ways that are helpful to student learning has been identified as an important way of serving students of colour. Elizabeth Moje and her colleagues (2001), who studied a 7th grade class of Latinos/as from the Dominican Republic, argued that constructing 'third spaces' for science and literacy is not about privileging everyday Discourses, but building on them to help students to make connections between everyday and science languages so that one does not only inform the other, but merge to construct a new kind of discourse and knowledge. However, this is not easy to achieve and the teacher is a critical factor. Moreover, conflicts can exist between home and school science Discourses in project-based approaches. At times, although words are spoken in two languages (Spanish and English), teacher and students 'talk across each other because the words that they use not only have technical meanings but are also embedded in particular Discourses and funds of knowledge' (p. 478), thus leading to 'bumpy classroom discourse' (Varelas and Pineda 1999).

Research on urban classrooms has contributed to our knowledge base about how students' identities are formed in science classrooms and the role that they play in scientific discourses and practices. Using a discursive identity perspective – identity construction based on an individual's use of language – Bryan Brown (2004) and his colleagues have designed an instructional approach (Directed Discourse Approach to Science Instruction [DDASI]) to help students of colour to bridge home and school science Discourses and learn science. DDASI uses 'double talk', pairing vernacular and academic modes of talk so that there are multiple access points of the same idea. In a study of a 5th grade class of African American students, Bryan Brown and Eliza Spang (2008) found that double talk can blend genres and has the 'potential to position [students] as particular type of persons…[by serving] as a public marker of [a student's] knowledge of scientific terms…[thus using] language as a learning tool' (pp. 725 and 730). The teacher's use of double talk was eventually reflected in the students' talk as they made this hybrid model part of their communication. As students were immersed in scientific language, they came to accept it as part of their own being. "Students were given a vision of science that was connected to their collective experience [and, thus, the classroom was transformed into] a linguistic environment where scientific discursive identities were the norm' (p. 731).

For an urban classroom to become a place where liberatory education is enacted requires a delicate dialectic. Individual children need to maintain their distinct voices (Wertsch 1998), but the class also needs to produce common language, understandings and modes of engagement. Individual children put forth different perspectives as they try to shape what is to be learned and constructed, which is what Wertsch calls 'alterity'. However, within the many differences, particular unities emerge – unities in meaning making, ways of doing, interacting, performing and producing that lead to making a class like an 'ensemble', a piece performed by multiple players who play their own parts, but produce one whole together. Wertsch calls this sharing of perspectives 'intersubjectivity'. It is the construct of what he called 'dialogic intersubjectivity' that allows us to balance voice and unity, and difference and a communal direction, and that might be the result of Mikhail Bakhtin's (1981) interplay of two forces – a centrifugal force that pushes away from a central point and out in various directions, and a centripetal force that pulls toward a central point – resulting in access to learning science.

As an example from our work, in a 3rd grade Latino/a classroom, children and their teacher 'pushed and pulled' in various ways to construct a position related to the humane treatment of animals (Arsenault et al. 2007). In the context of dialogic read-alouds of information books, children made intertextual connections sharing content of their own choosing and meaning which has been shown to be a productive learning approach (Pappas et al. 2003). Lorenzo, Samuel and eventually Antonia shared stories in which they or others had trapped fireflies in containers with no holes, or had killed bugs. As the teacher kept being concerned about the loss of life, first Christopher and Sally were able to pick up on her cues and position animals humanely, and then Andres offered that he had buried a chipmunk that he had found, and this drew positive feedback from the teacher. The humane treatment of animals had become an identity marker valued by the teacher that was eventually picked up by many students. Although, later on in the unit, Samuel again shared another story about killing lightning bugs, many children were offering stories that positioned them as 'nice to the animals', but also let them engage with science ideas related to what animals need for living, life cycles and animal interactions. The children's individual life experiences and everyday Discourses shaped the science Discourse that they collectively constructed in the classroom with their teacher, and the science Discourse shaped their ways of thinking of their own experiences.

Analysing classroom interactions in a 5th grade African American low-income public school in a major urban centre, and particularly focusing on three boys, Bryan Brown and his colleagues (2005) found that the types of people whom these three boys were perceived to be influenced their learning. They argue that ‘the values imbued in the interpretation of a student’s response may have lasting effects of students’ willingness to engage in the taken-for-granted scientific discourse and, ultimately, on how the student may be viewed as scientifically literate or not’ (p. 798).

Transformations of identity are influenced by various factors. Edna Tan and Angela Barton (2008a) focusing on one Latina, Melanie, among 20 girls whom they had studied in New York City middle schools, analysed how girls’ identities are transformed over time, and how instrumental teachers are in their development. Melanie changed from a ‘girl who passes’ to ‘shy presenter’ to ‘valuable group member’ to ‘Jane Goodall the primatologist’ to ‘confident presenter’ to ‘science talker, science storyteller’ to ‘member of core group of supportive friends’ and to ‘helpful co-leader of group’. Melanie was allowed to use her opinions and stories to gain access to the classroom discourse and teacher–student interactions fostered her participation in and learning of science.

Stacy Olitsky (2006) also conducted a series of identity studies with four female 8th grade students (three Black, one biracial) that show that student constructions of self as science learners are connected to successful learning in science. Students need to see themselves as members of the science community – as scientists – and thus teachers need to position themselves as learners so that they can create affordances for students to be part of the construction of knowledge (Olitsky 2007a). If teachers are ‘stage-front’ experts, students feel less involved and see science as ‘hard’. If teachers position themselves as learners and allow students ‘backstage’ to see the process of learning, students perceive themselves as part of the science community. It is not simply the relevancy of the content to students’ lives that draws them into science; rather, it is the feeling of group membership (Olitsky 2007b). As small groups do not always allow all students to participate equally, whole-class interactions are also needed so the teacher can be sure that all students are included.

Dialogic intersubjectivity was also evident in 3rd graders’ own narratives about their student identities (Kane 2009; Kane et al. 2007). For example, in our own ISLE research programme, Lawrence, an African American 3rd grader, thought of himself as having a distinct voice among his classmates because he noticed details and asked questions that others did not. He shared during an interview: ‘Like that boiling thing [hot pot for boiling water]. How do the boil thing make the ice melt? That’s what I ask and other students didn’t think of that’. He also thought that his teacher believed that he was unique and spoke differently to him than to others. From her tone of voice, he inferred that she was excited about something he had said, and he felt proud when told that she ‘never heard any student say that before’ or ‘she never saw another student do that before [referring to his artwork]’. He also saw himself as having an artistic voice, an ability to draw cartoons and write stories, which were activities that he had learned and had participated in at home. Nevertheless, Lawrence and his classmates developed similar views about scientists. Like several of his classmates, Lawrence saw himself as a scientist when he wanted 'to know what will happen' and he could 'experiment with stuff', and he saw scientists as people who learned a lot and could 'see things they've never seen before and keep doing it [seeing things anew]' to see if it will happen again and again. He felt frustrated in school because his classmates knew the answers more quickly than he did and rejected his sometimes unconventional scientific reasoning, and, thus, he preferred to work with Kenny who was a willing and patient listener.

Other recent research by Angela Barton and her colleagues (2008) shows how identity relates to the multifaceted ways of being in a classroom. Considering all 20 case studies of girls in failing New York City public schools (mentioned above), they identified three practices in which these girls engaged: creating signature science artefacts, playing with identity, and negotiating roles through strategic participation. 'Girls were playful with identities in ways that allowed them to transform their narrative authority they have through their lived experiences, into epistemic authority in the classroom' (p. 89). Girls showed that they cared about others, the quality of their work, art, music, movement and verve – funds of knowledge that African American girls and Latinas bring to the classroom, which allow them to take up knowledge resources and identities in new ways. This finding is consistent with Varelas and her colleagues' (2002) study which showed how the rap songs and plays that 6th grade African American students wrote served as sites where their own familiar, social and emotional meanings interconnected with the scientific disciplinary knowledge that they were trying to develop.

Achievement, Engagement and What Counts as Science

One of the commonly heard complaints about our knowledge base regarding classroom learning and engagement in urban classrooms is that achievement in learning scientific ideas has not been considered and/or studied. This is definitely changing. Eileen Parsons (2008), in a study of 23 African American middle school students, found higher student achievement in contexts that incorporated Black Cultural Ethos (BCE) (Boykin 1986; Nobles 1980) than those that did not. BCE includes sociality (playful behaviour by students), time as social phenomenon, verve (intensity and variability, multifaceted activities, patterned movement), movement (musically expressive) and participatory-interactive structure to classroom responses. Similarly, two 6th grade girls in a failing school in New York City authored a place in science (Tan and Barton 2008b) exercising agency by creating their own rules and thus securing a space for participation. 'Authoring acts [such as composing a song or making a puppet]…offered girls opportunities to engage with science content at a deeper level and also to open up a third space for their classmates' (p. 69). Thus, the study supported a strong connection between knowledge construction, learning, identity and science. This connection, however, is quite complex. Sherry Southerland and her colleagues (2005), studying a 3rd grade classroom of African American students, found that academic status influenced meaning making during group work but not in a straightforward fashion. Higher-status students spoke more often, and weaker students were more likely to be marginalised. When academic status was equal, it was rhetorical moves, such as assertive or aggressive utterances, that determined the flow and exchange of ideas, rather than empirical validity of explanation that might be related to African Americans' talk that 'emphasizes visibility and agency of the speaker, and places a premium on rhetorical moves and the affective dimension of talk' (p. 1056).

Furthermore, in the context of a project-based approach in which contextualising is an important principle, Ann Rivet and Joe Krajcik (2008) studied whether contextualising affects learning of scientific ideas. In a study of six students in two 8th grade urban, mostly low-income African American classrooms during a 10-week physics unit, they found a significant positive correlation between these students' contextualising score (determined from classroom observations throughout the unit) and their learning score (assessed through performance on individual instruments and one group artefact [group concept maps]). Although positive learning outcomes were seen, the authors noted that this study cannot shed light on whether contextualising during project-based instruction 'supports learning by providing a cognitive framework onto which students can connect or "anchor" ideas [or]…as a vehicle to motivate and engage students with the learning task' (p. 96).

Also, Okhee Lee and her colleagues (2006), in a 2-year study of 28 3rd and 4th grade students from seven classrooms in the Southeastern USA with predominantly Hispanic students and about 25% English language learners, found that children possess the necessary abilities to engage in inquiry when they are provided with supportive learning environments and explicit instruction to become aware of what inquiry involves. Moreover, using particular ways to scaffold student discussions, Leslie Herrenkohl and her colleagues (1999) have shown similar positive achievement in two classes, one of which was a 5th grade class with a majority of African American students in a Northwest urban school. Once again, the teacher's negotiation and guidance of roles that students assumed in small-group inquiry and when reporting their findings to the whole class were invaluable for student learning and constructing of scientific explanations in sinking/floating investigations. This is echoed in another study with middle-school children in Los Angeles, where Noel Enyedy and Jennifer Goldberg (2004) found that, although two teachers were implementing the same new environmental science programme at their school, the students performed differently on post-tests assessing curriculum concepts. The students who performed better were with a teacher who acted as a co-inquirer with her students by integrating activities and stressing genuine inquiry. The other teacher took on an authoritarian stance with students in activities that were undertaken in isolation and emphasised students closely following instructions.

Investigating a predominately Latino/a (with some African Americans) 8th grade class, Barbara Hug and her colleagues (2005) found that the quality and complexity of questions for investigation that students posed within a project-based science unit on communicable diseases varied, but that students did ask questions that addressed appropriate content (were worthwhile) and had relevance to their lives (were meaningful). Furthermore, although they rarely used scientific language, they were able to articulate and ask about complex scientific concepts. However, students had difficulty following procedures accurately and did not often do careful data collection or observation note taking, implying that students needed help to design and complete complex investigations and get into depth. In contrast, this was not the case in a study with 1st and 2nd grade students in which Susan Kirch (2007) found that 'young students engage in productive argumentation when pursuing open-ended investigations. Students can identify relevant evidence and use evidence to answer questions' (p. 802). Students showed skepticism expressed through questioning and demonstrated complex inquiry skills reflecting a scientific ethos. Again, such understandings developed because the teacher modelled for the students how to be skeptical and ask for evidence, and keyed in on the specific dimensions on which she wanted students to focus. The teacher's critical role in enabling students to reach depth and academic success is also supported by Southerland and colleagues' (2005) study, which showed that the teacher's presence was needed for students to have conceptual discussions.

Moreover, conceptual and linguistic components are intertwined in science learning and we need to understand how this affects students' struggles to succeed academically. Bryan Brown and Kihyun Ryoo (2008), in their study of 5th graders in a predominately Latino/a school in Oakland (California), explored the effect of separating conceptual and linguistic components of science instruction on student learning using the DDASI approach with web-based software they designed for teaching photosynthesis. An experimental class, that was a member of the e-Learning™ community and used the Internet regularly as an instructional tool, was taught by separating content from language – basic concepts were developed without scientific language. A control group was taught with an aggregate approach – concepts were introduced in both everyday and scientific languages simultaneously, and then development of concepts continued in scientific language. Brown and Ryoo found that the experimental group showed significantly greater learning gains between pre-tests and post-tests across various measures, including open-ended questions. Thus, it seems that 'content first yields greater conceptual understanding as expressed in everyday language as well as improved ability to understand and use scientific language' (p. 550).

Entangled with the issue of achievement is what it means to do science, what counts as science and the role that hybridity plays in achievement. As Kris Gutierrez and her colleagues (1999) showed, 'local knowledge', personal experience and narrative offered to a 2nd/3rd grade class opportunities to develop important understandings. Different ways of expressing scientific ideas leads to hybridity, which can become a learning resource. As we have also shown in our work with young 1st and 2nd grade children in urban classrooms (Varelas and Pappas 2006), hybridity of narrative and scientific language that emerged in the context of intertextuality – 'an act of discourse, and an act of mind' (p. 251) – provided a scaffold for children and teachers and eventually led to 'more conventional, public, scientific genres' (p. 252). Furthermore, Warren and her colleagues (2001) illustrated how the 'embodied imagining' (p. 543) in which a 5th grade Latino English language learner engaged when he was studying ants – imagining being an ant himself – offered him a valuable tool for thinking scientifically. Students' ideas and approaches can provide anchoring positions from which to build scientific knowledge. This is clearly a different position than the one that highlights and blames lack of academic success on the mismatch between students' and scientific ways of thinking. It is a position that foregrounds that scientific sense making encompasses a variety of resources, 'including practices of argumentation, the generative power of everyday experience, and the role of informal language in meaning making' (Warren et al. 2001, p. 532), as well as affect, feeling and humour (Varelas et al. 2002).

For such resources to be put to use, divergent talk should be allowed and encouraged so that students can test and explore their ideas and beliefs (Hudicourt-Barnes 2003). When teachers encourage overlapping talk and side conversations and enact dialogic teaching, students find their teacher 'fun', where fun means belonging. As Joanne Larson and Lynn Gatto (2004) argue, dialogic teaching means freedom, power and the feeling that students count as learners in ways that they do not usually experience in school. We also have evidence from the work of Patricia Baquedano-López and her colleagues (2005) that 'breaches' (i.e. places where normal classroom routines are interrupted) can be very productive sites of creation of new knowledge where home and school Discourses can be successfully merged. These breaches allow for teacher improvisation in which students' comments on everyday Discourses, such as 'sometimes uh a long time ago black people used to say solid like this [a raised fist]' (p. 11) in referring to strong friendships, become anchors for talking about properties of solids. In a similar way, we (Varelas et al. 2008) have shown that the use of 'ambiguous objects' in a sorting activity in which students classify them into solids, liquids and gases provide them with 'opportunities to debate, argue, think, and explore' (p. 90). Thus, such research encourages us to trust students' sense making and give them opportunities to engage with science in ways that go beyond constrained views of scientific inquiry and schooling.

To trust students also implies that teachers need to be able to listen to them and hear what they say, especially when they try to express emergent understandings in their everyday language. Ideas that, on the surface, may seem wrong, illogical or scientifically non-canonical can contain worthwhile and 'wonderful ideas', as Eleanor Duckworth (1987) wrote decades ago, or can indicate a deep quest for understanding, which is a genuine scientific practice. In our latest ongoing work in high-poverty schools that educate almost exclusively students of colour, we have found some extraordinary meaning making by young children. In a 1st grade classroom of predominantly African American children, students had to sort an array of solids onto three paper plates – rigid, flexible and smooth. They worked in pairs and were reporting to the whole class about how they sorted their objects as their teacher recorded their classifications on chart paper. Antoine and Keandre were the fourth pair to report and had put a piece of plastic tubing on the rigid plate, which was different from everybody else's so far. Antoine explained, 'If you fill [the tube] in it won't be any room', and kept repeating the same idea after several requests by the teacher to elaborate what he meant by filling it in. Because the class was quite antsy, the teacher asked everybody else to move onto their second way of sorting their materials so that she could talk more with Antoine and Keandre. After reassuring them that they should not change their way of sorting the tube and that they had an interesting idea that she wanted to understand, the teacher asked them to explain again. Antoine mumbled the same idea, but was gesturing that he was filling the tube with something. What Antoine was saying is that, if the tube gets filled in with something, it cannot bend and so it is rigid. Eventually he pointed to Keandre and said: 'Keandre put it in the rigid'. Keandre took the tube in his hand and holding it vertically, he put his fingers around the tube and attempted to squeeze it while saying 'see it's not flexible'. The teacher acknowledged that the tube could not be easily bent in that way and said that 'it's rigid because it cannot be bent that much'. But, then, Keandre turned the tube horizontally and pushed the two ends together as if he was attempting to make a circle, and the tube bent quite easily. Keandre said that it was flexible that way. Eventually Antoine and Keandre came up with the idea that the tube was both flexible and rigid and, therefore, put the two plates next to each other and the tube in between. This is indeed a powerful example of thinking and sense making. What is also important to note is the 'otherness' in Antoine's thinking. Antoine had made sense of Keandre's idea of putting the tube in the rigid section in a different way from the one that Keandre shared. What is important is that Keandre's sorting gave both boys opportunities to engage with the definition of rigidity and flexibility and to think through quite complex ideas. Although simplistically it would seem impossible for something to be categorised as flexible *and* rigid at the same time (two antonyms as teachers would say), the two boys' scientific thinking proved to be sophisticated and meaningful.

Furthermore, this and many other examples found in the literature cited in this chapter foreground the idea that voice is not individually owned and does not express the individual self but, rather, is filled with social content (Bakhtin 1981), thus encapsulating shared meanings that are enacted and modified in the dialogic spaces of the present. Leora Cruddas's (2007) term of 'engaged voices' captures better than 'student voice' the collectivity of thinking and being within an intertextual, highly provisional discursive space where students construct and negotiate social meanings.

Epilogue

We end by recapping the main research findings that we have on classroom learning of students of colour in urban elementary schools in the USA in the last decade. This research was mostly based on qualitative, interpretive methods, but also includes a couple of studies that used quantitative analyses and only one that used an experimental design. This scholarship, which seems to have picked up in the last few years, provides evidence of the thinking, doing, languaging, acting, behaving, feeling and being, which together define learning, that African American and Latino/a students can achieve if given productive opportunities. We know that these students do and can engage with scientific ideas. We know that bridging everyday and science Discourses matters in their engagement and achievement. We know that students' struggles with scientific language can interfere with their achievement and, thus, using approaches in which students can experience success with ideas is critical. Such approaches include: emphasising conceptual understanding and content first before delving into the rigour of scientific language; valuing hybridity and extending what it means to do science; and possibilities for allowing, recognising and nurturing students' ways of making meaning of the world around them.

We know that identity construction and development matters, and that it is associated not only with improved access and participation in science, but also with increased articulation of scientific ideas. We know that the teacher matters immensely, along with the curricular materials available in the classroom to give students access to and success in learning science. We know that power takes different forms in the classroom (discursive, ideological, symbolic and material) and needs to be redistributed and rebalanced so that low-income students of colour can experience and enjoy learning like their White, more affluent counterparts. All the research reviewed in this chapter seems to point to Freire's call for 'the invention of unity in diversity. The very quest for this oneness in difference, the struggle for it as a process, in and of itself is the beginning of a creation of multiculturality…[which] calls for a certain educational practice…it calls for new ethics, founded on respect for differences' (1992/1994, p. 137). Moreover, this research supports approaches that take advantage of differences and use them for creating spaces that not only respect or allow for differences, but also build on them.

Acknowledgment This research has been supported by a University of Illinois at Chicago Great Cities Institute Scholarship to M. Varelas, and a US National Science Foundation (NSF) ROLE (Research On Learning and Education) grant (REC-0411593) with M. Varelas and C. C. Pappas as Principal Investigators. The data presented, statements made and views expressed in this chapter are solely the responsibilities of the authors and do not necessarily reflect the views of NSF or UIC's Great Cities Institute.

Part II
Learning and Conceptual Change

Chapter 9
How Can Conceptual Change Contribute to Theory and Practice in Science Education?

Reinders Duit and David F. Treagust

Theoretical Developments in Conceptual Change

Conceptual change is not solely of interest to science educators. As noted in Stella Vosniadou's (2008) *International Handbook of Research on Conceptual Change*, whilst science disciplines are the dominant conceptual area for studies in conceptual change, this focus can be found in subject areas such as medicine and health as well as the philosophy and history of science. As is evident in many of the chapters in Vosniadou (2008), because any discussion of conceptual change needs to include the nature of conceptions, many of the chapter authors begin by defining the terms used in the discussion. The notion of what is a conception that could change is an area of current interest as evidenced by the debate between researchers in science education and social science about the nature and interpretation of findings seen as conceptual change (Tobin 2008).

Our position is that conceptions can be regarded as the learner's internal representations constructed from the external representations of entities constructed by other people such as teachers, textbook authors or software designers (Glynn and Duit 1995). From a conceptual change learning perspective, learners need to be able to use different representations of entities to make sense of difficult concepts. For

example, learning always involves some ways of representing the information learned and science teachers use different representational techniques such as speech, written text and gestures in the classroom to communicate ideas to students. Representations are ways to communicate ideas or concepts by presenting them either externally – taking the form of spoken language (verbal), written symbols (textual), pictures, physical objects or a combination of these forms – or internally when thinking about these ideas. These internal representations are often referred to as mental models and are the essential elements in some researchers' arguments about conceptual change (Treagust and Duit 2008a, b) but not necessarily of other researchers (Roth et al. 2008).

A recurring theme of research findings over the past three decades, as evidenced in many of the chapters in Sandra Abell and Norm Lederman (2007) and Stella Vosniadou (2008), is that students come to science classes with pre-instructional conceptions and ideas about the phenomena and concepts to be learned that are not in harmony with science views. Furthermore, these conceptions and ideas are firmly held and are often resistant to change. Whilst studies of students' learning in science that primarily involve conceptions of the content level continue, investigations of students' conceptions at meta-levels (namely, conceptions of the nature of science and views of learning, as well as characteristics of the learners) also have been given considerable attention in the past two decades (Duit 2009).

Research on the role of students' pre-instructional conceptions in learning science that developed in the 1970s draws primarily on the theoretical perspectives of Ausubel and Piaget. The 1980s saw the growth of studies into the development of students' pre-instructional conceptions towards the intended science concepts in conceptual change approaches. Over the past three decades, research on students' conceptions and conceptual change has been embedded in various theoretical frames with epistemological, ontological and affective orientations (Duit and Treagust 2003; Taber 2006; Vosniadou et al. 2008). A landmark paper by Paul Pintrich et al. (1993) argued that, up to that time, researchers of conceptual change had initially taken on an overly rational approach. Further, certain limitations of the constructivist ideas of the 1980s and early 1990s led to their merger with social constructivist and social cultural orientations that resulted in recommendations to employ multiple perspectives in order to adequately address the complex process of learning (Duit and Treagust 2003; Treagust and Duit 2008a; Tyson et al. 1997).

Amongst the theoretical positions described in Vosniadou (2008), aspects of epistemological and ontological challenges occur in many chapters. During the past decades, several researchers have developed theoretical positions that encompass some but not all of these challenges. Examples include framework theories/synthetic models (Vosniadou et al. 2008), hierarchical ontological categories (Chi 2008), intentional conceptual change (Sinatra and Pintrich 2003) and a multidimensional perspective (Duit and Treagust 2003). Within each of these frameworks, there are three essential aspects of conceptual change learning related to epistemology, ontology and affective/social/learner characteristics. We discuss each of these in turn.

An Epistemological Perspective of Conceptual Change

The classical conceptual change approach (Posner et al. 1982) involved the teacher making students' alternative conceptions explicit prior to designing a teaching approach consisting of ideas that do not fit students' existing conceptions and thereby promoting dissatisfaction. A new framework was then introduced based on formal science that might better explain the anomaly. However, it became obvious that students' conceptual progress towards understanding and learning science concepts and principles after instruction frequently turned out to be still limited because the students were not necessarily dissatisfied with their own conceptions and so the better explanations were not considered. Much research continues in this vein. However, students' conceptions tend not to be completely extinguished and replaced by the science view (Duit and Treagust 1998), but undergo a 'peripheral conceptual change' (Chinn and Brewer 1993) in that parts of the initial idea merge with parts of the new idea to form some sort of synthetic model (Vosniadou and Brewer 1992).

Kenneth Strike and George Posner (1985, pp. 216–217) expanded the conceptual ecology metaphor to include anomalies, analogies and metaphors, exemplars and images, past experiences, epistemological commitments, metaphysical beliefs and knowledge in other fields. Subsequently, many researchers have examined students' conceptual change using explanatory models (Clement 2008) and analogies (Treagust et al. 1996), though the actual mechanism for any observed changes is not explicitly known. One reason for the lack of conceptual change with analogy teaching is that, whilst the teacher's analogy is based on propositionally based knowledge, the student's is built on mental images (Wilbers and Duit 2006).

An Ontological Perspective of Conceptual Change

Researchers who use epistemology to explain conceptual changes do not overtly emphasise changes in the way in which students view reality. Other researchers do use specific ontological terms to explain changes in the way students develop their science conceptions (Chi 2008). Two candidates for these types of change are heat, which needs to change from a flowing fluid to energy in transit, and a gene, which needs to change from an inherited object to a biochemical process. There are many other concepts for which scientists' *process* views are incommensurable with students' *material* conceptions and the desired changes to students' ontologies are not often achieved in school science. For example Mei-Hung Chiu and her colleagues (2002) adopted Chi's ontological categories of scientific concepts in investigating how students perceive the concept of chemical equilibrium, arguing that 'although Posner's theory is widely accepted by science educators and easy to comprehend and apply to learning activities, … it does not delineate what the nature of a scientific concept is, which causes difficulty in learning the concept' (p. 689).

Affective/Social Aspects and Learner Characteristics of Conceptual Change

The third focus of conceptual change is the affective domain, particularly involving emotions, motivation and social aspects, such as group work, and learner characteristics, such as students' self-efficacy and control beliefs; the classroom social context and the individual's goals, intentions, purposes, expectations and needs are as important as cognitive strategies in concept learning (Pintrich et al. 1993). Group factors also can advantage concept learning and Vygotsky's theories recognise the importance of social and motivational influences.

Studies reported in Gail Sinatra and Paul Pintrich (2003) emphasised the importance of the learner, suggesting that the learner should play an active and intentional role in the process of knowledge restructuring. Whilst acknowledging the important contributions to the study of conceptual change from the perspectives of science education and cognitive developmental psychology, Sinatra and Pintrich note that the psychological and educational literature of the 1980s and 1990s placed greater emphasis on the role of the learner in the learning process. However, whilst there is strong support for the ideas, initiated by Paul Pintrich et al., that there is more to conceptual change than cognition, especially in the use of theoretical models as explained by Gail Sinatra and Lucia Mason (2008), there are still few empirical studies of the relationship between these factors and conceptual change.

Indeed, teachers who ignore the social and affective aspects of personal and group learning might limit conceptual change in their classrooms; we come back to this point in the second part of this chapter. In a review linking the cognitive and the emotional in teaching and learning science, Michalinos Zembylas (2005) goes a step further by arguing that it is necessary to develop a unity between cognitive and emotional dimensions in which emotions not only are moderating variables of cognitive outcomes, but also a variable of equal status. Zembylas advocates research in which affective variables are deliberately developed and undergo conceptual changes; but not many empirical studies incorporating affective variables are available. As noted by Steve Alsop and Mike Watts (2003), the effect of affect on learning science is an 'often overlooked domain' (p. 1044).

Impact of Conceptual Change Research on School Practice

In principle, from the extant research on conceptual change, there is a large potential for improving practice in the science classroom. However, so far, the research evidence concerning the impact of teaching informed by conceptual change instructional practices in normal classes is limited and tends to be associated with various teacher factors. We address these factors in the following paragraphs.

Teachers' Views of Teaching and Learning Science

One of the major obstacles to success in implementing science standards in the United States is that teachers usually are not well informed about the recent state of research on teaching and learning science and hold views of teaching and learning that are predominantly transmissive and not constructivist (Anderson and Helms 2001). Indeed, research has shown that many teachers hold conceptions of science concepts and processes that are not in accordance with the science view and often are similar to students' pre-instructional conceptions. Research has also shown that many teachers hold limited views of the teaching and learning process (Duit et al. 2007) and of the nature of science (Lederman 2007). Hence, teachers' conceptions of various kinds also need to undergo conceptual changes. Basically, the same conceptual change frameworks for addressing students' conceptions have proven valuable for developing teachers' views of science concepts (Hewson et al. 1999a, b).

Many studies of teachers' views about teaching and learning carried out since the 1990s suggest that it is essential to encourage science teachers to become familiar with the recent state of educational research and to help them to develop their views about efficient teaching and learning. Analysis of videotapes on the practice of German and Swiss lower secondary physics instruction showed that most teachers are not well informed about key ideas of conceptual change research (Duit et al. 2007). Teachers' views of their students' learning usually are not consistent with recent theories of teaching and learning. Indeed, many teachers appear to lack an explicit view of learning. Several teachers hold implicit theories that contain some intuitive constructivist issues; for instance, they are aware of the importance of students' cognitive activity and the interpretational nature of students' observations and understanding. However, teachers were identified who characterised themselves as mediators of facts and information and who were not aware of students' interpretational frameworks and the role of students' pre-instructional conceptions. These teachers mostly think that what they consider to be good instruction is a guarantee for successful learning.

Are Conceptual Change Approaches More Efficient Than More Traditional Ones?

Usually researchers who use a conceptual change approach in their classroom-based studies report that their approach is more efficient than traditional ones. Efficiency exclusively or predominantly involves cognitive outcomes of instruction. The development of affective variables during instruction is often not viewed as an intended outcome (Murphy and Alexander 2008). In summarising the state of research on the efficiency of conceptual change approaches, there appears to be ample evidence in various studies that these approaches are more efficient than traditional approaches dominated by transmissive views of teaching and learning. This seems to be the case, particularly if more inclusive conceptual change approaches, based on multidimensional perspectives as outlined above, are employed.

Recent large-scale programmes for improving the quality of science instruction (as well as instruction in other domains) include instructional methods that are oriented towards attempts to implement constructivist principles of teaching and learning into practice (Beeth et al. 2003). Three other characteristics of high-quality development approaches referred to by Michael Beeth et al. (2003) are: the need to support schools and teachers in rethinking the representation of science in the curriculum; the necessity to enlarge the repertoire of tasks, experiments, and teaching and learning strategies and resources; and showing how to promote strategies and resources that attempt to increase students' engagement and interests. This set of characteristics requires teachers to be reflective practitioners (Schon 1983) with a non-transmissive view of teaching and learning. Students need to be seen as active, self-responsible, cooperative and self-reflective learners. Indeed, these features are at the heart of inclusive constructivist conceptual change approaches.

The Practice of Teaching Science in Normal Classes

In summarising findings of student narratives from interpretive studies of students' experiences of school science in Sweden, England and Australia, Lyons (2006, p. 595) noted that 'students in the three studies frequently described school science pedagogy as the transmission of content expert sources – teachers and texts – to relative passive recipients'. Students were overwhelmingly critical of this kind of teaching practice, leaving them with an impression of science as being a body of knowledge to be memorised. The normal practice of science instruction described in the above studies was not significantly informed by constructivist conceptual change perspectives. Of course, there was large variance within the educational culture of certain countries and also between the educational cultures of the countries. But still there is a large gap between instructional design based on recent research findings on conceptual change and what is normal practice in most of the classes observed.

Conceptual Change and Teacher Professional Development

Investigating teachers' views of teaching and learning science and the means to improve teachers' views and their instructional behaviour through teacher professional development has developed into a research domain that has been given much attention since the late 1990s (Borko 2004). Two major issues are addressed in teacher professional development projects. First, teachers become familiar with research knowledge on teaching and learning by being introduced to recent constructivist and conceptual change views, and then they become familiar with instructional design that is oriented towards these views. Second, attempts to link teachers' own content knowledge and their pedagogical knowledge play a major role. The most prominent theoretical perspective applied is Shulman's (1987) idea of content-specific pedagogical knowledge or Pedagogical Content Knowledge (PCK, Abell, 2007).

It is important to note, however, that attempts to explicitly employ the more recent multidimensional and inclusive conceptual change perspectives, as outlined in the first part of the present chapter, currently appear to be missing. Clearly, Peter Hewson et al. (1999a, b) take into account teacher change processes of various kinds, but the conceptual change perspectives applied appear to be largely concerned with teachers' epistemologies.

Further Developments Needed to Enhance Conceptual Change Research in Science Education

We believe that researchers of conceptual change in science education can greatly contribute to this field of activity by investigating conceptual change from multidimensional perspectives; paying more attention to the context of learning; acknowledging the importance of dialogue in facilitating learning; emphasising the need for replication studies; and determining the necessary and sufficient evidence for identifying conceptual change. We discuss each of these points in this section.

Investigating Conceptual Change from Multidimensional Perspectives

Conceptual change approaches as developed in the 1980s and early 1990s contributed substantially to improving our understanding of science learning and teaching. Most of the early studies of learning science were oriented towards the epistemological views of learning and ignored other existing views such as Michelle Chi's ontological categories and Stella Vosniadou's framework theory. However, the latter perspective appears to have had little influence in encouraging science education researchers to follow these lines of research. Similarly, there is ample evidence in research on learning and instruction that cognitive and affective issues are closely linked. However, the number of studies of the interaction of cognitive and affective factors in the learning process is limited, except for studies of correlations between interest in science and cognitive results of learning. The interplay of changes of interest in science and conceptual change has been investigated only in a small number of studies.

Our view is that research on conceptual change approaches needs to take into account multiple perspectives and focus on ways in which the various theoretical perspectives are linked and can constructively interact in a complementary way. On the theoretical plane, individuals construct mental models which are consistent with theories that involve internal representations in thinking processes. Indeed, cognitive scientists view models as internal representations that reflect external reality and that are built from prior knowledge, perceptions, schema and problem-solving strategies.

By the very nature of an individual acting in his or her social environment, a single perspective, no matter how well argued, cannot identify the nature of these interactions (Duit and Treagust 1998, 2003; Greeno et al. 1997). One perspective is likely to miss more than is identified. In the study by Venville and Treagust (1998), for instance, science learning was investigated from four different theoretical positions of conceptual change. Each theoretical position (e.g. an epistemological position or an ontological perspective) enabled identification of learning issues that another theoretical approach did not. In a similar vein, Tiberghien (2008) argues that a theory which does not take into account different components – social situation, kinaesthetic perceptions, type of knowledge, types of lexical and syntactical forms of language – is not relevant to her research programme. Briefly summarised, multi-perspectives of conceptual change that encompass epistemological, ontological and affective domains have to be employed in order to adequately address the complexity of teaching and learning processes.

In contrast to the approach of being committed to one theoretical perspective of conceptual change as a framework for their data analysis and interpretation, Venville and Treagust (1998) utilised different perspectives of conceptual change – epistemological, ontological and affective – in analysing different classroom teaching situations in which analogies were used to teach genetics. Venville and Treagust (1998) found that each of the perspectives of conceptual change had explanatory value and enabled different theoretical frameworks for interpreting the role that analogies play in each of the classroom situations.

Paying More Attention to the Importance of Context in Learning

In the debates about conceptual change in *Cultural Studies in Science Education*, one of the points made by the social scientists was the importance of describing the context in more detail than is usual. In the chapters in Vosniadou (2008), whilst some authors (e.g. Brown and Hammer 2008, p. 135) state that 'there is a wide consensus … that at least some of the misunderstandings [of physics concepts] vary with context', there is little discussion of context throughout this volume.

Context in learning involves both the internal context as perceived by the learner and the external context of the discourse presented. From a sociocultural perspective, there is a need to recognise the importance of the emotions/affective domain as well as learner characteristics. The affective aspect of learning is much overlooked and its inclusion is encouraged when using a broader socio-cultural framework. A multi-perspective position of conceptual change recognises the importance not only of the context in which teaching and learning happens, but also of the environment in which student interviews or interactions take place in interpreting findings about conceptual change.

Acknowledging the Importance of Dialogue in Facilitating Learning

A key issue from the cultural studies aspects of conceptual change is the importance of dialogue. Learning is always deeply shaped by the particular social and material characteristics of the learning environment (Wells 2008). Hence, the discourse in small-group inquiry, individual learning or whole-class instruction is essential for discerning the quality of the learning outcomes (Duit et al. 2008). Further, we have discussed previously (Duit et al. 1996) the importance of co-construction of knowledge in exchanges between interviewer and interviewee.

Emphasise the Need for Replication Studies

In their synthesis and meta-analysis of research on conceptual change reported in the 5-year period, 2001–2006, Murphy and Alexander (2008, p. 584) considered conceptual change as 'a latent variable … a theoretical variable that cannot be directly observed or measured but is presumed to exert influence on other observable variables such as learning or achievement'. Their detailed analysis, which included 20 of an original 47 studies meeting specified criteria, supported the conceptual change models of Posner et al. and Vosnaidou. However, Murphy and Alexander reported few replication studies and that most studies included in the analysis were single interventions without the benefit of repeat trials.

Determining the Necessary and Sufficient Evidence for Identifying Conceptual Change: Towards Mixed-Methods Studies

In approaches near to the classical conceptual change model, data collection includes written tests, interviews and, less frequently, thinking-aloud protocols; however, this is developmental research and not conceptual change research. Because studies need to show how concepts have changed over time, it is usually necessary to include a quasi-experimental research design that involves pre- and post-measures and preferably continuous kinds of data. These process studies have shown evidence of conceptual change. The importance of good dialogue and detailed and careful analysis is crucial to making claims about conceptual change. Whilst recognising the importance of dialogue in investigating a student's conceptual change as he or she interacts with a teacher or a fellow student, Mercer (2008) also emphasises the need for conceptual change researchers to consider more deeply how both social and cognitive aspects of dialogue contribute to conceptual change.

Concluding Comments

This chapter discussed three distinct but closely connected issues concerning conceptual change in science. First, we discussed theoretical perspectives of conceptual change and illustrated how researchers have conceptualised teaching and learning science from these different perspectives. Second, we reported implemented conceptual change teaching and learning approaches and examined the degree of success of these interventions. Third, we suggested how conceptual change research involving science domains can be improved.

The state of theory building on conceptual change has become more and more sophisticated and the teaching and learning strategies developed have become more and more complex over the past 30 years. Whilst these developments are necessary to address the complex phenomena of teaching and learning science more adequately, there has been an increase in the gap between what is necessary from researchers' perspectives and what might be set into practice by normal teachers. Therefore, a paradox arises in that, in order to adequately model teaching and learning processes, research alienates the teachers and hence widens the theory-practice gap. However, we should deal with this paradox by developing theoretical frameworks, more finely focused research methods, and more efficient conceptual change instructional strategies. Fortunately, the frameworks for studying student conceptual change – being predominantly researched so far – also might provide powerful frameworks for teacher change towards employing conceptual change ideas. We believe that more research based on inclusive conceptual change perspectives is most desirable.

Chapter 10
Reframing the Classical Approach to Conceptual Change: Preconceptions, Misconceptions and Synthetic Models

Stella Vosniadou

The Problem of Conceptual Change in Science Learning

The idea that the learning of science could require conceptual change was first introduced by George Posner and his colleagues (Posner et al. 1982; see also McCloskey 1983) in order to explain students' difficulties in understanding science concepts. Since the late 1970s, many science educators (e.g. Driver and Easley 1978; Viennot 1979) became aware of the fact that students bring to the science learning task alternative frameworks or misconceptions that are robust and difficult to extinguish through teaching. Posner et al. (1982) proposed that the learning of science requires the replacement of such persistent misconceptions. They drew an analogy between Jean Piaget's concepts of assimilation and accommodation, and the concepts of normal science and scientific revolution offered by philosophers of science such as Thomas Kuhn (1962), and derived from this analogy an instructional theory to promote 'accommodation' in students' learning of science. According to Posner et al. (1982), there are four fundamental conditions that need to be fulfilled before conceptual change can happen in science education: (1) there must be dissatisfaction with existing conceptions; (2) there must be a new conception that is intelligible; (3) the new conception must appear to be plausible and (4) the new conception should suggest the possibility of a fruitful programme.

This theoretical framework, known as the *classical* approach to conceptual change, became the leading paradigm that guided research and instructional practices in science education for many years. In the classical approach, conceptual change is considered to be the result of a rational process of theory replacement by learners who are like scientists. It is supposed to take place in a short period of time – it is considered as something like a gestalt-type restructuring. According to this approach, the main

impediments to understanding scientific concepts are the four conditions named earlier. For this reason, within the classical approach, conceptual change was to be achieved mainly through the creation of cognitive conflict. Thus, cognitive conflict became the major instructional strategy for producing conceptual change.

Over the years, practically all of the above-mentioned tenets of the classical approach were subjected to serious criticism. Some researchers argued that conceptual change is slow and gradual and not a dramatic gestalt-type shift (Carvita and Halden 1997); that learners are not exactly like scientists in that they do not understand that their beliefs are hypotheses that need to be tested (Vosniadou 2003); that affective and motivational factors have an important role to play in conceptual change (Sinatra and Pintrich 2003) and that conceptual change is significantly influenced by social processes (Hatano and Inagaki 2003).

In addition to the above, Jack Smith et al. (1993) criticised the use of cognitive conflict on the grounds that it presents a narrow view of learning that focuses only on the mistaken qualities of students' prior knowledge and ignores their productive ideas that can become the basis for achieving a more sophisticated scientific understanding. Smith et al. (1993) argued that misconceptions should be reconceived as faulty extensions of productive knowledge, that misconceptions are not always resistant to change, and that instruction that 'confronts misconceptions with a view to replacing them is misguided and unlikely to succeed' (p. 153).

Since then, Andy diSessa (1988, 1993, 2008) put forward a different proposal for conceptualising the development of physical knowledge. He argued that the knowledge system of novices consists of an unstructured collection of many simple elements known as phenomenological primitives (*p-prims* for short) that originate from superficial interpretations of physical reality. P-prims appear to be organised in a conceptual network and to be activated through a mechanism of recognition that depends on the connections that p-prims have to the other elements of the system. According to this position, the process of learning science is one of collecting and systematising these pieces of knowledge into larger wholes. This happens as p-prims change their function from relatively isolated, self-explanatory entities to become integrated into a larger system of complex knowledge structures such as physics laws. In the knowledge system of the expert, p-prims 'can no longer be self-explanatory, but must refer to much more complex knowledge structures, physics laws, etc. for justification' (diSessa 1993, p. 114).

diSessa (1993) and Smith et al. (1993) provide an account of the knowledge-acquisition process that captures the continuity that one expects with development and has the possibility of locating knowledge elements in novices' prior knowledge that can be used to build more complex knowledge systems. We agree with them about the need to move from thinking of conceptual change as involving single units of knowledge to systems of knowledge that consist of complex substructures that can change gradually and in different ways. Finally, we agree with Smith et al.'s (1993) recommendation to researchers to 'move beyond the identification of misconceptions' towards research that focuses on the evolution of expert understandings and particularly on 'detailed descriptions of the evolution of knowledge systems over much longer durations than has been typical of recent detailed studies' (p. 154).

For a number of years now, we have been involved in a programme of research that attempts to provide detailed descriptions of the development of knowledge in specific subject-matter areas, especially the physical sciences, such as astronomy (Vosniadou and Brewer 1992, 1994; Vosniadou and Skopeliti 2005; Vosniadou et al. 2004, 2005), mechanics (Ioannides and Vosniadou 2002), geology (Ioannidou and Vosniadou 2001), biology (Kyrkos and Vosniadou 1997) and mathematics (Vosniadou and Verschaffel 2004). Our studies are mostly cross-sectional developmental studies into the knowledge-acquisition process in students ranging from 5 to 20 years of age. We have also used the results of our research to develop curricula and instruction that has been tried out in schools in Greece (Vosniadou et al. 2001). The results of these studies have led us to the development of a revised framework for thinking about conceptual change in the learning of science (Vosniadou et al. 2007, 2008). In the pages that follow, we outline the main tenets of this approach, which we will call the *framework theory* approach, highlighting its similarities and differences with the *classical approach* to conceptual change as well as with diSessa's *knowledge in pieces* position. Examples are given from cognitive, developmental and science education research focusing mainly on the concepts of the earth and of matter.

The Framework Theory Approach

Preconceptions Are Different from Misconceptions

Unlike the classical approach, the framework theory approach makes a fundamental distinction between *preconceptions* and *misconceptions* and considers many misconceptions to be synthetic conceptions or models. We consider preconceptions to be the initial ideas about the physical world and explanations of physical phenomena that children construct on the basis of their everyday experience in the context of lay culture *before they are exposed to school science*. On the contrary, we consider misconceptions to be students' erroneous interpretations of the scientific concepts *after they are exposed to school science*. We explain later in this chapter exactly in what way we consider misconceptions to be synthetic.

There is a great deal of cognitive developmental and science education research showing that young children, who have not yet been exposed to science, answer questions about force, matter, heat, the day/night cycle, etc. in a relatively consistent way that reveals the existence of initial conceptions or preconceptions (Baillargeon 1995; Carey and Spelke 1994; Gelman 1990). For example a substantial body of research supports the conclusion that, during the preschool years, children construct an initial concept of the earth based on interpretations of everyday experience in the context of lay culture. According to this initial concept, the earth is a flat, stable, stationary and supported physical object. Space is organised in terms of the dimensions of up and down and objects on the earth (the earth itself included) fall down when they are not supported (up/down gravity concept). The sky and solar objects are located above the top of this flat earth that is thought to occupy a geocentric universe (Vosniadou and Brewer 1992, 1994; Nussbaum, 1979, 1985).

Similarly, a great deal of research has shown that, before they go to primary school, many children have already constructed an initial concept of matter or material kind that is different from the concept of physical object (Carey 1991; Wiser and Smith 2008). They group solids, liquids and powders together as consisting of some kind of stuff, distinguishing them from gases (air) and nonmaterial entities (heat, electricity) or mental entities (ideas, wishes). These material entities are things that can be seen, touched and felt, and produce some kind of physical effects. Similar results can be found for biology (Carey 1985; Hatano and Inagaki 1997), mechanics (Ioannides and Vosniadou 2002; Chi 1992, 2008) and heat and temperature (Wiser and Amin 2001) amongst others.

Preconceptions Cohere

Children's initial conceptions, or preconceptions, are not superficial beliefs but represent a coherent, although relatively narrow, explanatory *framework theory* that some call intuitive or naïve. The term *theory* is used loosely to denote a network of interrelated beliefs that can be used to provide explanations and form predictions and not a fully developed scientific theory. For example, studies of children's explanations of the day/night cycle show that most children are capable of providing a mechanism to explain the alternation of day and night before they are exposed to the scientific explanation. They say, for instance, that the sun goes behind the mountains during the night, or behind clouds, and the moon comes up (Vosniadou and Brewer 1994). They also use this mechanism productively to answer generative questions – that is they are capable of saying that if we wanted to have day all the time in our part of the world, then we should prevent the sun from moving. They can also make predictions, such as that the moon cannot be in the sky during the day, which are often wrong and which can be exploited instructionally (i.e. when falsified, they can lead to cognitive conflict). Unlike scientists, however, children are usually not metaconceptually aware of their beliefs and they do not understand that they represent hypotheses that can be falsified.

Preconceptions Are Different in Their Ontology and Epistemology from Scientific Theories

The initial conception of a flat earth is deeply rooted in young children's categorisation of the earth as a physical object (as shown experimentally in Vosniadou and Skopeliti 2004) that has all the characteristics of physical objects, such as solidity and lack of self-initiated movement. Like other physical objects, it is conceptualised in the context of a space organised in terms of the directions of up and down and in which gravity operates in an up/down fashion. Understanding the scientific concept of the earth requires children to recategorise the earth from the ontological category of ‘physical object’ to the ontological category of ‘physical-astronomical object’. In other words, they have to think of the earth as a planet in space and not as a solid ground distinct from other astronomical objects. Our studies show that such recategorisations happen in the conceptual system of elementary school children between third and sixth grade (Vosniadou and Skopeliti 2005). Such recategorisations also require some epistemological sophistication and understanding of models, as they depend on children’s ability to understand how their initial, perceptually based representations of the earth are related to the conceptually based model of a spherical earth in space.

Similarly, children’s initial conception of matter is perceptually based. As Marianne Wiser and Carol Smith (2008) argue, an entity is material (made of some stuff) if it can be touched and seen. It can be thought of as being composed of homogeneous parts that are touchable and visible as well, or else they could not compose matter. Understanding the atomic theory of matter requires radical ontological shifts to take place, since atoms, although the sole constituents of matter have many counterintuitive properties, such as that they exist in vacuum and move in high speeds. Similar arguments are made by other researchers. For example Michelene Chi (1992) argues that ontological shifts are necessary for understanding many science concepts, such as the concepts of force, energy and heat. These concepts are all categorised as entities or substances in the initial conceptual system of novices but are recategorised as processes in the conceptual system of experts. Giyo Hatano and Kayoto Inagaki (1997) also offer examples of changes in ontology and causality in children’s acquisition of biological knowledge. Furthermore, these changes cannot be achieved without developing the ability to reason on the basis of theoretical models and an understanding of how such models relate to experimental evidence.

Conceptual Change Is Not a Sudden, Gestalt-Like Replacement of One Concept with Another

Unlike the classical approach, we do not believe that conceptual change can be achieved through some kind of sudden replacement of the initial conception with a scientific concept when the student becomes dissatisfied with it. Although some sudden restructurings might be possible in some cases, conceptual change is for the most part a slow process not only because it involves a complex network of interrelated concepts (Smith et al. 1993), but also because it requires the construction of new representations that, as we discussed earlier, involve radical changes in ontology and epistemology.

Conceptual change is achieved gradually as new ideas are added onto existing but conflicting conceptual structures sometimes enriching them and sometimes fragmenting them. Indeed, school science can often lead students to greater internal inconsistency and fragmentation in ways that are not often recognised by the science education community. It can also lead to the formation of misconceptions, many of which can be interpreted as synthetic conceptions or models.

Many Misconceptions Are Synthetic Conceptions or Models

We argue that many misconceptions are synthetic conceptions or models that are produced when students are exposed to scientific explanations without adequate instruction. As we have argued before (Vosniadou et al. 2008), misconceptions are often created as students unconsciously apply enrichment types of learning mechanisms to add scientific information to an existing but incompatible prior knowledge. For example in astronomy, children come to believe that the earth is a flattened or a truncated sphere with people living only on its flat top. Or, they might think that the earth is a hollow sphere with people living on flat ground inside it whilst the sky covers them on top like a dome (Vosniadou and Brewer 1992). All of these misconceptions can be seen as representing children's constructive attempts to synthesise the scientific information that the earth is a sphere with some of the beliefs that constitute their initial conceptions and which act as constraints in the knowledge-acquisition process. Some of these beliefs are that the ground is flat and that physical objects must be supported otherwise they will fall down.

Similar synthetic conceptions can be observed in children's attempts to understand the atomic theory of matter. An extremely powerful misconception that survives even through the college years is the belief that atoms are not the basic constituents of matter, but rather something *in* matter, as embedded in a material substrate (Anderson 1990; Pozo and Gomez Crespo 2005). The *matter-in-molecules model* is a synthetic model resulting from the integration of school information with students' initial conceptions. It is successful in integrating the new scientific information that matter consists of atoms, without fundamentally altering their original realistic representation of matter as something inherently continuous.

Unfortunately, traditional instruction does not always provide students with the necessary background information or with the tools that are necessary in order to acquire the new ontological categories and move from their epistemologically naïve and perceptually based explanations to an understanding of complex, conceptual models in science. Furthermore, sometimes the instruction provided reinforces the formation of misconceptions such as the ones mentioned earlier. For example, the language used in many textbooks, such as 'Atoms *in* solids vibrate, while atoms *in* liquids …', 'Molecules are less free to move *in* ice than *in* (liquid) water', Bonds are the *glue* between atoms', etc. reinforce the matter-in-molecules misconception. The same applies to textbook illustrations which present pieces of substances as coloured cubes with small black spheres (atoms) inside them (Wiser and Smith 2008).

Conceptual Change Requires Fundamental Changes in Students' Representations and in Ontological and Epistemological Commitments

These changes are not in place by the time the scientific theories are presented to students. For example understanding the scientific concept of the earth requires changing from a representation of a stable, flat, supported earth consisting of ground all the way down, to the representation of a spherical earth in space, rotating around its axis, and revolving around the sun. Such a representation is not created simply by presenting children with the model of a globe, as it is usually done. As we have shown in previous work (Vosniadou et al. 2005), understanding a conceptual model is an act of interpretation that is constrained by prior knowledge. Although children see the globe, they often do not understand how it relates to the perceptually experienced earth. As a result, they often distort the model to agree with their initial conceptions (e.g. the earth is flat or that gravity operates in an up/down fashion). These preconceptions act as strong constraints and limit their understanding of the scientific concept. Understanding the scientific concept requires explaining to children how it is possible for the earth to be flat and round at the same time, and how it is possible for people to live on this globe without falling down – a change in children's up/down gravity concept.

As mentioned earlier, the scientific concept and its related conceptual representation are not there to replace children's naive, perceptually based representation of the earth. On the contrary, children need to develop the ability to take different perspectives, perspectives from deep space or from evolutionary time, and understand how their phenomenal, naive conceptions are related to the scientific concepts which provide more powerful explanations of physical phenomena. Science instruction should be provided to move children from an epistemology based on naive realism and the belief that things are as they appear to be. Children need to develop an understanding of the nature and function of models and the processes of scientific reasoning through hypothesis testing and falsification and through extensive experience in model construction and revision.

Similarly, in the case of the concept of matter, students need to change from a naive representation of matter as a continuous entity to the atomic model. Again, this is a conceptual model that requires children to understand the distinction between perceptual and physical properties and how they are linked. The children would need to form the concept of emerging properties and understand how atoms, invisible to the naked eye, can form matter with physical and perceptual properties. Here again children need to move from an epistemology of naive realism and to understand that there is a macroscopic level which is related to and explains the macroscopic phenomena.

In summary, conceptual change in both of these domains requires substantial acquisition of new knowledge, the creation of new ontological categories and substantial reorganisation of existing conceptual structures. It also requires the development of epistemological sophistication and the understanding of the role of conceptual models in science and of hypothesis testing and falsification.

Relation to Other Approaches

Our synthetic models approach meets all the criticisms of the classical approach made by Carol Smith et al. (1993). First, we are not describing unitary, faulty conceptions but a knowledge system consisting of many different elements organised in complex ways. Second, we make a distinction between initial explanations prior to instruction and those that result after instruction and which we call synthetic models. Synthetic models are not stable but dynamic and they are constantly changing as children's developing knowledge systems evolve. Finally, our theoretical position is a constructivist one. It can explain how new information is built on existing knowledge structures and provides a comprehensive framework within which meaningful and detailed predictions can be made about the knowledge acquisition process.

Finally, our position is not inconsistent with the view that something like diSessa's p-prims constitute an element of the knowledge system of novices and experts. We believe that p-prims can be interpreted to refer to the multiplicity of perceptual and sensory experiences that are obtained through our observations of physical objects and our interactions with them. These perceptual experiences provide the basis, in the context of lay culture, for the construction of beliefs, presuppositions and mental models (i.e. of a conceptual system). A conceptual system is an organised knowledge structure, no matter how loose or naïve this initial organisation might be. Thus, the process of learning science is not one of simply organising the unstructured p-prims into physics laws but rather one during which preconceptions become re-organised into a scientific theory. This is a slow, gradual process which can cause misconceptions or synthetic models – a phenomenon which is not explained by the knowledge in pieces approach.

Implications for the Design of Curricula and Instruction

Following what we have already said regarding students' difficulties in learning science, we do not believe that instruction based only on cognitive conflict is adequate. Although limited uses of cognitive conflict can be useful in motivating students to learn, instruction for conceptual change needs to be designed carefully, for the long run, and to be based on research that shows the learning progression that students follow as they slowly change their initial conceptions to understand science.

In view of students' difficulties in learning science, it might be more profitable to design curricula and focus on the deep exploration of a few key concepts in one subject matter area rather than to cover a great deal of material in a superficial way. Some science curricula include short units on mechanics, energy, particulate nature of matter, processes of life, etc. This approach does not give students enough time to achieve the qualitative understanding of the concepts being taught. On the contrary, it encourages the causal memorization of facts and it is likely to lead to logical incoherence and misconceptions.

It is also important when designing curricula to distinguish new, scientific, information that is consistent with what students already know or believe from new information that runs contrary to students' conceptions. When the scientific information is consistent with what students already know, it can be easily incorporated into existing knowledge structures. But when it is not, it is very likely that it will be misunderstood. Thus, curriculum developers and teachers should utilise the findings of existing cognitive science and science education research so that they can pay particular attention to those initial conceptions and misconceptions of students that have been found to be persistent and difficult to extinguish. Because these conceptions can constrain the understanding of the scientific concepts, curricula should be designed to provide especially clear explanations, experiments, observations, models, etc. that would help students to restructure their prior knowledge (Vosniadou et al. 2001).

Instruction-induced conceptual change requires not only the restructuring of students' naïve theories, but also the restructuring of their modes of learning and reasoning, the creation of metaconceptual awareness and intentionality, and the development of epistemological sophistication (Sinatra and Pintrich 2003). There are several aspects of intentional learning that can be promoted in order to foster conceptual change and which we highlight below.

Cognitive developmental research suggests that students are not always aware of the beliefs and presuppositions underlying their reasoning and, even more important, they do not realise the hypothetical nature of these beliefs. Instruction should support students in realising the hypothetical nature of their beliefs and teach them how to test them and evaluate their explanatory power. Students' views of science as a discipline have an impact on the way in which they approach learning in the domains. If students believe that science provides a true picture of the state of affairs about the world (Driver et al. 1994), then they are less likely to develop critical thinking, engage in hypothesis testing or look for alternative explanations. Instead, they are more likely to rely on the he authority of the teacher or of the text. Christina Stathopoulou and Stella Vosniadou (2007) have shown that there is a strong correlation between students' epistemic beliefs and the way in which they approach studying in physics. Students who believe that knowledge is stable and certain and consists of pieces of information are more likely to adopt superficial, rather than deep, study strategies, and they are less likely to achieve conceptual change in mechanics (see also Mason 2003; Mason and Gava 2007).

The use of analogies, models and cultural artefacts is considered a significant component of powerful learning environments. However, it should be taken into consideration that the mere presence of such tools is not enough to mediate effective learning. External representations and conceptual models are interpreted on the basis of students' prior knowledge, and sometimes they are not interpreted correctly (Vosniadou et al. 2005). A problem with representations, in general, is that they are transparent to those who understand them and opaque to those who do not. Instruction needs to be developed to help students understand better the nature and function of models and engage in model-based reasoning.

As Hatano and Inagaki (2003) argue, this type of instruction cannot be achieved without substantial sociocultural support. One way in which teachers can provide the sociocultural environment to encourage comprehension is to ask students to participate in dialogical interaction, which is usually whole-class discussion. Whole-classroom dialogue can be effective because it ensures that students understand the need to revise their beliefs deeply instead of engaging in local repairs (Chinn and Brewer 1993) and that they spend the considerable time and effort needed to engage in the conscious and deliberate belief revision required for conceptual change (see also Miyake 2008). Another way is to ask, students to break up into smaller groups that compete with each other in discovering the correct solution and supporting it with the best arguments. This division of labour creates what Hatano calls ‘partisan’ motivation which amplifies ‘cognitive’ motivation and enhances deep comprehension and intentional learning (Hatano and Inagaki 2003).

Conclusion

It has been argued that students construct initial explanations of physical phenomena which are embedded in loosely organised but nevertheless relatively coherent explanatory frameworks which can constrain science learning. The learning of science requires substantial conceptual changes to take place in students’ initial conceptions as they are exposed to school science. Although these changes can be achieved through enrichment types of mechanisms, the assimilation of scientific information into students’ incompatible knowledge structures not only makes science learning very slow, but it also creates internal inconsistency and misconceptions. Many of these misconceptions are ‘synthetic models’ resulting from students’ constructive but inappropriate attempts to synthesise scientific information with incompatible initial knowledge, but without metaconceptual awareness. In order to achieve the learning of science in ways that avoid internal inconsistency and synthetic models, there needs to be provided instruction that gives students all the necessary information required to reorganise their ontological categories, whilst also developing epistemological sophistication and the hypothesis testing skills. It is important for students to move from their naive, perceptually based epistemologies to an understanding of conceptual models in science and to develop the top-down, deliberate and intentional learning mechanisms that scientists use for hypothesis testing. These changes cannot be achieved by cognitive means alone but require extensive sociocultural support.

Chapter 11
Metacognition in Science Education: Past, Present and Future Considerations

Gregory P. Thomas

Introduction

This chapter builds on Richard White's (1998) chapter in the previous edition of this *International Handbook of Science Education*. In that chapter, White focused on decisions and problems in research on metacognition. My intention in writing this chapter is to review progress in the area of metacognition over the past 10 or so years, particularly in science education, but also, as space permits, across the fields of education and cognitive psychology in general. My reasons for drawing broadly from the literature for this chapter relate to a growth in interest in the study of metacognition across education and psychology that is evident, for example, in the establishment of a Special Interest Group (SIG) on metacognition within the European Association for Research on Learning and Instruction (EARLI) and the publication of the journal *Metacognition and Learning*, the flagship publication of that SIG. Importantly, research in science education in the field of metacognition continues to draw on insights regarding metacognition from other areas, particularly cognitive psychology. In fact, Hacker (1998) considers that studies on metacognition in education are an emerging fourth category of metacognitive research alongside studies of cognitive monitoring, cognitive regulation, and cognitive monitoring and regulation. Therefore, it is reasonable to highlight, as necessary, significant contributions to understanding metacognition from outside science education and to consider how these might be useful for moving forward with research and scholarship on metacognition within our field. My intention is for those reading this chapter to come more fully to understand metacognition as it relates to the field of science education so that students' learning processes and consequently their science learning might be improved.

There is good reason to suggest that Richard White's (1998) concern regarding the quality of learning of science is still relevant to science education today. There is little evidence that the quality of students' learning of science has improved over the past decade or so. That this concern persists is itself a concern because it suggests that what we already know about how to improve science education and learning through the enhancement and development of students' metacognition is not finding its way into either the everyday practice of classroom teachers or the mindset and/or curricula of teacher educators and their teacher education programmes. In other words, whilst there are few who question the importance of metacognition, the recognition of this importance is not reflected in teachers' or teacher educators' practices. It has become increasingly evident that metacognition is a key to attending to the multiple agendas that characterise science education today. These agendas include the development of students' scientific literacy and their understanding of the nature of scientific inquiry, the nature of science itself and science concepts. For example to be able to undertake a process of scientific inquiry, there is a need for students to be able to consciously undertake particular procedures, both physical and cognitive, to monitor their progress towards the goal/s of the inquiry as they proceed, be aware of and evaluate their progress, and reflect on the outcomes of their inquiry with a view to improving their practices. This type of conscious thinking is the hallmark of a metacognitive individual. Further, as highlighted by Richard Gunstone (1994), metacognitive students are central to constructivist learning environments where students should continuously monitor new information that is presented to them and compare it with what they already know from their previous learning. It is such a constant and conscious reflection that is at the heart of conceptual change theories in science education.

Despite these obvious examples of how metacognition is important in science education, it remains a fringe area of study within the field that deserves increased attention. There are good reasons for this status, as White (1998) suggests. Indeed, as we have come to know more about metacognition and as more scholars have become involved in its study, new areas of contention have arisen, old debates have persisted to varying extents, and discussion continues about exactly what metacognition is, how it can be measured, and how best to bring about the development and enhancement of metacognition in students. Even though progress on these substantive matters has been uneven, there is agreement that, across science education and in education in general, metacognition is a useful predictor of successful learning. In what follows, I explore some of the issues and debates surrounding metacognition. It is through exploring these debates that readers can identify their own contentions and positions in relation to the field of metacognition as it currently stands. In other words, rather than promote a single view, I aim to highlight the diversity of opinions and attend to some contentious issues in this field in an attempt to promote and initiate further debate. No doubt, some readers will disagree with my positions on a number of matters. If the study of metacognition in the field of science education is to continue to mature and have a meaningful impact on students' learning and teachers' pedagogies so that improvements in students' learning can occur, we should acknowledge different viewpoints and begin to try to build a unified yet eclectic theory that attends to what metacognition is, how we can assess students' metacognition and how we can enhance and develop metacognition within and across everyday science learning environments. Such a theory must be able to guide reform so that metacognition is more visible and prioritised in science education reforms.

Fundamental Issues: Definitions and Premises

Two notions that should be challenged at the outset are that all metacognition is 'good' and that only one form or variety of metacognition is 'good'. These are dangerous premises because the social and educational environments within which students live and learn largely shape their metacognition. If we consider that metacognition should facilitate students' achievement of desired learning outcomes within their life contexts, then the metacognition that they develop and employ should be adaptive for those contexts. Therefore, we should consider students' metacognition as a consequence of the psychosocial environments within which they learn to reason rather than as some innate ability or process. What is adaptive for one environment might not necessarily be adaptive for another. Therefore, deficit or one-size-fits-all models of metacognition should be treated with some caution because it could be potentially dangerous, if not unreasonable, to assume that we will ever be able to construct a model of the ideal metacognitive student. This is because what is valued as effective thinking and thinking processes, and as appropriate metacognition, can vary across cultures as was noted by Gregory Thomas (2006).

Despite this caveat, it is known that metacognition is malleable to classroom interventions that are carefully implemented and that changing classroom environments to become more metacognitively oriented is a key to developing and enhancing students' metacognition. However, all efforts to develop and enhance students' metacognition take place within sociocultural contexts whose influence cannot be understated. Examples of successful interventions are considered later in this chapter. It is also known that there are student barriers that confront those who try to implement appropriate and well-reasoned interventions. However, these barriers often are not considered or are understated in most research into metacognition, especially in clinical and laboratory studies. One reason for this relates to the difficulty still experienced by scholars collectively in developing a precise and agreed-upon definition of metacognition.

A range of definitions continues to appear across the educational literature. Douglas Hacker (1998) and Gregory Thomas (2009) have suggested that the diversity of definitions might reflect different regional orientations and the past and present contexts of those working in this field. Further, as different schools of inquiry into metacognition have developed and as graduate students from different countries have increasingly come to study metacognition with established scholars, graduate students have taken back to their countries of origin the conceptual frameworks that framed their studies. The surge in the availability of literature regarding metacognition since the expansion of the information highway has brought metacognition to the attention of an increasing number of scholars worldwide. Therefore, it is no surprise that the various definitions of metacognition have spread as the technology has afforded increased information transfer, and as the notion of academic scholarship throughout the world has increasingly been constructed around research and publications that rely on existing literature as the source of theoretical frameworks. Finally, a further source of definitional unease arises from considering in the relationship between metacognition and self-regulated learning. Marcel Veenman et al. (2006) note that, according to some scholars, metacognition is subordinate to self-regulated learning, whilst others suggest that it has a superordinate relationship. Others contend that they are part of the same construct. Irrespective of the precise relationship, research related to both constructs is concerned with understanding and improving students' learning processes and outcomes and deserves attention. Interestingly, a review of the literature suggests that more research in science education has been conducted under the banner of metacognition than that of self-regulation.

Obviously there exists a multiplicity of opinions about exactly what metacognition is and this issue is unlikely to be easily or quickly resolved. However, amidst this uncertainty, there have emerged some understandings that seem to be more and increasingly shared than contested. These include acknowledging the more modern-day origins of the concept and the seminal work of John Flavell (1976, 1979) and Ann Brown (1978). Flavell (1976) considered metacognition to be 'one's knowledge concerning one's own cognitive process and products or anything related to them' (p. 232). Flavell (1979) further highlighted the importance of and distinction between metacognitive knowledge and metacognitive experiences. Metacognitive experiences are 'any conscious or affective enterprises that accompany or pertain to any intellectual enterprise'. These two constructs, metacognitive knowledge and experiences, are important for both methodological and pedagogical reasons discussed later in this chapter. Metacognitive knowledge encompasses 'knowledge or beliefs about what factors or variables act and interact in what ways to affect the course and outcome of cognitive exercises' and is not 'fundamentally different from other knowledge stored in long-term memory' (Flavell 1979, p. 907). Metacognitive knowledge can be further categorised as declarative, procedural or conditional. Recently, the nature of metacognitive knowledge has again been considered and finer categorisations of metacognitive knowledge have taken place. These categorisations relate specific metacognitive knowledge to the cognition with which it is aligned. For example Nelja Yürük (2005) refers to metaconceptual metacognitive knowledge as that metacognitive knowledge that relates directly to control, monitoring and evaluation of the cognitive processes that individuals employ to develop conceptual understanding. David Anderson et al. (2009) have identified metasocial metacognitive knowledge as an individual's metacognitive knowledge that relates to social interactions and relationships and how these influence cognition, learning processes and task behaviours. It is likely that further sub-categorisations of metacognitive knowledge using their aforementioned criterion will be forthcoming as researchers continue to consider more finely how elements of metacognitive knowledge relate to specific cognitive processes.

Whilst a uniform theory of metacognition is not yet agreed upon, there has been progress made in developing shared understanding. If we deconstruct existing definitions, it seems that their intent is often much the same. Further, elements such as metacognitive knowledge, regulation/control and monitoring/awareness are common between many of the definitions. Also emerging from the uncertainty as to what metacognition is, but not to the same extent as the previously mentioned definitional issue, is that metacognition refers to a conscious, reflected-upon and deliberate form of thinking that can be reported upon by individuals (e.g. Nelson 1996; Hennessey 2003). This perspective has significant implications for how research can be conducted in relation to metacognition and, consequently, is still the subject of some debate. Implications of this view are discussed further in the section that follows.

Methodological Considerations

Also highly contested in the field of metacognition studies is how best to collect data that provide confirming and disconfirming evidence for the existence, quality and extent of individuals' and groups' metacognition. As Richard White (1998) noted, because metacognition is a mental activity, 'its presence can be inferred, but not observed directly' (p. 1211). Therefore, because all measures of metacognition involve different degrees of inference, a source of contention is the extent to which different scholars agree to accept higher or lower degrees of inference in relation to data collected and its analysis and interpretation. Often, as pointed out by Anderson et al. (2009), researchers' approaches to investigating metacognition might be understood as influenced by a combination of the research paradigm with which they are aligned and the definition/s of metacognition that they employ. Two categories of research orientations in relation to metacognition emerged from the review of David Anderson and colleagues. The first of these, reflecting a *positivist-decontextualist* paradigm, is most often characterised by attempts to ignore or at least minimise the influence of important learner and/or context variables such as students' motives, the details and nature of the subject matter and learning environment under consideration, the cognitive and processing demands related to learning specific subject matter, and the effects of any intervention on the psychosocial nature of the learning environment itself. According to those subscribing to this orientation, these matters are considered at best as unwanted errors, a nuisance and of minimal interest. Hence, they tend to be largely, if not completely, ignored. Further, researchers aligned in such a way often use two or fewer methods within their research designs to reveal and/or understand metacognition and pay little attention to the context within which that data are collected. Such researchers are often more likely to have been trained in the traditions of psychology and rarely do their publications find their way into mainstream science education journals.

Researchers more aligned with the second of these orientations, which reflects a *relativist-contextualist* paradigm, regard contextual factors as highly relevant to metacognitive performance, development and enhancement. Their position is consistent with acknowledging the importance of the psychosocial constitution of students' learning environments in influencing students' metacognition. In other words, the ecology of the learning environment within which the learner is embedded is seen as vitally important to understanding the learner and the learner's metacognition. Studies reflecting this paradigm are typically interpretivist in nature and often employ qualitative or mixed methods. In science education, studies reflecting this paradigm have become most common in the literature. This in large part could be because of science educators continuing to be highly interested in the application of emerging theoretical perspectives from the field of psychology in understanding and attempting to enhance students' science learning. Further, those undertaking these studies are typically interested in providing vicarious experiences regarding the educational contexts within which the studies are undertaken. Examples of studies in science education reflecting this paradigm include Gregory Thomas and Campbell McRobbie (2001), Anat Zohar (2004), Jenni Case and Richard Gunstone (2006) and Anderson et al. (2009). Of course, as pointed out by John Dunlosky et al. (2009), this position can be problematic for those seeking to develop a generalised theory of metacognition and employ representative design principles but, to some extent, it attends to their contention that 'to obtain generalizability across environments, education researchers should begin by describing the environment to which they want their outcomes and conclusions to generalize'.

Irrespective of the paradigm employed within science education research into metacognition, there is a need to be aware of fundamental methodological considerations that extend beyond the aforementioned paradigm issue. Investigations of metacognition rely to a large extent on self-reports and, consequently, findings from studies relying on such measures have the potential to be queried. For example, verbal reports have been criticised on the grounds that (a) individuals might not be able to articulate the functioning of their own minds (Nisbett and Wilson 1977), (b) automated, recurrent processes can become routinised to the point that they are no longer distinguishable or reportable (Ericsson and Simon 1980), (c) interviewees can tell more than they know (Nisbett and Wilson 1977) and/or (d) interviewees could lack the verbal facility necessary to communicate their thoughts accurately (Cavanagh and Perlmutter 1982). Despite these potential shortcomings, verbal and self-reports have a long history in research into metacognition in cognitive psychology and science education, and therefore it is unlikely that their use will decline, at least in the near future. Douglas Hacker and John Dunlosky (2003) provided an overview of the three types of verbal reports (concurrent, retrospective and prospective) and they explored their relationships with three levels of verbalisations. They argued that Level 3 (concurrent verbalisation), in which students are asked to convey information 'that is currently in a verbal or nonverbal form and the additional thinking that is potentially contributing to that information' (p. 75), holds great potential for exploring and enhancing students' metacognition in relation to their problem solving. Their view coalesces with that of Marcel Veenman and colleagues (2006) who distinguish between off-line and online methods. Off-line methods relate to those presented either before or after task performance, whilst online methods are those conducted concurrently during task performance.

Whilst Veenman and colleagues (2006) acknowledge that all methods have pros and cons, they contend that (a) online methods appear to be more predictive of students' learning performances and (b) scores on questionnaires 'hardly correspond to actual behavioral measures during task performance' (p. 9). They argue further that there is a need for research with multi-method designs and, in so doing, echo White's (1998) view that more than one method or test is necessary to evaluate or measure metacognition and that 'good research on metacognition involves a battery of diverse but supportive measures' (p. 1211). Fortunately, exemplar science education studies by Thomas and McRobbie (2001), Zohar (2004), Peters (2007) and Anderson et al. (2009) employed multi-methods designs that are available for critique. Even though the findings from such studies might be debated in relation to the dependability and/or reliability of the corpus of methods employed, these studies are evidence of the substantial evolution in the methodologies used in investigating metacognition in science education.

Perhaps we need to consider seriously that conducting any research into metacognition (which involves seeking data from research subjects) is itself a form of intervention that has the potential to provide a metacognitive experience for the student. The degree of inference that we are prepared to accept is a key to how future research in metacognition will be undertaken and what value will be assigned to the findings of that research. The extent to which we agree on the transferability of findings from one context to another depends on the breadth and depth of the description of the research context that accompanies and frames those findings.

Intervention Considerations: How Best Can We Facilitate Metacognitive Development in Science Education?

As previously mentioned, a major focus of research in science education is the improvement of students' learning of science concepts. Alongside this focus is increased attention to developing students' learning processes and their metacognition as an integral priority. All attempts to develop and enhance students' metacognition hinge on researchers' and teachers' views on what metacognition is and what should be prioritised in science learning environments. Further, as will be explained, it is essential to acknowledge the role that students' existing metacognition, including their beliefs about the nature of learning and learning processes, plays in setting and influencing the context within which interventions occur. The position taken in this chapter is that the development and enhancement of students' metacognition should be a high priority for science teachers and science teacher educators. This section of the chapter explores how students' metacognition can be developed and enhanced and the conditions under which this might best be facilitated.

Developing Metacognition Using Metacognitive Activities

A review of the literature suggests that interventions that seek to develop and enhance students' metacognition can be categorised as one of two types. The first of these is characterised by a focus on the use of heuristics and learning strategies that have commonly become known as metacognitive activities. The more recent studies by Lisa Blank (2000), Bette Davidowitz and Marissa Rollnick (2003), Petros Georghiades (2006) and Lindsay Connor (2007) are studies that exemplify this approach. Notably, a major element of the Project for Enhancing Effective Learning (PEEL) (Baird and Mitchell 1986; Baird and Northfield 1992) was also developed around the principle that engaging students in activities that help them to consider subject material, its organisation and its manipulation in ways they had previously not considered can be metacognitive experiences that act as stimuli for the enhancement of students' metacognition. In other words, by changing the learning environment and providing new and alternative activities, it is possible to facilitate the development of students' metacognition.

This approach is appealing for a number of reasons. First, students are introduced to the new activities in the context of learning science concepts and skills. As Richard Gunstone (1994) has suggested, it is important to embed training in metacognition within the real-world demands of students' science learning. After all, because students come to science classes to learn science, embedding metacognitive training within everyday science tuition increases the chance that students will be motivated to attend to the activities that are suggested to them, thereby also increasing the chances that they will reflect on the use of these activities for learning science. Second, as suggested by Marcel Veenman and colleagues (2006) 'the vast majority of students spontaneously pick up metacognitive knowledge to a certain extent from their parents, their peers, and especially their teachers' (p. 9). Therefore, we might reasonably expect that students would spontaneously develop metacognitive knowledge to some extent from the embedding of metacognitive activities within everyday classroom instruction, and indeed such development is reported in these studies. Petros Georghiades (2004) has argued further that this way of developing metacognition is appropriate because metacognitive skills require awakening via the use of appropriate stimuli and because metacognition 'is not something to be "taught" to the learner in an "outside-in" process, but rather it is a skill that can be helped to develop in an "inside-out" manner' (p. 369).

Despite support for this approach and its obvious appeal to the majority of science education researchers investigating metacognition, a number of issues can be raised in relation to its appropriateness for developing metacognition. The question that might be asked is: 'If there is no conscious reflection by the individual in relation to the new demands of the learning environment for the value of his or her learning, then has metacognition been engaged and/or developed?' As previously noted, developing and enhancing students' metacognition requires that they undertake conscious reflection regarding the efficacy of the learning processes, activities and strategies that they employ or are asked to employ. Previously in this chapter the notion of metacognition was confined to those thinking processes that individuals consciously monitor, control and are aware of. Once again the distinction between metacognition and cognition needs to be acknowledged and considered in relation to this 'metacognitive activities' approach.

It could be argued that, because the use of heuristics (such as concept maps, reading charts, Venn diagrams, theory-evidence coordination rubrics, inquiry flowcharts and any other means of assisting students to develop and represent their understandings of science and its processes) target cognitive processes predominantly, it is only through conscious reflection on the use of these heuristics and frameworks that metacognition develops. Therefore, the use of this approach should be coupled with opportunities for students to reflect consciously on the metacognitive experience that accompanies their use of the strategies/heuristics. Unfortunately, the evidence that this happens frequently enough in science learning environments is not strong. Because the priority within those environments relates to the learning of the science itself, the development and enhancement of students' metacognition is seen as a secondary objective at best. This is not surprising given the strong subject-oriented background of most science teachers and their strong belief in the importance of developing students' conceptual science knowledge, scientific literacy and understanding and use of methods associated with scientific inquiry. Teacher education courses and professional development activities should make it obvious to prospective and practising teachers that there is a need for them to set aside time so that students can reflect on their learning processes, how they might be improved and what it might mean to be an effective science learner. If this does not occur, then the true potential of this approach to developing metacognition is never likely to be fulfilled.

Developing Metacognition Through Metacognitive Conflict

An alternative to the metacognitive strategies approach is reported by Thomas (Thomas 1999; Thomas and McRobbie 2001). This approach is consistent with the suggestions of Greg Schraw (1998) that it is appropriate to consider metacognitive knowledge as multidimensional, domain-general and teachable. This type of approach involves engaging and challenging students in considering what learning (science) is. Within the context of an upper secondary high school chemistry class, Thomas and McRobbie (2001) challenged students through the use of the metaphor 'learning is constructing' to consider what learning chemistry might 'look' like and therefore what mental processes might be engaged to facilitate their chemistry learning with increased understanding. The decision to employ metaphor was based on the notion that, consistent with constructivist epistemology, new ideas in any domain are constructed via ideas that one already possesses, language is a key element that mediates the thinking processes of students, and learners subscribe to their conceptual structures because they are viable for them individually, not because they are absolute. By working backwards from what students already believed effective chemistry and science learning to be, and also by challenging students to consider alternative and previously-unconsidered conceptions of chemistry and science learning, Thomas and McRobbie initiated metacognitive conflict in students' minds.

Metacognitive conflict can be considered analogous to cognitive conflict, which is a notion familiar to many science educators. It involves placing students in situations in which their existing conceptual frameworks related to science concepts are challenged and in which they have to consider new conceptions of science phenomena with reference to those already existing frameworks. Indeed, conceptual change and how to facilitate it in science classrooms have been the major foci of science education research over the past three decades because findings regarding students' alternative conceptions began to appear in the literature. If this framework for conceptual change is to be transposed onto students' conceptions and beliefs regarding what learning (science) is, how it can best be undertaken and how it can best be evaluated, then it follows that the same conditions are required to facilitate conceptual change in science concepts and students' metacognition (especially their metacognitive knowledge that consists of declarative, procedural and conditional elements). Metacognitive experiences therefore become those conscious experiences occurring when students are asked to consider the intelligibility and plausibility of conceptions of learning science, are encouraged to employ processes consistent with those new conceptions and then provided with opportunities to consider the fruitfulness of adopting new conceptions and associated processes/strategies for their ongoing science learning. Obviously, those students who decide to adopt such conceptions and related strategies/processes are making a conscious choice to do so (Thomas, 1999).

It is necessary for teachers adopting this approach to (a) be highly metacognitive, (b) have a thorough understanding of the nature and structure of the subject area and material that they are teaching and that is to be learned, (c) be able to converse with students about the cognitive processes and strategies that can be employed to bring about the conceptual understanding of the subject matter and (d) be able to model those cognitive processes and strategies for students to emulate (i.e. to act as cognitive and metacognitive role models). It is also necessary for them to be able to develop classroom environments that are metacognitively oriented as described by Gregory Thomas (2003). Metacognitively oriented science classrooms are characterised by: appropriate levels of metacognitive demands on students; student-student discourse and student-teacher discourse regarding the learning that occurs and the cognitive processes and activities that enable successful learning; students being able to query the activities in which they are asked to engage and having adequate levels of control and choice in relation to those activities; students being encouraged and supported by the teacher to improve how they learn science; and high levels of emotional support and trust between the teacher and students.

These conditions are often not found to coexist in many science classrooms, with most science learning environments continuing to be characterised by didactic teacher exposition, the teacher being an authority figure, and little discussion of possible alternative environments to those already existing and themselves largely determined by teachers, and existing social and systemic norms and expectations. This perspective should not come as too much of a surprise to those who are familiar with the day-to-day operations of science classrooms, teacher pedagogies, the enactment of mandated curricula, and the insidious creep of standardised testing into educational thought and practice. Further, as noted by Petros Georghiades (2004, p. 379), 'the notion of metacognition is largely unknown to the average science teacher'. This presents a highly problematic situation if students' metacognition is to receive increased attention that it deserves. Georghiades goes on to suggest that even those who are familiar with the concept of metacognition lack the resources or authority to facilitate metacognition in their teaching. It could reasonably be argued that time is the only resource that might not easily be available to teachers who adopt this second approach. It could also be argued that teacher education programmes should graduate science teachers who possess the characteristics identified above. As explained in the next section, more attention should be given to understanding, developing and enhancing teacher metacognition in science education.

Emerging Areas in the Study of Metacognition in Science Education

Two areas particularly require further research into metacognition in science education: metacognition in informal science learning environments; and science teacher metacognition. These areas also have potential for improving students' metacognition and learning and for increasing collaboration between scholars and science educators from across disciplines and locations. They are discussed briefly below.

Metacognition in Informal Science Learning Environments

David Anderson et al. (2003) noted that studies that focus on students' metacognition were absent from the research on learning on students' science learning environments. They proposed that increased understanding in this area had the potential to enhance students' learning and contribute to educational research in informal settings. The Metacognition and Reflective Inquiry (MRI) Collaborative, a multi-year, multi-case, research study that investigated the elusive nature and character of high school students' metacognition across formal and informal science learning contexts, followed from these realisations and involved a series of interpretive, layered hermeneutic case studies conducted over three years. Studies emanating from the MRI (e.g. Anderson and Nashon 2007) have shed light on students' metacognition in informal science learning settings, but further research is necessary to add to these emergent findings. Given the increased attention being given to science learning in informal contexts, it is anticipated that this line of metacognition research will continue for some time.

Science Teacher Metacognition

As previously noted, metacognition development requires that science teachers are themselves metacognitive and able to communicate with students regarding the benefits of particular ways of thinking about learning science and how it might best be facilitated. However, the extent to which science teachers are themselves metacognitive is not altogether clear. Anat Zohar (1999, 2004) highlighted the importance of teachers' metacognitive knowledge and the difficulty that teachers have in changing from traditional instruction to that which focuses on the teaching of higher-order thinking. She also noted the difficulty that teachers have in articulating their thinking patterns during problem solving and concluded that adequate and appropriate teacher metacognitive declarative knowledge is essential for the teaching of higher-order thinking. In a similar vein, Mary Leou et al. (2006) found that challenging teachers regarding their own metacognitive knowledge in relation to higher-order thinking processes is important in facilitating transfer of that knowledge into their own pedagogical practices. More research on teacher metacognition might enable increased effectiveness of professional development activities that aim to help teachers to develop higher-order thinking and metacognition in science learning environments.

Looking to the Future: Revisiting White's 'Decisions and Problems'

Richard White (1998) highlighted the need, in research on metacognition, to study subject-rich contexts, for studies to be long term, and to attend to scale, focus and variations within extended studies. He also drew attention to issues in recording and describing interventions and in measuring and reporting the effects of interventions. Whereas this chapter has provided evidence that there have been advances within and beyond science education in the study of metacognition and how to facilitate its development and enhancement, the concerns raised by White persist and still deserve earnest concerted attention. It should be added that seemingly ever-increasing ethical requirements for conducting research, especially in school contexts within which students that have not yet reached the age at which they can give informed consent, also have the potential to influence the type and length of research conducted, the questions asked, the means of data collection, and the nature and details of the interventions attempted.

The eventual aim of studying and facilitating metacognition in science education environments is to lead to improved individuals' learning within and beyond science education. Dialogue regarding the issues facing the study of metacognition by those working in the field is vibrant and ongoing. As stated previously, the aim of this chapter has been to stimulate ongoing discussion and debate within the science education community by addressing a range of perspectives on metacognition, some of which are more contested than others. This was chosen in preference to taking a conservative, middle-ground approach to the issues. It is only through such dialogue and willingness to engage in debate that we can continue moving forward in the study of metacognition in the field of science education.

Chapter 12
Learning From and Through Representations in Science

Bruce Waldrip and Vaughan Prain

There is now broad agreement that the representational tools through which we think influence 'how we think and what we can think about' (Eisner 1997, p. 349). In learning to think and act scientifically, students therefore need to know how to integrate the multimodal discourses of science for which different modes serve different purposes in reasoning, recording scientific inquiry and producing knowledge. Mathematical, verbal and graphic modes are used individually and in coordinated ways to represent knowledge claims in this subject, with more recent technology-mediated representations of science consistent with, rather than a deviation from, this evolution of science as a discipline. In this chapter, we review current approaches to researching how students might be supported to acquire this disciplinary literacy, identify ongoing challenges to these approaches and discuss future agendas for this research.

Research Agendas About Learning Science Literacy

Over the last 15 years, science education research into student acquisition of this disciplinary literacy – variously defined as 'metarepresentational competence' (diSessa 2004, p. 293), as the metacognitive skill of 'visualization' (Gilbert 2005, p. 9), or more broadly as the capacity to construct appropriate meanings from and through science representations – has had two major foci. One perspective has entailed researcher analysis and construction of representations as a basis for investigating factors affecting

student learning from interactions with these representations (see Ainsworth 1999, 2006, 2008a, b, c; Gee 2004; Gilbert et al. 2008; Ginns 2005; Jewitt 2007; Jewitt et al. 2001; Rahm 2004; Unsworth 2001, 2006; Van der Meij and de Jong 2006). This research has often been driven by the perceived affordances of new multimedia for enhancing student learning. The second perspective has focused predominantly on student-generated representations, incorporating both new and old technologies, as a strategy to promote science literacy (Cox 1999; Greeno and Hall 1997; Hand 2007; Hayes et al. 1994; Prain 2006, 2009; Prain and Hand 1996; Ritchie et al. 2008; diSessa 2004; Treagust 1995; Tytler et al. 2006; Waldrip and Prain 2006).

Both perspectives have been guided by recent research in cognitive science, semiotics and sociocultural theories, and have aimed to identify the nature and complexity of learning tasks in this domain, as well as contextual factors affecting this learning, including classroom teaching and learning strategies for different cohorts of learners. Both perspectives are necessarily symbiotic, in that students clearly need to know how to interpret as well as construct representations in this domain to achieve science literacy, as noted by Stephen Norris and Linda Phillips (2003). However, researchers have tended to focus predominantly on only one area, perhaps partly because of the complexity and novelty of various emerging representational options, given continuous new developments in multimedia, but also because of contrasting traditions and assumptions within and across these research agendas regarding how this literacy learning is best facilitated.

Learning Through Interpreting Representations

Within this general orientation, and drawing mainly on cognitive science perspectives, Shaaron Ainsworth (1999) asserted that, in order to learn from engaging with multiple representations of science concepts, students need to be able to (a) understand the codes and signifiers in a representation, (b) understand the links between the representation and the target concept or process, (c) translate key features of the concept across representations and (d) know which features to emphasise in designing their own representations. In this context, 'translation' means being able to recognise conceptual links between representations or invariant conceptual features across representations. These learning processes are also consistent with Allan Paivio's (1986) theoretical account of the function and value of multiple coding in learning.

In focusing on the number, type, style and sequence of representations to support student learning, researchers predominantly from cognitive science perspectives have identified a range of factors impacting on student learning. These include the need for effective design in representations, with clear links between words and images and excluding extraneous material (Kozma 2003; Mayer 2003; Moreno and Valdez 2005; Schnotz and Lowe 2003). Robert Kozma (2003, p. 226) found that 'symbolic environments' supplemented with classroom laboratory activities can effectively support science learning. Other researchers have identified the crucial role of student background knowledge in effective learning through multimedia environments (Ainsworth 2008c; Cook 2006; Schnotz and Bannert 2003; Seufert

2003), as well as the value of student self-explanation about representations (Ainsworth and Burcham 2007). In other words, students need to reflect on the clarity and adequacy of the meanings that they are deriving from engagement with these representations if effective conceptual understandings are to be achieved. Whilst some of this research has focused on clinical trials of representational options outside mainstream classroom contexts, other researchers such as Carey Jewitt et al. (2001), Jewitt (2007) and Len Unsworth (2001) drew on semiotic frameworks to focus on diverse classroom practices to facilitate student interpretation of scientific representations, including technical vocabulary, diagrams, tables, flowcharts and graphs in both traditional and web-based multimedia texts. Researchers have also investigated the extent to which dynamic representations, such as spoken voice, animation and dynamic graphs, enhance or impede interpretation of represented information when contrasted with static representations (Ainsworth 2008c; Lowe 2004; Lowe and Schnotz 2008). Shaaron Ainsworth (2008c) noted that student viewing of animations often failed to enhance metacognitive understanding, and that their transient nature also posed problems for student perceptual processing and memory.

Another area of focus is the extent to which interpretive constraint in a representation, such as graphic simplicity, helps or hinders student understanding, and under what conditions (Ainsworth 2008a, b, c; Eilam and Poyas 2008). Ainsworth (2008c) claimed that too often students' simultaneous exposure to multiple representations make learning more difficult, and that students needed peer and teacher support in an effectively structured learning environment. In evaluating multimedia environments, Ainsworth (2008b) noted that, whilst experimental designs are useful for analysing some effects, a more extended focus on the processes through which students coordinate representations could yield important insights into an effective environment. Other researchers have investigated the challenges for students in developing conceptual understanding across microlevel and macrolevel representations of the same topic (Pilot et al. 2009).

As noted by Ainsworth (2008a), recent research on student interpretation of multiple representations has revealed both the complexity of factors affecting this learning and their interdependence. For example, increasing the options in relation to interactivity between a student and an expert representation might increase motivation (for some learners), but also entail increased cognitive demands. Ainsworth (2008a, p. 62) also pointed out that, whilst the dominant cognitive science orientation to this research has identified potential cognitive challenges and learning gains, this perspective has tended to ignore 'expressive, perceptual, affective, strategic, metacognitive and rhetorical' aspects of students' responses and understandings, which are all critical factors in how students engage with representations, and learn from this interaction. There is also a need for more research focus on the influence of particular teacher practices, classroom contexts and routines on different learners. To address this complexity of influences, Ainsworth (2008a) advocated the value of multimethod approaches and multifocus research that identifies how the interplay of diverse factors affects different student cohorts. Rolf Ploetzner and colleagues (2008), Michelle Cook (2006), Jannet Van Drie and colleagues (2005) and Erica De Vries (2005), and many others, acknowledge that students' interactions with multiple representations require considerable supplementary support to ensure enhanced learning.

In summary, research on student learning from engagement with, and interpretation of, representations remains in an emergent phase because of (a) the rate of change in representational options in new technologies for conducting and reporting scientific activity and for designing teaching and learning multimedia resources in science, (b) the growing recognition of the considerable complexity of factors that influence student understanding, engagement and learning in this field and (c) the increased acceptance of the need for multimethod research that includes analysis of the effects of different classroom and out-of-school settings and practices on student learning. There is growing acceptance that this research requires a matching conceptual complexity in research design and focus in order to address the intricate ecology of learning opportunities and desirable learning outcomes in this field.

Learning Through Student-Generated Representation

Research on this learning pathway has received less attention than analysis of students' responses to authorised representations, perhaps because it does not fit easily into traditional assumptions about effective student induction into disciplinary norms through exposure to authorised representations, and because it makes considerable demands on teachers' conceptual science knowledge and teaching skills in building bridges between students' representations and scientific discourse. However, there is a range of theoretical justifications for this approach as well as a growing body of evidence to support the value of student-generated representations in promoting learning.

Rationale for This Approach

This approach has been justified in terms of theories drawn from semiotics, sociocultural theories of science as a practice of knowledge production, recent research in cognitive science, and pedagogical principles about conditions for effective learning. From a semiotic perspective, students' diverse interpretive capacities can be understood as representational competence (diSessa 2004), and as crucial to science learning in primary and secondary school. As noted by Jay Lemke (2004), drawing on Charles Peirce (1931–1958), representational competence is about knowing how to interpret and construct links between an object, its representation and its meaning. A representation becomes a sign when it signifies something (a key idea or explanation) about the object (or referent) to someone (the learner). Meaning-making practices in school subjects, including science, can be understood in terms of this triadic account of the necessary components of meaning making. In this model, when applied to science, distinctions can be made between a representation in a sign (e.g. arrows in diagrammatic accounts of force), the interpretation or sense made of this sign (the scientific idea of force) and its referent (the phenomena to which both the interpretation and signifier refer, such as the specific operation of force on objects in the world). This implies that, for learners to understand or explain concepts in science, they must use their current cognitive and representational resources to learn new concepts at the same time as when they are learning how to represent them. In this way, student representations and their revision can function variously as exploratory tools for initial thinking, scaffolding for building understanding, and as records of new thinking and reasoning, depending on the purpose or purposes of the representation. Michael Ford (2008) argued that, in this approach, consistent with science as a practice of knowledge production through claim and counterclaim, a key role of the teacher is to build and support communities that explore new knowledge claims through representation.

Recent research in cognitive science also provides some support for a focus on student-generated representation as a strategy for learning the literacies of science (Barsalou 1999; Klein 2006; Schwartz and Heiser 2006). This research provides a rich picture of diverse factors that influence effective learning generally, and science in particular, with conceptual knowledge being seen more as implicit, perceptual, concrete, and variable across contexts, rather than as primarily propositional, abstract and decontextualised (Barsalou 1999). This research recognises the fundamental role in learning of context, perception, motor actions, identity, feelings, embodiment, analogy, metaphor and pattern completion. This implies that students are more likely to learn science concepts effectively when they can coordinate perception and actions, such as when attempting to represent teacher-guided explanations or claims about a topic. Schwartz and Heiser (2006) noted that students can visualise and imagine situations and predict outcomes accurately even if they cannot verbalise, because perceptual resources and contextual clues provide the bases for this thinking. Perry Klein (2006) and Russell Tytler et al. (2006) and others asserted that students are more likely to remember appropriate meanings for science experiences when they can also connect them to their personal histories, to meaningful everyday contexts, to representational challenges and to an identity that includes acting scientifically. The implications of this research for representational work are that students need to be supported to (a) map perceptual links between science activities and their 2D and 3D representation and (b) connect representations with meaningful everyday experiences and interests.

Apart from these theoretical justifications, there are strong pedagogical reasons for giving students opportunities to construct their own representations of developing understandings of science topics. Ronald Giere and Barton Moffatt (2003) make this point through a comparison with learning long-multiplication in mathematics. They note that many people learn to multiply large numbers, a task that would be difficult to do mentally, by using a representational framework of written numbers, symbols and manipulations:

$$
\begin{array}{r}
\hline
456 \\
\times\, 789 \\
\hline
4{,}104 \\
36{,}480 \\
319{,}200 \\
\hline
359{,}784 \\
\hline
\end{array}
$$

This representation functions as a thinking tool or scaffold during the manipulation, and then becomes an artefact of this thinking, shifting from a 'live' representation during the process of constructing an answer to a 'dormant' representation, unless used for more re-interpretive thinking. A mathematics teacher would not consider students 'mathematically competent' in long multiplication if they had never practised this computation and, instead, had just observed the constructed representation and learned to recall it by rote. For Ronald Giere and Barton Moffatt (2003), the same idea applies in science learning, for which students should learn how to use representations as thinking tools for predicting, understanding and making claims, rather than for memorising 'correct' representations for knowledge display. Supporting this view, Andrea diSessa (2004, p. 299) asserted that students bring to learning in science some understanding of the need for 'conciseness, completeness and precision' in representing ideas, and that 'good students manage to learn scientific representations in school partly because they can almost reinvent them for themselves'. This implies that students are likely to learn more effectively in science when they see the aptness of representational conventions used in this subject, and also when they recognise the persuasive nature of particular scientific explanations.

Classroom Research Based on this Approach

Drawing on these different theoretical orientations, various researchers have investigated the learning potential of student-generated representations (Cox 1999; Danish and Enyedy 2006; Greeno and Hall 1997; Hand 2007; Hayes et al. 1994; Prain 2009; Prain and Hand 1996; Ritchie et al. 2008; Treagust 1995; Tytler et al. 2006; Waldrip et al. 2006). This approach involves students in using a more diversified range of representations, both formal and informal, to engage with the practices and intent of scientific investigation. The approach assumes that mobilising students' current representational capacities is crucial to achieving effective engagement with, and learning of, the literacies of science. In advocating text diversification, these researchers accept that students need to demonstrate a capacity to use accurately the current vocabulary and multimodal representations of science discourse. However, they argue that there are motivational gains and enhanced learning opportunities when students engage in a cycle of planning and guided revision of different text types, which involves a strong emphasis on clarification of claims in science and their justification for both self and others. James Greeno and Roger Hall (1997) pointed out that, if students only participate in teacher-designed activities, then various learning opportunities are constrained. They argued that student construction and interpretation of representations enabled students to see these representations as important tools for constructing and communicating understanding that is adaptable to the purpose at hand, and that students could be engaged in discussing the properties of representations, including their strengths and limitations.

Hand (2007) reported strong learning gains for students when they constructed a modified laboratory report for which they were expected to make and justify claims.

Dorothy Hayes et al. (1994) suggested that student-constructed drawings had the potential to develop skills, knowledge and understanding, and that drawing was an underutilised tool in learning and recording thinking, which is in agreement with Margaret Brooks (2005) and Jane Dove et al. (1999). According to Lilian Katz (1998) and Paula Goolkasian and Paul Foos (2002), drawing helped students' reflection about their learning, observations, activity and thinking, as well as assisting in conceptual development. In investigating Grade 4 students' drawing of optics, Yongcheng Gan and Marlene Scardamalia (2008) claimed that student-generated drawings promoted deeper understanding of content, improvement of ideas and conceptual change, problem-solving and theory-building and modelling. Stephen Ritchie and colleagues (2008) reported high levels of students' interest when they wrote an extended ecological mystery story that combined an illustrated narrative with factual knowledge relevant to the story. The researchers also asserted that student learning was enhanced through this combination of extended field work and a team-authored narrative supported by strategic teacher guidance. Other researchers, such as Janice Gobert and John Clement (1999) and Peggy van Meter (2001), have claimed that some modes can be more supportive of student learning than others, noting that students can 'draw to learn' effectively when the visual media affords 'specific advantages over the textual media' (Gobert and Clement 1999, pp. 49–50). According to Andrea diSessa (2004, p. 298), 'students start with a rich pool of representational competence' based on their past experiences with interpreting visual texts, and are 'strikingly good at … designing representations'. He considered therefore that 'rich and engaging classroom activities are relatively easy to foster' (p. 298) and are highly motivating for learners.

These studies indicated that representations in science serve many different purposes. Whilst these purposes are conventional and functional for producing knowledge in the science community, they can also serve learning purposes for students in the science classroom. In this way, representations can be used as tools for initial, speculative thinking, as in constructing a diagram or model to imagine how a process might work, or find a possible explanation, or see if a verbal explanation makes sense when re-represented in 2D or 3D. They can be used to: record precise observations; identify the distribution of types; classify examples into categories; identify and explain key causes; integrate different ideas; contextualise the part to the whole; identify the inner workings of a machine or object; show key parts; show a sequence or process in time; identify the effects of process, predict outcomes, sort information, clarify ideas, show how a system works, organise findings; explain how parts of a topic are connected and work out reasons for various effects.

These studies have also raised questions about how teachers and students might assess the adequacy of a representation. For Andrea diSessa (2004), this means that students need to understand that a single representation cannot cover all possible purposes or all aspects of a topic. Therefore, they need to learn how to select appropriate representations for addressing particular needs, and be able to judge their effectiveness in achieving particular purposes. He claimed that junior secondary students intuitively have an understanding of the attributes of a good scientific representation, recognising that it must be clear and unambiguous, give minimal but sufficient information and be comprehensive for its purpose. By implication, when students are not clear about these criteria or their rationale of producing clear communication, then these aspects need to be taught explicitly.

Researchers have also sought to identify principles to guide this teaching and learning approach (Carolan et al. 2008; diSessa 2004; Greeno and Hall 1997; Hackling and Prain 2005; Prain 2006; Tytler et al. 2006). Consistent with a conceptual focus in science generally, in this approach, teachers need to be clear at the topic's planning stage about the key concepts or big ideas that students are intended to learn. This focus provides the basis for the teacher to consider which sequence and range of representations, including both teacher- and student-generated ones, are likely to engage learners, develop their understanding, and count as evidence of learning at the topic's end. This approach to science learning is evident in a national professional learning programme, *Primary Connections* (Australian Academy of Science 2007), in which key concepts are emphasised at the start of units of work, and students are expected to develop understanding of these concepts through engaging in guided investigations related to a sequence of representational and re-representational work. Research on the learning outcomes of this programme (Hackling and Prain 2005) revealed that students were more motivated than when using past approaches, and that learning performance was also enhanced. This approach emphasises teacher and student negotiation of the meanings evident in verbal, visual, mathematical and gestural representations in science, with students benefiting from multiple opportunities to explore, engage, elaborate and re-represent ongoing understandings in the same and different representations. However, students still need strong teacher guidance to develop their own representations into the authorised ones of the science community.

In summary, this approach made increased demands on teachers' knowledge base and their teaching and assessment skills, but led to enhanced learning outcomes when implemented effectively. Current research has identified the need for ongoing identification of representational challenges posed by different topics, for further analysis of classroom interactions during which students design and interpret the represented claims that they are making, and for the need for professional learning support for teachers to engage effectively with this approach.

Future Research Agendas

Researchers in both areas acknowledge the complexity of cognitive and other factors that impact upon science literacy learning, whether the focus is predominantly on students interpreting or constructing representations. As suggested in this chapter, there is a need to develop and integrate diverse research methods, to draw on various theoretical frameworks including semiotics, cognitive science, sociocultural perspectives, pedagogical studies and neuroscience and, to address cognitive, strategic and metacognitive dimensions of this learning, as well as expressive, aesthetic, rhetorical and affective aspects of students' responses. These different foci of research will need to be embedded in analysis of the impact of different teaching and learning routines in classrooms and other learning environments. This is not to argue for an overarching synthesis of approaches or a set of universal principles, but rather to suggest that research in this area needs to proceed through both tightly focused studies of representational cases around specific science topics. It is important to recognise the need for diversity of approaches, as well as cross-method, multiframed investigations that establish new insights through research dialogues and build transdisciplinary understanding to guide science literacy learning.

Chapter 13
The Role of Thought Experiments in Science and Science Learning

A. Lynn Stephens and John J. Clement

In this chapter, we review selected studies of thought experiments used by both experts and students and attempt to develop some useful definitions and conceptual distinctions. We then apply these in an analysis of a classroom episode as an example of the roles thought experiments can play in productive whole class discussions. We are interested in this area because thought experiments are one example of the kinds of creative reasoning of which experts and students appear to be capable under the right conditions.

Review of Selected Studies on Thought Experiments of Science Experts

Certain writers in philosophy of science have been intrigued with thought experiments (TEs) for some time, because if effective, they seem to contradict the spirit of empiricism that dominated the philosophy of science for much of the twentieth century. The idea of obtaining new knowledge from internal mental manipulations alone does not sit comfortably within an empiricist framework.

Authors such as J.R. Brown (1991) and Roy Sorensen (1992) have compiled collections of TEs that were important in the history of science. By now it is widely recognised that at least some TEs in the history of science have been noticeably, if not spectacularly, germane to a scientist's investigation. Famous examples include those used in the Einstein–Bohr debates on quantum mechanics. Nancy Nersessian (1992) has analysed historical records of Maxwell's breakthroughs in electromagnetic

field theory, finding that a series of thought experiments involving gears and then fluid vortices played a role in his theory formulation.

TEs also have been considered somewhat enigmatic and exotic. The reason for this is captured in what John Clement (2002, p. 32) called the Fundamental Paradox of Thought Experiments, namely, 'How can findings that carry conviction result from a new experiment conducted entirely within the head?' The idea of an experiment (involving observation) being conducted in the head (without observation) appears self-contradictory.

Purposes for Thought Experiments

One line of investigation is to examine the purpose served by thought experiments. Thomas Kuhn (1977) argued that the purpose of a TE is to disconfirm a theory by disclosing a conflict between ones existing concepts and nature. Undoubtedly, TEs are probably most impressive when they act to disconfirm an established theory in science; they then actually seem to be doing something as powerful as a critical experiment or anomaly can do.

On the other hand, Brown (1991) identified several purposes for TEs including constructive as well as destructive (conflict-generating) purposes. He also theorised that a few special TEs could serve both functions. Similarly, Nersessian's (1992) analysis of Maxwell's work hypothesised that a TE could expose conflicts in an existing theory but also point to new constraints that help guide positive modifications of the theory, thus playing both a destructive and constructive role. Interestingly, Athanasios Velentzas et al. (2005) found that textbooks in relativity and quantum mechanics use constructive but not destructive TEs; they feel that the inclusion of destructive TEs could increase student interest.

Clinical Studies

Evidence in historical and philosophical studies has been indirect because these studies have not been able to examine real-time evidence for purposes and mechanisms of TEs as they are being used. Clement (2008, 2009) attempted to collect such evidence by interviewing experts thinking aloud about unfamiliar explanation problems. Think-aloud transcripts are not perfect or complete records of thinking but they do provide considerably more detail than historical papers. He found cyclical sequences of model construction and evaluation, and different TEs being used for model generation (constructive) and model evaluation purposes. He also found that within the evaluation category, TEs could be either disconfirmatory or confirmatory. These studies also confirmed that TEs could be used as a part of the actual thinking process, not just pedagogically.

One problem used was the Spring Problem, which asks whether a first spring would stretch more than a second spring that is identical except with coils twice as

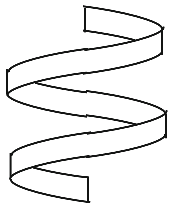

Fig. 13.1 Band spring

wide in diameter. In the simplest possible example of a TE, one subject simply tried to imagine which spring would be harder to pull, saying:

> Episode 1: I'm **going to try to visualize it** to imagine what would happen – my guess would be that it [wider spring] would stretch more – this is a kind of **kinesthetic sense that somehow a bigger spring is looser**….

This is certainly a more primitive experiment than the famous TEs in history of science, and yet it has the basic qualities of imagining the results of an experiment in the head. (The bold type in these episodes denotes imagery indicators, to be discussed later.)

A more creative experiment was generated when this subject engaged the question of whether the deformation in the spring wire is due primarily to bending or to twisting of the wire as the spring stretches. He generated the case of a spring made of a vertically oriented band of material, depicted in Fig. 13.1. The reader might imagine the thin metal strip unwound from a coffee can, reshaped to make a spring 8 cm or so in diameter:

> Episode 2: How about a spring made of something that can't bend. And if you showed that it still behaved like a spring you would be showing that the bend isn't the most important part – **How could I imagine** such a structure? – I'm thinking of something that's made of a band – **we're trying to imagine configurations** that wouldn't bend. Since its cross section is like that [see Fig. 13.1] – it can't bend in the up-down **[indicates up/down directions with hands]** direction like that because it's too tall. But it can easily twist **[gestures as if twisting an object]**.

He inferred that such a spring can still stretch even though it cannot bend, arguing against the theory of bending as necessary for stretching. Here it is more clear that there is a design process leading to a contradiction.

Definitions

Problem in the literature is that there is no consensus on a definition of a TE. Sorensen (1992, p. 205) defines a thought experiment as '(A)n experiment that purports to achieve its aim without the benefit of execution'. However, this shifts much of the burden to the term 'experiment'. Experiment is defined as 'a procedure for answering or raising a question about the relationship between variables by varying one (or more) of them and tracking any response by the other' (p. 186). But as we shall see, some TEs appear to be less formal than a procedure and some appear to envision a single event without systematic variation; alternative definitions may be worth exploring.

The range of TEs in the above episodes – from simple to complex – motivated our formulation of a broad definition and a narrow definition for TEs (Clement 2008), as follows:

> Broad definition: Performing an (untested) thought experiment (in the broad sense) is the act of considering an untested, concrete system (the 'experiment' or case) and attempting to predict aspects of its behavior. Those aspects of behavior must be new and untested in the sense that the subject has not observed them before nor been informed about them.

The word 'untested' is used to rule out cases where the subject simply replays a previously observed event. Still, the above definition is intentionally quite broad and encompasses cases as simple as in the first episode above.

> Narrow definition: Performing an evaluative Gedanken experiment is the act of considering an untested, concrete system designed to help evaluate a scientific concept, model, or theory – and attempting to predict aspects of the system's behavior.

The second band spring episode above had these characteristics since it was designed to test the theory that bending is the source of stretching in springs. In the first episode, the subject was trying to make a prediction only for the specific system and not to test a broader theory.

Possible advantages of these definitions are that they are more inclusive by not depending crucially on the subject having proposed a formal experiment; they are somewhat more operational (possible to agree on recognising) in emphasising a process rather than a product; and the first one fits the Fundamental Paradox better by being somewhat broader than the set of carefully designed scientific Gedanken experiments.

Mechanisms: What Processes Do Scientists Use to Run TEs?

It is difficult to analyse the mental processes that allow a scientist to generate and run a TE during an investigation by using historical data because the original thought process can easily be buried under many changes and refinements the author carries out before publishing a thought experiment. Also, for many TEs it is hard to know whether they were originally part of a discovery process or created after the investigation to convince others. Nevertheless, working from the thought experiments themselves, a number of authors have hypothesised at least a rough description of processes that may have been involved. Debates have emerged amongst disparate theories ranging from those defending an empiricist view to those proposing a rationalist alternative.

Several intermediate positions have been postulated. Miriam Reiner and John Gilbert (2000) ask what is the source of conviction in TEs. They point out, for instance, that Poisson conducted a TE that led him to make a professionally high-risk claim – without having performed the experiment. They theorise that the intellectual power of a TE is in the integration of conceptuo-logical beliefs, mental visual imagery and bodily knowledge, and suggest that the last two bring tacit knowledge to bear on the problem. Nersessian (1992) hypothesised that TEs utilise simulative mental models and that The constructed situation inherits empirical force by being abstracted from both our experiences and activities in, and our knowledge, conceptualizations, and assumptions of, the world (p. 297). Likewise, Reiner (1998) posited that one necessary component for thought experimentation is construction of mental imagery in order to build the hypothetical world of a TE.

Clement (1994) attempted to speak to mechanism questions on the basis of real-time data by looking for imagery indicators in videotapes of experts. The bold type in the two episodes above denotes several instances of imagery indicators. In order of appearance, they are: Episode 1 – announces intent to form image, kinesthetic imagery report; Episode 2 – announces intent to form image, imagery report and depictive gestures.

Such imagery indicators accompanied many TEs in these videotapes, leading to the proposal that a process of imagistic simulation underlay those TEs. In this process, a perceptual motor schema generates dynamic imagery, complemented by nonformal, rationalistic contributions from general spatial reasoning operations and the ability to combine two such schemas in new combinations. Evidence from these studies suggests that premises can be in the form of implicit physical intuitions apprehended in imagistic simulations rather than being explicit linguistic propositions or axioms, and that reasoning with these can involve spatial reasoning or constructed compound simulations that are less formal than rule-based arguments. These mechanisms provided a way to speak to the TE paradox, showing how a TE could feel empirical but actually involve a considerable amount of reasoning inside the head (Clement 2008, 2009). Much of the prior work on this topic has involved the analysis of TE cases from the history of science; only recently has data been collected on the process of producing and running TEs.

Analytical Schemes for TEs

Several investigators have suggested analytical schemes for TEs. For instance, Reiner (1998) identified a five-part structure of TEs: hypothetical world, hypothesis, experiment, results and conclusion. She hypothesised that the conclusion of a TE is based on logical derivations, although in a later paper (Reiner and Gilbert 2000) she stressed that TEs have a nonpropositional aspect. The extent of the role of logical derivation has also been examined by Clement (2008). This analysis of spontaneous expert TEs indicates that TEs are often run in a nonformal, imagistic or intuitive manner.

How TEs Can Go Wrong

Miriam Reiner and Lior Burko (2003) analyse five TEs from history of science according to Reiner's five stages (1998) and identify stages at which errors occurred.

In the TEs studied, errors were usually made in the first two stages: constructing the hypothetical world and formulating the hypothesis. Reiner and Burko draw implications for the use of TEs in education; this will be discussed further below.

Review of Previous Studies on Roles Thought Experiments Can Play in Science Instruction

TEs Can Be Used by Students

Early work by Hugh Helm et al. (1985) describes students spontaneously generating their own TEs. Since then, a number of studies have documented the fact that TEs can be used by students in educational contexts. In most of these studies, Sorensen's definition is used or the concept of TE is left undefined.

Reiner (1998) found that episodes containing at least three parts from her five-part structure of TEs (described in the expert section above) were prevalent in the transcripts of 12 grade-eleven students working in small groups at computers with interactive schematic representations. In this study, it was assumed that interactive graphical dynamic representations generated by computer served as 'basic tools for learning processes that require(d) imagery' (p. 1046). Therefore, the imagery of the students was scaffolded by a display jointly viewed by several students. It might not seem surprising that, in Reiner's view, these students appeared to share mental animations that yielded similar results. However, Reiner also documents instances where students reasoned about variations of the system that had not yet been shown on the screen and agreed on predictions for these absent configurations. Especially in these instances, she argues, the students appeared to be relying on mental imagery. Working with older students, Reiner and Gilbert (2000) observed senior undergraduate physics majors and physics education majors as they solved problems designed to elicit TEs. They found that thought experimentation was a frequently used strategy.

In another instructional approach, Gilbert and Reiner (2004) found that 12- and 13-year-old students working in small groups constructed and ran thought experiments intertwined with the processes of conducting physical experiments. Transcripts showed students making progress towards scientific ideas by alternating between these imaginary and physical models. The students also used gestures and drawings to communicate ideas when trying to model how a physical system worked. This study suggests that the interplay between experiments, drawings and thought experiments can be very rich.

Maria Nunez-Oviedo et al. (2008) investigated the role of TEs with a similar age group. In middle school classrooms, the teacher was observed inviting students to run TEs both to support modification of ideas and to disconfirm ideas. Nunez-Oviedo et al. report that students were able to reason with the scenarios to arrive at scientifically accepted ideas. They argue that TEs can be used and are plausibly important at the middle school level.

Thought experiments – even Gedanken experiments – spontaneously generated and run by high school students need not be jointly constructed, though they may be inspired by the comments of other students. Lynn Stephens and John Clement (2006) found that students independently could generate novel scenarios, make predictions from those scenarios and evaluate those predictions on their own during class discussion. David Hammer (1995) considered thought experiments in high school physics class discussions as one of several kinds of process skills that were exhibited by students when the teacher in his case study took care to foster an open attitude towards contributing ideas.

Importance of TEs in Teaching and Learning

Gilbert and Reiner's (2004) work suggests that TEs can play an important role in physical (real) experimentation by suggesting modifications to physical experiments and alternating with them to lead to a convergence on accepted scientific concepts. (In their case, the concepts were of unusual sophistication for middle school level, as the students themselves spontaneously generated the beginnings of a concept of magnetic field.) Helm et al. (1985) speculate that TEs can play an important role in conceptual change because they have the ability to arouse dissatisfaction with existing conceptions. There are several questions they believe need to be answered, including: Is the classic structure of TEs drawn from physics the ideal structure of TEs to be used in pedagogical contexts? How far does TE overlap with analogy? What can be done to support students in their spontaneous generation of TEs?

Some recent studies have begun to address these and similar questions. For instance, what gives a model the ability to generate dynamic imagery, which then can be used to generate predictions during a TE? Clement (2008) hypothesised that some primitive physical intuitions have this kind of 'runnability' built into them in the form of perceptual motor schemas (such as a schema embodying ideas about pressure). When these are used as components in an explanatory model, the model can inherit this capability for generating dynamic imagery. This transfer of runnability is used to explain the ability of some analogies to serve as seed material for developing an explanatory model. So, for example, a student can develop a model of electric circuits based on a metaphor of electric pressure, with pressure spreading equally throughout equipotential (connected) areas of a circuit and pressure differences driving flow through resistors. When such a model is used to make a prediction for the first time, or used flexibly on a transfer problem involving a circuit with a type of geometry the student has never seen before, this is an instance of a thought experiment in the broad sense of the term used here; they are making an as yet untested prediction. In this case, it is being run via an imagistic simulation.

This hypothesis of transfer of runnability was supported by case study evidence (Clement and Steinberg 2002). A subject's spontaneous use of depictive gestures over drawings whilst she processed an air pressure analog case, and her use of similar gestures during later instructional circuit episodes, indicated that she was using a similar type of imagistic simulation in the two cases. Furthermore, the subject's spontaneous use of similar depictive gestures during a later posttest provided evidence that the instruction fostered development of a dynamic mental model of fluid-like flows of current caused by differences in electric pressure, a model that could generate new imagistic simulations for understanding relatively difficult transfer problems.

Thus, in addition to the use of Gedanken experiments, students making a prediction for an unfamiliar analogy or running a new model for the first time, or applying a model to an unfamiliar transfer problem, are doing an untested thought experiment. There is case study evidence from both experts and students that all of these operations can involve imagistic simulation (Clement 2008). This suggests that this kind of rationalistic, hypothetical, imagistic thinking via TEs can be important in many more learning situations than we might initially imagine, and that it is an extremely important complement to empirical and algorithmic work. A related theme was developed by Hammer (1995), who identified a number of rationalistic process goals being fulfilled in whole class discussion that are quite different from the classic, more empirically oriented process goals in science originally identified by Michael Padilla (1991). This points to the importance of understanding student use of TE processes in both the broad and narrow senses.

A Case Study

In the interest of aiding further research on TEs in instruction, we will illustrate a method using the two-tiered definition of *thought experiment* from Clement (2002) to identify transcript evidence that students can generate TEs at both tiers. We will also illustrate how a set of imagery indicators from Clement (2008) can be used to show that there is evidence for the involvement of mental imagery as students ran the TEs.

These recent analytical methods (Stephens and Clement 2010) are aimed at questions such as the following:

- Can we identify evidence that students use TEs?
- Can we identify evidence that students can generate and run their own TEs?
- Are the appearances of TEs isolated or do they have impact on classroom discussion?
- Can students evaluate TEs? Can they modify or improve them?
- Can we associate student use of imagery with the running of TEs?
- If so, can we identify evidence for particular kinds of imagery; i.e., visual or kinesthetic?

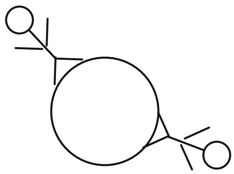

Fig. 13.2 US/Australia case

The Two-Tiered Definition Applied to Transcript Analysis

We have examined a number of transcripts of classroom activity to see whether evidence for student-generated TEs could be identified (Stephens and Clement 2006). In most of this classroom activity, guided inquiry methods of teaching and learning were being employed. We developed coding criteria based on the two-tiered definition for TEs, and we selected, for more detailed analysis, portions of transcripts where creative student reasoning appeared to be occurring. We were able to identify what seemed to us a surprising number of instances that met our criteria for student-generated thought experiments including several evaluative Gedanken experiments.

For coding purposes, the definition for the broad category of untested TEs (above) was broken into two requirements, which were coded for separately:

1. Subject attempts to predict behaviour of concrete system.
2. Subject has neither observed the experiment before nor been informed about its behaviour.

Example. A physics class is discussing possible causes for gravity including the rotation of the Earth (a common misconception). A student refers to a chalkboard drawing of the Earth with a stick figure of a man standing on it (Fig. 13.2).

> Line 40, S5: Well, I just think that gravity has nothing to do with rotation, but maybe with rotation, like, that guy is trying to get thrown off the Earth. So he's getting pulled at the same rate but he's also getting pushed away.

S5 attempts to predict the behaviour of a concrete system, a rotating Earth with a man standing on it. He has never observed the Earth from this vantage point and certainly has not experienced it spinning rapidly enough to feel the effects of being thrown off. Although his statement includes another misconception, this meets our criteria for a TE in the broad sense.

For all episodes that had been coded as having evidence for TEs in the broad sense, we applied more restrictive coding criteria to establish whether each episode also met our definition for TEs in the narrow sense, evaluative Gedanken experiments. In addition to 1 and 2 above, we required that:

3. The case appears to have been designed or selected by the subject in order to help evaluate a scientific concept, model or theory.

The TE of Line 40 above appeared to have been selected by the subject in order to help evaluate the theory that rotation is a cause of gravity and so met the additional criterion of a Gedanken experiment.

All cases that met criteria for TEs in either the broad or narrow senses were also analysed for the following factors:

- Whether the TE was generated by the teacher or the student
- Whether the TE was run by the teacher or the student

The distinction between generating a TE and running it is an interesting one. A pedagogical TE[1] can be generated in order to ask an audience to make a prediction about a system where the results are unknown to the audience but known to the generator. Often, the pedagogical TEs in the transcripts we analysed were generated by the teacher and run by the students; however, there are several incidences where we believe a student generated a TE, the outcome of which he or she was already certain, in order to convince fellow students of a point. At other times, a student generated and ran an untested TE and another student refined and reran it as a Gedanken with differing or refined results, or a student proposed a concrete case as an exemplar of some idea and another student used the case to generate an untested prediction, thus running it as an untested TE. Because of this network-like aspect of suggested test cases, untested TEs run on those cases, and Gedanken experiments (which might incorporate multiple earlier TEs from either tier), it was difficult to count the TEs in an unambiguous way until we considered the generation of TEs separately from their running.

Evidence of Spontaneous TEs from a Classroom Transcript

In Stephens and Clement (2006), the transcript under analysis was of a whole class discussion that comprised 42 min over the span of 2 days in a senior level high school physics class. The transcript began when the teacher first introduced the topic of gravity.

We organised our data by ‘case’ (denoted Case 1, Case 2 and so on), ‘variation of a case’ (denoted 1a, 3f and so on) and ‘episode’ (‘S5 reruns Case 2d as a Gedanken’). A case is a concrete example of a system, such as the case of one person standing in the United States and another standing in Australia, each person experiencing gravitational forces. A variation of a case involved the same concrete example of the system but with some variable changed in a significant way (such as being taken to extreme beyond the normal range for the system) or an additional variable highlighted. For instance, when a student introduced the rotation of the Earth into the discussion about Case 1, we counted this as Case 1a. An episode involved a single student either generating or running a case or variation.

We identified six separate cases that were topics of discussion in this transcript. These included: Case 1, a spherical mass such as a planet with one or more people

[1] This is a broader category than Gilbert and Reiner’s (2000) teaching TE in that a pedagogical TE need not be related to any existing consensus TE.

upon it experiencing gravitation; Case 2, two small objects not touching and not experiencing noticeable gravitational forces due to each other; Case 3, gravity inside a bell jar; Case 4, a spinning fair ride and the forces due to spinning felt by the riders; Case 5, a catapult and the forces experienced by a projectile and Case 6, a space ship rapidly orbiting the sun. The teacher introduced Cases 1 and 3 as part of the planned lesson; Case 1 then gave rise to numerous variations by students. The other four cases were introduced spontaneously by students.

The discussion begins with the teacher asking the students to consider a drawing on the board (Fig. 13.2). The teacher explains that the upper stick figure is standing in the United States and the lower in Australia and asks the students to vote on a ballot they have been given.

> Line I–5, T: Now. Vote Number 1 … (A)h, compared to the United States, gravity in Australia is: a little less, equal, a little bit more.

Students have differences of opinion on this, leading to a very active discussion. This is Case 1 in the chart in Fig. 13.4 below.

Soon after the teacher presents this case, S4 responds that he thinks that ‘somehow the fact that [the Earth] spins causes a lot of the main force of gravity’. This is the Spinning Earth variation, Case 1a. The student has introduced spinning as an important variable, indicating that his model of gravity includes spinning. This was not coded as a TE because the student did not make a prediction about the behaviour of the system; the outcome (that spinning causes the main force of gravity) was assumed beforehand.

Several students attempt to address this student’s misconception, including S5, who reruns the Spinning Earth case as a TE (Line 40, described above). In fact, S5’s prediction that spinning will throw ‘that guy’ off the Earth becomes a hot topic of debate in the class. Note that S5 speaks of ‘that guy’ as though it were the drawing on the board along with its stick figure that is doing the rotating. The student appears to use the case to help evaluate the effect of spinning in his mental model of gravity. Because the student did not generate the case, we have classified the episode as the running of a TE (rather than generation of a TE), and in the narrow sense (i.e., as Gedanken experimentation).

In spite of the attempts of several students to counter the idea, S4 and S6 continue to defend rotation as a cause of gravity. This leads to an incident where a student appears to adopt the case another student invented, convert it into an extreme case, and then run it as an evaluative Gedanken experiment. In Line 49, S7, who had been quiet until this point, suggests the following.

> Line 49, S7: Well, in reference to rotation and gravitational force, I think of them as being two opposite forces because if you stand on – let’s just imagine a ball floating in space you tape your feet to. And you start spinning the ball around, you’re gonna feel like you’re gonna be thrown off. But if it’s a small ball, then the attraction between you and that little small mass is negligible so that you’re just gonna feel the forces being spun around in a centrifugal force.

The massive earth has shrunk to a small ball and the spinning has increased from one revolution a day to many times a minute judging from his gestures on the videotape.

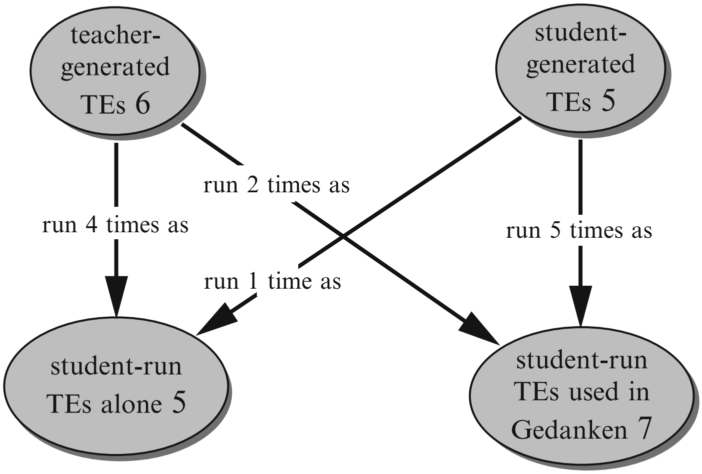

Fig. 13.3 Breakdown of TEs: TEs were run multiple times and in various combinations, so the number of TEs generated (*top row*) does not match the number of times TEs were run (*bottom row*). If the same TE was run twice by the same student, it was not double-counted

The transcript of the first day provides sufficient evidence to code five episodes of generation of untested TEs, two of them by students. Both of the latter were also coded as Gedankens. In addition, there is evidence that two students ran TEs generated by the teacher. At other points, students appear to be generating predictions but in each of those instances there is not enough information to determine whether the system in question was untested for those students (Lines 88 and 89). Coding in this conservative manner yielded four episodes in less than 20 min of tape where there was evidence for students generating and/or running TEs.

On Day 2, there was a new round of discussion in which, over 25 min, there is evidence for the generation of six new untested TEs, the first three by the teacher and the last three by students. Again, all three of the student-generated TEs were judged to be Gedankens. In addition, there were instances where students appeared to run TEs generated by other students or by the teacher.

The methodology used here resulted in the identification of evidence in 42 min of videotape for 11 episodes of TE generation, 5 of them Gedanken experiments generated by students. In addition, there was evidence for 7 episodes of students running TEs formulated by others, including 2 where they were run as Gedankens. Figure 13.3 gives a breakdown of coding results.

Evidence of Imagery Use

Whether TEs are considered in the broad or the narrower sense, there is some evidence that they can involve imagery-rich mental simulation and that this dynamic imagery can enable the user to access implicit knowledge, rendering it more explicit

(Clement 1994, 2009). Identification of imagery-use indicators (Clement 2008; Clement et al. 2005) has allowed us to address further the question of whether classroom TEs can involve dynamic imagery.

We regard depictive gestures, which appear to depict an imaginary image 'in the air' near the speaker, as providing some evidence for the involvement of mental imagery. In particular, we are interested in evidence for the use of animated or runnable mental imagery, which we obtain from gestures that appear to depict an imaginary motion or force. Identifying these types of gestures gives us a potential foothold on distinguishing between static and animated mental imagery.

For the Gedanken experiment of Line 40 discussed above, here is the same passage with gestures described.

> Line 40, S5: Well, I just think that gravity has nothing to do with rotation, but maybe with [right forefinger rotates quickly, inscribing tiny circles in the air] rotation like [points to chalkboard] that guy is trying to get [emphatic, sweeping movement with his right hand and arm, moving across the front of his body from right to left] **thrown** off the Earth. So he's getting [repeats sweeping movement] **pulled** at the same rate but he's also getting [reverses previous movement, pulling his right hand and arm back to the right] **pushed** away.

With the exception of the pointing gesture, which refers to a real object rather than an imaginary image, the rest of these gestures were coded as depictive. With video sound off, the first depictive gesture was classified as motion indicating [2] and the last three as force indicating. The written transcript was then coded for force-indicating terms. Examining the results, our classification of the last three gestures as force indicating was confirmed by the fact that force-indicating terms (in bold) co-occurred with them. In fact, the co-occurring gestures appear to depict the terms – throwing, pulling, pushing. Throughout this videotape, depictive gestures were observed in abundance.

Coding Results

After reaching agreement on the coding for the gestures, the verbal imagery indicators, TEs in the broad sense, and Gedankens, we compared the results to see how often imagery indicators coincided with evidence for TEs. Figure 13.4 is a chart of the results. The discussion is represented chronologically from left to right and top to bottom; the numbers across the top of each row are transcript line numbers. Table 13.1 shows the key to Fig. 13.4.

A sampling of features that can be seen in the kind of chart in Fig. 13.4:

- There are large blocks of transcript with no teacher-generated cases as in Lines 1–52 and Lines 199–239. Here, the students were generating the cases and maintaining the discussion.

[2] With sound off, classifying a gesture as motion indicating was considered more conservative than classifying it as force indicating. The fact that rotation implies a force to the physicist was not deemed sufficient here.

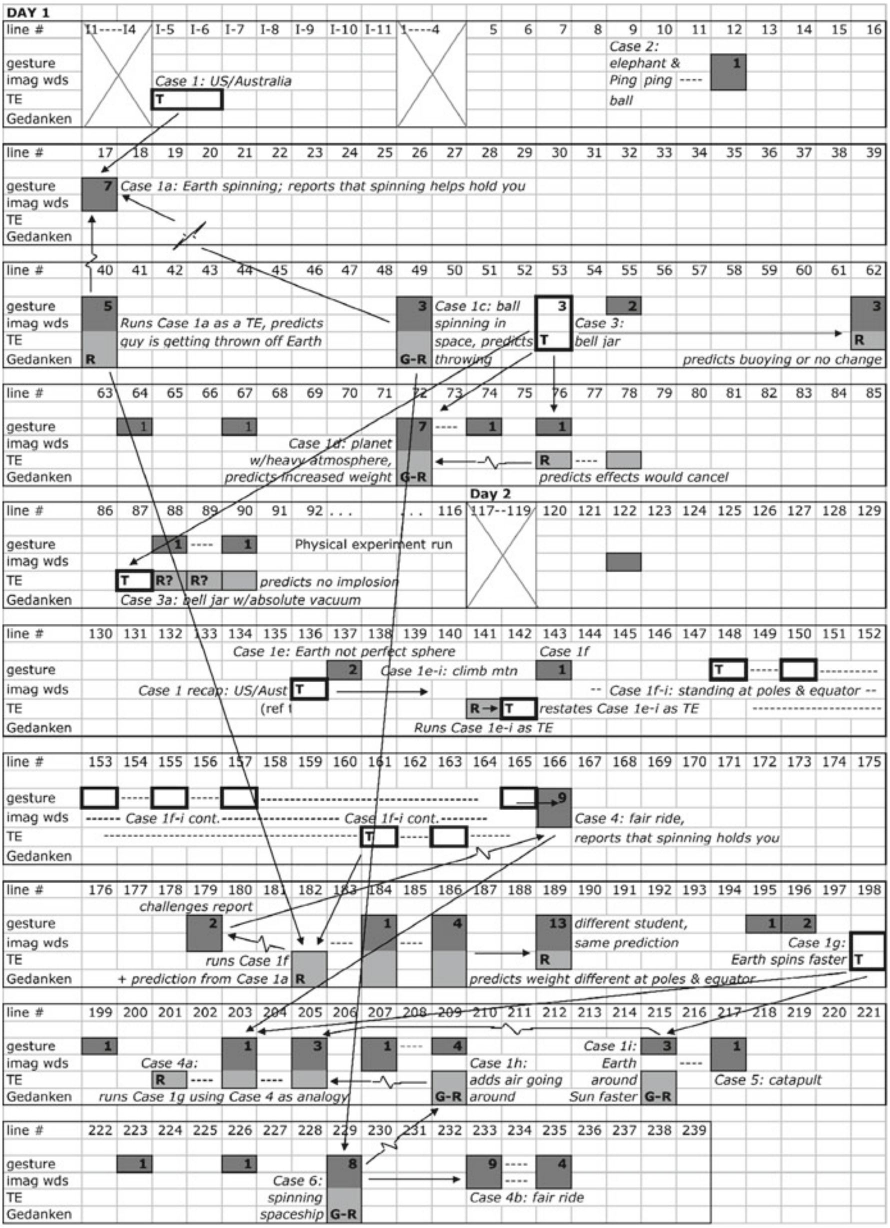

Fig. 13.4 Gravity class TEs and imagery use, Days 1 and 2

Table 13.1 Key to the chart in Fig. 13.4

Symbol	Meaning
	Imagery indicators are present.
	Both gestures and verbal imagery indicators are present.
	There is evidence for a TE in the broad sense, an untested TE.
	There is evidence for a TE in the narrow sense, a Gedanken Experiment.
T	The teacher is introducing a new case or explicitly proposing a TE.
	The later case is a variation of the earlier case or incorporates it.
	The later case appears designed to dispute the results of the earlier one.
7	7 depictive gestures (for ex.) were coded for this line of dialog.
G-R	There is evidence that a Gedanken was Generated and Run.
	An evolving case was described by a single speaker through multiple transcript lines interspersed with transcript lines spoken by others.
R?	Though a TE appears to have been run, there is not sufficient evidence to determine whether the system was untested by the student.

- We can see at a glance whether a TE was confirmatory or disconfirmatory of the idea it sought to address by whether the line connecting it to a previous case under discussion is straight or jagged.
- The individual TEs appear reactive to other TEs and to other ideas.
- We can easily see which TEs were associated with evidence for imagery by whether light grey blocks on the bottom two rows are paired with dark grey blocks directly above them.

Potential of the Methodology: Sample of Findings

This analysis, using the conceptual categories and methodology developed, demonstrates that evidence can be collected for the following (see also Stephens and Clement 2006):

1. *Thought experiments in the broad sense.* In the transcript discussed above, we found evidence for six teacher-generated and five student-generated untested TEs. There was explicit evidence from 12 transcript statements for the TEs being run by students.
2. *The involvement of imagery during the running of the TEs.* There were 14 episodes where evidence for generation or running of TEs was paired with evidence for the use of imagery. Eleven of these episodes had evidence for imagery from both gesture and verbal data.

3. *Kinesthetic imagery.* The most frequent form of evidence for imagery use in these transcripts was the use of force terms coupled with gestures that appeared to depict what the force terms were describing.
4. *Evaluative Gedanken experiments.* Students designed cases and used them to evaluate explanatory models. A few of these were discussed, but, as a look at Fig. 13.4 will reveal, there were many other instances coded.
5. Students can make sense of and discuss TEs proposed by the teacher; likewise for TEs proposed by other students.
6. TEs can spread 'contagiously' between students in a discussion, becoming modified and improved; this is an indication of the coherence of discussion.

Conclusions

Definitions

A problem in the literature is that there is no consensus on a definition of TE. In much of the literature, Sorensen's definition (Sorensen 1992) is used or the concept of TE is left undefined. An issue with Sorensen's definition is that it shifts much of the burden to the term *experiment*. TEs pose a paradox (Clement 2002, p. 32), namely, 'How can findings that carry conviction result from a new experiment conducted entirely within the head?' Motivated by the paradox, a two-tiered definition is proposed; it is more inclusive by not depending crucially on the subject having proposed a formal experiment, slightly more operational in emphasising a process rather than a product, and the broader tier fits the paradox better than the narrower set of carefully designed scientific Gedanken experiments.

Reiner (1998) has proposed a five-part structure of TEs: hypothetical world, hypothesis, experiment, results and conclusion. This provides a potentially useful fine structure; however, expert studies indicate that TEs can also be run in a nonformal or intuitive manner. A less fine-grained but perhaps more easily codable breakdown between generating and running a TE is proposed by Stephens and Clement (2010).

Existence in Classrooms

There is some initial evidence that middle and high school students can run teacher-generated TEs and Gedankens and generate and run TEs of their own. Given the broader definition for TE that has been proposed, it is possible that additional middle or elementary school student utterances will be reinterpreted as evidence for this kind of TE in the future. As for student-generated Gedankens, this may be an advanced skill. There is evidence from case studies that, on occasion, some students in physics classes have done this. An interesting question for future research is whether this skill can be taught.

Overall, this suggests that rationalistic, hypothetical thinking via TEs can be important in many more learning situations than we might initially imagine. A related theme was developed by Hammer (1995), who identified a number of rationalistic process goals being fulfilled in whole class discussion that are quite different from the classic, more empirically oriented process goals in science originally identified by Padilla (1991).

Purpose

Different kinds of TEs can be used to construct or evaluate (disconfirm or confirm) a model. Clement (2008) has identified a number of thinking processes that can incorporate and utilise TEs (defined in the broad sense), including the use of analogies, extreme cases and runnable mental models.

TE Mechanisms

There is case study evidence from gestures and other indicators from both experts and students that TEs used for all of the above purposes can involve imagistic simulation. This suggests that imagistic thinking via TEs can also be important in many more learning situations than we might initially imagine.

Ongoing work on mechanisms in expert TEs points to the involvement in many TEs of perceptual motor schemas that drive imagistic simulations with the help of spatial reasoning processes. This is providing some initial explanations for the thought experiment paradox concerning the origins of conviction in TEs.

Instructional Implications Effectiveness

In the gravity transcripts described earlier, we saw examples of creative co-construction of explanatory models for phenomena and argumentation about their validity (see also Clement and Rea-Ramirez 2008). These are valuable higher order process goals for science instruction. The generation of TEs in favour of the scientific model indicates the potential of student TEs to contribute also to content goals.

Gilbert and Reiner (2004) found that the process of alternating between experimenting empirically and experimenting in thought can lead towards a convergence on scientifically acceptable concepts. However, to date, findings on effectiveness come exclusively from case studies (e.g., Reiner and Gilbert 2000; Stephens and Clement 2006).

We end by hypothesising a possible general framework for viewing the role of imagery and TEs in instruction. First, TEs require somewhat risky, hypothetical reasoning that is different from the security of deduction or induction by enumeration. But because they usually involve stretching a concept or schema to use it in a new domain, they may be a very important learning tool. The idea of extending a schema to be used for a problem outside of its normal domain of application is one way to promote sense making by building on what is known and extending or modifying it.

Second, imagistic simulation may be a very important sense making process. If imagistic simulation is a major mechanism for sense making, then we need to find ways to foster it, as it is a very different mode of thinking from recalling memorised facts or executing algorithms. TEs in the broad sense could provide a way of promoting imagistic simulation as a key element of sense making.

Chapter 14
Vygotsky and Primary Science

Colette Murphy

This chapter examines some of Vygotsky's ideas in relation to children's development and early learning in science. The literature concerning children's learning in science at primary (elementary) school is surprisingly neglectful of the work of Vygotsky, with most emphasis still being placed on Piagetian ideas (Anne Howe 1996). Three main Vygotskian ideas are explored in this chapter in relation to young children's learning of science: the zone of proximal development, cultural mediation and the importance of play for the development of abstract thought. The chapter contextualises Vygotsky's ideas specifically in relation to improving both children's experience of primary science and their development of scientific concepts.

Science education has historically moved between three broad theoretical frameworks that have governed policy and practice in school science: behaviourism, cognitive constructivism and sociocultural theory. Behaviourism is based on the principle that scientific learning is a behavioural change that can be induced via appropriate stimuli; it follows the work of Ivan Pavlov (1849–1936), Edward Lee Thorndike (1874–1949) and Burrhus Skinner (1904–1990). In cognitive constructivism, it is supposed that children discover scientific concepts as a consequence of applying logical thought to results of interaction with objects and phenomena; it is based mostly on the work of Jean Piaget (1896–1980). Sociocultural theory applied to science learning would suggest that learning science is bound by the specific social and cultural context available to the learner. It presupposes that learning occurs first between people and then in the individual. It argues that scientific concepts are *not* formed by repeated experiences, but by combining experiences with intellectual operations guided by language; much of this work is based on the writing of Lev Semenovich Vygotsky (1896–1934).

Both Vygotsky and Piaget maintained that children are not just small adults and that children's minds work in a different way from those of adults, using different

means. However, whilst Piaget argued that children need to reach a certain stage of development before they can learn more complex abstractions, Vygotsky contended that learning actually leads development and that the teacher should always be challenging the children. Piaget maintained that we need to discover innate, internal laws that govern the child's mind, whereas Vygotsky highlighted the importance that culture plays in determining a child's development. Essentially, Piaget was more interested in the 'average' child, whereas Vygotsky focused on the importance of the unique social and cultural conditions that govern the learning environment of each child. Vygotsky made the case that each child is born into a particular cultural society and that his or her development is mainly directed by the internalisation of cultural signs and symbols which he or she later uses as psychological tools (e.g. memory, thinking, speech, etc.) to mediate learning (Elena Yudina 2007). Yudina gives the example of a child learning to eat with a spoon, which is mediated by an adult (usually the mother). The way in which the child uses the spoon depends on those cultural norms expressed by the mother. The spoon could be considered as an external tool to aid eating; language and gestures become internal tools to aid learning.

In terms of primary school science, Piaget's work led to the idea that children cannot be taught certain concepts until they have reached a certain developmental level and also that skills-based science learning and 'hands-on' approaches provide the most effective learning environments for classroom science. Vygotsky, on the other hand, maintained that child development is *not* a linear process and that there are different levels of development for different functions: at the one time, some cognitive functions can have 'matured', whilst others are in the process of maturing. So, children will *not* develop concepts using skills-based and hands-on approaches unless these are contextualised within an appropriate conceptual framework. Only then can the child abstract meaning from the experience. New, similar experiences can then be integrated into the conceptual framework, which becomes more familiar and concrete with each subsequent related experience.

Zone of Proximal Development

There is currently much discussion and debate about what Vygotsky actually meant by the 'zone of proximal development' (ZPD). My experience of the term was that it was the only reference to the work of Vygotsky in many education textbooks, and was never adequately explained. The simplistic definition of the ZPD found in many textbooks and other publications involves the 'gap' between what a child can achieve unaided and with help; for example, Louis Cohen et al.'s (2004) in *Guide to Teaching Practice*. This definition could be said to imply little more than that teachers need to help children! Anton Yasnitsky (2008) cites Annemarie Palincsar (1998), who argues that the ZPD is probably one of the most used and least understood educational concepts, and Mercer and Fisher (1992), who point out the danger in the term ZPD being used as a fashionable alternative to Piagetian terminology. Yasnitsky (2008) also cites Jonathan Tudge's (1999) observation that, in the six volumes of

Vygotsky's collected works, the ZPD only appears on a few pages in the thousands that he wrote. Bert van Oers (2007), however, discusses the complexity of the ZPD and shows how the concept was an evolving notion even during the short research life of Vygotsky; he used it initially as an index for intellectual potential and later as an educational concept focusing on the conditions needed to establish a ZPD.

Margaret Gredler and Carolyn Claytor Sheilds (2008) describe Vygotsky's argument that two children of the same age and the same 'actual' level of cognitive development not being able to solve a new problem with the same amount of help. Despite being measured at the same level, one child might solve the task with very little help, whilst the other might not solve it even after several different interventions designed to support the learning. Such interventions could involve: demonstrating the problem solution and seeing if the child can begin to solve it; beginning to solve it and asking the child to complete it; asking the child to solve the problem with the help of another child who is considered to be more able; and explaining the principle of the needed solution, asking leading questions, analysing the problem with the child, etc. Vygotsky considered performance on summative tests as an indication of the child's past knowledge and argued that 'instruction must be orientated towards the future, not the past' (Vygotsky 1962, p. 104). He defined the ZPD as: 'those functions which have not yet matured but are in the process of maturing… "buds" or "flowers" of development rather than "fruits" of development. The actual development level characterises the cognitive development retrospectively while the ZPD characterises it prospectively' (Vygotsky 1978, p. 86). He suggested that teaching/learning in the ZPD creates new levels of cognitive development that would not have been reached otherwise and that formal instruction is necessary to lift the child to the level of systematic scientific thinking. Useful instruction 'impels or awakens a whole series of functions that are in a stage of maturation lying in the zone of proximal development' (Vygotsky 1987, p. 212).

Bert van Oers (2007, p. 15) points out that the ZPD 'is *not* (emphasis added) a specific quality of the child, nor is it a specific quality of the educational setting or educators… it is… collaboratively produced in the interaction between the child and more knowledgeable others'. Gordon Wells (1999) and Tudge and Scrimsher (2003), together with many other researchers, also discuss the ZPD as an interaction between the students and co-participants. The interaction definition, whilst popular, is contested. Seth Chaiklin (2003) argues that the maturing functions described above by Vygotsky (1978) are not created in an interaction, but that interaction helps in identifying the existence of such functions and the extent to which they have developed.

Vygotsky contended that a full understanding of the ZPD should result in a re-evaluation of the role of 'imitation' in learning. His notion of 'imitation' is not meant as copying – more as emulation of an activity as part of the learning process. For example, a child learning to add, knit or dance emulates the teacher before doing the task by himself or herself. This type of activity coincides with the ZPD in the sense that it bridges what the child can do with help and then alone.

Vygotsky's description of the ZPD was that of maturing psychological functions that are required for the understanding of more abstract, scientific concepts. The conditions required to 'create' a ZPD to promote maturation of these functions is

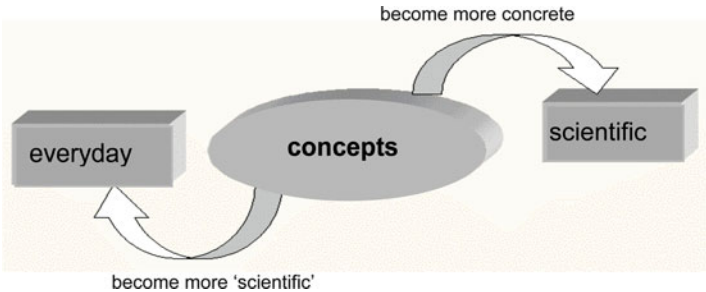

Fig. 14.1 Science concept formation as a dialectical process

of prime importance to children's early development of scientific concepts. Vygotsky maintained that scientific concept development is dialectical, as opposed to a linear process, in which spontaneous, or everyday, concepts become more abstract or scientific as a child learns. The scientific concepts, in becoming more familiar, become more concrete (see Fig. 14.1).

A zone of proximal development (ZPD), which can aid in the formation of scientific concepts, can be set up by involving children in shared activities in which they are afforded *meaningful* participation. Vytaly Rubtsov (2007) describes such a setting involving 7- to 9-year-old children:

> Two children must work together to balance a set of weights on a calibrated arm by moving, adding or removing weights. To solve this problem, they must take into account the relationship between each weight and its distance from the arm's centre of gravity. One participant is allowed to move the weights along the arm but not to add or remove weights; the other may increase or reduce the number of weights, but not move them. This division of activities, therefore, requires the two participants to work together, coordinating their activities in order to solve the task successfully. As the children move to the next problem, they switch roles. (p. 12).

Rubtsov (2007) cautions that such activities, whilst promoting reflective thinking, do *not* guarantee that each child will be able to identify the essential elements of the task. He suggests that, to increase the effectiveness of the activity, children should also use *pictorial and symbolic models* to represent the problems that they are solving and the steps that they use to solve them. Hence, they will be applying a conceptual framework into which their activity can be contextualised and made scientifically meaningful. This, I believe, is the crux of improving primary science by using a Vygotskian perspective. The pictorial and symbolic models, together with the discussion, become more meaningful to the children (and more so again with continued use with new, similar activities). Such work promotes thinking and stimulates pupils to reflect and explain in order to understand how their experiences and context-bound knowledge fit into a larger system (Howe 1996). The teacher is essential here to guide the work and provide the conceptual framework. Howe (1996) argues that, in contrast, a Piagetian approach involves children working on their activity without teacher intervention. She maintains that 'decontextualized tasks, chosen to represent a process but unrelated to children's everyday knowledge or interests, would not have a place in a science curriculum informed by a Vygotskian perspective' (p. 46).

Most science educators contrast this approach with the conceptual change model, popularised by George Posner et al. (1982) and Roger Osborne and Peter Freyberg (1985). This assumes that children come to school with misconceptions, or alternative frameworks, about natural phenomena that need to be elicited and then challenged (typically via demonstration or experimentation) to induce cognitive conflict and eventual reconciliation and acceptance of the logical, scientific concept. The conceptual change approach has been found wanting in several respects, including the observation that many 'misconceptions' persist, even after teaching involving cognitive conflict and initial acceptance of the scientific explanation has taken place (e.g. Shulman 1986). Perhaps a reason for such persistence of 'misconceptions' is the lack of relevant context for the pupils when the learning takes place. Howe (1996) argues that, using a Vygotskian perspective, children's ideas would be elicited, *not* to be challenged, and used to 'establish a foundation on which to build new knowledge or as a point of entry into the system of relationships that are eventually to be understood' (p. 48). Such understanding requires *time* so that children can move back and forth between everyday and scientific concepts, making sense of and discussing experiences in relation to the conceptual framework. The emphasis here is *not* on the solitary learner, but on interacting, negotiating and sharing to help integrate everyday concepts into the system of relational concepts. Howe (1996) raises some very important research questions based on a Vygotskian approach to science learning: 'What problem solving strategies do children use in everyday life that have been ignored in school and can be used as a basis for science teaching? What are the differences between the everyday science concepts of children from different socioeconomic, ethnic and regional backgrounds and how does this affect what is learned?' (p. 48).

Play

There is a vast amount of literature about play in primary science, with much of it debating whether the focus should be on teaching academic skills or engaging young children in make-believe play as a developmental activity (Elena Bodrova and Deborah Leong 2007). Recently, much of the focus tends to be more in the direction of the former. Bodrova and Leong (2007) suggest that there is a false dichotomy between play and academic skills when considered from a Vygotskian perspective. Indeed, Vygotsky maintained that creating an imaginary situation in play is a means by which a child can develop abstract thought. He considered play as a precursor to academic learning in two ways (Fig. 14.2).

The best kind of play to develop abstract thought involves children in using unstructured and multifunctional props, as opposed to those that are realistic. The former type of props strongly promotes language development to describe their use (e.g. a cardboard box can serve first as a shop, then as a school, then as home). Vygotsky said that this repeated naming and renaming in play helps children to master the symbolic nature of words, which leads to the realisation of the relationship

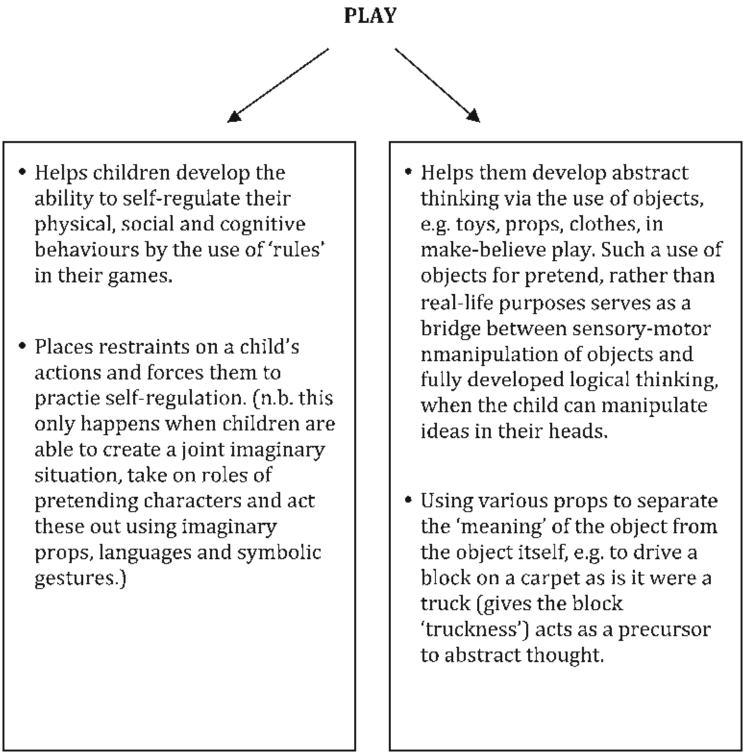

Fig. 14.2 Ways in which imaginative play is a precursor to academic learning

between words and objects and then of knowledge and the way in which knowledge operates.

This type of play is not often seen in the classroom in school – many 3- to 5-year-old children are playing like toddlers, just manipulating objects and not engaging significantly with other children.

Vygotsky's perspective on play connects it to the social context in which a child is brought up. He suggested that adults and older children should also be involved to enable younger children to model both roles and the use of props. Vygotsky promoted the notion that play, as learning, should lead development, as opposed to the more accepted one of development leading learning or play. Nikolai Veresov (2004) discusses learning that takes place in or within children's play. He uses the Vygotskian example of a child playing with a stick by using it as a horse. The child learns about the object (stick) and its objective physical properties, but also decides whether such properties allow or prevent the stick from becoming a horse. If the object does not suit the play task, the child stops playing with it. Veresov, in the same article, proposes that learning in play is a movement from the field of sense to the field of meaning; 'sense finds a suitable object, that is, sense objectifies itself' (p. 13). He exemplifies the sense-meaning dimension using a teacher-child two-part vignette in which the teacher first asks the child to suppose that he has two apples, and then gives one to someone and asks the child how many apples he now has. ‘Two’ replies the child and, on further questioning, he tells the teacher that he has two because he never gives his apples to anyone else. In the second part, the teacher asks the same child to suppose that someone else has two apples and gives one to him – she asks how many apples the other person now has. The child replies ‘one’ and explains that he or she would have one each. Veresov (2004) argues that the task is the same (a calculation of 2–1=1), but that the sense of the task must be in the child’s zone of proximal development.

Vygotsky theorists point towards empowering children through play. For example when modelling a situation in play involving, say, an imaginary parent or teacher or grocer or doctor, the child becomes, in Vygotsky’s terms, ‘a head taller’. Vygotsky (1978, p. 102) himself suggested that play creates a ZPD of the child:

> This strict subordination to rules [during play] is quite impossible in life, but in play it becomes possible: thus, play creates a zone of proximal development… In play a child always behaves beyond his average age, above his daily behavior; in play it is as though he were a head taller than himself.

In primary science, a Vygotskian perspective would presuppose that teachers promote role-plays and imaginary play in science learning for children throughout the primary school in order to further the development of abstract, conceptual thought. There would be a lot less focus on individual play with objects and more on collective play, preferably involving older children who can model both roles and the use of props for the younger ones.

Cultural Mediation

Whilst it is a common observation that children learn from adults and other children, it is less obvious how this happens. Vygotsky suggested that the child appropriates cultural tools and ways to use them; the child interacts with the environment via the mediation of cultural agents. The child is the subject, not the object of learning (Yudina 2007). Piaget, on the other hand, argued that the child’s learning represented biological adaptation to the environment, a far more passive role.

The main cultural tool, according to Vygotsky, is language, which can be thought of as a sign system. For learning to take place, language first needs to be internalised by the child (see Fig. 14.3). Vygotsky noted the importance of cultural mediation of these sign systems in humans, which does not occur in animals. For instance, in the everyday activity of eating, animals of a particular species all eat in the same way whereas, in humans, the way in which a person eats strongly reflects the culture in which they were raised and there are many, many different ways in which humans consume their food. Vygotsky argues that cultural mediation is just as important in the consideration of how, and indeed what, children learn.

In terms of learning, it must be remembered that the ‘mediator’, such as language, carries *meaning and sense*, as well as functioning as a tool, and therefore must be *interpreted* by the child (Vladimir Zinchenko 2007). Therefore, the child contributes

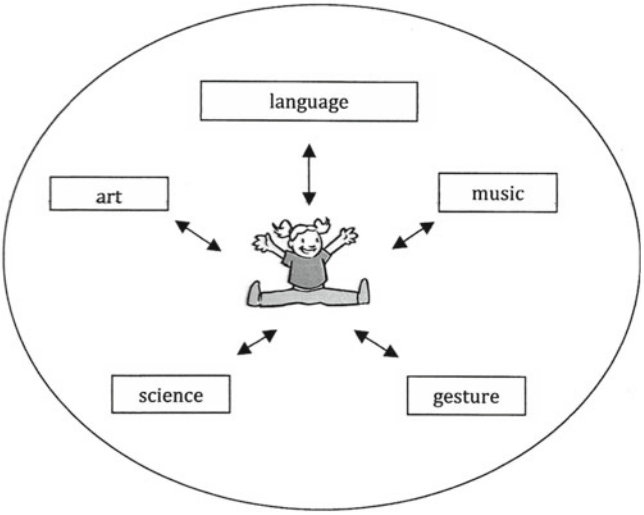

Fig. 14.3 Examples of sign systems used by a child to interact with the external world

to the culture, and continues this contribution in many ways throughout his or her life. Children's learning by way of cultural mediation can be summed up as follows:

$$\text{child} \xrightarrow[\text{mediated by cultural agent}]{\text{interacts with environment}} \text{higher psychological functions}$$

Yuriy Karpov and Carl Haywood (1998) argued that Vygotsky maintained that education entails two fundamental forms of mediation: mediation via cultural concepts and mediation via social interaction, which can be considered separately, but are in reality inseparable. It is through such mediation, according to Vygotsky, that 'we can take stock not only of today's completed processes of development, not only of cycles that are already concluded and done, not only of processes of maturation that are completed; we can also take stock of processes that are now in the state of coming into being, that are ripening, or only developing' (Wertsch (1985), pp. 447–448; cited in Wertsch 1985, p. 68). In order to aim the mediation at those abilities that are in the process of ripening, teachers must be assessing the children's learning before and during, as well as after, each learning sequence. The current emphasis on different modes of formative assessment, or assessment for learning (AfL) (see Black and Wiliams 1998), provides a basis upon which this can be achieved.

The role of the children in learning and development is much more active and agentic in a Vygotskian interpretation of how learning occurs through interaction with their environment, than if we use the Piagetian model based on their adaptation to the environment. Piaget's model leaves little room for the child to alter the environment as a consequence of his or her learning. In primary science learning, the Vygotskian interpretation allows for the sharing of ideas about phenomena between children and their peers and teachers, which is essential for the exposure of different levels of understanding to be addressed. Vygotsky contended that higher cognitive functions originate from the interaction between people, but we need to *teach* decontextualised contexts to enable the facilitation of cognitive growth. Teaching decontextualised concepts with the experience enables the students to create and enliven a cognitive framework in which they can contextualise and abstract their experiences! The fact that a person boils water in a kettle and observes steam coming out for years, does not necessarily (and only very rarely) lead to them discovering the concept of evaporation. Only when they are taught about evaporation and encouraged to link this learning with the kettle experience can most people make sense of the decontextualised concept of evaporation, and to situate other experiences, such as the drying up of puddles, within the initial framework of evaporation and then in the broader conceptual framework of the water cycle.

Conclusion

According to Vygotsky, learning *leads* development; so do not wait until children are 'old' enough to learn! Leif Strandberg (2007) contends that, as teachers, we need to promote activities that: develop interactions between children and between adults and children; give children access to tools and words; change around the learning environment to suit different activities and involve children as creative coworkers (see Fig. 14.4).

Such methods liberate adults and children from a retrospective, diagnostic and resigned pedagogy and enable a more forward-looking perspective on learning comprising performing as opposed to explaining. They also provide, according to Strandberg (2007), a sense of hopefulness for what comes next.

In primary science activities, teachers might consider expanding their use of curricular activities that include:

- Think, pair share
- Peer learning
- Mediational artefacts
- Science term of the day (or week)
- Adaptation of the learning environment
- Use of role-play and stories to promote Vygotsky-type imaginary play
- Extending 'play' activities to older children to aid abstract concept formation.

In summary, a Vygotskian approach to primary science highlights the importance of ensuring that practical activities are contextualised within a conceptual framework, children are encouraged to discuss their developing understanding with peers and teachers, and time is allowed for contextualised experiences that foster the development of such concepts. Role-play and collaborative, imaginative play with children of different age groups would be encouraged throughout the primary school to facilitate the development of abstract thought. Teachers mediate pupils' learning by addressing social and cultural influences in their provision of appropriate educational tools and

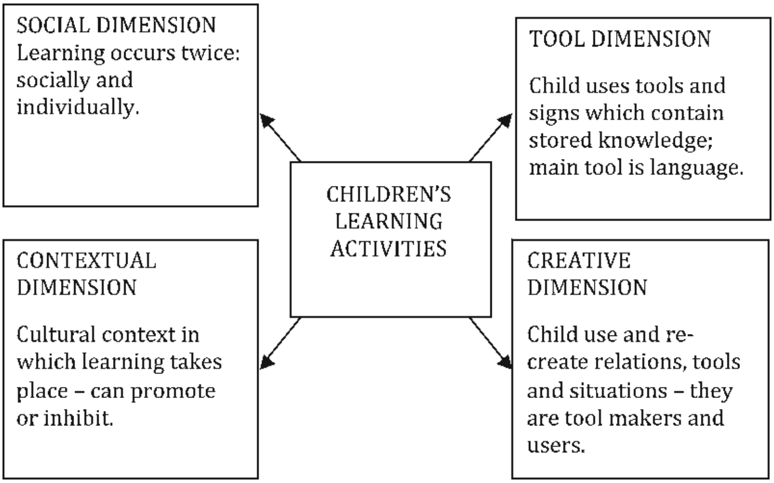

Fig. 14.4 Strandberg's four dimensions to children's activities

they monitor children's progress as they attempt to identify and teach within their zones of proximal development. Teachers use formal instruction alongside hands-on practical activities that are relevant to their experience and interests to enable children constantly to switch between everyday and scientific concepts until they have been adjudged to have achieved an appropriate understanding. It could be argued that such a change in teaching/learning approach requires a level of theoretical synthesis between some of Piaget's ideas, which dominate much of the current enactment of science teaching, with the more operational aspects of Vygotskian theory. In this regard, we can learn a lot from the literature on incorporating Vygotskian approaches to teaching in early years and in second language learning.

Chapter 15
Learning In and From Science Laboratories

Avi Hofstein and Per M. Kind

Introduction: The Science Laboratory in School Settings

Since the nineteenth century when schools began to teach science systematically, the laboratory became a distinctive feature of science education (Edgeworth and Edgeworth 1811 cited by Rosen 1954). After the First World War, with the rapid increase of science knowledge, the laboratory was used mainly as a means for confirmation and illustration of information learnt previously in a lecture or from a textbook. With the reform in science education in the 1960s, both in the USA and the UK, the ideal became to engage students with investigations, discoveries, inquiry and problem-solving activities. In other words, based on Lee Shulman and Pinchas Tamir's (1973) review, the laboratory became the core of the science learning process and science instruction. Over the years, the science laboratory was extensively and comprehensively researched and hundreds of research papers and doctoral dissertations were published all over the world (Hofstein and Lunetta 1982, 2004; Lazarowitz and Tamir 1994; Lunetta et al. 2007). This embrace of practical work, however, has been contrasted with challenges and serious questions about its efficiency and benefits (Hofstein and Lunetta 2004; Hodson 1993; Millar 1989). For many teachers (and often curriculum developers), practical work means simple recipe-type activities that students follow without the necessary mental engagement. The aimed-for ideal of open-ended inquiry, in which students have opportunities to plan an experiment, to ask questions, to hypothesise and to plan an experiment again to verify or reject their hypothesis, happens more rarely – and when it does, the learning outcome is much discussed.

B.J. Fraser et al. (eds.), *Second International Handbook of Science Education*, Springer International Handbooks of Education 24, DOI 10.1007/978-1-4020-9041-7_15,

This chapter reviews research on practical work in order to demonstrate not only its potential but also its challenges and problems. A main point to be made is that practical work is not a static issue but something that has evolved gradually over the years, and which is still developing. The development relates to changing aims for science education, to developments in understanding about science learning, to changing views and understanding of science inquiry and to more recent developments in educational technologies. To demonstrate this, we start with a review along historical lines, looking back at practical work research over the last 50 years during three periods: (1) 1960s to mid-1980s, (2) mid-1980s to mid-1990s and (3) the last 15 years. Following from this review, the second part of the chapter elaborates four different themes that summarise the state of affairs of practical work at the beginning of the twenty-first century and points towards new possibilities: how is practical work used by teachers, the influence of new technologies, 'metacognition' as a factor in laboratory learning and the issue of 'scientific argumentation' as a replacement for 'scientific method'.

Throughout the chapter, we use interchangeably the terms *practical work*, which is common in the UK context, and *laboratory work*, which is common in USA. A precise definition is difficult because these terms embrace an array of activities in schools, but generally they refer to experiences in school settings in which students interact with equipment and materials or secondary sources of data to observe and understand the natural world (Hegarty-Hazel 1990).

Fifty Years of Laboratory Work Research and Practice

1960s to Mid-1980s: Unfulfilled Ideals

This period is associated with the many curriculum projects that were developed to renew and improve science education. The projects started in the late 1950s with focus on updating and re-organising content knowledge in the science curricula, but soon reformists turned their attention towards *science process* as a main aim and organising principle for science education, as expressed by Sunee Klainin (1988) in Thailand:

> Many science educators and philosophers of science education (e.g. in the USA: Schwab, 1962; Rutherford and Gardner, 1970) regarded science education as a process of thought and action, as a means of acquiring new knowledge, and a means of understanding the natural world. (p. 171)

The emphasis on the processes rather than the products of science was fuelled by many initiatives and satisfied different interests. Some educators wanted a return to a more student-oriented pedagogy after the early reform projects which they thought paid too much attention to subject knowledge. Others regarded science process as the solution to the rapid development of knowledge in science and technology: mastering science processes was seen as more sustainable and therefore a way of making students prepared for the unknown challenges of the future. Most importantly, developments in cognitive psychology drew attention towards reasoning processes and scientific thinking. Psychologists such as Bruner, Piaget and Gagne helped to explain the thinking involved in the science process and inspired the idea that science teaching could help to develop this type of thinking in young people.

Although this development was found in its explicit form in the US, it was soon echoed in many other nations (Bates 1978; Hofstein and Lunetta 1982). Everywhere, the laboratory and practical work were put into focus. John Kerr (1963) in the UK suggested that practical work should be integrated with theoretical work in the sciences and should be used for its contribution to provide facts through investigations and, consequently, to arrive at principles that are related to these facts. This became a guiding principle in many of the Nuffield curriculum projects that were developed in the late 1960s and early 1970s.

The interest for practical work in science education research in this period is clearly demonstrated by Reuven Lazarowitz and Pinchas Tamir (1994) in their review on laboratory work. They identified 37 reviews on issues of the laboratory in the context of science education (Bryce and Robertson 1985; Hofstein and Lunetta 1982; Shulman and Tamir 1973). These reviews expressed a similarly strong belief regarding the potential of practical work in the curriculum, but also recognised important difficulties in obtaining convincing data on the educational effectiveness of such teaching. Not surprisingly, the only area in which laboratory work showed a real advantage (when compared to the nonpractical learning modes) was the development of laboratory manipulative skills. For conceptual understanding, critical thinking and understanding of the nature of science, there were little or no differences.

Lazarowitz and Tamir suggested that one reason for this relates to the use of inadequate assessment and research procedures. Quantitative research methods were not adequate for the research purpose but, at the time, qualitative research methods generally were disregarded in the science education community. Avi Hofstein and Vincent Lunetta (1982) identified several methodological shortcomings in research designs: insufficient control over laboratory procedures (including laboratory manuals, teacher behaviour and assessment of students' achievement and progress in the (laboratory); inappropriate samples and the use of measures that were not sensitive or relevant to laboratory processes and procedures.

Another issue was that teaching practice in the laboratory did not change as easily towards an open-ended style of teaching as the curriculum projects suggested. Teachers rather preferred a safer 'cookbook' approach (Tamir and Lunetta 1981). Alex Johnstone and Alasdair Wham (1982) claimed that educators underestimated the high cognitive demand of practical work on the learner. During practical work, the student has to handle a vast amount of information regarding the names of equipment and materials, instructions regarding the process, data and observations, thus causing overload on the student's working memory. This makes laboratory learning complicated rather than a simple and safe way towards learning.

Adding to this rather ominous picture, however, are some research studies and findings during this period that came to influence later developments more positively.

One area that was researched quite extensively concerns *intellectual development*. Jack Renner and Anthony Lawson (1973) and Robert Karplus (1977) (based on Jean Piaget 1970) developed the *learning cycle* that consisted of the following stages: *exploration*, in which the student manipulates concrete materials; *concept introduction*, in which the teacher introduces scientific concepts and, finally, *concept application*, in which the student investigates further questions and applies the new concept to novel situations. Many interpreters of Piaget's work (e.g. Robert Karplus 1977) inferred that work with concrete objects (provided in practical experiences) is an essential part of the development of logical thinking, particularly at the stage prior to the development of formal operations.

Another important contribution was made in the UK by Richard Kempa and John Ward (1975), who suggested a four-phase taxonomy to describe the overall process of practical work: (1) planning an investigation (experiment), (2) carrying out the experiment, (3) observations and (4) analysis, application and explanation. Tamir (1974) in Israel designed an inquiry-oriented laboratory examination in which the student was assessed on the bases of manipulation, self-reliance, observation, experimental design, communication and reasoning. These could serve as an organiser of laboratory objectives that could help in the design of meaningful instruments to assess outcomes of laboratory work. In addition, these had the potential to serve as a basis for continuous assessment of students' achievements and progress and also for the implementation of practical examinations (Ben-Zvi et al. 1976; Hofstein 2004; Tamir 1974).

Mid-1980s to Mid-1990s: The Constructivist Influence

During the period from the mid-1980s to the mid-1990s, practical work was challenged in two different ways. One was related to an increasing awareness amongst science education researchers of a failure of establishing the intended pedagogy in the reform projects from the previous period. This was expressed by Paul Hurd (1983) and Robert Yager (1984), who reported laboratory work in schools tended to focus on following instructions, getting the right answer or manipulating equipment. Students failed to achieve the conceptual and procedural understandings that were intended. Very often, students failed to understand the relationship between the purpose of the investigation and design of the experiments (Lunetta et al. 2007). In addition, there was little evidence that students were provided with opportunities and time to wrestle with the nature of science and its alignment with laboratory work. Students seldom noted the discrepancies between their own concepts, their peers' concepts and the concepts of the science community (Eylon and Linn 1988; Tobin 1990). In sum, practical work meant manipulating equipment and materials, but not ideas.

The other challenge involved the theoretical underpinning of laboratory work. The process approach was challenged by a new perspective on science education known as *constructivism*. The constructivist area started in the late 1970s with increasing criticisms against the Piagetian influence on science education. New voices argued that too much attention had been paid towards general cognitive skills in science learning and that science educators had missed the importance of students' conceptual development (e.g. Driver and Easley 1978).

The effects of this criticism can be followed in the UK in the aftermath of the Nuffield curriculum reform projects, which had contributed towards a strong foothold for the science laboratory. John Beatty and Brian Woolnough (1982) reported that 11–13-year olds typically spent over half of their science lesson time doing practical activities. This was also a period of the Assessment for Performance Unit (APU), a national assessment project within a process-led theoretical framework (Murphy and Gott 1984), which later influenced the national curriculum and its aligned assessment system.

During the 1980s, researchers started to question this practice and its theoretical underpinning in the light of philosophical and sociological accounts associated with constructivism (Millar and Driver 1987). The argument was that the entire science education community had been misled by a naïve empiricist view of science, referred to by Robin Millar (1989) as the Standard Science Education (SSE) view. The SSE view presents science as a simple application of a stepwise method, and further relates these steps to particular intellectual and practical skills. In other words, by having the right skills and by applying 'the scientific method', anyone can develop scientific knowledge. With the denial of this view of science inquiry, science educators were in need of an alternative, but finding this took some time and required a series of developments.

Two different attempts to develop alternative theoretical platforms appeared on the UK scene in the late 1980s and early 1990s. The first attempt had its inspiration from Michael Polanyi's (1958) concept of 'tacit knowledge'. This approach had similarities to the process approach, but denied the possibility of identifying individual processes (Woolnough and Allsop 1985). Rather, it was claimed that science is like a 'craftsmanship' and that investigations should be treated like a 'holistic process' based on understandings that cannot be explicitly expressed. The belief was that inquiry at school with a trained scientist (i.e. the teacher) developed this craftsmanship, and made students generally better problem solvers (Watts 1991). Retrospectively, we can see this approach as avoiding the challenge of identifying what it really means to do science by making the process hidden and mysterious.

The other theoretical approach also held on to science as a problem-solving process, but avoided the mistake in previous theories of focusing too strongly on skills. Richard Gott and Sandra Duggan (1995) claimed that the ability to do scientific inquiry was based fundamentally on procedural knowledge (i.e. understanding required in knowing how to do science). When scientists carry out their research, they have a toolkit of knowledge about community standards and what procedures to follow to satisfy these. The aim of science inquiry is not only to find new theories, but also to establish evidence that a theory is 'trustworthy'. They therefore claimed that students should be taught procedural understanding along with conceptual understanding, and then get practice in problem solving based on these two components.

At the end of the second period, constructivism was well established in science education. The teaching of skills and procedures of scientific inquiry had lost much of its status as science educators paid more interest to conceptual learning. One influential idea was the use of Predict-Observe-Explain (POE) tasks (Gunstone and Mitchell and the Children Science Group 1988). In these tasks, observations in the laboratory are used to challenge students' ideas and help to develop explanations in line with the correct scientific theories. Richard Gunstone (1991) and Richard White (1991) also made another statement about of the constructivist message for the science laboratory teaching. In particular, it was claimed that all observations are theory-laden. This means that doing practical work is no guarantee for adopting the right theoretical perspective. Students need to reflect on observations and experiences in light of their conceptual knowledge. Kenneth Tobin (1990) wrote that: 'Laboratory activities appeal as a way of allowing students to learn with understanding and, at the same time, engage in the process of constructing knowledge by doing science' (p. 405). To attain this goal, he suggested that students should be provided with opportunities in the laboratory to reflect on findings, clarify understandings and misunderstandings with peers and consult a range of resources that include teachers, books and other learning materials. His review reported that such opportunities rarely exist because teachers are so often preoccupied with technical and managerial activities in the laboratory. Richard Gunstone and John Baird (1988) pointed towards the importance of metacognition for this to happen. White (1991) also argued that the laboratory helps students in building up 'episodic' memories that can support later development of conceptual knowledge.

Period After Mid-1990s: A New Area of Change

During the last 15 years, we have seen major changes in science education. These were caused partly by globalisation and rapid technological development, which call for educational systems with high-quality science education to meet international competition and develop the knowledge and competencies needed in modern society. In the USA, we have seen developments regarding 'standards' for science education (NRC 1996, 2005) that provide clear support for inquiry learning both as content and as high-order learning skills that include, in the context of the laboratory, planning an experiment, observing, asking relevant questions, hypothesising and analysing experimental results (Rodger Bybee 2000). In addition, we observed internationally that there has been a high frequency of curriculum reforms. A central point has been to make science education better adapted to the needs of all citizens (AAAS 1991).

It is recognised that citizens' needs include more than just scientific knowledge. In everyday life, science is often involved in public debate and used as evidence to support political views. Science also frequently presents findings and information that challenge existing norms and ethical standards in society. Mostly it is cutting-edge science and not established theories that are at play. For this reason, it does not help to know textbook science, but rather it is necessary to have knowledge *about* science. Robin Millar and Jonathan Osborne (1999) suggested in this context that citizens need to understand principles of scientific inquiry and how science operates at a social level. The natural question, of course, is to what degree and in what ways the science laboratory can help to provide students with such understanding.

Another area of change in the recent period has been further development of constructivist perspectives into sociocultural views of learning and of science. The sociocultural view of science emphasises that science knowledge is socially constructed. Scientific inquiry, accordingly, is seen to include a process in which explanations are developed to make sense of data and then presented to a community of peers for critique, debate, and revision (Duschl and Osborne 2002). This re-conceptualisation of science from an individual to a social perspective has fundamentally changed the view of experiments as a way of portraying the scientific method. Rather than seeing the procedural steps of the experiment as the scientific method, practical work is now valued for the role that it plays in providing evidence for knowledge claims according to Rosalind Driver, John Leach, Robin Millar and Philip Scott (Driver et al. 2000). The term scientific method, as such, has lost much of its valour (Jenkins 2007).

The *sociocultural* view of learning is based on a Vygotskian perspective pointing towards the role of social interaction in learning and thinking processes (Vygotsky 1978). It is believed that thinking processes originate from socially mediated activities, particularly through the mediation of language. As a consequence, science learning is seen as socialisation into a scientific culture (Driver et al. 2000). Students therefore need opportunities to practise using their science ideas and thinking through talking with each other and with the science teacher (Scott 1998).

All these changes have obvious relevance for practical work. Rather than training science specialists, the laboratory should now help the average citizen to understand *about* science and to develop skills useful in evaluating scientific claims in everyday life. Rather than promoting the scientific method, the laboratory should focus on how we know what we know and why we believe certain statements rather than competing alternatives (Duschl and Grandy 2007). The socialcultural learning perspective also provides reasons to re-visit group work in the school laboratory. Most importantly, the current changes have finally produced an alternative to the science process approach and the SSE-view (Millar 1989) established 50 years ago. We now find a new rationale for understanding science inquiry and how this can link with laboratory work at school.

Emerging Themes

In the remainder of this chapter, we look into four themes that further elaborate the current situation for laboratory work in science education research and practice.

Teachers' and Students' Practice in Science Laboratories: How Are Laboratories Used?

To what degree has the use of practical work changed at schools? In this section, we look at research into how laboratories are used by teachers and students, as well as the nature of laboratory activities and facilities.

On the basis of a comprehensive study of the implementation of the laboratory in schools in British Columbia (Gardiner and Farrangher 1997), it was found that, although many biology teachers articulated philosophies that appeared to support a hands-on investigative approach with authentic learning experiences, the classroom practices of those teachers did not generally appear to be consistent with their stated philosophies. Several studies have reported that very often teachers involve students principally in relatively low-level, routine activities in laboratories and that teacher–student interactions focused principally on low-level procedural questions and answers. Ron Marx et al. (1998) reported that science teachers often have difficulty in helping students to ask thoughtful questions, design investigations and draw conclusions from data. Similar findings were reported regarding chemistry laboratory settings (De Carlo and Rubba 1994). More recently, Ian Abrahams and Robin Millar (2008) in the UK investigated the effectiveness of practical work by analysing a sample of 25 typical science lessons involving practical work in English secondary schools. They concluded that the teachers' focus in these lessons was predominantly on making students manipulate physical objects and equipment. Hardly any teacher focused on the cognitive challenge of linking observations and experiences to conceptual ideas. Neither was there any focus on developing students' understanding of scientific inquiry procedures. A comprehensive and long-term study on the use (and objectives) of laboratories in several EU countries was conducted by Marie Sere (2002). In this research, based on 23 case studies, it was found that laboratory work was perceived as an essential ingredient of the experimental sciences. However, it was also found that the objectives stated for practical work (including conceptual understanding, understanding of theories and laws and high-order learning skills) were too numerous and demanding to be implemented by the average science teacher in their respective classrooms.

These findings echo the situation at any time in the history of school science. Basic elements of teachers' implementation of practical work do not seem to have changed over the last century; students still carry out recipe-type activities that are supposed to reflect science procedures and teach science knowledge, but which in general fail on both. This is not to say everything is the same. Science education has moved forwards during the last decades with associated improvement in teachers' professional knowledge and classroom practice, but this improvement has not sufficiently caught up with the challenges of using laboratory work in an efficient and appropriate way. Teachers still do not perceive what is required to make laboratory activities serve as a principal means of enabling students to construct meaningful understanding of science, and they do not engage students in laboratory activities in ways that are likely to promote the development of science concepts. In addition, many teachers do not perceive that helping students to understand how scientific knowledge is developed and used in a scientific community is an especially important goal of laboratory activities for their students.

Today's conclusion has therefore not changed substantially from what Brian Woolnough and Terry Allsop (1985) claimed:

> Teachers at present are ill prepared to teach effectively in the laboratory. A major reason is that most science teachers have themselves brought-up on a diet of content dominated cookery book-type practical work and many have got in their habit of propagating it themselves. (p. 80)

Aligned with this situation for teachers, we find a matching picture in students' experiences and laboratory teaching materials. Attempts have been made to develop protocols for analysing laboratory activities (Lunetta and Tamir 1979; Millar et al. 1999). Darrell Fisher et al. (1999) used Lunetta and Tamir's protocol to analyse laboratory guides in Australia. The analyses suggest that, to date, many students engage in laboratory activities in which they follow recipes and gather and record data without a clear sense of the purposes and procedures of their investigation and their interconnections. Daniel Domin (1998) in the USA found that students are seldom given opportunities to use higher-level cognitive skills or to discuss substantive scientific knowledge associated with investigations, and many of the tasks presented to them continue to follow a cookbook approach that concentrates on the development of lower-level skills and abilities.

The reviews discussed earlier in this chapter revealed a mismatch between the goals articulated for the school science laboratory and what students regularly do during those experiences. Ensuring that students' experiences in the laboratory are aligned with stated goals for learning demands that teachers explicitly link decisions regarding laboratory topics, activities, materials and teaching strategies to desired outcomes for students' learning. The body of past research suggests that far more attention to the crucial roles of the teacher and other sources of guidance during laboratory activities is required, and that researchers must also be diligent in examining the many variables that interact to influence the learning that occurs in the complex classroom laboratory.

Developing Inquiry and Learning Empowering Technologies

In the early 1980s, digital technologies became increasingly visible in school laboratories and were recognised as important tools in school science (Lunetta 1998). Much evidence now documents that using appropriate technologies in the school laboratory can enhance learning of important scientific ideas. Inquiry empowering technologies (Hofstein and Lunetta 2004) have been developed and adapted to assist students in gathering, organising, visualising, interpreting and reporting data. Some teachers and students also use new technology tools to gather data from multiple trials and over long time intervals (Dori et al. 2004; Friedler et al. 1990; Krajcik et al. 2000; Lunetta 1998). When teachers and students properly use inquiry-empowering technologies to gather and to analyse data, students have more time to observe, reflect and construct conceptual knowledge that underlies their laboratory experiences. Using appropriate technology tools can enable students to conduct, interpret and report more complete, accurate and interesting investigations. Carla Zembal-Saul et al. (2002) suggested that such tools can also provide media that support communication, student–student collaboration, the development of a community of inquirers in the laboratory classroom and beyond and the development of argumentation skills.

Two studies illustrate the potential effectiveness of particular technology in school science. Marry Nakleh and Joe Krajcik (1994) investigated how students' use of chemical indicators, pH meters and microcomputer-based laboratories (MBL) affected their understanding of acid-base reactions. Students who used computer tools in the laboratory were more able to draw relevant concept maps, describe the acid-base construct and argue about the probable causes of why their graphs formed as they did. Judy Dori et al. (2004) developed a high school chemistry unit in which students pursued chemistry investigations using integrated desktop computer probes. Using a pre-post design, these researchers found that students' experiences with the technology tools improved their ability to pose questions, use graphing skills and pursue scientific inquiry more generally. To sum up, there is some evidence that integrating information and communication technology (ICT) tools into the science laboratory is promising. However, this development is still at an early stage. The level at which ICT is used in laboratory classes varies a lot. We assume that, in the future, this will expand. In addition, it is expected that ICT will be used to achieve more integration between practical work and computer-based simulations. This is an area that needs more research regarding its educational effectiveness.

The Development of Metacognitive Skills in the Science Laboratory

As we have seen, the high hopes for developing thinking skills in the laboratory failed partly because of inadequate alignment of learning theories with school science practice. One factor that has brought new understanding to this area is *metacognition*, which refers to higher-order thinking skills that involve active control over the thinking processes involved in learning. Activities such as planning how to approach a given learning task, monitoring comprehension and evaluating progress towards the completion of a task are metacognitive in nature (Livingston 1997). There is no single definition used for metacognition and its diverse meanings are represented in the literature that deals with thinking skills. Gregory Schraw (1998), for example, presents a model in which metacognition includes the two main components: knowledge of cognition and regulation of cognition. Knowledge of cognition refers to what individuals know about their own cognition or about cognition in general. It includes at least three different kinds of metacognitive knowledge: declarative knowledge about oneself as a learner and about factors that influence one's performance (knowing 'about' things); procedural knowledge about doing things in terms of having heuristics and strategies (knowing 'how' to do things) and conditional knowledge about when to use declarative and procedural knowledge and why (knowing the 'why' and 'when' aspects of cognition). Regulation of cognition refers to a set of activities that help students to control their learning. Although a number of regulatory skills have been described in the literature, three essential skills are included in all accounts: planning involves the selection of appropriate strategies and the allocation of resources that affect performance; monitoring refers to one's online awareness of comprehension and task performance and evaluating refers to appraising the products and efficiency of one's learning. Other researchers such as John Baird and Richard White (1996) have made different divisions and categorisations of metacognition.

When applied to science learning generally, metacognition is related to meaningful learning, or learning with understanding (Baird and White 1996; Rickey and Stacy 2000; White and Mitchell 1994), which includes being able to apply what has been learnt in new contexts (Kuhn 2000). Metacognition is also related to developing *independent learners* (NRC 1996, 2005), who typically are aware of their knowledge and of the options to enlarge it. One key component is *control* of the problem-solving processes and the performance of other learning assignments. Researchers link this *control* to the student's *awareness* of his or her physical and cognitive actions during the performance of the tasks (Baird 1998; White 1998). Another element is the student's *monitoring* of knowledge (Rickey and Stacy 2000). Learners who properly monitor their knowledge can distinguish between the concepts that they know and the concepts that they do not know and can plan their learning effectively.

The link between metacognition and scientific inquiry seems to be obvious. Scientists depend on their ability to control reasoning when working out new ideas and weighing up the evidence confirming or contrasting these. Dianne Kuhn et al. (2000) argue that students who experience inquiry activities in a similar way 'come to understand that they are able to acquire knowledge they desire, in virtually any content domain, in ways that they can initiate, manage, and execute on their own, and that such knowledge is empowering' (p. 496).

Baird and White (1996) claim that four conditions are necessary in order to induce the personal development entailed in directing purposeful inquiry: time, opportunity, guidance and support. The science teacher should provide students with experiences, opportunities and the time to discuss their idea about the problems that they have to solve during the learning activity. The role of the teacher is to provide continuous guidance and support to ensure that students develop control and awareness over their learning. This can be accomplished by providing students with more freedom to select the subject of their project and to manage their time and their actions in the problem-solving process. The social learning perspectives described earlier also draw attention to the support that students might get from peers in the laboratory. Students can clarify their ideas and the way they had developed them, in order to explain those ideas to their classmates. Moreover, laboratory experiences in which students discuss ideas and make decisions can present many opportunities for teachers to observe students' thinking as they negotiate meaning with their peers. Carefully observing students' actions and listening to their dialogue creates opportunities for teachers to focus questions and make comments within learners' zones of proximal development (Duschl and Osborne 2002; Vygotsky 1978, 1986) that can help the students to *construct* understandings that is more compatible with the concepts of expert scientific communities.

An application of these perspectives is demonstrated in a chemistry laboratory programme titled Learning in the Chemistry Laboratory by the Inquiry Approach was developed by Hofstein et al. (2004) at the department of Science Teaching at the Weizmann Institute of Science in Israel. For this programme, about 100 inquiry-type experiments were developed and implemented in eleventh and twelfth grade chemistry classes in Israel. A two-phased teaching process was used, including a guided pre-inquiry phase followed by a more open-ended inquiry phase. Based on their research, Mira Kipnis and Avi Hofstein (2008) have linked metacognitive skills (based on the model of Schraw 1998) to various stages of the inquiry-oriented experiments. First, whilst asking questions and choosing an inquiry question, the students revealed their thoughts about the questions that were suggested by their partners and about their own questions. In this stage, *metacognitive declarative knowledge* is expressed. Second, whilst choosing the inquiry question, the students expressed their *metacognitive procedural knowledge* by choosing the question that leads to conclusions. Third, whilst performing their own experiment and planning changes and improvements, the students demonstrate the *planning* component of *regulation of cognition*. Fourth, at the final stage of the inquiry activity, when students write their reports and have to draw conclusions, they utilise *metacognitive conditional knowledge*. Fifth, during the whole activity, students made use of the *monitoring* and *evaluating* components concerned with *regulation of cognition.* In this way, they examined the results of their observations in order to decide whether the results are logical.

Scientific Argumentation and Epistemologies – A New Rationale for Practical Work

When Rosalind Driver et al. (2000) presented their introduction to argumentation in science education, they quickly pointed towards the relevance for practical work. They saw argumentation as correcting the misinterpretation of the scientific method that has dominated much of science teaching in general and practical work in particular. Rather than focusing on the stepwise series of actions carried out by scientists in experiments, they suggested a focus on the *epistemic practice* involved when developing and evaluating scientific knowledge. Gregory Kelly and Richard Duschl (2002) similarly present science learning as *epistemic apprenticeship*: the appropriation of practices associated with producing, communicating and evaluating knowledge. Within this framework, practical work becomes a way of introducing students to *community standards* applied by scientists. We sense two overlapping learning aims: students should understand the scientific standards and their guiding epistemologies; and students should be able to apply these standards in their own argumentation.

We find many ways of approaching research into students' epistemological understanding and argumentation skills. One contribution comes from psychologists who identify scientific argumentation as the key element of scientific thinking (Kuhn et al. 1988). Dianne Kuhn et al. work from the perspective that certain reasoning skills related to argumentation are domain general. People who are good at scientific argumentation are able to (1) think *about* a scientific theory, rather than just think *with* it; (2) encode and think about evidence and distinguish it from theory and (3) put aside their personal opinions about what is 'right' and rather weigh a theoretical claim against the evidence. Kuhn (2000) demonstrates how these abilities develop naturally from childhood to adulthood, but also that the quality varies amongst people. Scientists are good at this thinking because it is embedded in their culture and, importantly, explicit training in the science laboratory seems to help (Kuhn et al. 2000).

Another contribution comes from research on *procedural knowledge* (Gott and Duggan 1995) presented earlier in this chapter. Glen Aikenhead (2003) illustrates the relevance in society and work life of understanding issues related to the way in which scientists use data as evidence to draw conclusions. The underlying idea is that knowledge about data and the use of data developed in the laboratory can be transferred to these situations. One study of university students supports this (Roberts and Gott 2007), but little evidence yet exists for younger pupils.

Several research studies indicate that the development of students' argumentation skills and science epistemologies is rather complicated. Students, for example, might hold some beliefs about professional science and very different beliefs about their own practices with inquiry at school (i.e. students have one set of *formal* epistemologies and another set of *personal* epistemologies) (Hammer and Elby 2002; Sandoval 2005). Many years of teaching 'ideas and evidence' in the UK through practical investigations illustrate this complexity (Driver et al. 1996). Per Kind (2003) suggested that the overall picture has been that students become good at doing specific types of routine experiments, and solve these using school-based strategies rather than a general understanding of formal scientific epistemologies. Jim Ryder and John Leach (2005) assume that one reason for these problems is that learning objectives are not sufficiently made explicit to the students. Most students are able to articulate the learning objectives following a lesson focused on science content knowledge, even if they struggle to understand the concepts. However, when the objective of a lesson has an epistemological or procedural focus, students are much more unclear about what they are intended to learn.

Many writers have also related the problems with developing epistemological views and practices in school science to the teachers' background and competencies. Maher Hashweh (1996) has found connections between the epistemological beliefs expressed by teachers and their preferred ways of teaching, but the relationship is not simple. It is teachers with naïve epistemological beliefs who most easily support teaching 'real science' in the school laboratory. In addition, it is suggested by Nam-How Kang and Carolyn Wallace (2005) that such teachers more easily view students as 'young scientists' who are able to construct meanings on their own. For a teacher with a more sophisticated epistemological understanding of science, the relationship is more complicated. They tend to disconnect 'real science' from 'school science' and more rarely allow their epistemological beliefs to be reflected in their teaching practice, as shown in studies conducted by John Barnett and Derek Hodson (2001) and by Nam-How Kang and Caroline Wallace (2005). Teachers with sophisticated epistemologies also seem to separate science from students, treating students as more as 'spectators' of science (e.g. Randy Yerrick et al. 1998).

Pilar Jimenez-Aleixandre et al. (2000) suggested that a better understanding of how practical work might contribute towards the development of students' epistemological understanding and argumentation skills could involve a closer look at the 'teaching ecology' of the laboratory. It is strongly argued that bringing argumentation into science classrooms requires the enactment of contexts that transform them into knowledge-producing communities, which encourage dialogic discourse and various forms of cognitive, social and cultural interactions amongst learners (Duschl and Osborne 2002; Newton et al. 1999). An ecology that promotes this practice is created through the social and physical environment (Wolff-Michael Roth et al. 1999), the laboratory tasks (Clark Chinn and Betina Malhotra 2002) and the organisation principles used by the teacher (Issam Abi-El-Mona and Fouad Abd-El-Khalick 2006; Phil Scott 1998). A reconsideration of all these factors is therefore needed for the science laboratory to contribute meaningfully and effectively towards the new learning goals.

Concluding Remarks

The biggest challenge for practical work, historically and today, is to change the practice of 'manipulating equipment not ideas'. The typical laboratory experience in school science is a hands-on but not a minds-on activity. This problem is related to teachers' fear of loosing control in the classroom and giving students more responsibility for their learning. Also, the current situation can be blamed on assessment practices that do not pay enough attention to higher-order thinking and a long tradition of developing foolproof laboratory tasks that guide students through activities without requiring deep reflection. This chapter has demonstrated a relationship between these problems in practical work and commonsense ideas about science inquiry as a stepwise method.

It has taken science education research a long time to reveal this practice, analyse its underlying rationale and present alternatives. The development has required a move away from quantitative data-collection methods, which are not sensitive to students' learning in the laboratory, towards more authentic ways of studying what actually goes on in the laboratory. It has also required a thorough analysis of the nature of science inquiry and what makes someone good at doing it. The alternatives that are prominent today not only combine sociocultural perspectives on science and learning, but also link to new aims for school science as an important provider of skills and knowledge for citizenship.

At the turn of the century, we might claim that science education is in a better position than ever before for developing meaningful and appropriate practices for laboratory work. The situation is most promising because of the results and knowledge that have been accumulated and achieved. There are many places to start in developing new laboratory teaching strategies and professional development provisions for teachers. These and other tasks call for science education researchers to engage with practical work and to help to develop this area further.

Chapter 16
From Teaching to KNOW to Learning to THINK in Science Education

Uri Zoller and Tami Levy Nahum

Introduction

The development of students' learning via higher-order cognitive skills (HOCS)-promoting teaching is a continuous overriding challenge for many educators and researchers in science education. This chapter focuses on the paradigm shift from the traditional lower-order cognitive skills (LOCS) rote-algorithmic teaching to know, to HOCS-promoting learning to think, while referring to the relevant multicomponents educational system of teaching strategies, learning styles and assessment methods.

Worldwide, a major driving force in the current effort to reform science education is the widely held conviction that it is vital for our students to develop their HOCS capacity, to enable them to actively function and meaningfully participate in the relevant decision-making processes operating in the context of the complex science-technology-environment-society (STES) interfaces of multicultural societies.

HOCS is conceptualized as a non-algorithmic, complex, multicomponent conceptual framework of reflective, reasonable, and rational systemic evaluative thinking, focusing on deciding what to believe and do, or not to do, to be followed by a responsible action (Zoller 1993, 2000).

In this chapter, we envision HOCS as an umbrella encompassing various overlapping and interwoven forms of cognitive capabilities (Fig. 16.1), such as critical thinking, system thinking, question-asking, evaluative thinking, decision making, problem solving and, most importantly, transfer. Thus, critical thinking (Ennis 2002) and lateral (system) thinking (de Bono 1976) involve uncertainty, application of

multiple criteria, reflection, and self-regulation (Resnick 1987), and these are all interwoven components within the HOCS framework.

Figure 16.1 illustrates schematically our complex conceptual model of HOCS, referring to interrelated generic (non-content-wise) cognitive capabilities, making sense in context. It is a nondirectional superordinate model, not specifically ordered or linearly hierarchical. The important LOCS components of basic cognitive capabilities are inherently embedded in the various components of the model and are not dealt with in this chapter.

In Bloom's taxonomy of cognitive development (Bloom et al. 1956), analysis, synthesis, and evaluation are considered as HOCS whereas recall of information, comprehension, and application are envisioned as LOCS. The HOCS conceptual model is different in its (1) being non-linearly ordered from bottom-up as far as the various capabilities and/or skills are concerned; (2) being not demanding, nor suggesting a particular hierarchy in the development or the acquirement of the HOCS components; and (3) being an overlapping synergistic collection of capabilities and skills such that linear progress from the bottom (knowledge) to the top (evaluation) should not, necessarily, be maintained in the learning process of individuals, nor should it be applied in this linear bottom-up mode by them.

We refer to the *Transfer* capability (Fig. 16.1), as the superordinate HOCS capability, required for "bringing home" the overriding objectives of HOCS learning in different situations and real-life problem-solving contexts. This suggests designing science teaching, assessment and learning as a challenging enterprise, purposed at promoting the capability to generate ideas and alternatives rather than just to select among given/known available alternatives (Zoller and Scholz 2004).

The main components of the HOCS framework are briefly presented and discussed, targeted at translating the HOCS model into a viable, applicable science teaching practice. In doing that, we shall avoid using definitions of HOCS key components, since definitions, by definition, are limiting rather than opening the scope for multidimensional interpretation and flexibility in the evolving teaching practices.

Critical Thinking

In our real world, people are more and more required to adequately respond to the complex problems they are confronted with, by making rational decisions, based on evaluative, critical system thinking, rather than to passively accept solutions provided, or imposed by others (people, authorities, or society at large). Therefore, the development of students' HOCS capabilities encourages them to raise doubts, investigate situations, and probe alternatives, in the context of both school and daily life (Zoller 1993, 1996).

Meeting such challenges requires the development of a student's capacity for *Critical Thinking* (Fig. 16.1), which is necessary for the in-depth analysis of unfamiliar situations, so that their related HOCS will be based on rational thinking (Ennis 2002; Barak et al. 2007). Indeed, critical thinking has been defined as the skill of taking responsibility and control of our own mind, or as logical and reflective thinking that focuses on a decision what to believe in and what to do (Zoller et al. 2000). It involves a variety of skills such as the identification of the source of the information, analyses of its credibility or bias, reflecting on whether this information is consistent with prior relevant knowledge and, ultimately the drawing of conclusions based on critical thinking (Linn 2000). This capability is considered to be essential for the promotion of metacognitive understanding (Kuhn 1999). It is conceptualized by us as result-oriented, rational, logical, and reflective evaluative thinking, in terms of what to accept (or reject) and what to believe in, followed by a decision what to do (or not to do) about it; then to act accordingly and to take responsibility for both the decisions made and their consequences (Zoller 1999).

Question-Asking

Question-asking is an essential component of the HOCS model, particularly in the context of the critical thinking problem-solving process. Therefore, the development of this capability should be an integral component within the teaching process (Dori and Hershkovitz 1999; Zoller 1993). This requires a purposed effort on the part of science teachers to encourage and challenge their students to ask relevant, in-context meaningful questions and, persistently, to exercise this capacity. The contemporary dominant practice of students conditioned just to provide a one correct answer without wait time to mostly algorithmic-type questions asked by the teacher or by the textbook, is leading, at best, to successful algorithmic-learning; that is, knowledge acquisition, not evaluative thinking capability (Tami Levy Nahum et al. 2010).

An examination where the student asks the questions is one of our proposed strategies to translate into practice the agreed upon objective of shifting from knowing to thinking (Zoller 1994). This unique assessment strategy, which has been longitudinally practiced and research evidenced, is described later in this chapter.

System Thinking

System or lateral thinking (de Bono 1976) is a key-cognitive component within the HOCS conceptual model that enables us to deal with our world's complex problems in their real context. Although it doesn't guarantee a single, unidimensional solution to the problem at point, it does enable deep and comprehensive dealing with the complexity of the problem and referring to different solutions. System thinking means the cognitive ability to see and consider the whole (system), the parts (sub-systems) of the whole, the mutual interrelationships between them (the dynamics and change intra-impact), and the overall mode of operation. Developing system thinking helps to perceive the importance of, and to meaningfully deal with, multidimensional complex phenomena and to consider the significant interdisciplinary relationships in the system. That is, system thinking offers us a cognitive tool that is broadening, expanding, and re-formulating our regular, simplistic way of thinking regarding complicated subjects. Therefore, developing system thinking in science education isn't only geared toward providing additional skill, but also for the crystallization of a comprehensive view point that would create a basis for the meaningful productive co-application of other HOCS (Zoller and Scholz 2004; Ben-Zvi Assaraf and Orion 2005).

Evaluative Thinking

In the broad context of science education, we conceptualize a learner who has acquired evaluative thinking capability as a self-reflective, doubting, and rational, who purposely applies critical system thinking, followed by an in-context decision concerning the course of action that should be taken, in order to resolve or relate to problem-solving situations and the entire spectrum of real-life issues (Levy Nahum et al. 2009). Within the HOCS conceptual framework, we consider evaluative thinking as a complex cognitive ability, encompassing/integrating the various overlapping components of other cognitive abilities such as critical system thinking, and creative judgments. We expect the evaluation process to be followed by a responsible decision of the evaluator as to what course of action has to be taken in order to resolve the issue at point.

Decision Making

As citizens in a modern world of conflicting interests, we should be able to use a whole spectrum of various multidimensional HOCS such as asking relevant meaningful questions and thinking systemically and critically, in order to make intelligent and rational decisions in dealing with solving personal, social, or scientific-technological problems (Facione and Facione 2007; Zoller and Tsaparlis 1997). It appears to be agreed upon that, in confronting complex issues within operating complex systems, science educators should focus in their science teaching on multifaceted issues, discuss their problematic components and, in this context, encourage students to develop and ultimately apply their HOCS practice throughout their related learning process. Equipped with these cognitive tools, students will, hopefully, be able to make rational decisions, and act accordingly. The key role of decision making in this context is straightforward (Levy Nahum et al. 2010).

Problem Solving

Problem (not exercise) solving is one of the most important human capabilities in our multicomponent, complex world. So, what do we mean by a problem? John Hayes (1981) suggested that, whenever there is a gap between where you are now and where you want to be but you don't know how to cross that gap, you have a problem.

Problems in science, in science education, or in any other discipline, come in many forms and styles and are presented in various modes and contexts. Alex Johnstone (1993) categorized problems according to three parameters: (1) whether or not data was given, (2) whether or not the method was familiar to the solver, and (3) whether or not the problem posed lead to a specific and well-defined solution/goal. Using this model, Johnstone identified several different types of problems ranging from a purely algorithmic task, to a task, which is not accompanied with given data, requires the application of unfamiliar (to the learner) methods, and has ill-defined characteristics. The former may be considered to be an exercise rather than a problem, while the latter is considered to be an open-ended problem, or simply a problem – as distinct from an exercise.

The use of additional context can make a problem or a science course more engaging for students, but it can also make it more complex. In such cases an individual's ability to "see the wood for the trees" and pull out relevant and useful information or hints from a complex situation could enhance their success in solving the problem (Overton and Potter 2008). Thus, problem-solving activities within HOCS-promoting teaching strategies may expect to promote HOCS learning, while exercise solving centered teaching may (but not necessarily so) result, at best, in algorithmic knowledge gain (Ben Chaim et al. submitted).

Transfer

As mentioned previously, in our view, the transfer capability is central in science education and highly essential for applying HOCS in different contexts and situations. It constitutes an effective way to measure conceptualization (Cohn 2005; Solomon and Perkins 1989). In fact, attaining the capacity of transfer within the domain and even more so – outside of the particular subject matter taught, is considered by the educational community to be the ultimate overriding goal of both science education and education at large (Zoller 2000). Training in the application of problem solving and decision making within a wide range of situations has been demonstrated via research, to promote transfer in new situations and contexts. The transfer is, therefore, advanced by exposing the learner to a wide variety of non-algorithmic tasks in different contexts, by experiencing a wide range of applications. Such experiences enable the learner to represent problems and ideas in their appropriate levels of abstraction and complexity, and to develop flexible representations and deep conceptualizations of what is learned. All of this, as an extension of the domain-specific situated cognition is to be encouraged by teachers and to be applied in their science teaching.

Learning Science in the Interdisciplinary STES Interfaces Context

Societies, worldwide, are continuously coping with sustainability related complex issues in the Science-Technology-Environment-Society (STES) interfaces' context. An interdisciplinary approach, accompanied by evaluative thinking has the potential of providing a balanced world outlook and a meaningful understanding of the different operating systems and their interrelationships. Thus, we suggest that if teachers purposely and persistently promote students' HOCS capabilities within interdisciplinary STES contexts in their classes, there is a solid research-based evidence of a good chance for a consequent positive development of the targeted capabilities, decision making, and problem solving included.

The implementation of science for all (American Association for the Advancement of Science (AAAS) 1989) in science education has been strongly advocated since the 1980s. As a result, massive efforts were invested and huge resources were allocated for the design of new science curricula (Tomorrow 98 1992). The fusion of the Science-Technology-Society (STS) movement (Yager 1993; Solomon and Aikenhead 1994) and environmental education for sustainability has yielded the STES orientation in science education (Zoller 1991, 2000). Seven such STES modules have been developed and implemented within a science curriculum. These modules, entitled *Science, Technology and Environment in Modern Society* (Zoller 1998) were developed by seven different teams of teachers in the schools. Each module was designed to serve as an effective STES-oriented curriculum unit, incorporating research-based HOCS-promoting teaching, learning, and assessment strategies. The ultimate goal was the conceptualization by students, of fundamental concepts in science; for example, reversible and irreversible processes, dynamic equilibrium, and periodicity (see also later sections in this chapter).

HOCS Development

From Theory to Practice

The literature in science education emphasizes the importance of promoting students' HOCS capabilities. It is well known, however, that even widely accepted educational theories (or reforms) are not as easily implemented in the classroom as originally planned (Barak et al. 2007). Consequently, there is a gap between educational guiding theories and the related goals to be attained through the developed and implemented curricula, teachers' professional development programs, and the actual practice implemented in the classroom (Boddy et al. 2003).

The translation of a LOCS-to-HOCS shift into practice in science education is inhibited by conflicting pressures and major systemic factors such as the traditional high-stakes assessment and grading systems in both in-class and external examinations (Lerry Nahum et al. 2007; Zoller 1999). Therefore, any progress toward the attainment of HOCS learning-related goals constitutes a great challenge in contemporary science education; that is, it would require the application of a new pedagogical approach, different from the teaching to know strategies and, most importantly, to constitute an alternative to the currently dominant, traditional assessment methodologies, within newly designed appropriate science curricula and courses that would mesh with the leading desired learning outcomes.

Pioneered by Uri Zoller's group and others (Leou et al. 2006; Overtone 2001), an extensive range/set of innovative research-based teaching and assessment strategies and methods complying with the HOCS conceptual model and its guiding objectives have been developed and implemented worldwide during the last two decades. Selected examples of these strategies, methods, exemplary HOCS-type questions, or tasks and tools are presented in the following sections.

Teaching Strategies and Assessment Methods for HOCS Development: How to Do It?

A crucial issue is how to translate the above into manageable and effective HOCS-oriented courses, teaching strategies, assessment methods, and HOCS-promoting examinations that will be in consonance with the desired HOCS-learning outcomes and be implemented by professionally prepared and conceptually converted teachers.

Traditional science teaching is based on textbooks presenting neat, clear-cut, authoritative, unchallenged theories, rules of nature, and ultimately one correct solution to each related problem posed (Nakhleh 1993). Typically, this line of teaching emphasizes formal definitions, equations, facts, formulas, and algorithms, in terms of knowing, remembering, defining, and identifying, all of which empower students to respond successfully to LOCS-requiring questions (Zoller and Tsaparlis 1997).

Because assessment constitutes an integral part of the teaching-learning process, HOCS-oriented science teaching requires the same orientation in assessment. Within efforts to promote science students' HOCS, we have incorporated a formative and summative-type practice-oriented research program targeting at finding to what extent and under what circumstances, HOCS learning is attainable (AAAS 1994; Zoller et al. 1999, 2002). In our view, one of the more important issues in science education and in education at large, at all levels, is the agreed-upon perception by educators and teachers of the teaching and assessment strategies as an integral entity. The whole attitude regarding these crucial factors should be significantly changed; specifically, examinations as well as other assessment means must not only be an integral part of the teaching process and aligned with the HOCS-learning goals, but also to meaningfully foster them as well as contribute to their promotion and attainment (Zoller 1990).

A shift from focusing on what should our students know in order to succeed in the examination, to what should our students be able to think, decide, resolve, do, or act, must be operationized. We suggest that our practice-oriented research efforts contribute to the application of this paradigm shift.

Teachers are generally acknowledged as the key figures in making any type of curriculum significantly different. Accordingly, we do expect the science teacher to be capable of designing her or his own curriculum and restructuring available curriculum suggestions, in accordance with her or his needs and aligned with the HOCS goals. Students should be guided by the science curriculum materials as well as their teachers, on how to develop these skills purposely and intelligently through persistent practice.

For successful pursuit of the above, teachers' pedagogies should include a few of the numerous possible ways of how to do it proficiently. Based on the findings of our longitudinal practice-oriented active research, a LOCS-to-HOCS paradigm shift in science/chemistry and STES education requires the purposeful implementation of teaching strategies (Zoller 1993, 2000), such as those presented in Fig. 16.2.

In the HOCS-learning context, a task is conceptualized as a problem type whenever the student is confronted with unfamiliar elements. Her or his engagement with such a novel component of the task is an effective means for the development of their related HOCS capabilities (Zoller and Tsaparlis 1997; Ben-Chaim et al. submitted).

Explaining ideas and interpreting information to someone else often requires the explainer to think about the problem in question in new ways, translating it in different terms, or generating new examples. These socio-cognitive activities induce the explainer to clarify related concepts, to elaborate on them, and to reconceptualize whatever is involved in some other manner. Thus, by actively interacting with peers

- Promoting an open and supportive atmosphere in the science classrooms
- Defining, explicitly, the course's and particularly the lesson's goal and objectives to enhance active participation of the students in the learning process
- Providing students with opportunities to explore
- Examine and consider different possible alternatives for resolutions when confronted with problems
- Encourage students to ask HOCS-type questions concerning the issues involved by fostering of in-class 'Question-Asking' and critical (evaluative) thinking
- No specific course textbook to be assigned; teach, learn and assess beyond the formal textbook framework
- Students cover/learn material *before* it is ‘covered’ by the instructor in class
- Lecture, recitation and lab sessions are integrated within the course
- Administration of specially designed HOCS- oriented examination
- Include students' learning materials (textbooks, notebooks, personal notes est.) in all examinations, take-home examination, oral or 'paper and pencil'-test
- Provide/use open HOCS-type, rather than multiple choice or true-false questions
- Provide and encourage explanations and foster argumentation skills rather than just relying on narrow-scope clear-cut definitions
- Focusing on problem, rather than exercise solving, should be 'the name of the game' in science education (Zoller et al. 1999)
- Cooperative learning environments can be an ideal setting for developing HOCS (Lazarowitz R., Hertz-Lazarowitz R., 1998).

Fig. 16.2 Selected teaching and assessment HOCS-oriented strategies

and teachers and having relevant information, students will be able to accomplish much deeper understanding rather than just memorizing the subject matter.

An innovative science teacher’s metacognition and HOCS-promoting professional development course, integrating formal and informal science and environmental education, was developed and implemented within a science teaching course, focusing on the leading role of HOCS in science education (Leou et al. 2006). The HOCS-promoting teaching and assessment strategies applied in this professional development course not only enabled participants to reflect on their own learning, but also facilitated their self-reflective metacognition-related assessment, utilizing a pre-post-designed research-based methodology. By reflecting on what has been done during the learning process, students are provided with the opportunity to develop their thinking skills within the context of science learning and, consequently, to be able to recognize the usefulness of these skills for practical purposes as well (Weinberger and Zohar 2000).

Our accompanying teaching practice-oriented research projects were based on the assumption that those traditional instructional strategies of teaching and assessment in science education are not compatible with the development and fostering of students’ HOCS. Our research findings corroborate this (Tal et al. 2001).

HOCS questions/tasks (Zoller and Tsaparlis 1997) are operationally defined as follows: HOCS problems are unfamiliar to the student and require for their solution, beyond knowledge and application, analysis and synthetic capabilities, as well as making connections and evaluative thinking on the part of the solver; this can include the application of known theories and HOCS to unfamiliar situations (transfer).

LOCS questions/tasks (Zoller and Tsaparlis 1997) are defined as follows: knowledge questions that require for their solution simple recall information or a simple application of known (to the student) theory or knowledge, to familiar situations and contexts; they can also be problems, solvable by means of algorithmic processes that are already known to the solver through specific directions or practice.

To this end (the development of students' HOCS), we have developed and validated appropriate teaching-assessment instruments. Selected examples of these cognitive tools are found in later sections.

An Action Model – The Decision-Making-Problem-Solving Act

A decision-making action model was developed and proposed to guide the science teaching of STES-oriented curricular modules in science education (Zoller 1990). It was later supported by the Mary Ratcliffe's (1997) model that described a similar framework based on other normative models. The Decision-Making-Problem-Solving Act model was successfully implemented in several curricular modules and courses (Tal et al. 2001). This model contains eight steps, not all are expected to be followed and not necessarily in the order given below in each case. Rather, it is suggested to be flexibly applied in alignment with each specific case, course, or curriculum:

1. Look at the problem and its implications, and recognize it as a problem.
2. Understand the factual core of knowledge and concepts involved.
3. Appreciate the significance and meaning of various alternative possible solutions (resolutions).
4. Exercise the Problem-Solving act:
   - Recognize/select the relevant data information
   - Analyze it for its reasonableness, reliability, and validity
   - Devise/plan appropriate procedures/strategies for future dealing with the problem(s), at point
5. Apply value judgments (and be prepared to defend!)
6. Apply the Decision-Making act:
   - Make a rational choice between available alternatives, or generate new options
   - Make a decision (or take a position)
7. Act according to the decision made.
8. Take responsibility!

HOCS-Promoting Questionnaires and Tasks

Questionnaires and tasks constitute an effective means for promoting the teaching-learning process, beyond just serving as assessment tools. We have developed several questionnaires for HOCS assessment and successfully used them in different

Read the following paragraph:

Resources and energy: What are the future options and alternatives?

Almost every aspect of the Western world is based on the consumption of energy and products derived from the finite crude oil and natural gas resources. There are sufficient reserves of coal that could lead to the production of enough synthetic fuel and gas for the present time. However, energy alternatives (e.g., solar, wind, tide, and waves) should be developed to satisfy the need for the production of electricity. This would involve the substitution of diminishing resources by available non-finite resources. Nuclear energy is another possibility. Future alternatives concerning resource exploitation and energy supply require an in-depth analysis and intelligent decision …and the sooner the better.

Four out of the 7 questions in this questionnaire are as follows:

1. Formulate three questions that you would like to, or think, are important to ask concerning the subjects dealt with in the paragraph.
2. Can you, based on the given paragraph (and the information it provides), decide on the desirable alternatives of energy supply in your country? Explain your answer.
3. *Formulate* two *criteria* that guides you (or will guide you) in your decision concerning the most desirable alternative.
4. Briefly explain the pros and cons of the alternative(s) that you have chosen with regard to future implications. Compare your alternative(s) with any other alternatives that you did *not* choose.

Fig. 16.3 The Decision Making Questionnaire

modes/formats and settings for promoting HOCS. An illustrative multicomponent STES-oriented HOCS questionnaire, with respect to decision making, is presented in Fig. 16.3 (Zoller and Scholz 2004).

Similarly, Evaluative Thinking questionnaires have been developed, designed, and validated (Levy Nahum et al. 2009). One focuses on Barbeque-Health-Ecology Interfaces and the other deals with Water-People-Environment.

Both have been content-wise and structurally validated by three experts in the field and showed a satisfactory inter-rater level. All these questionnaires were developed on the basis of the following: (1) the items posed have no right or wrong answer; namely, no item requires a single-dimension, one correct response; (2) they are linked to the STES context; and (3) they are associated with just first approximation relevant information, potentially useful for the respondents. Two of the twelve questionnaire's items are given below as examples:

Question 1. The title of the paragraph – Barbeque, Health and Ecology – includes ecology, although in the paragraph there is no mention of it. In your view, *are there any links* between barbeque and ecology? *Justify* your opinion in case you think that there are links and in case you think that there aren't.

Question 2. In your estimation, *what is the main aspect* that might have an impact on the future of people (or your) behavior concerning the discussed issue? *Justify* your evaluation.

The accumulated experience, accompanied by action research, suggests that the persistent implementation and practicing of HOCS-oriented teaching and assessment strategies is the key for the attainment of meaningful disciplinary and interdisciplinary generic HOCS learning (Levy Nahum et al. 2010).

Although the road to HOCS learning is rocky, this educational goal is attainable; it can and should (!) be done. Our longitudinal HOCS-related research suggests that only prolonged, consistent, and systemic persistence may advance students' HOCS capabilities (Ben-Chaim et al. submitted; Zoller & Pushkin 2007). In the next section, how to do it in chemistry teaching will be demonstrated.

HOCS Development: The Case of Chemistry Education

Traditional chemistry teaching has focused on the presentation of a sequence of definitions, equations, and facts to be memorized and the acquisition of algorithms to be applied or reproduced by students (Cracolice et al. 2008). Given this reality, the students' epistemological perspective on chemistry is one of receiving knowledge (Zoller 1993). Students do not really try to, and are not being challenged to, conceptualize the underlying key ideas (Levy Nahum et al. 2007). Commonly, students collect facts without applying judgments; they do not, and nor are they required to develop opinions. Chemistry knowledge is thus perceived as a rigid body of facts revealed by authority (professor or text) and the students' role is to return their rote-knowledge to these authorities, without processing it. Since students are not exposed to novel problems, their chemistry problem-solving skills as well as other relevant HOCS capabilities cannot be expected to be developed meaningfully (Zoller 1990; Zoller and Pushkin 2007).

The development of students' HOCS capacity in chemistry requires the use of appropriate teaching strategies such as inquiry-oriented class discussions, cooperative learning, and active participation of students in the teaching-learning-assessment processes (Zoller 1993). Such practices are useful when students are exposed to relevant real-world problem-solving/decision-making situations that require the application of their value judgment and critical thinking skills (Facione and Facione 2007). It also requires inquiry-oriented class discussions and open-ended HOCS-type examinations (Zoller 1991), rather than the traditional multiple choice objective tests (Nakhleh 1993).

The LOCS-to-HOCS Shift in Chemistry Education: How to Do It?

One of the several possible HOCS-promoting teaching strategies is an examination where the student asks the questions. From our long experience, this is the most successful teaching-learning strategy for translating HOCS-objectives into practice. This assessment strategy is innovative, oriented toward HOCS-promoting teaching/evaluation that has been ideated, developed, and successfully implemented, initially, within the teaching of chemistry to freshman science students (Zoller 1994).

The core element of such an examination in contradiction to the traditional pencil-and-paper class examinations (in which the students respond to a series of questions prepared by the teacher) is a pre-arranged in-class oral session, in which the course teacher or professor is examined by their students orally using their home preprepared written questions related to the course. Two to five of the student-formulated questions (which have not been treated during the class session) are selected by the teacher and redistributed to all course participants to serve as a take-home examination. Students respond individually to their pool-selected questions at home and return their responses to their professor for evaluation.

Obviously, this is only one of various possible alternative procedures for conducting examinations promoting HOCS. It definitely poses an intellectual challenge to students, leading to the application of students' self- and peer-assessment strategies in science education. Furthermore, if we engage students as partners in activities involving self-assessment or evaluation of their performance on tests and progress in learning, they can not only enhance their cognitive strengths and HOCS capabilities, but also learn in greater depth (Zoller et al. 1999). This means more time to be allocated for HOCS-promoting teaching that emphasizes the development and improvement of students' cognitive skills, mainly through their self-learning and active participation in the learning process. However, related difficulties such as time limitations and large classes associated with the design, administration, management and grading of HOCS-oriented homework and examinations, constitute a barrier for their implementation.

Class Discussions and Student Involvement

Class discussions initiated by the class teacher or the students, should present relevant problems and inquiry-type questions, rather than making just explanatory statements related to the course topics. In classes that never have experienced such a strategy, the following (or similar) responses are to be expected.

The following issue was presented by an organic chemistry professor to his sophomore class: "Which of the two, toluene or bromobenzene, would you expect to be more reactive toward electrophilic substitution, and why?… Let's think about it." The spontaneous response of one of the students was: "We are not supposed to think; you-the professors-are supposed to tell us the answer." The spontaneous responses of other students' on that occasion ("…do not venture off…teaching necessary for..[passing]..the final examination"; "…complete the reactions on the board … don't leave it for us all the time…") suggest that the teaching practice of traditional lecture-centered and LOCS-level final examination in chemical courses have already taken their heavy toll.

Figure 16.4 shows examples of questions that were used to initiate inquiry-oriented class discussions in an organic chemistry freshman course (Zoller 1999).

The point is that dispositions for HOCS thinking within the context of science/chemical education are contingent on provisions and opportunities to exercise and experience the related generic HOCS. Based on our experience, inquiry-oriented

1. Arrange pyridine, pyrrole, and imidazole in the order of their (a) water solubility, (b) capability of hydrogen bonds formation, (c) basicity, (d) nucleophilicity toward electrophilic (Lewis acid-catalyzed) substitution. Explain and rationalize your determinations.

2. The Aldol condensation presented above is a facile reaction which takes place under relatively mild conditions. (a) What is the driving force for this overall transformation? (b) Why is the base needed? (c) Why is the carbanion/enolate obtained during the reaction from the acetone and not from the benzaldehyde? (d) Can one obtain additional products in the given reaction? Explain your answers. (e) Is there any question(s) concerning the above that you might have? Formulate the question and try to briefly respond to it.

Fig. 16.4 Inquiry-oriented class discussions in an organic chemistry freshman course

BOTTLED mineral water can be a source of food poisoning responsible for thousands of cases of illness, according to new research. Scientists found that it could account for 12% of infections by the bug campylobacter, the biggest cause of food-borne infection in the Western world….The new research shows, for the first time, that bottled mineral water is a potential hazard. Bottled water was found to account for 12% of the cases studied, salad 21% and chicken 31%. Scientists compared 213 campylobacter cases with 1,144 patients… with stomach problems but were not infected with the bug. In Europe, legislation states that mineral water must be free from parasites and infectious organisms but, unlike tap water, it cannot be treated in anyway that may alter its chemical composition.

Fig. 16.5 Bottled water link to fatal food bug (The Scotsman/Craig Brown, Oct 2003)

class discussions (either in groups or in planar) constitute feasible and manageable teaching strategies that facilitate the synthesis between HOCS-oriented strategic knowledge and chemistry understanding.

The following question taken from a freshman general chemistry (Chem 1 type) midterm examination (Zoller et al. 1999) is an illustrative case study example of an intended HOCS-promoting examination question:

> Which, the atom or the ion, in each of the following three pairs: (P^+, P; Cl^-, Cl; and Br^-, Br) do you expect to have the *lower ionization potential*? *Explain* your ordering.

As a second illustrative case study, two LOCS questions versus two HOCS questions, based on the framed recent online e-mail publication (Fig. 16.5) are given in Table 16.1. We suggest that these and/or similar HOCS-type questions could be incorporated in homework assignments, midterm examinations in freshman as well as in high school chemistry courses within HOCS-oriented science education (Zoller 2004).

Selected illustrative HOCS versus LOCS problems are provided in Fig. 16.6.

The above problems related to real-life scenarios, situations, issues, and questions posed are unfamiliar to students in science/chemistry courses. Responding to such questions requires much beyond just basic knowledge (LOCS-type) that students are usually exposed to in general chemistry courses. The most meaningful aspects here are: (1) the required students' HOCS-level responses to those HOCS questions, (2) their making connections, and (3) their critically evaluating options concerning

Table 16.1 Illustrative LOCS vs. HOCS-Requiring Questions

LOCS-type questions	HOCS-type questions
According to the article: Is the higher mineral content of the bottled water (compared to "ordinary" tap water) – responsible for the higher health risk of the former?	Suggest a *controlled experiment* in the lab, via which you'll be able to unequivocally determine, that the difference in the "minerals content" between bottled and tap water is *not* responsible for the difference in their relative health risk
The disinfection of bottles used in the food industry is being done by Cl_2 (gas) in basic aqueous solution. Write the reaction mechanism in this oxidation process. Which is the *active* specie?	Assuming that the reported research has been conducted properly and the presented data are reliable and valid; what, in your opinion, is *the reason* for the poisonous potential of bottled water? Justify your conclusion

In a battery factory, workers are exposed to ZnS and $CdCl_2$ *(in the manufacturing of electrodes), HCl (in the preparation of the electrolytic bridge); oily grease (from oily metal parts);* CH_2Cl_2 *(a solvent for cleaning the grease); and* H_2S*. A suggestion was made to replace the water by petroleum for washing the workers' working clothes.*

1.1 Do you think that the idea of replacing the water with petroleum is good from the point of view of cleaning the cloth? Explain (Question level: HOCS).

1.2 What is the possible source of the (poisonous) H_2S in the battery factory? Explain and write the relevant chemical equation (Question level: LOCS).

1.3 Based on the chemistry that you know, propose a simple practical method to overcome the H_2S problem in the factory (Question level: LOCS+).

1.4 Do you think that the idea of replacing the water with petroleum is good from the point of view of the environment outside the factory? Explain (Question level: HOCS).

Fig. 16.6 Exemplary HOCS versus LOCS questions

the decisions to be made based on their thinking and conceptualization beyond the LOCS level (Ben-Chaim et al. submitted).

Additional illustrative examples of LOCS- and HOCS-level questions actually applied within a mid/final chemistry examination for freshman science students are presented in Fig. 16.7.

The difference between the two sample multi-item HOCS- and LOCS-level examination questions is apparent. Because the ultimate objective of HOCS-oriented teaching in contexts of science teaching is the development of students' HOCS, the way to advance in this direction is to shift from the merely formal presentation of a sequence of equations, facts, or algorithms.

Rocket fuels [HOCS-level problems]

Different fuels are used for different purposes and applications. Fuels, which are used in rockets, are dimethyl hydrazine $C_2H_8N_2$ and hydrogen according to the following reactions:

(1) $C_2H_8N_2 + 2N_2O_4 \rightarrow 3N_2 + 4H_2O + 2CO_2$

(2) $H_{2(g)} + \frac{1}{2}O_{2(g)} \rightarrow H_2O_{(g)}$

a) Choose one of these two reactions and explain: what, do you think, are the main considerations in choosing this reaction as an energy source?

b) Why, in your opinion, N_2O_4 is used in reaction 1 instead of oxygen? Explain.

The emphasis in, and importance of, the questions above is not their level of difficulty but, rather, the HOCS level required for meaningfully dealing with them.

Buffer Solution [LOCS-level questions]

At your disposal is H_3PO_4 0.1M. You are to prepare, by adding sodium hydroxide, a buffer solution for PH=7. (Dissociation constants of Phosphoric acid are provided).

a) What are the concentrations of the main ions of the phosphoric acid in the buffer solution? Accompany your response with appropriate explanation and calculation.

b) If $Ca(NO_3)_2$ (a readily soluble salt) will be introduced into the solution that you have prepared, in a concentration of 10^{-3}M, would the salt $Ca_3(PO_4)_2$ precipitate? The Ksp of the Calcium Phosphate is $2.1x10^{-33}$. In your response to this question be helped by appropriate explanation and calculation.

Fig. 16.7 Examination questions for freshman science students

Students' Reflections Within HOCS Development

Students' appreciation of HOCS-oriented teaching within the study (Zoller 1999) is evident from the students' comments on the official evaluation questionnaires that were administered at the end of HOCS-promoting courses. In their words, "You (the teacher) have helped me to analyze problems and to use common sense to understand them, rather than simply memorizing a whole bunch of examinations…", or "I have benefited immensely from the emphasis on understanding rather than memorizing the material. However, I wish that this [i.e., understanding rather than rote learning] were reflected in final examinations"; and "… instead of spoon feeding us, you made us think—good!" . . . "I like to think that this is the way the doctors we trust for our health learned"; and "I appreciate your attitude of wanting us to really understand the material instead of just memorize it . . .".

The following quotes illustrate the participants' struggles along the traditional LOCS to the nontraditional HOCS assessment trail (Leou et al. 2006)

> This course began with a questionnaire which was the beginning of my journey of formulating questions and generating explanations for various situations using HOCS. This questionnaire exposed me to the practice of question-asking, problem solving, and the conceptualization of fundamental concepts. (p. 76)

The ultimate objective of HOCS-oriented teaching in the contexts of chemistry (science) and real-life situations is the development of students' HOCS, not their preparation for the LOCS-type final examination. Therefore, teaching strategies require venturing from the merely formal presentation of a sequence of equations, facts, and algorithms. It also requires, among others, social interaction among active participants within problem-solving situations (Zoller 1990, 1991).

In science/chemistry contemporary teaching, HOCS are usually developed and practiced within specific disciplinary areas, thus being subject matter-focused. Yet, their nature is generic not content-dependent. Therefore, their implementation in different contexts, should be worked out while taking care of the relevant constraints, and thus promote the transfer of these HOCS skills.

Although HOCS are not content-dependent, they are context-dependent. So, if acquired in a chemistry class, they do not transfer automatically to HOCS-promoting courses of other subject matter. Factors that affect the generalizability and transferability of cognitive thinking skills include understanding when a particular skill may be useful, capability of modifying the skill to fit different settings and contents, having the opportunity to practice with new material and to operate within new settings, and believing that a particular/relevant skill will be useful within new contexts or setting (Salomon and Perkins 1989).

Main Research-Based Findings and Insights

Our research supports the efforts being made worldwide, to implement HOCS-promoting teaching strategies/pedagogies in the science classrooms. Our studies reflect upon the importance of translating research findings into applicable teaching strategies for the development of students' HOCS capabilities and thus strengthen their conceptual understanding of science with all the implications involved.

Thus:

1. HOCS-promoting curricula, teaching materials, strategies, and in accord assessment tools are to be developed and implemented to endow our students with more than just algorithmic level in science learning.

2. Attaining STES-oriented chemistry literacy by students, requires an interdisciplinary systemic HOCS promoting approach in science teaching, targeting at evaluative HOCS learning for transfer.
3. Goals and expected outcomes of STES-oriented science course/program should be predetermined, to be followed by an appropriate, in accord, HOCS-promoting teaching assessment and learning practice.
4. Science/chemical education for sustainability should be an imperative within science education, at all levels.

Summary and Implications for Future Promotion of HOCS in Science Education

An important challenge for contemporary science education at all levels is the development and implementation of instructional practices that will foster students' HOCS capabilities of solving interdisciplinary, ill-structured complex problems. Our longitudinal research and implemented practice provide some fundamental insights into the way HOCS-type problems should be treated within science/chemistry teaching and assessment. The implications of these studies are as follows:

1. Problems (not exercises), which are integrated in HOCS-type homework assignments and examinations within the learning process, have the potential of developing students' problem-solving capability, because problems have the potential of eliciting HOCS-level responses on the part of the students.
2. The same applies to the other HOCS capabilities – system critical thinking, question-asking, decision making, and evaluative thinking. Continuously and persistently exposing students to the corresponding HOCS-promoting practice, accompanied by encouragement and support, does improve their overall HOCS capability and self-confidence in this mode of learning to think.

Because traditional science/chemistry teaching was shown by research to result in mainly LOCS level gain, the persistent integration of HOCS-promoting teaching, targeting at learning to think, will not only challenge students, but also will contribute, meaningfully, to the LOCS-to-HOCS paradigm shift as is evidenced by research. We have presented how to do it, providing a methodology for the design, development, application, and assessment of HOCS-oriented learning implemented within HOCS-promoting science teaching.

All of the above reflects the importance of translating research into applicable and manageable instructional HOCS-promoting strategies, thus strengthening students' conceptualization of science/chemistry fundamental principles and their capabilities of transfer in these and other scholarly and life domains. Because we strongly believe that students' HOCS development should be a prime instructional goal in science teaching, we recommend that HOCS-promoting examinations (including high-stakes examinations) should become an integral part of the teaching and learning process and meaningfully contribute toward the attainment of the

HOCS learning goal. We, the authors, believe that this goal can and should be achieved. Further research purposed at promoting this paradigm shift, and "how to do it" in different settings and contexts of our multicultural societies, will continue to be an issue of concern in science education research and teaching.

Chapter 17
The Heterogeneity of Discourse in Science Classrooms: The Conceptual Profile Approach

Eduardo F. Mortimer, Phil Scott, and Charbel N. El-Hani

Classrooms are peculiarly complicated social places with one teacher trying to interact with maybe 30 to 40 students in order to support them in developing particular points of view. In the case of science teaching, such views include a meaningful understanding of science concepts. With so many individuals ostensibly engaged in a single event, it is hardly surprising that students and teacher display a range of understandings. In any classroom, there is an inevitable heterogeneity in talking and thinking, which will be the focus of this chapter.

First of all, we pose the question 'What is a concept?' and argue for a perspective that sees conceptualization as a process and concepts as being actualized when they are put to use. At the same time we propose that conceptualization has a permanence associated with it and develop this point by making a distinction between sense and meaning and by referring to the literature on memory. This takes us to the heart of the chapter, where we discuss conceptual profiles as a way of characterizing the heterogeneity of modes of thinking in the classroom. Finally, we explore how conceptual profiles can be used as tools in analyzing the discourse of science classrooms, thereby making the link between talking and thinking.

What Is a Concept?

Concepts are treated in the science education literature in two different ways. A common approach is to view concepts as learners' mental models or schemes of an object or event. In this view, learners are treated as having concepts in their minds. This implies that concepts are relatively stable mental entities and are possessed by, or belong to, an individual.

The second perspective on concepts is quite different. It conceives concepts as something that only exist in a Popperian third world (Popper 1978; Wells 2008), as part of either a natural language or structured system of knowledge, such as science. Karl Popper (1972, 1978) referred to concepts as third world objects, distinguishing World 3 from the other two worlds in his model: World 1, the physical universe, and World 2, the world of conscious experience. Thus, Popper differentiates knowledge in the objective sense, which belongs to World 3 and exists in texts and language, from knowledge in the subjective sense, which belongs to World 2, and assumes the form of thought processes, related in turn to brain processes, which belong to World 1. What occurs in the mind of the individual, as part of the Popperian second world (Wells 2008), is not an instance of a concept, but a dynamic process, conceptualization, or in Lev Vygotsky's terms, conceptual thinking. Conceptualization is brought into play through an interaction between the individual and some external event or experience, and the process of conceptualizing is, in this respect, always social in nature.

From this point of view, concepts are not internal, more or less stabilized things, nor are they mental structures (Vosniadou 2008b) that are read aloud when an individual uses them. Nevertheless, there is an aspect of permanence in the process of conceptualization, that is, when conceptual thinking is fully developed, in a Vygotskian sense, it tends to operate in a similar manner in the face of experiences we perceive as being similar. It is this permanence – as a product of our enculturation – that allows us to both think through concepts and communicate with them effectively.

To elaborate on what is permanent in conceptualization, we will appeal to the distinction between sense and meaning (Vygotsky 1987). Vygotsky explains sense as follows: "A word's sense is the aggregate of all psychological facts that arise in our consciousness as a result of the word. Sense is a dynamic, fluid, and complex formation which has several zones that vary in their stability … In different contexts, a word's sense changes" (Vygotsky 1987, pp. 275–276). In turn, according to Vygotsky, meaning is stable and repeatable, offering the possibility of intersubjectivity, that is, the sharing of the meaning of a word by two or more people, despite the variation in the senses they attribute to it. Vygotsky also assumes that all concepts are generalizations. This explains why a particular word for a young child can signify differently than the same word for an adult. The word for the child is not yet a generalization; it does not have meaning, only a range of senses. As the child grows up, she undergoes a process of enculturation in which she faces many social situations in which she uses the same word, and it is through this social process that the word gradually acquires a generalizable, stable meaning. From this perspective the meaning of the word can never be something purely internal to a person; rather, it is a social construct in the sense of being socially developed.

For words belonging to everyday language, which have concrete referents, like table or dog, this process leads to relatively stable meanings, although these words are open to a variety of senses (such as referring to somebody as a 'dog'). This stability is a consequence of the social nature of conceptualization. It is because in language we have the word dog for referring to several carnivorous mammals of the family Canidae that the concept dog acquires this stability in individuals' conceptual thinking. But for scientific concepts, things are more complicated and we should read the texts of science before going to a university class and teach something like thermodynamics. If you go to this class without any preparation you will find yourself in difficulties, since some of the things that are perfectly clear in the book might not be in the same state in your mind.

From a Vygotskian perspective, therefore, conceptual thinking is an emergent process, resulting from the socially and culturally situated interactions between an individual and her experiences. Concepts are actualized when they are put to use. From this idea, it follows that heterogeneity in the nature of the socially and culturally situated experience can be translated into heterogeneity in conceptual thinking.

That is, a concept does not exist prior to the individual speech act that actualizes it. What is internal is thinking and memory, both assumed as processes, not as products. The literature on memory describes two subjective states of awareness associated with memory: remembering and knowing. Remembering refers to intensely personal experiences of the past, in which we seem to be reliving previous events and experiences mentally, while knowing refers to other experiences of the past, in which we are aware of knowledge we possess but in a more impersonal way (Gardiner and Richardson-Klavehn 2000).

These two subjective states of awareness are related to two different memory systems: episodic and semantic memory. Episodic memory refers to personal events and spatiotemporal relations among those events; semantic memory refers to knowledge possessed about words and other verbal symbols, their meaning and referents, the relations between them, and the rules and algorithms for the manipulation of symbols, concepts, and relations (Tulving 1983). Encoding in these two systems is assumed to be serial, in the sense that events have to be first encoded into semantic memory and then encoded into episodic memory (Tulving 1994). Before we can think conceptually about an event encoded into episodic memory, we should master the meaning of this concept as a social construction, encoding it into semantic memory.

The distinction between semantic and episodic memory can contribute to clarifying the interplay between the dynamic process of conceptualization, through which the sense of a word emerges, and the more stable, socially constructed meanings of words. When we think about an event, we conceptualize it in a particular manner, attributing specific senses to the words we use. However, there is some stability in the way we understand these words, since meaning, as a social construct, constrains the range of senses we ascribe to a given word. In this sense, a memory of an event, just as the sense of a word, is always dynamically constructed during the process of recall. When we recall and use a concept several times, we have the impression of having it, since it becomes very familiar to us. Nonetheless, recall is always a process in which we reconstruct the semantic memory and, often, also the episodic memory related to the concept.

To summarize, in the first approach to concepts, individual conceptualizations and concepts are treated as one and the same thing. This position tends to elide the Popperian distinction between the third and the second worlds. In this position, concepts are treated as having an enduring existence, independently of the context of use, due to their more or less fixed internal structures. These two characteristics of concepts – a concept as an internal artifact, with a decontextualized nature – are shared by most of the authors in the conceptual change movement, such as Stella Vosniadou, Xenia Vamvakoussi, and Irini Skopeliti (2008), and some other chapters in the *International Handbook of Research on Conceptual Change* (Vosniadou 2008a).

According to the second position, concepts and conceptualizations are distinguished and we can develop different ways of conceptualizing objects and events depending on the context. The conceptual profile approach is congruent with this latter view.

The Conceptual Profile Approach

Several authors have argued that people can have different ways of seeing and conceptualizing the world (e.g., Schutz 1967; Tulviste 1991). It can be argued, however, that the concepts and categories available in all the spheres of the world are held in an essentially similar form by a number of individuals, in such a manner that effective communication become possible. These collective representations (Durkheim 1972) are supra-individual in nature and are imposed upon individual cognition. When Vygotsky pointed to the social dimension of human mental processes, he was drawing from this position (Kozulin 1990). According to his famous general genetic law of cultural development, "any function in the child's cultural development appears twice, or on two planes. First it appears on the social plane, and then on the psychological plane. First it appears between people as an interpsychological category, and then within the child as an intrapsychological category" (Vygotsky 1978, p. 163). In these terms, individual thinking develops through the appropriation of cultural tools made available by means of social interactions. From this process of appropriation, it follows that we all share concepts and categories that can be used to signify the world of our experiences, but, since they are also constituted through our experience, the weight each of them has in our personal profile fundamentally depends on the extent to which they have been fruitfully used throughout our development.

The idea of a conceptual profile – that people can exhibit different ways of seeing and representing the world, which are used in different contexts – was proposed in the 1990s (Mortimer 1995), inspired by Bachelard's (1968) epistemological profile, even though its philosophical bases have substantially moved away from Bachelard's ideas in subsequent years. The conceptual profile approach was first proposed as an alternative to conceptual change theory (Posner et al. 1982) and is aligned with criticisms from other perspectives, such as William Cobern's (1996) contextual constructivism.

The conceptual profile approach is grounded in the idea of heterogeneity of thinking, that is, that in any culture and in any individual there exists not one homogeneous form of thinking, but different types of verbal thinking (Tulviste 1991). Conceptual profiles can be seen as attempts to model the heterogeneity of modes of thinking available for people with a given cultural background to use in a variety of contexts or domains (Mortimer 1995, 2000). Modes of thinking are treated here as the aspects of permanence in subjects' conceptual thinking, and, thus, are related to the socially constructed meanings attributed to concepts.

Conceptual profiles are built for a given concept and are constituted by several zones, each representing a particular mode of thinking about that concept, related to a particular way of speaking. Each individual has his or her own individual conceptual profile, as shown by the different weighting each zone exhibits in that particular profile. These differences depend on the individual's experience, which offers more or less opportunities for applying each zone in its appropriate contexts. For example, consider the concept of mass. The empiricist notion of mass, as something that can be determined with a scale, has a bigger weighting in the profile of a chemist who works daily in a chemical laboratory weighing samples than a rational notion of mass as the relationship between force and acceleration. The opposite holds true for a physics teacher who teaches Newton's laws every year to several classes. But notice that, according to the conceptual profile approach, it is only the relative importance of zones that varies from person to person. The zones or modes of thinking themselves are shared by individuals in a society, as maintained by sociocultural approaches to human action.

Assuming the existence of conceptual profiles as a manifestation of heterogeneity of thinking implies recognizing the coexistence of two or more meanings for the same word or concept, which are accessed and used by the individual in the appropriate contexts. Science itself is not a homogeneous form of knowing and speaking, and can provide multiple ways of seeing the world, which can coexist in the same individual, and be drawn upon in different contexts. For example, the concept of the atom is not restricted to one unique point of view. When explaining several properties of substances, chemists deal with the atom as a rigid and indivisible sphere, like the Daltonian atom. This model is not suitable, however, for explaining several phenomena, such as chemical reactivity, where more sophisticated models, including those derived from quantum mechanics, are used. Furthermore, it is not only in science that we find heterogeneity of thinking. Countless scientific words are also used in everyday language and, consequently, show several meanings other than those compatible with scientific points of view. In a conceptual profile, this means that one or more modes of thinking that are not compatible with the scientific ones will be present.

In the face of this heterogeneity, what does it mean to learn about atoms at school? We argued above that the different meanings of a concept, modeled as zones in a conceptual profile, can be accessed in appropriate contexts. Nevertheless, there is no guarantee that an individual does indeed work with appropriate meanings from the relevant zone. This is something to be learnt, and to learn this is to learn about the very heterogeneity of thinking and speaking and the diversity of contexts in which we use our thoughts and speech.

Accordingly, the conceptual profile approach conceives learning as involving two interwoven processes: (1) enriching an individual's conceptual profile, and (2) becoming aware of the multiplicity of modes of thinking that constitutes a profile as well as of the contexts in which they can be applied (El-Hani and Mortimer 2007). In science teaching, the first process typically involves learning scientific modes of thinking which students generally do not have access to by other means. In the second process, it is necessary to give the students a clear view about which modes of thinking are appropriate for which contexts.

For example, a student can become aware that the scientific concept of heat or heating, as a process of energy transfer between systems at different temperatures, is complementary to her everyday concept of heat, which assumes heat as being substantive in nature and proportional to temperature. If the notions are complementary, there are contexts in which one of the concepts is more appropriately used than the other. In the science classroom, students should learn the scientific concept. But the pragmatic value of everyday language will preserve meanings that are at odds with the scientific view. For example, to ask in a shop for a warm woolen coat is far more appropriate than asking for a coat made from a good thermal insulator. But if the students know that this warmth of the wool is in fact due to the warmth of our body as the wool only isolates it from the environment, they will show a conscious awareness of this profile, being capable of drawing on everyday and scientific ideas of heat in a complementary way.

Thus, learning involves not only understanding the scientific modes of thinking. Since students are not directed to break away from the other modes of thinking they use, which, albeit being nonscientific, play a role in their interpretation of experience, it is also a crucial learning goal that students become aware of the heterogeneity of modes of thinking and the demarcation between the contexts or domains in which each mode of thinking shows pragmatic power. To become aware of a multiplicity of meanings and contexts involves a dialog between new and old zones in a conceptual profile. Any true understanding, or meaning making, is dialogic in nature because we lay down a set of our own answering words for each word of an utterance we are in the process of understanding (Voloshinov 1973, p. 102). The conceptual profile approach thus also entails a Bakhtinian approach to understanding. From this perspective, understanding demands that we populate the discourse of others with our own counter-words. In these terms, a student will only be able to understand and learn scientific ideas by negotiating their meanings within her conceptual ecology, usually organized around nonscientific views.

In these terms, the relationship between scientific and everyday meanings for the same words is not one of subsuming all other forms of knowledge into science, but rather of developing dialogs between forms of knowledge in order to distinguish clearly between them and among the contexts in which they can be best applied. In this sense, nonscientific modes of thinking and meaning making are not treated as inferior, but as culturally adequate for some but not all spheres of life in which we act and talk. This also entails that scientific views are indeed more adequate in a number of spheres of life, and, for this reason, should be mastered by students if science education is to socially and culturally empower them. Moreover, it is not that one should necessarily avoid being critical about commonsense and other culturally based views, but rather that one is entitled to restrict the validity of these criticisms to the domain in which science is valid. In criticizing, for instance, the commonsense view that heat is proportional to temperature and is the opposite of another form of heat called cold, a teacher should insist that this latter view is different from the scientific one. She should also recognize that it can be more convenient to speak about cold and hot things in everyday life, since this approach has a deep cultural root, is part of our language, and allows for communication in most everyday situations. Nevertheless, in other everyday life situations, the scientific view of heat as a process of energy transfer is far more powerful than the commonsense view of heat and cold as properties of materials. Consider, for example, a situation in which one has to decide which type of drinking vessel will be better to keep a drink cold on a warm day, one made of aluminum or one made of glass. The commonsense view might lead us to choose the aluminum, since it is cold. The scientific view, on the other hand, helps us to understand that since aluminum is a better thermal conductor than glass (and therefore feels cold to the touch), the drink will get warmer quicker in the aluminum vessel than in the glass. In this sense, the conceptual profile approach helps us to comprehend how a student can come to apply a scientific idea in some but not all contexts of her daily life. If we help a student to become aware of her profile of meanings ascribed to a given concept, after learning the scientific view, she can comprehend in which contexts of daily life scientific views might best be applied.

Conceptual Profiles and the Analysis of Classroom Discourse

Several studies have highlighted the importance of investigating classroom discourse and other rhetorical devices in science education (e.g., Lemke 1990; Roth 2005). This new direction for science education research (Duit and Treagust 1998) signals a move away from studies focusing on individual students' understanding of specific phenomena toward research into the ways in which understandings are developed in the social context of the science classroom. Following a Vygotskian research tradition, more emphasis has been given to the role of social mediation, through language and other socially constructed symbolic systems, in meaning making in the instructional context of the science classroom (Mortimer and Smolka 2001; Mortimer and Scott 2003). In this section, we consider how the conceptual profile approach fits into an analysis of classroom discourse.

Discourse is quite generally conceived as a social phenomenon (van Dijk 1997). According to van Dijk, to characterize discourse in this broader perspective we should conceive it as a "socially situated communicative event" (p. 2), in which people verbally interact in order to communicate ideas and beliefs, or to express emotions. Thus, the integrated description of three dimensions of discourse is usually taken as a research goal: (1) language use – a linguistic phenomenon; (2) the communication of beliefs and ideas – a cognitive phenomenon; and (3) interaction in social contexts – a social phenomenon.

Mortimer (2001) suggests that the production of new meanings in the classroom can be investigated through a discourse analysis structured around the relationship between modes of thinking and ways of speaking. Conceptual profiles (Mortimer 1995 1998) are a heuristically powerful tool to analyze modes of thinking, that is, the cognitive dimension of discourse, while ways of speaking can be characterized in terms of Mikhail Bakhtin's (1981, 1986) social language and speech genres. Since it is only the relative importance of shared modes of thinking that varies from individual to individual, we need a tool to analyze these more stable modes of thinking amidst the conceptualizations that emerge in discursive interactions in the classroom. Conceptual profiles can be used as such a tool in discourse analysis.

Since conceptual profiles are constituted by zones representing modes of thinking and ways of speaking shared by individuals in a society, to build a conceptual profile, one should consider a diversity of meanings attributed to a concept and a variety of contexts of meaning making, encompassing at least three of the four genetic domains considered by Vygotsky, namely, the sociocultural, ontogenetic, and microgenetic domains (Wertsch 1985).

In order to establish the zones in a conceptual profile, one should consider data from several sources, not in a linear, but in a dialogic manner, in the sense that all sets of data are at the same time in interaction with each other. The following sources can be used: (1) secondary sources about the history of science and epistemological works about the concept at stake, which helps in understanding its sociocultural development; (2) literature on students' alternative conceptions about the concept, which are useful to investigate the ontogenetic domain; and (3), original data gathered by means of interviews, questionnaires, and video recording of discursive interactions in a variety of contexts of meaning making, particularly in educational settings, in order to investigate the ontogenetic and microgenetic domains.

It is important to clarify that the construction of the zones of a conceptual profile goes beyond categorizing extracts of data (although it typically involves this step), since the zones of a profile are signified by means of epistemological and ontological commitments that structure different modes of thinking about the concept at stake, and often are not explicitly given in utterances or statements. Moreover, a conceptual profile is intended to represent possible genetic routes for the development of different meanings of a concept. Thus, the commitments characterizing the zones should be seen from a dynamic perspective, as both posing limits and creating possibilities for meaning making. They not only bring difficulties to the construction of new meanings, but also hold the seeds for changes in signification.

For analyzing classroom discourse taking conceptual profiles into account, we use a framework proposed by Mortimer and Scott (2003). Following Vygotskian principles, we consider that science teaching entails a kind of public performance on the social plane of the classroom. This performance is directed by the teacher, who has planned the script for the performance and takes the lead in staging the various activities of the science lessons (Leach and Scott 2002). Central to the teaching performance is the job of developing the scientific story on the social plane of the classroom (Ogborn et al. 1996) and the support given to students in understanding scientific ideas. Of course, the teacher cannot exert absolute control over the ways in which the interactions are played out with students in the classroom (Candela 1999; Erickson 1982) and, consequently, the teaching and learning performance may develop along unexpected pathways.

Mortimer and Scott's framework was developed to analyze the speech genre of science classrooms and, in particular, the ways in which science teachers act to guide meaning making interactions on the social plane of high school classrooms. The framework is the product of an ongoing research program conducted over a number of years (Mortimer and Scott 2000; Scott 1998) and a detailed description of its development is set out elsewhere (Mortimer and Scott 2003). It is based on a sociocultural perspective on human action, just as the conceptual profile approach, and has been developed through a series of detailed case studies.

Central to the framework is the concept of communicative approach, which provides a perspective on how the teacher works with students to develop ideas in the classroom. The distinction between authoritative and dialogic functions, which is at the core of the communicative approach, is based on the notions of authoritative and internally persuasive discourse (Bakhtin 1981), and on the functional dualism of texts introduced by Yuri Lotman (1988, as cited in Wertsch 1991, pp. 73–74). Different classes of communicative approaches are defined in terms of whether the classroom discourse is authoritative or dialogic in nature and whether it is interactive or noninteractive (Mortimer and Scott 2003, p. 33). Dialogic discourses are open to different points of view. At different points in a sequence of science lessons, dialogic talk inevitably takes on a different character. Thus, at the start of a lesson sequence, the science teacher might elicit students' everyday views about a particular phenomenon. Later on, the teacher might encourage students to discuss how to apply a newly learned scientific idea in a novel context. In both cases, we can see the students agreeing on some points and disagreeing on others, but working together to understand any points of difference as they develop their explanation. It is possible to see, thus, an ongoing, dialogic interanimation of ideas.

In dialogic discourse, there is always an attempt to acknowledge the views of others, and through dialogic discourse the teacher attends to the students' points of view as well as to the school science view. By way of contrast, authoritative discourse does not allow the bringing together and exploration of ideas. Here the teacher focuses on the school science point of view. If ideas or questions that do not contribute to the development of the scientific story are raised by students, they are likely to be reshaped or ignored by the teacher. Alternatively, if a student's utterance is perceived by the teacher as being helpful to the development of the scientific story, it is likely to be seized upon and used. More than one voice may be heard in authoritative discourse, through the contributions of different students, but there is no exploration of different perspectives, and no explicit interanimation of ideas, since the students' contributions are not taken into account by the teacher unless they are consistent with the developing school science account.

A sequence of talk can be dialogic or authoritative in nature, independently of whether it is uttered individually or between people. What makes talk functionally dialogic is the fact that different ideas are acknowledged, rather than whether it is produced by a group of people or by a solitary individual. This point leads us to a second dimension in the communicative approach: that talk can be interactive, in the sense of allowing for changes of speech turns between people, or noninteractive, in the sense that only one person speaks, with no changes of turns.

Combining the two dimensions, four classes of communicative approaches can be identified:

1. *Interactive/dialogic*: Teacher and students consider a range of ideas. If the level of interanimation is high, they pose genuine questions as they explore and work on different points of view. If the level of interanimation is low, different ideas are simply made available.
2. *Noninteractive/dialogic*: Teacher revisits and summarizes different points of view, either simply listing them (low interanimation) or exploring similarities and differences (high interanimation).
3. *Interactive/authoritative*: Teacher focuses on one specific point of view and leads students through a question and answer routine with the aim of establishing and consolidating that point of view.
4. *Noninteractive/authoritative*: Teacher presents a specific point of view.

We will analyze two episodes to show how we work with the conceptual profile in the analysis of classroom discourse. These two episodes are from a sequence of science lessons to introduce some basic concepts of thermal physics and their analysis will use insights from a conceptual profile of heat (Amaral and Mortimer 2001). The teaching sequence content was organized around the topic of the thermal regulation of living beings. It included the study of heat, temperature, thermal equilibrium, and the balance of energy in organisms. The students in the target class had been introduced previously to the kinetic particle model of matter through an approach based on the interpretation of phenomena such as gaseous diffusion and changes in the physical states of matter. The lessons involved a combination of work carried out in small groups followed by whole-class discussions led by the teacher. In the small group work the students performed experiments and discussed their observations and findings. The teacher introduced each experiment with a preliminary presentation, in order to contextualize the problem and locate it within the developing teaching and learning story. In the subsequent whole class discussion, the teacher and students talked through the ideas and explanations that the students had proposed.

We will neither use all the zones of the conceptual profile of heat nor discuss how we arrived at them. We will simply consider two zones. The first one is the commonsense view that heat is proportional to temperature and is the opposite of another form of heat, cold. The second one is the scientific view of heat or heating as a process of energy transfer between systems or bodies, in which heat is proportional to differences between temperatures. Even though it may seem that we are simply contrasting a commonsense view with a scientific understanding, this is just a consequence of our choices in this particular argument. The conceptual profile of heat includes more than these two zones, as interested readers can verify in the original source (Amaral and Mortimer 2001).

The first episode took place during the first lesson of the teaching sequence. An initial activity involved students immersing one hand in cold water and the other in warm water before plunging them both into a tank of water at room temperature. The purpose of the activity was to show the limitations of the senses in monitoring temperature. During the group work the teacher noticed that students were talking about what was happening in several different ways. In the subsequent whole-class discussion the teacher encouraged the students to explain what they meant by heat and temperature during the activity.

In presenting the episodes, we decided to leave out technical marks and add punctuation to the original transcripts in the cases of pauses and interrogative intonations. We have also left out some turns of speech that are not relevant here, since they concerned issues of classroom organization and maintenance of discipline. The most delicate step in the reconstruction of classroom interactions was the translation of the Brazilian Portuguese transcripts into English.

1 Teacher: So, how do you explain it? What happens when we feel hot and cold?
2 Student 2: Maybe the temperature of the water passes to your hand when you put it in the water.
3 Teacher: What passes to your hand?
4 Student 2: The temperature.
5 Teacher: The temperature? Do you agree with that?
6 Student 5: There was a heat change.
7 Teacher: Heat change. What's that? Can you explain please?
8 Student 3: There was a kind of diffusion. The temperature of the water passes to your hand and from your hand to the water.
9 Student 6: One swops heat with the other Miss.
10 Student?: I think that it's a change of temperature.
11 Student 6: The heat warms the cold water until a point at which the temperature will transfer neither cold nor hot.

Here, Student 2 (turn 2) uses the idea of temperature in a way which is closer to the school scientific concept of heat. Students 5 and 6, in turn, refer to a heat change. In turn 11, Student 6 refers to some kind of equilibrium being achieved and in his explanation temperature is something that is able to transfer either heat or cold (probably both). In this way, a range of ideas are presented for consideration. The teacher does not evaluate or correct them, but simply asks for further clarification and prompts others to position themselves in the debate.

12 Teacher: I don't understand what you're saying. I want to know what changes between the water and the hand. . . temperature or heat?
13 Students: Temperature.
14 Student ?: It's heat, a heat change.
15 Teacher: Well, you must justify your ideas.
16 Student ?: It's because the temperature is made by heat.
17 Teacher: Hmm. . . .

Some confusion now arises in the class as one of the students, Student 4, provides a long description of the activity and other students conclude that the hand absorbs heat from the water. We do not present this part of the talk, which consists of 11 turns. The teacher, after Student 4's intervention, asks whether anybody thinks differently.

29 Student 1: I think there is a heat change because our body is always around the same constant temperature.
30 Teacher: Hmm. . . .
31 Student 1: So, if you put your hand in a bowl of warm water your temperature remains more or less the same, it doesn't change. There is a change of heat. Heat relates to what you feel, so there is a heat change and not a change of temperature.
32 Student 7: That's it. And heat can be cold or hot. It can be a cold or hot heat.
33 Teacher: Do you agree with that? Movement of cold heat and hot heat?
34 Student ?: No.
35 Student ?: Temperature is only a measure.
36 Teacher: But she is saying that. Please Student 7, explain again, because when you were saying hot and cold heat I saw someone looking surprised.
37 Student 7: I think that heat, when we talk about heat it does not mean just a hot heat, it can be cold, cold heat. For instance, in cold water we have cold heat and we felt it cold.

Throughout this episode, the teacher adopts a neutral stance, not offering evaluative comments. She prompts the students to present their ideas and asks for elaboration and justification of points of view. She also helps the students to recognize the existence of different possible interpretations of the phenomenon. For example, in turn 36, the teacher gives special attention to Student 7's explanation, which is based on the existence of two kinds of heat, corresponding to one of the zones in the conceptual profile, namely the commonsense zone. Although Student 7's explanation is not fully explored at this point, the teacher returns to it later (as we shall see in the next episode). In this way, an interactive/dialogic communicative approach is developed by the teacher and the two kinds of heat ideas are foregrounded as a theme to be further discussed.

The next episode took place in the next lesson of the sequence. It shows an example of the use of the conceptual profile of heat to build a turning point in the discourse, in which the dialog played out through the first episode changes to an authoritative discourse without giving up the commonsense zone. In the lesson, the teacher had organized a small-group activity to address explicitly the idea, from the first lesson, that there are two kinds of heat. The activity entitled, 'Can cold be hot?' involved preparing a system (ice chips with salt) that is colder than melting ice and observing what happens to the reading of a thermometer when it is moved from a beaker containing ice and salt to one with melting ice. The reading of the thermometer actually goes up as it is placed in the melting ice. The episode starts at the end of the activity, with a whole-class review of the question that had arisen in the previous discussions:

Teacher: Now let's return to our question. Last week some groups were talking about there being two kinds of heat. . . hot and cold heat. In fact, this is not a new idea. In the history of science it's been around for a long time. Also, we often think about heat in terms of our sense of touch and we have distinct senses of hot and cold. So, we naturally tend to accept that there are two opposite and separate things – hot heat, which warm objects have, and cold heat, which cool objects have. But, we have to examine these ideas to see whether they can help us understand the notion of heat or not. So, there are two things. The first relates to what we call cold, or the cold. There is nothing which is absolutely cold, isn't there? For example, melting ice. . . we think it is really cold, but is it compared to ice plus salt? Is it cold?

Student?: No.

Teacher: No, it's warm. It's a source of heat. If you put both in contact, pure melting ice will pass heat to the ice with salt. What is cold? I can say that it is less hot and the opposite is also true, hot is less cold. Cold and hot are relative ideas, aren't they? It's a matter of comparing things. So, does it help to think about two kinds of heat, one associated with hot objects and the other with cold?

Here the teacher returns to the idea, introduced by Student 7 in the first episode, that there are two kinds of heat, both hot and cold. The teacher starts by referring to the historical origins of this idea and makes a link to the students' commonsense ideas. She then refers to the findings of the earlier practical activity and challenges the two kinds of heat view, giving support to the scientific perspective that cold and hot are relative ideas. Hence, initially, the teacher adopts a noninteractive/dialogic communicative approach, comparing and contrasting points of view from the first lesson. However, once the teacher acknowledged and positively appraised the two kinds of heat point of view (by making a link to historical perspectives and to the physical sensations of hot and cold), she introduces the scientific perspective. There is a clear movement toward the authoritative pole of the dialogic/authoritative dimension. This episode thus constitutes a turning point (Scott et al. 2006) in the flow of discourse of this lesson sequence, as the teacher brings together everyday and scientific views and makes an authoritative case for the scientific view that there are not two kinds of heat. The teacher has developed the case by engaging the students in an activity that offers a vivid example of a cold object (melting ice) actually being warmer than another object (ice plus salt). The noninteractive/authoritative argument that the teacher develops is based on the shared outcomes of this activity. At this point, she is doing all the talking and it would certainly be wrong to assume that all students have taken on the scientific view. Nevertheless, in subsequent small group and whole-class discussions, there were many opportunities for students to articulate their developing ideas about heat, and the two kinds of heat idea was not raised again, either by the teacher or the students.

The sequence of communicative approaches in these two episodes enabled the dialog between old and new zones of a conceptual profile, and we believe this is of fundamental importance in supporting meaning making by students. Thus, the students have the opportunity to position the authoritative discourse of the disciplinary knowledge in relation to their everyday views and, in so doing, we believe that they are better placed to appropriate this discourse and to make it their own. In simple terms, the students are better placed to see how the different ideas fit together.

These episodes provide an example of how conceptual profiles can both inform discourse analysis of classrooms and the planning of activities to deal with science teaching and learning. Conceptual profiles have already been built for three basic quite general definitions – matter (Mortimer 2000), energy (Amaral and Mortimer 2004), and life (Coutinho et al. 2007a, b), and the related concepts of particulate models of matter, atom, and molecule (Mortimer 2000; Mortimer and Amaral 1999); heat, entropy, and spontaneity of physical and chemical processes (Amaral and Mortimer 2004); life and living beings (Coutinho et al. 2007a, b); and adaptation (Sepulveda et al. 2007). Several studies about meaning making in science classrooms are being carried out using conceptual profiles as tools for investigating the cognitive dimension of discourse. Other studies have been employing conceptual profiles as grounds for devising teaching sequences at different educational levels.

Concluding Remarks

In this chapter, we have addressed the issue of heterogeneity in talking and thinking in science classrooms, drawing upon several related theoretical perspectives and culminating in the conceptual profile approach. We see the kind of discussion presented here as being important not only in terms of the theoretical analysis, but also in relation to the potential for developing greater clarity in understanding the interactions and learning in real classrooms and for planning more effective instruction.

Chapter 18
Quality of Instruction in Science Education

Knut Neumann, Alexander Kauertz, and Hans E. Fischer

International large-scale assessments revealed remarkable differences in students' science achievements between countries. In the 1995 iteration of the Third International Mathematics and Science Study (TIMSS), students' achievements were less than expected for countries as developed as the United States, Germany, and France (Beaton et al. 1997). These results were confirmed by the Programme for International Student Assessment (PISA) studies (e.g., Organisation for Economic and Cultural Development (OECD 2001). In consequence, a discussion arose in major western countries about the quality of education in general and the quality of instruction in particular.

Attempts to identify and describe quality of instruction and its components were undertaken already in the 1960s. These attempts were followed by extensive research programs on teacher effectiveness in the late 1960s and 1970s. Systemization of results from research on teacher effectiveness on the basis of quality of instruction models led to another boom in research in the late 1970s and 1980s – mainly comprising metaanalyses. Since these efforts were not satisfying with respect to explaining instructional outcomes in general, with the TIMSS study, a new attempt was

made to investigate instruction and to relate instructional characteristics to students' achievement. This was mainly because video analysis of lessons became technically possible. Video analyses allowed to record classrooms and analyze instruction in an extensive and thorough manner in multiple iterations.

This chapter presents a review of research on quality of instruction in science education including different general theoretical frameworks. Firstly, early attempts in modeling quality of instruction will be described. Based on these models, the extensive amount of studies on teacher effectiveness research will be summarized by the help of metaanalyses and research reviews. Furthermore, recent video-based studies and their results will be described. From the discussed works, finally, dimensions of quality of science instruction will be derived.

Models of School Learning

A first consideration of instructional quality can be found in John Carroll's (1963) model of school learning. In this model, students' degree of learning is described as the ratio of the time a student actually spends on learning and the time a student needs to spend on something in order to learn it. Carroll (1963) defined the time actually spent for learning as a function of opportunity and perseverance, and the time needed as a function of aptitude, ability to understand instruction, and quality of instruction. As to quality of instruction, he suggested a constituting set of characteristics – namely clarity of the learning goals, adequate presentation of the learning material as well as a planned series of learning steps (cf. Carroll 1989).

In the light of research on learning processes by Robert Gagné (1965), Benjamin Bloom (1976) takes a shift away from the relevance of time as such and towards the learning process itself. While he emphasizes the importance of students' prerequisites, in particular their cognitive abilities, for the learning process, he also identifies a set of characteristics influencing the learning process: According to him, cues and feedback have a moderate influence on achievement gains, while reinforcement and participation have a small influence only. However, the overall influence of quality of instruction as well as of students' affective characteristics on student achievement is considered to be only moderate while students' cognitive abilities are considered to have the highest influence (cf. Bloom 1976).

Two other works, by Robert Slavin (1987) and Bert Creemers (1994), set off to systematize existing results from research on instruction on the grounds of Carroll's (1963) model. Creemers (1994) described quality of instruction as the quality of curriculum and its implementation in instruction, grouping procedures as well as characteristics of teachers' behavior. Essential characteristics of teacher behavior are the structuring of content, clarity of presentation, questioning, immediate exercise after presentation, evaluating whether goals are achieved, and corrective instruction (van der Werf et al. 2000). Slavin (1987) reduced Carroll's (1963) model to four elements: quality of instruction, learning time, appropriate levels of instruction, and incentive. Whereas all four elements were considered equally important for effective

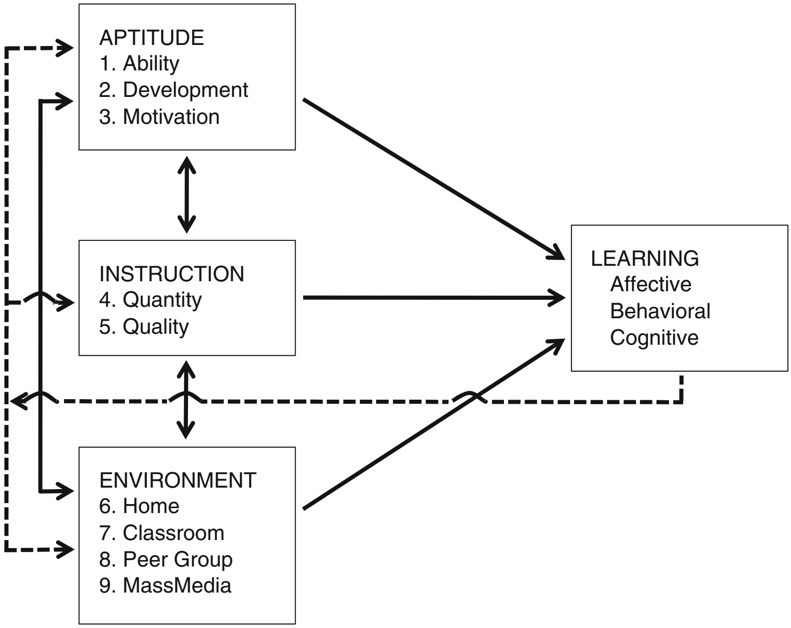

Fig. 18.1 Walberg's (1981) model of educational productivity. Adapted from Fraser et al. (1987, p. 157)

instruction, none of them can be compensated by one of the others. As to quality of instruction, Slavin (1987) compiles a list of characteristics similar to Creemers' (1994) list of teaching or teachers' characteristics, respectively (cf. Gruehn 2000).

Another model that has evolved from Carroll's (1963) model of school learning is the model of educational productivity proposed by Herbert Walberg (1981). Walberg (1981) presented a first systematization of research on modeling school learning and the products of school learning (Gruehn 2000). A major new feature in Walberg's (1981) model was the provision of the learning environment and its influence on students' learning time. Altogether, Walberg (1981) identifies at first seven and in later works nine factors that influence affective, behavioral and cognitive learning: ability or prior achievement, age and development, motivation or self-concept, quantity of instruction or time engaged in learning, quality of instruction, home environment, classroom environment, peer group environment, and the mass media (Fig. 18.1; cf. Fraser et al. 1987). Quality of instruction in this model is related to the degree of direct instruction (Rosenshine 1979).

Summarizing, it has to be maintained that within the above models instruction is described as a function of student individual characteristics, instructional characteristics, and characteristics of the learning environment providing information on the quality of the learning process and in consequence of instructional outcomes. Quality of instruction is considered a set of instructional characteristics, as for example, clarity and structure or teacher–student interactions. Outcomes can be affective, behavioral or cognitive, where the focus is mostly on the latter, that is, students' achievement. Walberg's (1981) model takes an exceptional position in scope of the discussed models. It is a synthesis of all proceeding models at least with respect to the first five factors it embraces, while it accounts for the learning environment through inclusion of the remaining four factors (Gruehn 2000). Finally, it describes quality of instruction on the basis of empirical research on teaching effectiveness. The models discussed so far are proposed for instruction and learning in general. Specific characteristics of individuals and environments are taken into account but domain specifics, that is, subject matter or subject specific learning processes, remain unconsidered.

Teacher Effectiveness Research

Early research on teacher effectiveness followed two different research approaches: The teaching process paradigm on the one hand and the criterion of effectiveness paradigm on the other (Gage 1972). Within the teaching process paradigm, what characterizes a good teacher was defined based on experts' experience or observations of classroom learning (Rosenshine and Furst 1971). The criterion of effectiveness approach on the other hand drew on outcome criteria, for example, student achievement, for identifying characteristics of effective teaching (Shavelson and Dempsey-Atwood 1976). A first major review of research on the latter is given by Barak Rosenshine and Norma Furst (1971). They derive a set of 11 different variables, amongst which Clarity, Variability, Enthusiasm, Task-oriented and/or Businesslike Behaviors, and Students' Opportunity to Learn Criterion Material are considered as particularly important. However, Rosenshine and Furst (1971) state a lack of substantial research on teachers' characteristics relating to higher student achievement and demand further research in this field to back up the relevance of the characteristics compiled by them.

In another attempt to summarize the general factors that influence classroom learning, Michael Dunkin and Bruce Biddle (1974) developed the so-called "process-product model" of classroom learning. The model embraces four classes of variables: teacher characteristics (e.g., personality), context variables (e.g., classroom environment), process variables (e.g., learning activities), and product variables (e.g., student achievement) (cf. Shuell 1996).

In the decade following Dunkin and Biddle's (1974) work, the research base has been considerably broadened. The 1970s and 1980s provided a substantial amount of correlational and experimental studies that documented causal relationships between teacher behaviors and student achievement. In reference to the model suggested by Dunkin and Biddle (1974), this research is termed *process-product research*. Studies provided evidence that classroom management influences student achievement (Good 1979). Other studies indicated that managing classrooms effectively begins on the first day of school with a systematic approach, advance preparation, and planning (Evertson 1985). With reference to the core idea of Carroll's (1963) model of school teaching and learning, much research focused on the investigation of time-on-task. Results documented the importance of time-on-task, pointing out that students must become actively engaged in learning during instruction time (Anderson 1981).

In a review of several metaanalyses, Ronald Anderson (1983) summarizes the results of research on teacher effectiveness specific to science education. His analysis confirms the superiority of an inquiry approach in, for example, curricula or teaching techniques, although effect sizes vary heavily between metaanalyses. Additionally, effects with respect to the teaching of process skills were found. Interestingly, effects were noticeably larger in studies testing students for specific techniques but small in those testing for scientific methods in general.

An all-embracing review of process-product research was written by Jere Brophy and Thomas Good (1986) identifying two dimensions of characteristics: characteristics related to quantity and pacing of instruction on the one hand and qualitative characteristics on the other. As to quantitative characteristics, they find the amount of opportunities to learn and the content covered, role definition/expectations/time allocation, classroom management/student engaged time, consistent success/academic learning time, and active teaching to have a positive impact on instructional outcomes. With respect to qualitative characteristics, giving information (including structuring, redundancy/sequencing, clarity, enthusiasm and pacing/waiting time), questioning the students (including difficulty level of questions, cognitive level of questions, clarity of questions, selecting the respondent, waiting for the student to respond), as well as reacting to students' responses (including, for example, reactions to correct and incorrect responses), handling seatwork, and homework are identified (cf. Brophy 1986). These results, although formulated in a different way, strongly support the characteristics of effective teaching found by Rosenshine and Furst (1971). The aspect of clarity can be found in both reviews; variability in Rosenshine and Furst's (1971) review relates to the cognitive level in discourse and, thus, is included in questioning students – as is enthusiasm. Task/business-like behaviors refer to characteristics subsumed under quantitative characteristics. In addition, Brophy and Good (1986) emphasize the importance of structuredness of content as suggested by David Ausubel (1968), Jerome Bruner (1966) and other cognitive structuralists.

Particularly interesting is the work of Barry Fraser et al. (1987) as it presents a synthesis of educational research. Based on Walberg's (1981) model of educational productivity, research reviews of the 1970s were analyzed, from which productive factors of learning were obtained. In addition, quantitative syntheses or metaanalyses of studies of these factors were accomplished. Fraser et al. (1987) found that three groups of aptitudinal, instructional, and environmental factors have influences on instructional outcomes, that is, cognitive, affective, and behavioral learning. The strongest effects were found for variables of students' aptitude, wherein intelligence was found to be the strongest factor. As to quality of instruction, Fraser et al. (1987) found a mean effect size for time and strong effects for reinforcement, instructional cues, engagement, and feedback. The works of Fraser et al. (1987) are remarkable in another way as well, as the authors derive a model to describe contextual and transactional influences on science outcomes, which after the work of Anderson (1983) is a particular attempt in describing a model of instructional quality specifically for science education. Fraser et al. (1987) found the strongest factor of quality of instruction to be the time between a teachers' question and students' answers, followed by focusing (e.g., organizers), students' hands-on activities, use of teacher questioning or – in line with Anderson (1983) – inquiry learning. The overall mean effect size of the factors established was one-third of a standard deviation (Fraser et al. 1987).

A further probe of the model of educational productivity is accomplished by Herbert Walberg et al. (1981) using data from the National Assessment of Educational Progress (NAEP) program. By regression analysis, the factors Socioeconomic Status, Motivation, Quality of Instruction (measured by a questionnaire on students' perception of the degree of direct, didactic instruction), Class (social psychological environment), and Home conditions were each found to be significant. While other factors such as race and gender where controlled, "Under a stringent probe, however, the Class social-*psychological* environment appears as the only unequivocal cause of science learning in the data" (Walberg et al. 1981, p. 233). These results are confirmed by Margaret Wang et al. (1990), who find classroom management and climate together with student-teacher interactions to form an important set of instructional characteristics related to effective instruction.

Altogether, from research on teacher effectiveness, five dimensions of variables may be identified: clarity, structuredness, cognitive activation, pacing, and classroom management. Clarity refers to the clarity of learning goals, the presented content and so on, and structuredness refers to a systematic approach in the design of instruction. Cognitive activation embraces all variables relevant to activate students cognitively, for example, the cognitive level of tasks as well as variables related to students' engagement. Pacing is related to the adequate sequencing of tasks, in which adequateness means adequate with respect to students' abilities rather than an adequate content structure. Finally, classroom management refers to an adequate learning climate that allows for an effective learning. An important characteristic, which is not part of the above dimensions, would be teacher enthusiasm. This characteristic is not considered part of the actual instruction but rather is part of a whole set of characteristics related to a teachers' traits. These characteristics certainly will have to be included in a model of quality of instruction as they influence design and implementation of instruction (Wayne and Youngs 2003).

Video Studies of Instruction

Quality of instruction research received a major revival with the so called TIMSS Video Study (Stigler et al. 1999). As video recording and analysis became technically possible, this offered a new approach to the analysis of instruction. Video analysis preserves classroom activity so it can be viewed several times allowing for a detailed examination of the complex actions taking place in classrooms. In scope of the TIMS Video Study, this method was used to analyze mathematics lessons from Germany, Japan, and the United States to identify instructional characteristics relevant for differences observed in students' achievements in the TIMS study (Beaton et al. 1997). Analysis covered the content of the lessons, the teachers' aims as well as teachers' and students' manuals, verbal activities, and the material used. The analysis revealed the existence of specific patterns of instruction in Germany, the United States, and Japan – so-called lesson scripts (Stigler and Hiebert 1997). While instruction in Japan is characterized by a rather constructivist approach, instruction in Germany was identified as narrowly guided and result-oriented. Lesson scripts were considered to be highly culture specific (Stigler and Hiebert 1997). Despite that, no explanation for performance differences between the participating countries could be found (Stigler et al. 1999).

Thus, an aim of a further video study in scope of the 1999 iteration of TIMSS was to investigate whether high achieving countries share a common method of teaching (Hiebert et al. 2003). This time, science instruction was also video recorded and analyzed. In mathematics, lessons were videotaped in Australia, the Czech Republic, Hong Kong, the Netherlands, Switzerland, and the United States. Additionally, Japanese lessons from the earlier study were reanalyzed. Results of the preceding video study could be confirmed in general. Again, lesson structures similar to the ones found in the scope of the TIMSS Video Study could be observed. Differences appear, however, when investigating the characteristics of tasks. While in most countries the majority of problems presented during instruction were of low complexity, in Japan about 40% of the problems used were of high complexity. Also, in Japan in over 40% of the tasks, a previous task's solution was used to solve the given task, whereas at least 65% of the tasks in other countries were repetitive, that is, a task was the same or mostly the same as the preceding one (Hiebert et al. 2003). Yet, as the majority of Japanese mathematics lessons dealt with geometry and was videotaped 4 years earlier, the interpretation is not very powerful.

Results of the science part of the study were published in 2006 by Kathleen Roth et al. (2006). Based on an extensive literature review of research on teacher effectiveness, criteria of instructional quality were compiled and categorized in three classes: science content, teacher actions, and student actions embedded in school culture. Analyzing science instruction in Australia, the Czech Republic, Japan, The Netherlands, and United States on the grounds of this framework, Roth et al. (2006) found that high achieving countries shared two common characteristics: high content standards and a content-focused instructional approach. However, these high content standards were embodied by different characteristics per country, as, for example, the density and challenge of content ideas or students being held responsible for their own independent learning.

In summary, while the TIMSS video studies provided an extensive description of mathematics and science instruction, they failed in relating instructional characteristics to student achievements. This lack of reliable findings on the influence of country-specific patterns of instruction on students' performance led to a series of research projects investigating instruction by means of video analysis.

In an effort to shed more light on the complex matter of science instruction, a video study was undertaken by the Institut für die Pädagogik der Naturwissenschaften (IPN) in Kiel, Germany. The scope of this video study of physics instruction was to investigate teaching and learning processes (Seidel et al. 2007). Based on the results of research on teacher and teaching effectiveness, taking the "complex mediating process from instructional activities to student learning" (Seidel et al. 2005, p. 552) into account, a theoretical framework was used as a basis of a multitrait multimethod approach to examine physics instruction. Classroom activity patterns were investigated, aspects of instructional quality were surveyed, and finally these findings were related to student reports on cognitive learning processes, quality of learning motivation, and perception of supportive learning conditions (Seidel et al. 2005). Results on physics instruction were in line with the findings from the TIMS video study on mathematics instruction: German physics instruction is characterized by a narrowly focused questioning–developing teaching style. This was confirmed by Thomas Reyer (2004) who found that physics instruction is mainly characterized by a teacher-centered instruction using demonstration experiments and seldomly by student-centered instruction using experimental group work. However, Tina Seidel et al. (2007) could not find an influence of either approach on student learning. A more in-depth analysis, though, provided empirical evidence for several assumptions on quality of instruction: Goal clarity and coherence have a positive influence on students' perceptions of supportive learning conditions. Interactions in class work were found to be related to motivational affective development (cf. Seidel et al. 2005). Further, students perceived themselves as being more self-determined and motivated in classrooms with high quality classroom discourse (Seidel et al. 2003), that is, with high cognitive activation. Analysis of the use of experiments pointed toward a lack of support and self-contained learning during experimental phases (Tesch and Duit 2004).

Similar results could be found in a Swiss-German cooperation project "Instructional Quality and Mathematical Understanding in Different Cultures" (Rakoczy et al. 2007). Based on an opportunity-to-learn model of instructional quality (Fig. 18.2), a three-lesson unit was videotaped in 20 German and 20 Swiss classes. Analysis was based on three dimensions of teaching quality: classroom management, cognitive activation, and student-centered orientation (Lipowsky et al. 2005) as well as structure of the content presented (Rakoczy et al. 2007). Results provided evidence that student achievement is higher in classes with high cognitive activation. Also, classroom discourse was found to have an influence on student achievement. Together, both characteristics explained 9% of students' achievement (Lipowsky et al. 2005). Additionally, a structured presentation of content was found to have a particular influence on student achievement (Rakoczy et al. 2007).

In another approach, the data were analyzed with respect to instructional patterns (Hugener et al. 2007). Altogether, three patterns with respect on how the solution to problems posed during instruction is handled could be identified: a presenting pattern, a development pattern, and a discovery pattern. In line with the results of the TIMS Video Study described above, the discovery pattern was related to the highest

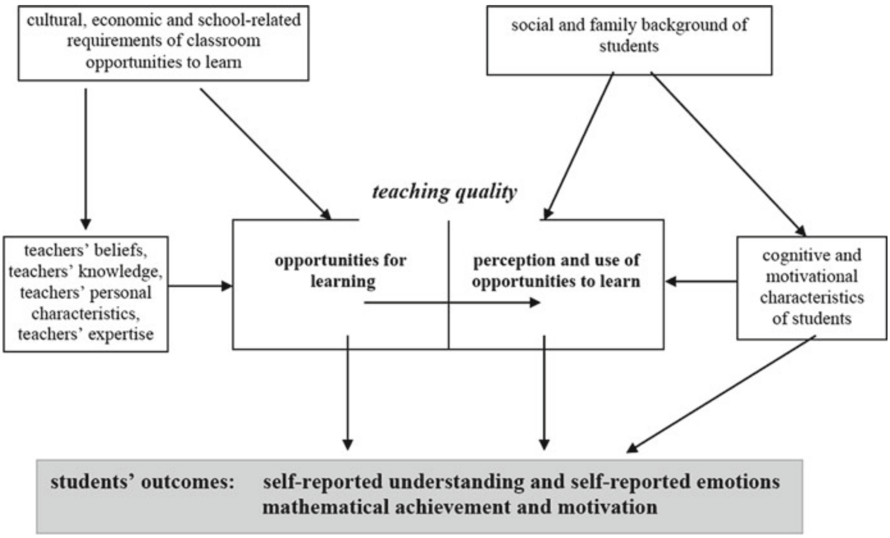

Fig. 18.2 Model of instructional quality. Taken from Lipowsky et al. (2005)

cognitive activation although again no influence on student achievement could be observed. This allows for the conclusion that while instruction might look the same on a surface level of instruction, instructional characteristics influencing students' achievement might be located on a deeper level.

Apart from the presented video studies investigating instruction as a whole, a lot of studies have taken into focus different aspects of instruction on a descriptive base or correlational base with respect to student outcome. Eduardo Mortimer and Phil Scott (2003), for example, focus on a description of classroom or student–teacher interaction, respectively, particularly on dialog structures in the classroom. Others investigate the teachers' role in supporting learning in different teaching-learning environments (e.g., Viiri and Saari 2004). However, it is too early, yet, to draw conclusions as more studies will be needed to confirm the findings and allow for metaanalyses to create a larger picture of how these characteristics relate to each other and how they contribute to quality of instruction in general.

In summary, earlier video studies of instruction were not able to establish a relation between characteristics of instruction and students' achievement, whereas later ones were more successful as they set a stronger focus on deep-level characteristics of instruction and were based on more elaborate models of instructional quality. Results of the later investigations show that clarity, classroom management, cognitive activation, and structuredness have an impact on outcome criteria. This confirms the dimensions that could be identified from teacher effectiveness research. And while these dimensions are not specific to science education, their relevance to science education can be concluded from the described studies.

Summary and Outlook

Early models of school learning describe quality of instruction as a set of instructional characteristics influencing the learning process and thus mediating the influence of students' prerequisites on students' outcomes. In later models, the extensive amount of research on teacher effectiveness is systematized leading to five dimensions of instructional quality: clarity, structuredness, cognitive activation, pacing, and classroom management. The rapidly developing video recording technology allowed for a large-scale use of video equipment to record and to analyze lessons. And while early video studies struggled to identify instructional characteristics, later ones were – on the basis of theoretically founded models of instructional quality – able to provide evidence on the importance of the above dimensions. However, more research is needed especially on science-specific aspects of instructional quality. That is, on science-specific operationalizations and the interplay of the above dimension as well as the relevance of science-specific instructional characteristics, that is, the use of experiments.

Moreover, further research should take characteristics of students, teachers, and the classroom environment and their influence on the above dimensions of instructional quality into account. This is especially important as there is evidence that a mere change of instructional patterns does not influence student outcome and that quality of instruction is to be sought on the deep level of instruction. This again means that teacher training programs seeking to improve quality of instruction have to focus on teachers' professional knowledge to efficiently change the way instruction is designed and implemented.

Finally, as it seems that aptitudes are powerful correlates of learning; they deserve inclusion in theories of educational productivity.

Chapter 19
Personal Epistemology and Science Learning: A Review on Empirical Studies

Fang-Ying Yang and Chin-Chung Tsai

Personal epistemology is usually perceived by psychologists and educators in psychology research as beliefs about the nature of knowledge and knowing. The pioneer study about personal epistemology is John Perry's (1970) study on intellectual development. Based on 20 years of longitudinal studies, Perry proposed the Perry Scheme that shows the developmental stages of personal epistemology starting from dualism, to multiplicity, and relativism. A critical perspective of the Perry Scheme is that the transformation of personal epistemology progresses with years of higher education. The developmental perspective about personal epistemology is supported by many scholars such as Patricia King and Karen Strohm Kitchener (1994) and Deanna Kuhn (1991), even though they studied different cognitive behaviors and suggested different developmental models.

In addition to the developmental stand, some researchers (e.g., Marlene Schommer-Aikins 2002) claimed independence among epistemological belief dimensions, whereas others (e.g., Barbara Hofer 2001) argued the systematic or ecological interrelation among dimensions of personal epistemology. As a matter of fact, studies about personal epistemology have been conducted in various branches of psychology and education with different labels such as epistemological beliefs, reflective judgment, epistemological reflection, epistemological theories, and so forth. Although there is no united definition for personal epistemology, a common interest among epistemological researchers is evident in individuals' thinking and beliefs about knowledge and knowing (see the review by Jean E. Burr and Barbara K. Hofer 2002).

According to Barbara Hofer and Paul Pintrich (1997), personal epistemology consists of four well-recognized dimensions, including certainty of knowledge, simplicity of knowledge, source of knowledge, and justification for knowing. From a developmental point of view, beliefs about the nature of knowledge and knowing are articulated by educational experiences (Hofer and Pintrich 1997; Perry, 1970). Accordingly, an individual's view about the nature of learning should also be an indicator of a person's epistemological theory. In view of that, Schommer-Aikins (1990, 2002) proposes that beliefs about learning are also a significant constituent of personal epistemology. Although Schommer's model of an epistemological system has received criticisms (Hofer and Pintrich 1997), her work initiates an important line of research linking epistemological beliefs to issues about classroom learning.

Psychological studies have shown that personal epistemological beliefs mediate cognitive activities relevant to learning and reasoning. For example, King and Kitchener (1994) verify the developmental association between personal epistemology and reflective reasoning; Kuhn (1999) proposes a similar link between personal epistemology and critical thinking; Perry (1970) and Hofer (2001) point out that education affects belief and epistemological development; and Goayin Qian and Donna Alvermann (2000), and Schommer-Aikin (1990, 1993) further demonstrate the significant contributions of personal epistemology to school performance. In addition, Chin-Chung Tsai (2000a) and Fang-Ying Yang (2005) with Taiwanese samples also confirm that personal epistemology is significantly correlated with learning approaches and scientific reasoning in informal contexts.

Although the role of personal epistemology in human cognition is well recognized, there remain many unsolved issues regarding operational definitions for the construct, dimensions of personal epistemology, domain specificity, assessments, developmental trajectory, and so forth. Many review and empirical papers have thoroughly discussed these issues. For instance, Hofer (2000, 2001) analyzed the dimensions of personal epistemology and discussed the educational implications of relevant research; Burr and Hofer (2002) examined thoroughly the conceptions of personal epistemology; and Orpha Duell and Marlene Schommer-Aikins (2001) reviewed assessment of personal epistemology. More recently, Krista Muis, Lisa Bendixen, and Florian Haerle (2006) explored the issue of domain specificity. Thus, these issues are not the foci of this chapter. In this chapter, we intend to discuss the role of personal epistemology with particular attention to science learning.

Personal Epistemology and Science Learning

Based on Benjamin Bloom's taxonomy (1956), education activities can be categorized into cognitive (knowledge), psychomotor (skills or processes) and affective (beliefs, values, and attitudes about science) domains. Accordingly, in addition to factual knowledge and process skills and/or problem solving strategies, it has been widely agreed among science educators that students need to be taught about the nature of science as they are expected to appreciate the differences between science and other disciplines. In the relevant literature that deals with factors affecting science learning, considerable attention has been placed on examining the effects of prior knowledge. For example, exploring misconceptions and/or alternative frameworks is a popular research topic regarding concept learning (Carmichael et al. 1990; Vosniadou and Brewer 1992). As far as the learning of process skills is concerned, the practice of inquiry skills has been found to be influenced by domain-specific knowledge (e.g., Lazonder et al. 2008; Trumbull et al. 2005). As for learning about the nature of science, students' prior understanding about the structure of theory and evidence (data) and subject-matter knowledge are the central topics of discussion (e.g., Lederman 1992; Sadler and Zeidler 2004). In addition to prior knowledge, affective factors such as attitudes, interest, expectations, and values have also been found to play a significant role in mediating science learning (e.g., Pintrich 1999; Spinath and Stiensmeier-Pelster 2003).

As mentioned previously, psychological studies about personal epistemology have gradually gained attention since the 1970s, and it has been shown that this psychological construct contributes significantly to school achievement and mediates learning (e.g., Hofer 2001; Schommer-Aikins 1993). Nevertheless, in science education research, the effects of personal epistemology have only been explored over the last decade. By this literature review, we attempt to make clear what we know and do not know about the role of personal epistemology in science learning.

In this study, 37 empirical papers that investigated the relationships between personal epistemology and science learning are reviewed. These papers are mostly selected from the Social Sciences Citation Index (SSCI) database in the ISI web of knowledge. The methods and assessment tools for detecting personal epistemology and dimensions of personal epistemology in relation to science learning are summarized in Appendix. By reviewing these studies, we try to disclose the trend of research that has been developed in the last 10 years, and reveal future research possibilities. In the following sections, we will present firstly the methods and tools used to assess personal epistemology in the context of science learning, followed by introduction of dimensions of personal epistemology scrutinized by researchers of science education. The third part of the presentation is the effects of personal epistemology on science learning. Finally, suggestions for future studies are discussed.

Assessing Personal Epistemology in the Contexts of Science Learning

Among the 37 selected papers, 22 involved high school students (grades 7–12), 10 involved university students, two studied both high-school and university students, and only four investigated elementary learners (among the four, one involved both elementary and high school subjects). As listed in Appendix, 16 selected studies used quantitative instruments, 14 employed qualitative methods, and 7 adopted mixed methods using both qualitative and quantitative tools to assess students' personal epistemological beliefs in the context of science learning. In general, quantitative studies usually employed five-point Likert-scale questionnaires that can be divided into domain-general and domain-specific types. The most popular domain-general tool is those questionnaires modified from Schommer's Epistemology Questionnaire (SEQ) developed by Schommer-Aikins (2002, 2004), which focuses on describing the nature of knowledge and learning. As shown in the Appendix, there are six papers developing modified SEQ surveys including papers such as Enman and Lupart (2000) and Lodewyk (2007). Other than the SEQ, E. Michael Nussbaum, Gale Sinatra, and Anne Poloquin (2008) used the Epistemic Beliefs Assessment (EBA) instrument developed by Deanna Kuhn, Richard Cheney, and Michael Weinstock (2000). Yang (2005) employed the Learning Environment Preference (LEP) questionnaire developed by William Moore (1989) to detect student epistemological development on the dimensions established by Perry (1970). It should be noted that when these questionnaires are used for investigations in the context of science learning, the referred knowledge domain in the questionnaires should be science.

Development or use of the domain-specific questionnaires for assessing students' personal epistemological perspectives in science was found in 11 papers. Questionnaires of this kind include the Greek Epistemological Beliefs Evaluation Instrument for Physics (GEBEP) (Stathopoulou and Vosniadou 2007), Pomeroy's (1993) questionnaire (e.g., Tsai 1998a, b), the Scientific Epistemological Views (SEV) survey (Liu and Tsai 2008; Tsai and Liu 2005), Elder's (2002) Epistemological Beliefs Questionnaire (EBQ) (Conley et al. 2004), and the Conception of Learning Science (COLS) questionnaire (Lee et al. 2008). Items in these questionnaires reflect largely the nature of knowing in science, justification criteria, social/cultural attributes, and beliefs about learning science. The contents of these questionnaires will be described more in the next section.

In addition to the quantitative studies, 14 papers adopted qualitative designs to explore personal epistemological beliefs. As shown in the Appendix, 10 papers used interviews' Chu and Treagust (2008) and Hogan (1999) were two examples. There was one study employing an open-ended questionnaire (Zeidler et al. 2000) and one using essay (Roth and Lucas 1997). Three studies made use of e-journal writing (May and Etkina 2002; Sandoval 2003; Sandoval and Reiser 2004). Some researchers have constructed written survey items that describe detailed information about lab work and the nature of theory and data (e.g., Leach et al. 2000). In addition, there are seven studies using both interview and Likert-scale questionnaires to probe students' epistemological beliefs. These seven papers are shown in the Appendix and include papers such as Hogan and Maglienti (2001) and Tsai (1998a, b). They either collected responses from limited subjects for construction of Likert-scale questionnaires or employed existing questionnaires to distinguish different types of students for in-depth interviews.

In summary, participants involved in the investigations in these selective studies were mostly high school and university students. The use of quantitative instruments to assess learners' epistemological beliefs is dominating in research about science learning. Epistemological questionnaires modified from the SEQ are the most popular domain-general tools while more and more researchers are developing domain-specific assessments. As for qualitative studies, interview and open-ended questionnaires are frequently utilized in the qualitative designs. Likert-scale questionnaires usually suffer from the unstable reliabilities of the instruments. Although qualitative analysis is recognized as the highly valid method for assessing epistemological beliefs (Hofer 2002), given the time constraints, they are limited in the number of subjects that can be involved in an analysis. Consequently, the mixed use of qualitative and quantitative methods could be a promising approach. However, the number of such studies on the record is lower than those of either qualitative or quantitative methods.

Dimensions of Personal Epistemology in the Contexts of Science Learning

From a philosophical perspective, personal epistemology concerns an individual's beliefs about the nature of knowledge and knowing. Although it is still in debate, some psychologists such as Andrew Elby (2009) and Schommer-Aikins (2004) think that the inclusion of beliefs about learning in personal epistemology is necessary because in a way learning indicates the nature of knowing and knowledge construction. In epistemological studies relevant to science learning, the above-mentioned three aspects of beliefs are constantly the foci of attention, that is, beliefs about the nature of knowledge, beliefs about the nature of knowing, and beliefs about learning. Nevertheless, because of different research objectives and research methods, different researchers use different terminologies to describe students' epistemological beliefs. Therefore in this section, the dimensions of personal epistemology proposed by researchers in the area of science education are analyzed.

As mentioned previously, among the papers analyzed in this chapter, questionnaires modified from the SEQ are popular domain-general instruments to assess personal epistemological beliefs. Basically, dimensions of personal epistemology defined by the modified SEQ surveys fall within the scope of beliefs about the nature of knowledge and learning. Significant dimensions discussed in these papers included beliefs in certain knowledge, simple knowledge, quick learning, and fixed ability (e.g., Lodewyk 2007; Rodriguez and Cano 2007). Apart from the nature of knowledge and learning, Nussbaum and colleagues (2008) who employed EBA call attention to the dimension pertaining to the judgment of knowledge.

Scholars who utilized or developed domain-specific questionnaires for assessing students' scientific epistemological beliefs tend to emphasize the nature of scientific knowledge and the construction of scientific knowledge. For example, studies that employed Pomeory's questionnaire distinguish epistemological views into empiricist and constructivist perspectives about scientific knowledge (e.g., Tsai 1999a, b) and activities in science (Tsai 2000a, b). The SEV questionnaire developed by Chin-Chun Tsai and Shiang-Yao Liu (Tsai and Liu 2005; Liu and Tsai 2008) highlights the tentative nature of scientific knowledge and social/cultural aspects of scientific communities. In addition to the structure and the stability of scientific knowledge, the GEBEP questionnaire developed by Cristina Stathopoulou and Stella Voniadou (2007) has taken into account the source and judgmental aspects of knowing. Anne Marie Conley et al. (2004) employed EBQ to assess epistemological beliefs about science, which focused on the dimensions of source, certainty, development, and justification. A study (Min-Hsien Lee et al. 2008) examined high school students' conceptions about learning science that reflect the beliefs in the goals and process of science learning, representing students' beliefs particularly toward science learning.

Those with qualitative methods display a wider range of epistemological dimensions about the nature of scientific knowledge and construction of scientific knowledge. For instance, Wolff-Michael Roth and Keith Lucas (1997) showed in their study that students displayed nine discourse resources to justify ontological, epistemological, and sociological claims. Hyun Ju Park (2007) proposes the epistemological commitments (concerning the truth of a piece of knowledge and justifications for knowledge and knowing), the metaphysical beliefs (regarding beliefs about the ultimate existence of qualities or properties of objects or phenomena), and the beliefs about knowledge, learning, and conception, as major components of conceptual ecologies. Other epistemological dimensions appearing in the collection of papers in this review were found in student discussions or discourses about issues related to the nature of scientific knowledge and knowledge construction. These dimensions included beliefs about the nature of data and explanation or conclusions (Sandoval 2003), beliefs about the goal of science, the nature of evidence, theory, and experiments/investigations (Sandoval and Morrison 2003; Zeidler et al. 2000), beliefs about changes and processes of change in science (Hogan 1999; Sandoval and Morrison 2003), and beliefs about processes of learning different science disciplines (Hye-Eun Chu and Treagust 2008; Watters and Watters 2007).

In summary, when the research about personal epistemology is placed in the context of science learning, three types of epistemological beliefs are found to be significant. One is related to beliefs about the nature of knowledge with dimensions emphasizing tentativeness, structure, and forms of scientific knowledge. Another is belief about the nature of knowing the dimensions of which include nature of scientific activities, judgmental criteria for knowledge construction, and social/cultural impacts of scientific community. The other dimension is belief about the nature of learning with respect to the goals of science learning, and processes of learning different scientific disciplines.

Effects of Personal Epistemology on Science Learning

As mentioned before, education activities include not only cognitive (knowledge) and psychomotor (skills or processes) domains but also the affective domain that entails beliefs, values, and attitudes about science. In the section, we will examine the effects of personal epistemological beliefs on science learning of different domains.

Cognitive Domain: Concept Learning

Among the selected 37 studies that examined the effects of epistemological beliefs on science learning, there are 12 papers targeting concept learning. The general conclusion is that personal epistemological beliefs mediate concept learning. For studies using modified versions of the SEQ, it was found that the most influential epistemological beliefs are those related to beliefs about certainty and structure of knowledge. Relevant discussions can be found in the works of Lodewyk (2007), Sinatra et al. (2003), and in an earlier work by Windschitl and Andre (1998). Among other studies, beliefs about the process of learning, the goal of learning (e.g., Chu and Treagust 2008; Watters and Watters 2007), and learning from authority (Sinatra et al. 2003) are also shown to affect concept understanding. Moreover, Nussabum et al. (2008) used the EBA to show that epistemic beliefs related to judgmental criteria affected conceptual change.

For those analyzing domain-specific epistemological beliefs, Tsai (1998b) found that students' scientific epistemological beliefs were significantly related to the recall and structure of knowledge derived from instruction of basic atomic theory. By analyzing weekly reports, David May and Eugenia Etkina (2002) showed that physics students' epistemological reflections on learning were associated with conceptual gains. Stathopoulou and Vosniadou (2007) found that beliefs about construction and stability of physics knowledge and beliefs about the structure of physics knowledge predicted physics concept understanding. It should be noted that the science subjects involved in these studies are largely related to biology and physics.

Psychomotor Domain: Strategy and Skill Learning

As mentioned, another domain of science learning is the psychomotor domain, which is related to skill and strategy learning. According to our analyses of the selected papers, two prominent competencies in the psychomotor domain are learning strategies/approaches and reasoning skills. In our collection of papers, six studies discuss associations between epistemological beliefs and learning strategies or approaches. These works are described in the following paragraph.

Tsai (1998a) found that students with a constructivist-oriented epistemology of science tended to adopt more meaningful learning strategies. In the work of Mark Windschitl and Thomas Andre (1998), students with more sophisticated epistemological beliefs seemed to have better explorative strategies when given implicit instruction about how to use simulation. Further, Hogan (1999) found that students' epistemological perspectives interacted with their sociocognitive engagements in the collaborative learning task. More recently, Heinz Neber and Marlene Schommer-Aikins (2002) demonstrated that science-related self-efficacy and epistemological awareness predicted the use of regulatory strategies in science learning while Watters and Watters (2007) showed that many students in their study held a highly dualist perspective about knowledge and described approaches to learning or learning strategies that emphasized rote learning and memorization. Furthermore, they noticed that high-performing students who displayed beliefs about learning and knowledge that reflected sense-making and relationships in the learning process and the relevance and connectedness of ideas, tended to employ constructivist-oriented learning strategies. Moreover, Lourdes Rodriguez and Francisco Cano (2007) found that students who had more mature beliefs about knowledge and learning adopted approaches representing deeper ways of learning. Overall, empirical findings suggest that learning approaches were associated more with epistemological beliefs regarding structure of knowledge, knowledge construction, justification of knowledge, learning process, and intention of learning.

In the context of science, argumentation represents the core of the scientific activity (Newton 1999). Thus the improvement of argument skills is taken as an important aim of science learning. In schools, there seems to be a common belief among many teachers that the fluent use of the logic rules in science classrooms can be transferred to everyday contexts. However, empirical research has not confirmed this. For example, many studies showed that when placed in life contexts, even educated adults could not make sound scientific arguments (e.g., Jiménez-Aleixandre and Pereiro-Munoz 2002; Kuhn 1991). While some studies point out that the performance of scientific reasoning has much to do with the acquisition of domain-specific knowledge (e.g., Yang and Anderson 2003; Zimmerman 2000), other studies show that the influence of domain-specific knowledge is not clear particularly when the problem in discussion is ill-structured by nature (Perkins 1985; Means and Voss 1996).

Kuhn (1991) has shown that use of argument skills in everyday contexts appears to be predicted by a level of epistemological understanding, and Michael Nussbaum and Lisa Bendixen (2003) discovered that personal epistemological beliefs predicted avoidance of arguments. A cross-age study conducted by Michael Weinstock, Yair Newman, and Amnon Glassner (2006) revealed that older high school learners with greater epistemological sophistication identified more informal reasoning fallacies. A similar result was obtained among college students (Ricco 2007). In short, the studies reviewed indicated the developmental relation between argumentation in general contexts and personal epistemology.

In our collection of studies, there are five papers placing argumentation in the context of science learning. William Sandoval and Kelli Millwook (2005) reported that although high school students were attentive to the need of evidence for supporting claims, they failed to articulate how specific data related to particular claims when engaged in a scaffolding inquiry-based science instruction. They concluded that the quality of argument is linked with learners' epistemological understanding about warrants and data. When examining eighth grade students' argumentation skills in reasoning about science-related controversial issues, Lucia Mason and Fabio Scirica (2006) showed that epistemological understanding about knowledge and knowing is a significant predictor for making arguments, counterarguments, and rebuttals. Recently, Michael Nussbaum et al. (2008) reported that epistemic beliefs about knowledge and knowing (judgment of knowledge in particular) affect students' learning of scientific argumentation. Yang and Tsai (2010) also found that the performance of argument skills was more associated with epistemological beliefs about certainty of and justification for knowledge.

As far as learning and improvement of argumentation are concerned, by analyzing performances of scientific reasoning across different ages of students (sixth, eighth, and twelfth grade students), Yang and Tsai (2010) proposes a developmental model that showed the interplay between the development of epistemological beliefs and improvement of scientific reasoning. It has also been demonstrated that a one-year-long socioscientific issue (SSI) instruction emphasizing argumentation and discourse advanced students' epistemological beliefs concerning concepts of knowledge and justification (Zeidler et al. 2009).

In sum, the studies reviewed imply that the most critical epistemological dimensions that mediate argumentation in science are the nature of scientific knowledge and justification for knowing. The curriculum that allows learners to reflect on personal beliefs about certainty of knowledge and the process of knowledge construction will have better chance to improve scientific argumentation.

Affective Domain: Learning About the Nature of Science

An equally important goal of science education is to promote learners' appreciation for the interdependence of science and society. To this end, students must be introduced to and gradually develop the beliefs, values, and attitudes that are highly respected in the community of science. The nature of science is, in general, described as a way of knowing or the values and beliefs inherent to the development of scientific knowledge (Lederman and Zeilder 1987; McComas et al. 2000). Thus, teaching and learning the nature of science (NOS) have become critical components of science education programs that reflect the affective domain of science learning. In the literature, considerable efforts have been made to develop NOS-rich curricula. However, the effects of such curricula to change or improve understanding about NOS are not always positive (Lederman 1992). In recent years, the role of epistemological beliefs in mediating the learning and understanding about the NOS has gained attention of more and more science educators.

For example, Tsai (1999a) shows students with constructivist and empiricist views about science hold different perceptions about science laboratory activities.

Michael Enman and Judy Lupart (2000) reveal that an individual's beliefs about the nature of knowledge and learning predict his or her commitment to science. In a review of studies exploring students' understanding about the NOS, Kathleen Hogan (2000) argued that learners' personal epistemological beliefs in science, and perceptions about learning derived from experiences of school science learning, interact with their understanding about the nature of professional science. Yang (2005) found that the higher epistemological position, the better the understanding about the role of expert and evidence in science. In summary, empirical studies as listed in this section suggest that the difficulty of enhancing learners' understanding of the NOS could have resulted from the fact that they have not developed compatible epistemological beliefs.

Suggestions for Future Studies

In this chapter, we have reviewed 37 empirical studies that explore relations between personal epistemology and science learning. Based on our analyses, research on personal epistemology in the context of science learning consists of three aspects of beliefs with respect to the nature of knowledge, knowing, and learning. Dimensions of beliefs about the nature of knowledge include certainty or stability, structure, and forms of scientific knowledge. Construction of scientific knowledge, source of scientific knowledge, justification of knowledge, and nature of scientific method, activity, and community are frequently mentioned dimensions of beliefs about the nature of knowing. As far as dimensions of beliefs about learning in science are concerned, goals of science learning, processes of learning different disciplines, and ideal science learning environments are the main categories.

As discussed earlier, both domain-general and domain-specific instruments were utilized to examine beliefs about the nature of knowledge and knowing in science, but for beliefs about learning, only a few studies assessed student perceptions using domain-specific methods (Tsai 2004; Lee et al. 2008). Domain-general instruments allow science educators to draw a general picture about students' epistemological development. However, when it comes to instructional practice, detailed information about different learners' epistemological perceptions in different classroom settings is required. Thus, we expect more studies discussing the developments and the uses of domain-specific instruments for assessing students' beliefs about learning of different science subject matters. Moreover, science learning is a complex process that is individual, social, and culturally relevant. Current existing studies probe mostly beliefs at the individual level. Therefore, studies that examine beliefs about science learning in the social and cultural context are desirable.

As presented in this chapter, the role of personal epistemology in mediating concept learning in science is widely agreed. However, longitudinal effects have not been thoroughly studied. In addition, it has been shown that concept learning in science as indicated in the selected studies was mostly discussed in the contexts of biology and physics. Further studies are needed to explore learning in different scientific disciplines.

As for learning approaches, the selected studies in this chapter have confirmed that different forms of personal epistemology induce different learning approaches. Although these studies were conducted in various subject areas, similar correlational patterns between personal epistemology and learning approaches were found (e.g., the higher epistemological status, the more constructivist-oriented the approach). For future studies, more attention should be placed on analyzing the complex interplays among the instructional designs, personal epistemology, and learning approaches. Such studies will provide science educators with more information about how to create beneficial classroom settings for different learners.

Developing a science learning environment that supports and promotes argumentation has become an important objective of practice for science educators. According to Richard Duschl and Jonathan Osborne (2002), one of the necessary components of such instruction is exposing learners to epistemological criteria of argumentation in science. As discussed in this chapter, the selected studies argue that learning of argument skills is greatly influenced by personal epistemological beliefs. Thus, as Yang and Tsai (2010) mentioned, while it is critical to introduce students to the epistemological criteria of science, taking into account epistemological development, instructors should at the same time encourage children to reflect on their own epistemological thoughts rather than force them to accept the formal epistemology of science. In fact, some researchers have started to take notice of the design of epistemology-based science instruction (e.g., Yang and Tsai 2010; Zeidler et al. 2009). In the future, more experimental studies are needed to analyze the designs and the effects of such instructions.

Lastly, it has been mentioned that most of the epistemological studies in science learning involved mainly students at high-school or university levels. Given that the development of personal epistemology is an on-going process that is shaped by educational experiences, more studies with elementary school learners are necessary to clarify the developmental characteristics about personal epistemology in the context of science learning.

Appendix Summaries of research methods, epistemological instruments, and dimensions of epistemological beliefs for empirical studies regarding personal epistemology and science learning (the papers are listed in alphabetical order of authors)

#	Paper	Methodology	Epistemological instruments	Dimensions of epistemological beliefs
1.	Chan and Sachs (2001)	Quantitative study with 46 grade 4 and 37 grade 6 students	Implicit Learning Survey	Shallow view about learning vs. deep, constructivist view
2.	Chu and Treagust (2008)	Qualitative study with 10 freshmen	Interviews	1. Beliefs about physics knowledge 2. Beliefs about learning physics
3.	Conley et al. (2004)	Quantitative study with 187 fifth graders	Elder's (2002) Epistemological belief about science questionnaire (EBS)	1. Source 2. Certainty 3. Development 4. Justification
4.	Enman and Lupart (2000)	Quantitative study with 151 undergraduates	Schommer's (2002) Epistemolgy Questionnaire (SEQ)	1. Quick learning 2. Fixed ability 3. Simple knowledge
5.	Hogan (1999)	Qualitative study with 12 eighth graders	Interview	Nature of theory development and change in science: 1. Inductivist 2. Realist 3. Relativist
6.	Hogan and Maglienti (2001)	Mixed method: qualitative (interviews) and analyses with 24 eighth graders, 21 adults (16 science professionals and 5 nonscience majors)	Evaluations on 10 conclusions that hypothetical students (HS) made based on a given body of evidence	Epistemological criteria: 1. Coherence with personal inferences from the data 2. Coherence with prior knowledge, beliefs, or values 3. Specificity of conclusions
7.	Leach et al. (2000)	Qualitative study with 731 high school students and university students	Five written survey items including (3) contextual and (2) decontextual questions	1. Data focused reasoning 2. Radical relativist reasoning 3. Knowledge and data-related reasoning

8.	Lee et al. (2008)	Quantitative study with 474 high school students	Conception of Learning Science (COLS) questionnaire	1. Memorizing 2. Preparing for test 3. Calculate and practice 4. Increase of knowledge 5. Applying 6. Understanding and seeing in a new way
9.	Liu and Tsai (2008)	Quantitative study with 220 freshmen majoring in science, nonscience, and science education	Scientific Epistemological Views (SEV) Questionnaire	1. Role of social negotiation 2. Invented and creative nature of science 3. Theory laden exploration 4. Cultural impacts changing a 5. Tentative feature of scientific knowledge
10.	Lodewyk (2007)	Quantitative study with 447 tenth graders in science classes	SMEQ (Schommer's Modified Epistemology Questionnaire)	1. Fixed ability and quick learning 2. Simple knowledge 3. Certain knowledge
11.	Mason and Scirica (2006)	Quantitative studies with 62 eighth graders	1. Kuhn's Epistemology Assessment (EA) 2. Qualitative analysis for reasoning	Beliefs about knowing and knowledge 1. Absolutist 2. Multiplist 3. Evaluativist
12.	May and Etkina (2002)	Qualitative study with 12 physics students	Journal writing	Beliefs about the nature of physics knowledge 1. Applicability of knowledge 2. Concern of coherence

Chapter 20
Science Learning and Epistemology

Gregory J. Kelly, Scott McDonald, and Per-Olof Wickman

This chapter examines the relationship of science learning and epistemology. We begin with the assumption that theories of learning necessarily presuppose views of knowledge. We consider how different theories of learning draw on epistemology, and how through the process of investigating science learning, researchers define their respective theories of knowledge. Traditionally, epistemology is a branch of philosophy that investigates the origins, scope, nature, and limitations of knowledge (Boyd et al. 1991). Thus, the interpretation of what is learned, how it is learned, and by whom, and under what conditions, poses epistemological questions for research in science learning. While this is a traditional definition of epistemology, studies of learning conceptualize epistemology in different ways for different purposes. We consider the ways that history and philosophy of science have informed learning theory (disciplinary perspective), ways that students' personal epistemologies influence learning (personal ways of knowing perspective), and emerging studies of practical epistemologies that consider ways that disciplinary practices are enacted interactionally in learning contexts (social practices perspective). We will consider how conceptions of knowledge are operationalized in science learning research and draw implications for research in science education.

In our review, we identify how these three different conceptualizations of epistemology are seen to influence science learning. Each view allows the respective researchers to view knowledge in a unique way and inform research from these perspectives. These views of knowledge are not necessarily mutually exclusive,

but rather, each perspective places emphasis on certain aspects of epistemology, with less attention to other aspects. One view (*disciplinary perspective*) considers the important role of disciplinary knowledge for science learning. This position conceptualizes epistemology as a discipline concerned with examining issues such as the nature of evidence, criteria for theory choice in science, role of theory-dependence in scientific research methodology, and the structure of disciplinary knowledge (Duschl 1990; Grandy and Duschl 2008). The disciplinary perspective is a philosophical view of epistemology, largely normative in nature (i.e., it considers the reasons for theory change and the evidence relevant to such changes), focusing on knowledge within practicing scientific communities (Kelly 2008).

A second view of knowledge emanates from psychologically oriented studies of learning (*personal perspective*). These studies are concerned with the ways that individual learners conceptualize knowledge and how such personal views of knowledge influence their learning (Hofer 2001). Rather than offering a normative point of view, this psychologicalized view of epistemology, treats theories of knowledge as personal, empirical, and contingent. The focus is centered on internal representation of cognitive structures (Duschl et al. 1992), and personal views of truth, rather than on disciplinary considerations of rationality, truth, and justification. Studies consider normative approaches about how education should foster epistemological development and empirical studies that examine how personal theories of knowing influence further learning.

The third view of epistemology considers the social practices that determine what counts as knowledge in local, contingent contexts (Knorr-Cetina 1999). These studies do not view theories of knowledge as either extant disciplinary entities or solely personal views, but rather view knowledge as accomplished through social interaction. This *social practices* view of epistemology examines how, through particular learning events, questions of justification, reasonableness, and knowledge claims are negotiated among members of a group. This view describes the ways that being a member of an epistemic culture, observing from a particular point of view, representing data, persuading peers, engaging in special discourse, and so forth, locally define knowledge (Kelly 2008; Wickman 2004).

Each of the three perspectives offer expressive potential that defines the research programs in particular ways (Kelly and Green 1998). While the perspectives may show some overlap and mutual recognition, they represent some unique contributions to research in science education.

Disciplinary Perspectives on Science Learning

Philosophy of science has served as an intellectual referent for the development of science curricular materials and weighed heavily in thinking about the aims of science education (e.g., Duschl 1990; Schwab 1962). One example of this line of work would be conceptual change theory (Posner et al. 1982), which was based initially on theory-change models in scientific fields, and continues to benefit from epistemological analogies between scientists and science learners (e.g., Tyson et al. 1997;

Duschl and Hamilton 1998). Theory change in science offers ways to conceptualize the learning tasks for students and suggests ways of organizing knowledge to support learning. These perspectives are typically normative in nature, that is, they consider how rationality is defined and how concepts change through reasoning. For example, Nancy Nersessian (1992) identified a number of epistemologically relevant abstraction techniques (i.e., analogy, imagery, thought experiment, limiting case analysis) that can support student learning. The history and philosophy of science were central to the focus on conceptual change theory, and studies of science learning continue to progress toward interests in the ways that theories and models are developed, examined, and evaluated in both science and learning contexts.

A second way disciplinary perspectives have informed science education, concerns the process of legitimation. Both intended science curricula and their enactment are often informed by views of the discipline. While some curricula may be created with implicit views of science, or various disciplines within science, others specifically rely on philosophy of science. Obvious in this respect are efforts to teach about the nature(s) of science to change students' conceptions or images of the epistemology of science (Lederman 2007). A number of scholars, including Sherry Southerland, Gale Sinatra, and Michael Matthews (2001) and Derek Hodson (1988), have implored the field to consider the epistemological bases for choices about science curricula. For example, John Leach, Andy Hind, and Jim Ryder (2003) used the history of science as a framework to design units in electromagnetism and cell membranes to help students understand the status of scientific theories. Through careful curriculum design they were able to improve some students' epistemological ideas – that is, to a limited extent, the students were able to engage with scientific models and not just focus on collecting empirical data.

The disciplinary view of epistemology continues to be informed by a number of fields, beyond just history and philosophy of science, that consider the ways that scientific theory and knowledge evolve. Known collectively as science studies, these fields offer ways of reexamining and reevaluating science learning (Kelly 2008). Science studies include examining scientific communities from an empirical point of view through the study of practices in situ. The central contribution has been to move away from the presentations of final form science in classrooms to a focus on the consensus building dynamics present in knowledge-building communities (Duschl 2008). Such dynamics are rooted in the argumentative nature of scientific discourse, where evidence is considered within theoretical traditions. Science studies research points to the very social nature of consensus building in science fields and offers a valuable referent to consider changes in knowledge structure. Thus, while a focus on scientific theories and models developed in philosophy of science offers opportunities for students to understand certain aspects of the epistemology of science, science studies offer a view into the social and epistemic practices determining what counts as science. For example, Duschl (2008) identified how science studies can inform science learning by noting that scientific actions include building theories and models, constructing arguments, and engaging in the social languages of special communities. A shift to the practical actions of scientific communities offers the opportunity to integrate various cognitive and sociocultural views of learning into the design of science learning environments and curricula (Leach and Scott 2003). The focus on learning poses epistemological issues for personal ways of knowing and disciplinary practices, perspectives we examine in the subsequent sections.

Personal Epistemologies and Learning Science

The notion of personal epistemologies developed out of the work by William Perry (1970) regarding the intellectual development of college students. Personal epistemology research has since evolved in two primary veins: developmental stages and patterns of beliefs. Recently, there has been a movement to unite the stages and patterns of beliefs models and also to reconceptualize personal epistemologies. In general, the vein focusing on developmental stages examines the progression of beliefs from simple, certain, and dualistic (right/wrong) notions of knowledge, through relativist or uncertain subjectivity, and on to beliefs allowing for multiple views whose validity is considered in relation to context. Patricia King and Karen Kirchener's (1994) reflective judgment, for example, contains seven stages covering this continuum. In contrast, the research examining patterns of epistemological beliefs tends to take a broad view and include beliefs about intelligence and learning (Ken Lodewyk 2007), but views them as individual factors impacting a variety of correlates including motivation, cognitive development, conceptual change, self-efficacy, and task performance. Barbara Hofer (2004) has recently described epistemic metacognition, an attempt to unify the views of personal epistemology, which characterizes epistemic beliefs as theory-like patterns of belief that develop over time and are drawn on in more context-dependent ways.

Science learning has been informed in many ways by research from both the developmental and patterns of beliefs perspectives. Much of the focus of science learning has traditionally been on students' alternative conceptions and how, through systematically designed learning sequences, students can come to richer, more reason-based ways of understanding natural phenomena. Within this research framework, learners' ways of conceptualizing knowledge has been shown to influence science learning. Hofer (2001) characterizes this research as "personal epistemology" and notes the focus on "ideas individuals hold about knowledge and knowing" (p. 353). Within the focus on personal epistemologies, Orpha Duell and Marlene Schommer-Aikins (2001) identified five directions of research for personal epistemology studies: justification of knowledge, coping with uncertainty, gender issues, multiplicity of epistemological beliefs, and academic domain specificity. The general theoretical issues concern learners' beliefs about knowledge and how these beliefs change. Methodologically, this research tradition focuses on developing instruments to measure learners' beliefs about knowledge and learning (Duell and Schommer-Aikins 2001; Schraw 2001) and correlating them to a variety of other student factors.

In science learning contexts, learners' views of knowing and knowledge acquisition have been used to develop a framework for evaluating the authenticity of classroom science inquiry tasks (Chinn and Malhotra 2002). There have also been examinations of the alignment of students' personal epistemologies of science with those of their science teachers (e.g., Roth and Roychoudhury 1993). Furthermore, Andrew Elby and David Hammer (2001) noted that philosophically correct epistemological positions do not necessarily align with the heuristic value of certain epistemological beliefs. They identified how a sophisticated epistemology needs to consider relevant contextual information to make judgments about inquiry processes involved in learning through engagement with nature. It is clear that attention to students' epistemological views is important to an understanding of science learning; however, both the nature of these views and the relationship to science learning are not unambiguous.

Hammer and colleagues (e.g., 2003, 2008) have attempted to ontologically reconceptualize epistemic beliefs in much the same way that Andrea diSessa's (1993) knowledge in pieces did for misconceptions. Hammer suggests that epistemology should be considered in finer grained and context-specific form – epistemic resources. Students' views of knowledge are thus manifestations of those parts of the raw material activated within a particular context. Data from elementary school students' beliefs in physics are used to support this view (Hammer et al. 2008). Hammer's epistemic resources can be seen as a bridge from a highly situated, contextually bound personal view of epistemology to a sociocultural approach to epistemology – the notion of epistemology as a social practice.

Epistemology as Social Practice

Studying epistemology as social practice entails seeing epistemology as constituted through situated interaction. The aim is to describe actual epistemological practice, that is, how people proceed in action to accomplish certain purposes. This definition of epistemology is close to that of Richard Rorty (1991, p. 1), who maintained that we should not "view knowledge as a matter of getting reality right, but as a matter of acquiring habits of action for coping with reality". Studies of epistemology as social practices draw on sociocultural, ethnographic, and pragmatist studies of learning as talk and action in science classrooms. Jay Lemke (1990) is an early example of an analysis of the meaning given to science in classrooms through talk. Another example is Wolff-Michael Roth (1998), who studied the significance of social networks and artifacts for the meaning made in science classrooms. Also important are those experimental and interview studies examining the significance of artifacts and the communicative context for what students know (Edwards 1993; Schoultz et al. 2001). Although studies like these are not explicitly concerned with students' epistemologies, they demonstrate the holistic and empirical stance the social practice perspective has toward knowledge and learning and so toward epistemology. Within the social epistemology perspective, there is great variation regarding the nature and extent of the social in developing scientific knowledge, from relativist positions to those dedicated to examining the social basis for evidence use (Kelly et al. 1993).

Within this perspective, knowledge is seen as competent action in a situation rather than as correct, static representations of the world. To decide on what ways student actions are competent, they need to be examined in an activity with some human purpose. Hence, communication and action primarily has meaning within purposeful practice, in doing something (Kelly 2005; Wickman 2006). This tenet from Ludwig Wittgenstein (1967) is central for the epistemological analysis from this perspective (Lynch 1993). Epistemology as social practice is a description of how a community must continually construe what counts (Knorr-Cetina 1999). This means that we must study both science proper and school science as “science-in-the-making” (sensu Latour 1987, p. 4) to describe their epistemologies (Kelly et al. 1993). Only when we have these descriptions of how the participants themselves go about making sense can we suggest meaningful improvements from the educational researcher’s outside perspective (Kelly 2005; Wickman 2006). In science education research, description starts from that of school science-in-the-making without beforehand imposing outside analytical constructs such as positivism or constructivism on the patterned actions of students (Kelly and Crawford 1997).

Knowledge when studied in this way is encountered in transition as part of practice; continual learning is needed to transform knowledge to the contingences of each situation. Knowledge in this way is not propositional but enacted. However, the patterns of actions are not entirely contingent. They form certain jointly constituted discursive ways of dealing with people, objects, and events, and in particular ways of deciding what and whose knowledge counts (Kelly et al. 1998). Crawford et al. (1997) followed two bilingual high school students and studied the presentation of their science project across different audiences. The students’ descriptions varied across audiences such as teachers, classmates, and fifth-grade students. What counted as knowledge was construed depending on the communicative setting, suggesting that different communicative contexts afford students different ways of understanding what may first seem to be the same subject matter content. Hence, an ethnographic study from a first person perspective, although not normative in itself, can be used to inform our decisions in science education.

Studying epistemology as social practices can be used more directly to study how meanings concerning the nature of science are negotiated in science class. Gregory Kelly, Catherine Chen, and William Prothero (2000) developed such a method drawing from sociological and anthropological studies of scientific communities. Using this approach they analyzed talk and writing in a university oceanography class to examine such epistemological issues as the uses of evidence, role of expertise, relevance of point of view, and limits to the authority of disciplinary inquiry. Their study has implications for how epistemological issues can become an integrated part of science courses at the university.

Per-Olof Wickman and Leif Östman (2002a) and Wickman (2004) have developed a so-called practical epistemology analysis to study how certain meanings are made through interactions in science class as discursive practices. This approach can be used to study how different encounters with the teacher, among students, and between students and artifacts influence the direction learning takes through talk and action in a science class. Malena Lidar, Eva Lundqvist, and Östman (2005) examined how different kinds of epistemological moves by a teacher influence the learning of middle school students. An epistemological move is how the teacher directs the students in ways that determine what counts as knowledge and appropriate ways of getting knowledge in a specific school science practice. Wickman and Östman (2002b) studied the practical epistemologies of zoology students at the university to see to what degree students could use induction and deduction to produce testable hypotheses when making observations of real pinned insects. This study demonstrated that students' practical epistemologies were more experiential and holistic, using whatever they could apply from previous experiences to understand the structure of the studied insects. The situated and locally construed epistemology was shown to be more functional than the typical inductive and deductive stances to learning about insects. An analysis of high-school students' practical epistemologies in chemistry lab (Hamza and Wickman 2008) showed that learning was more influenced by local and contingent aspects of the situation than by the cognitive constraints implied from interview studies of students' misconceptions. It has also been demonstrated that the learning of science is not a merely a cognitive affair. When epistemology is studied as social practice it is clear that aesthetic judgments play a crucial role for what counts as knowledge. This was found in elementary school science, as well as in university science (Jakobson and Wickman 2008; Wickman 2006). Studying epistemology as social practice thus opens up possibilities to study learning processes that the personal perspective sees as mental entities (e.g., aesthetic experience, misconceptions) and to analyze how knowledge as action develops and is changed by the various experiences and other circumstances that meet in education.

In the social practice approach, conceptions and views are not primarily seen as something that determines action, but rather as units of action themselves. That a student repeatedly argues that 'science is tentative' is seen as a habitual way of reasoning, rather than a propositional personal understanding that causes certain ways to talk and act, which could be described by this propositional statement. William Sandoval (2005) borrowed the term practical epistemology from Wickman and Östman (2001) to designate a belief about knowledge in school science that influences students' ways of doing science inquiry in school. However, approaching epistemology as social practice or as practical epistemology in the original sense of the word does not assume that beliefs necessarily are the reasons why people have certain habitual ways of doing things (Wickman 2004). It might simply be the way they do things, without further reflection. It then becomes an empirical question as to why certain social practices develop and how they might be made more purposeful based on what we value in science education (e.g., McDonald and Kelly 2007; Sensevy et al. 2008).

Evolution of Epistemological Perspectives on Learning in Science Education

Learning theories in and informing science education recognize the importance of epistemology. Disciplinary, personal, and social practice views each offer unique and potentially complementary views about how knowledge and learning interact in science settings (Sandoval 2005). Across the different perspectives some common themes emerge. First, increasingly, science education researchers are viewing meaning as public, interpreted by participants (and analysts) through interaction of people via discourse including signs, symbols, models, and ways of being. Second, learning is increasingly examined through the everyday social practices of members of a group, for example, school settings, museums, research laboratories, and so forth. This research draws on the social knowledge of analysts to consider the ways that science is framed through discourse practices (Lundqvist et al. 2009). Thus, the measure of learning is not the results of student performance on tests, but rather how students are able to use language in authentic social settings (e.g., McDonald and Kelly 2007; McDonald and Songer 2008). Third, the epistemology is interpreted, not only in the traditional sense, concerning the origins, scope, nature, and limitations of knowledge, but as an interactional accomplishment among members who define for themselves what counts as knowledge in a particular context. Thus, the interactional nature of competent actions taken by members of a group in a situation comes to define knowledge. This view suggests that knowledge be examined as it occurs in practical actions, rather than as measured by students' decontextualized views of epistemology, nature of science, and so forth. Thus, through interaction with the world and each other, members of communities come to define what counts as knowledge, evidence, explanation, and so forth, and embody an epistemology through such actions. Finally, across the perspectives, the evolving nature of disciplinary knowledge and the confluence of perspectives on learning, suggest a focus on the epistemic moves made by teachers (Lidar et al. 2006). Further study of the different ways the teacher directs the students regarding what counts as knowledge is needed to develop desired learning situations for their students (Hammer and Elby 2003; Jiménez-Aleixandre and Reigosa 2006).

Future Directions for Studies of Epistemology and Learning

Our review of research involving epistemology and learning suggests that the emerging research directions draw from and are informed across perspectives. These perspectives may be mutually supportive, or in some cases, offer divergent directions for research and importantly, research methodology. There is fertile ground for additional studies in each area. However, there are also numerous directions that could plausibly emerge from the current knowledge base. We propose three for consideration. First, sociohistorical activity theory (CHAT) offers a direction that takes serious disciplinary knowledge and the acculturation associated with learning, and recognizes the need to examine knowledge in practice (Leach and Scott 2003; Van Eijck et al. 2009). Van Eijck et al. (2009) provide a cogent view of how measures of "students' 'images of science'" (p. 612) represent a snapshot of students' responses to research instruments and offer little insight into how students can engage in collective practices. In contrast, drawing from CHAT, they examine instead the coproduction of students' images of science at a moment in time, embedded in a particular context. This view suggests a methodological focus on the interactional accomplishment of science in an activity system. Second, drawing from the learning sciences, Duschl (2008) proposed a shift away from the unitary goal of conceptual understanding to a more balanced set of goals focused on the conceptual, epistemic, and social goals for science learning. Central to this view is the development of learning progressions, centered on the most core and generative concepts of the respective science disciplines – concepts that are learned through engagement in situated scientific practices (Leach et al. 2003). Importantly, these learning progressions include social and epistemic goals for assessing and evaluating the status of knowledge claims, methods, tools for measurement, and representations or models (Duschl 2008). Third, theories tying the epistemological moves of teachers to consequences for what counts as science for students offer a way to develop practical epistemologies in classroom conversations (Lundqvist et al. 2009). Across perspectives, we envision research that considers seriously the social, contextual, and contingent nature of epistemic activity associated with learning science.

Acknowledgments We would like to thank Richard Duschl and Karim Hamza for their helpful comments and suggestions on an earlier version of this chapter.

Part III
Teacher Education and Professional Development

Chapter 21
Science Teacher Learning

John Wallace and John Loughran

Introduction

The recognition of the central place of teacher learning in school reform is a recent phenomenon. As Marilyn Cochran-Smith and Kim Fries (2008) suggest, we have seen the evolution of teacher development from being seen as a curriculum problem (1920s–1950s) to a training problem (1960s–1980s) to a learning problem (1980s–2000s) to a policy problem (1990s–present). Over the past 20 years, there has also been a developing interest in the nexus between student learning and teacher learning (Sykes 1999) and the notion of teaching as a learning profession (Darling-Hammond and Sykes 1999). Building on the work of Peter Senge (1990) and others, the crux of this argument is that schools, more than most organisations, are in the business of learning, and that all members of the organisation, administrators, support staff, teachers and students, should operate in an environment where learning is actively and explicitly valued and supported. Rather than seeing teacher learning as the effect of teacher development, this new perspective sees learning as *both* effect *and* affect: teachers learn as students learn and students learn as teachers learn.

In this chapter, we focus our attention on science teacher learning. Our perspectives are informed by literatures from fields as diverse as psychology, sociology, teacher development, school effectiveness, curriculum change, organisational change, and science and mathematics education. We are interested in theories of teacher learning, the nature of science teachers' professional knowledge, science

teacher learning through teacher research, the relationship between student learning and teacher learning, and the contexts for science teacher learning.

Theories of Teacher Learning

Theories of science teacher learning can be characterised by various images of teachers' work – including the metaphors of computer, craft and complexity (Mullholland and Wallace 2008). Under the *computer* database metaphor, the teacher is seen as a consumer of a wide range of discrete professional development offerings, with each offering being designed to add (or plug in) an additional component to the teacher's knowledge base. Such a model is contextually agnostic and knowledge acquisition is seen as a logical manipulation of symbols within the individual mind. Under the *craft* metaphor, the teacher is an independent artisan, gradually building a repertoire of practice-based knowledge and skills through cognitive apprenticeship. The *complexity* metaphor sees the teacher as a social being working in particular societal, school and classroom contexts and communities. According to Dominic Peressini and colleagues (2004, p. 69), knowledge acquired under this metaphor is specific to those settings and learning is viewed as 'changes in participation in socially organized activity'.

These three metaphors can also be viewed as points on a continuum between an individual-cognitive perspective in which knowledge and beliefs are the primary factors that determine action, and a collective-situative one in which 'knowledge and beliefs, the practices that they influence, and the influences themselves, are inseparable from the situations in which they are embedded' (Peressini et al. 2004, p. 73). Theorists from the individual-cognitive end of the range could include Jean Piaget (1965) (cognitive development), Fred Korthagen and Jos Kessels (1999) (gestalt theory), Ernst von Glasersfeld (1995) (radical constructivism) and, from the situative-collective end of the range, Lev Vygotsky (1978) (cultural-historical psychology), Jean Lave and Etienne Wegner (1991) (situated learning and communities of practice), Ralph Putnam and Hilda Borko (2000) (situated knowing), Marlene Scardamalia and Carl Bereiter (2003) (knowledge building), Edwin Hutchins (1995) (distributed cognition) and Paul Ernest (1998) (social constructivism). Concomitant approaches to teacher development include (from the cognitive end of the range) professional development workshops and conceptual change strategies, and (from the situated end of the range) problem-based learning, case methods, teacher self-study, action research and collaborative learning communities.

Science Teachers' Professional Knowledge

Learning theories and strategies aside, there is general agreement that science teachers' learning needs to focus on improving teachers' professional knowledge. The literature is replete with different ways of thinking about that which comprises teachers' knowledge (e.g. Clandinin and Connelly 1995; Fenstermacher 1994). Sandra Abell's (2007) review of research on science teacher knowledge illustrates how the shift from research *on* teachers (1960s and 1970s) to research *with* and *by* teachers (1980s) led to a serious focus on the nature of teachers' knowledge as opposed to how well teachers do their work. This shift led to a greater appreciation of teaching as something more than the simple delivery of information and highlighted the importance of knowledge of teaching in moving beyond transmission models of practice.

While there is much agreement about the importance of teacher knowledge, there is also considerable discussion and debate about how teacher knowledge is constructed, organised and used (Feldman 2002; Fenstermacher 1994). In a longitudinal case study of one teacher of science, Judith Mullholland and John Wallace (2008) attempted to portray a range of different, though related, teacher knowledge representations. As mentioned earlier in the chapter, the metaphors were

> … teacher knowledge as *computer*, whereby knowledge is viewed as an interactive database or sets of skills and understandings; as *craft*, whereby teachers are seen as artisans whose skills exist in accomplished performance against a backdrop of the teaching context; as *complexity*, whereby knowledge is developed in complex interaction with the total environment and inseparable from this environment; and as *change*, whereby knowledge grows, evolves or develops over time. (p. 42, original emphasis)

This study, like many others concerned with knowledge of teaching, inevitably involved the concept of pedagogical content knowledge or PCK (Shulman 1986, 1987). PCK, is 'subject matter knowledge for teaching' – an amalgam of knowledge of content and knowledge of practice, brought together in a particular way through the specialist teacher's expertise (Shulman 1986). As the literature continually demonstrates, PCK appears to resonate strongly with scholars concerned with researching knowledge of practice – but perhaps none more so than in science. PCK offers a lens into the complexity of science teachers' professional knowledge in ways that draw attention not only to teacher learning, but also to how that learning might be recognised in, and influence the development of, practice. In recollecting how he arrived at the concept of PCK, Lee Shulman explained:

> I understood how complex it was to teach and learn that set of [Biology] ideas … Because [in Biology] you've got to deeply understand what it is that makes evolutionary theory…, whether you think ecologically or cellularly, what makes it difficult, and then what the variety of misunderstandings students might have, with the resilience of their misunderstandings. … They'll pass your test and then three weeks later you… ask them to: 'Explain the idea of bacteria that develop a resistance to antibiotics' and they'll give you a classic Lamarckian interpretation. … There's a big idea that's sitting in the middle of the field [PCK is therefore evident in how a science teacher recognizes and responds to such a situation]. (Berry et al. 2008, p. 1276)

PCK has been interpreted and studied in many and varied ways (Gess-Newsome and Lederman 1999). However, despite its allure to academics, it only really makes sense to teachers when it becomes 'real' and moves from an abstract concept to a concrete, useable form of knowledge for practice. This is well demonstrated in the work of a number of scholars. For example, Appleton (Appleton 2006; Appleton and Harrison 2001) studied PCK in elementary teachers and illustrated how, for these teachers, PCK encompasses 'activities that work'. Likewise, PCK has been examined by van Driel and colleagues (1998, 2001) with pre-service chemistry teachers, by Pernilla Nilsson (2008) with pre-service elementary teachers, and by Kira Padilla and colleagues (2008) with university science teachers. Common to all of these studies is the way in which, through the lens of PCK, science teachers can learn about and, therefore, better value, their knowledge of practice.

A particular approach to making PCK concrete for science teachers is that of the CoRe (Content Representation) and PaP-eRs (Pedagogical and Professional-experience Repertoires), which were developed by a team of science education researchers at Monash University (Loughran et al. 2004, 2006). This approach has been successfully used in many studies of the knowledge of science teachers, but particularly so by Jim Woolnough (2007) in his work with pre-service teachers and Marissa Rollnick and colleagues (2008) with in-service teachers. In each of these studies, it is clear that participants frame their knowledge of teaching in new ways as a consequence of using a CoRe and PaP-eRs approach and situate themselves as learners and generators of knowledge of teaching. Such engagement in learning about teaching has been described by Robyn Brandenburg (2008) as reflective traction and can be a catalyst for more formalised inquiry into practice through teacher research.

Teacher Learning Through Teacher Research

Advocates such as Marilyn Cochran-Smith and Susan Lytle (Cochran-Smith and Lytle 1999, 2004; Lytle and Cochran-Smith 1991) have long argued that teacher research is an important cornerstone of educational reform. Although in many ways teaching might be described as involving ongoing inquiry into practice, it is through the more formalised approach of teacher research that teacher learning is able to move beyond the individual practitioner and be accessible and useful for others.

Many science teachers' initial forays into teacher research are as a consequence of apprehending the problematic in their own practice. John Wallace and Bill Louden (2002) drew attention to the problematic nature of teaching when they worked with science teacher researchers to explore the dilemmas of teachers' own practice through case writing. The notion of dilemmas is important because, as dilemmas are managed rather than resolved, teacher research based on dilemmas inevitably opens to scrutiny the myriad of decisions that teachers face in constructing meaningful learning experiences for their students. This work, like that of others working in the field of case writing (e.g. Lundeberg 1999; Shulman 1992) offers insights into one form of teacher research that begins to 'unpack' the complexity of teaching and learning.

Cases have proved to be an effective way of supporting and disseminating the learning from teacher research. For example, Berry and colleagues (2009) conducted a longitudinal study through which science teacher researchers published their cases. Berry's analysis suggests that, as a consequence of the careful attention to the detail necessary to write a case, many authors come to see into their classrooms in new ways, which itself then becomes an impetus for change. She illustrates how cases can empower teachers by opening up possibilities for dialogue about practice in ways that encourage and support risk-taking in practice – which is at the heart of learning from experience. Case reading and writing invites professional scrutiny and highlights the value of articulating knowledge of teaching which further supports teacher learning.

In a similar vein, Louden and Wallace worked with groups of teachers to focus on *specifics* (of teaching, often involving cases), on *standards* (of teaching and learning), on *quality conversations* (focused on teaching and with colleagues) and on *contexts* (structured formal and informal learning situations). In one example provided by Bill Louden and colleagues (2001), a group of experienced science teachers met regularly with academic collaborators over a 2-year period in a cyclic process of data collection, discussion and practice. Teachers videotaped their own classrooms, came together with colleagues to discuss their teaching videos in relation to a set of professional standards, and returned to the classroom to try some new ideas. The video segments, colleague commentaries and other artefacts were also assembled into a set of multimedia video cases for use as source material for further discussion.

Through case writing experiences, some science teachers have developed rigorous and systematic research into their practice and/or their students' learning. An example of this is to be found in the work of Ian Mitchell (1999), co-founder of the Project to Enhance Effective Learning (Baird and Mitchell 1986; Baird and Northfield 1992) and the subsequent Perspective and Voice of the Teacher (Loughran et al. 2002). These two influential projects involved science teachers documenting and learning from their own practices and collaborating in the hope that the same might happen for others. As a teacher researcher, Mitchell recognised that

> [t]eachers want to see classrooms via credible, contextually rich accounts of specific incidents … that provide teachers with ways into either experiencing the problem (e.g., ways of uncovering students' alternative conceptions in science) or into starting to do something about it. The accounts need to provide advice and ideas that will allow readers to experiment at different levels of risk. Accounts that gloss over difficulties and present stories of unmitigated triumph are unlikely to be credible to teachers… Communicating teacher research, in accessible and useful ways to other teachers involves some very different issues from those associated with communicating the same research to academics. (Mitchell 2002, pp. 263–264)

A common theme that emerges from teacher research is the value of teachers listening to, and therefore learning from, their students. The connection between science teaching and science learning should be such that they are not separate and distinct activities but partners in a symbiotic relationship. Therefore, just as it is anticipated that students learn from their teachers, so too it should be expected that science teachers learn from their students.

Teacher Learning Through Student Learning

Any serious examination of the notion of teacher learning must consider the reflexive and synergistic relationship between students' learning and teachers' learning. There are two ways to approach this subject, from science teachers to their students (as has been attempted by Kwang Yoon and her colleagues, 2007) or from students to their teachers. Here we chose to focus on the latter approach, that is, how science student learning can influence science teacher learning. The starting point for this approach is student science learning.

In their review of students' understanding of science concepts, Phil Scott et al. (2007) explained the roots of the field of 'alternative conceptions', moving from Piaget through to the influential work of Ros Driver (1983) and Roger Osborne and Peter Freyburg (1987). Much of the learning from this field has been captured in Helga Pfundt and Reinders Duit's (2000) *Bibliography: Students' alternative frameworks and science education*. However, knowing about students' conceptions, and doing something about it in practice are not necessarily the same thing.

In the final chapter of their influential book, *Learning in science: The implications of children's science*, Roger Osborne and Peter Freyberg (1987) consider what it means to introduce children's ideas of science to teachers.

> When we have talked to fellow teachers and teacher educators … [Some colleagues] have initially found it difficult to accept that their assumptions about what children interpret from their well-prepared lessons could be so different from what they (as teachers) intended. … When teachers become aware of children's ideas on the consequential difficulties pupils can have in learning science, they experience conflicting feelings as to what they can do about it. (p. 136)

Helping teachers to find appropriate ways of responding to children's ideas was the focus of the Children's Science group, initiated by Dick Gunstone (1990). The group was comprised of elementary and secondary science teachers who met on a regular basis with academic collaborators. Over a decade of work, the group developed and documented new teaching procedures designed to approach practice by taking into account students' prior views and/or to challenge students' thinking about science phenomena.

As the work of the Children's Science group demonstrated, listening to and learning from students focuses attention on the notion of meta-cognition:

> [Metacognition is the] amalgam of learner knowledge, awareness and control of their learning … [it] is learned, and so can be reconstructed if the learner is willing and able. It is not, however, in any way easy to have learners do this. It requires recognition of existing views, evaluation of these views, and then learner decisions about whether or not to reconstruct. … If the learners' ideas and beliefs about the processes of learning and teaching are in conflict with them recognizing, evaluating, reconstructing their existing science ideas and beliefs then little progress is possible. (Gunstone 1990, p. 17)

Meta-cognition is important not only to student learning but also to teacher learning. Clearly, just as students need to act meta-cognitively if they are to confront and reconstruct their conceptions of science, so too science teachers need to pay careful attention to that which is occurring in a classroom situation and to actively respond to what they see, hear and do, in a pedagogically appropriate way. Being sensitive to the 'student voice' is a fundamental element that underpins quality in science teaching.

Similarly, Robin Millar (2006) draws attention to the value of inviting students into their own learning of science through the notion of engagement. He suggests that, through a careful consideration of engagement, teachers can facilitate students' science learning by helping them to make powerful links between the science that they learn in school and the science that they know about from their out-of-school experiences. Again, the importance of recognising the synergies in teaching and learning are crucial here as exemplified Keith Bishop and Paul Denley's (2007) book. In their chapter on 'student voice', the authors show how science teacher learning is inextricably linked to learning from students:

> Our view is that it would seem odd to make no attempt to find out, or even be aware of, what the students you teach think of their science education or what they expect from it. … [T]he evidence suggests that the student voice offers exciting possibilities to innovative and creative science teaching and enhanced student engagement. From our own research, and from research in the public domain, we advocate that listening to students is an essential part of any science teacher's professional learning. (pp. 167–168)

It naturally follows that the way in which the practice setting is organised and structured influences not only how teachers learn, but also what they learn and what they do as a consequence of that learning. Therefore, the contexts in which teachers work and learn require just as much attention as the nature of that learning if the conditions for learning are to be supported and enhanced.

Contexts for Teacher Learning

What are the appropriate contexts for teacher learning? How can science teacher learning be nurtured and encouraged? For a simple answer to these questions, we might look at the recent empirical literature on 'reform' style teacher development to identify characteristics such as connection to the classroom, sustainability, collective participation, focus on content and student inquiry, active learning and coherence (Garet et al. 2001).

Another approach is to examine the typologies of teacher development strategies suggested by the individual-cognitive and the collective-situative, with the individual typified by out-of-school and workshop-style offerings and the collective characterised by in-school and collaborative activities. The advantage of the individual approach is that generalised solutions to curriculum problems can be identified and widely disseminated. Further, teachers can pick and choose offerings depending on their perceived needs and motivations. The disadvantage is that these activities are typically not grounded in the teacher's practice, and are often conducted in isolation from the communities that they are intended to serve. While collective approaches are more locally effective, they are often complex and unwieldy and suffer from a lack of transferability. However, as Dominic Peressini and his colleagues (2004) point out, the individual-collective dichotomy is misleading because the relationship between classroom practices and individual reasoning is reflexive. 'Students contribute to the development of practices within the classroom; these practices, in turn, constitute the immediate context for [teachers'] learning' (p. 71).

A further dimension to this discussion is offered by Lee Shulman and Judith Shulman (2004), co-investigators of the Fostering Communities of Learners programme. In attempting to fathom and explain the different learning experiences of two Grade 8 science and mathematics teachers, the authors concluded that, in order to learn, a teacher must be 'Ready (*possessing vision*), Willing (*having motivation*), Able (*both knowing and being able "to do"*), Reflective (*learning from experience*), and Communal (*acting as a member of a professional community*)' (Shulman and Shulman 2004, p. 259, original emphasis). As the authors point out, these attributes – readiness, willingness, ability, etc. – have both an individual and a collective component. 'The individual and community levels are both interdependent and interactive' (p. 267). They conclude: 'While the "subject matters" in these settings, there is so much more going on simultaneously that at times the ever-important content differences can be swamped by other critical features of the context' (p. 269).

Like many other scholars, we favour a pragmatic model of teacher learning that incorporates both theoretical positions. Paul Cobb and Janet Bowers (1999) talk about the 'choice between any particular case being a pragmatic one that depends on the purposes at hand' (p. 6). Such a position highlights the interrelatedness of elements within systems, and the notion of 'individual-in-social-action' used by Gary Hoban (2002) to represent the interaction of the cognitive and the situated.

A pragmatic perspective would suggest that teachers need the opportunity to engage in authentic activities, participate in rigorous and critical debate within discourse communities, and develop facility with the various tools used in that community. Often, these conditions are not always available in the one place. While authentic activities are most often associated with the classroom and the school, it is difficult for teachers to break out of routine ways of teaching, especially as schools do not always value or support critical and reflective practice. The more sophisticated cognitive, cultural and language tools of practice are often to be found in discourse communities outside the school – for example, in professional associations, universities and district and central offices. Moreover, organisational learning and learning across the profession are more likely to proceed if teachers also engage in communities beyond the four walls of the classroom.

We argue that supporting teacher learning entails the creation of formal and informal opportunities for learning to proceed in multiple contexts (settings, communities and learning foci). Deborah Ball and David Cohen (1999, p. 25) refer to a 'pedagogy of professional development' that comprises of the tasks and materials of practice, the discourse to support learning with these tasks and materials, and the roles and capabilities of leaders who provide guidance and support for this work. In this chapter, we have provided several examples of locally managed teacher development linked to other discourse communities, such as universities and school boards. The strength of these systems models is in the bringing together of the various components of the science education enterprise – students, teachers, teachers' knowledge, school leaders, research-based inputs, academic and systemic supports, etc. – in such a way as to build local relevance and ownership while developing both individual and organisational learning.

Conclusion

Teacher learning is, we maintain, a central tenet for educational reform. In this chapter, we argue for a model of teacher learning that encompasses both the individual-cognitive and the collective-situative stances on learning. This position recognises that teachers operate as individuals, making choices about levels of engagement, processing information and reflecting and acting on that information. Also teacher learning is inextricably linked to the learning of others – to students' learning, colleagues' learning and organisational learning.

We favour an approach to teachers' learning that focuses on research with and by teachers, on building teachers' knowledge about teaching and for practice, and capitalises on the inextricable connection between teachers' learning and students' learning. Such learning takes place in multiple learning contexts, combining out-of-school activities, theory and practice-based learning experiences with ongoing support for teachers to learn from their students and to integrate ideas into their classroom practice. In this chapter, we have described some promising examples of teacher learning, including action research projects, case writing, video clubs and content representation among others. These models have individual and collective components. They foster classroom-based, teacher research within a context of theory-driven ideas and collegial and other support. They also attempt to build a discourse community around science education, not only across the school but also in the wider school community.

Simply stated, teacher learning is about teachers building and sustaining knowledge of classroom practice across various discourse communities. It includes principles such as teacher ownership, focus on practice, coherence, collegiality, active learning and systemic support. Putting these principles into practice, however, is a different story. Teacher learning is complex because it is about the complicated interplay between the individual and the collective. In this chapter, we have argued for a model of teacher learning that acknowledges this complexity, and that marshals the various components of the science education enterprise to respect and support teachers' attempts to build knowledge of their own practice.

Chapter 22
Teacher Learning and Professional Development in Science Education

Shirley Simon and Sandra Campbell

The Institute of Education in London hosts one of the nine Science Learning Centres set up in England in 2004 to promote the professional development of science teachers in each region of the country. The Centres are part of a government initiative to enhance science teaching and learning and offer Continuing Professional Development (CPD) courses that are perceived to be most needed by teachers. A CPD course could focus on technical aspects of teaching science, such as practical procedures, or more fundamental pedagogical practices, such as formative assessment. Courses may be just 1 day, or 2–3 days over a period of time with teachers taking ideas and activities to try out in their schools so that they can reflect and subsequently feed back ideas to colleagues on the course. A model of professional development that entails teachers coming out of school to attend short courses may be limited in its impact on pedagogy, even though such a model is financially and organisationally the most viable. Our concern as Institute researchers is to work in partnership with the Centre, sharing our research findings on teachers' response to innovations to develop a greater understanding of what makes professional development effective. Recently, the Centre has initiated outreach activities in schools in response to science departments requesting such support whilst they attempt to initiate fundamental changes in practice, such as assessment, and these are tailored to be more relevant to teachers' contexts and needs. Our ongoing research, informed by the wider international literature on professional development, attempts to explore other models of professional development that can enrich the work of the Centre.

This chapter presents a review of the literature that has informed our perspective and research on teacher learning and professional development. We address some questions that help to clarify our perspective and discuss models that have informed

our work. We also draw on our own research on professional development to illustrate practices that provide insights to the success and limitations of professional development design.

What Do We Mean by Professional Development?

In 1996, Beverley Bell and John Gilbert published a book called *Teacher Development: A Model from Science Education*. The model they proposed was based on a 3–year study documenting how a group of New Zealand science teachers changed as they implemented new teaching approaches that would take account of students' existing thinking. The study arose from substantial research into children's ideas and learning in science (Osborne and Freyberg 1985) and constructivist views of learning (Osborne and Wittrock 1985), which had implications for teachers' roles and activities in science classrooms. Essentially, teachers were challenged to change their teaching from a process of transmitting knowledge to a process of helping students to construct scientific knowledge through questioning and testing existing ideas, engaging in different activities and contexts for learning, and reflecting on learning. Bell and Gilbert based their model on a view of learning that takes into account human development and the development of self-identity, social constructivism, and reflective and critical enquiry. The model portrays teacher development as taking place in three intertwined domains, the personal, professional and social, and identifies how progress occurs in each of these three domains. What makes this model so relevant and enduring is that it arose from a study where teachers *reconstructed* their understanding of what it means to be a science teacher in fundamental ways. In recent years there have been other innovations in science teaching that are also underpinned by substantial theoretical research, and we shall document some of these; however, results show that unless teachers really want to change, or really value how a particular change can make their and their students' experience more worthwhile, they will not alter how they perceive themselves as science teachers or radically change their practice.

In our view, Bell and Gilbert's model for teacher development continues to be powerful and relevant as it was underpinned by fundamental questions about teacher learning that we are still concerned with today, and which are appropriate to other innovations being implemented in science classrooms. Bell and Gilbert use the term teacher development interchangeably with teacher learning, yet a distinction between the terms 'development' and 'learning' has since received some attention in the literature. Garry Hoban (2002), for example, rejects the term development as conveying a mechanistic, linear view of learning, characterised by one-off workshops that tend to reinforce existing practice. Hoban argues for a paradigm based on complexity theory where teachers generate new ways to rethink and change existing practice within a professional learning system. Our view of teacher learning and how it can be facilitated coincides with Hoban's, as we show later; however, our interpretation of 'development' as used by Bell and Gilbert, encompasses the notion of ‘learning’, and their underpinning questions could be read as development or learning:

> What is the nature of teacher development?
> What factors help and hinder teacher development?
> What model of teacher development can be used to plan teacher development programmes and activities?
> What teacher development activities promote growth?
> (Bell and Gilbert 1996, pp. 9–10)

The following account in this section addresses the first three questions in terms of teacher learning, drawing on international perspectives and experiences from our own work in science education. The fourth question is addressed in a further section and focuses on specific examples from our experience of activities and contexts for learning within science education initiatives.

What Is the Nature of Teacher Learning?

The durability of the Bell and Gilbert model is also evidenced by its continued use in more recent attempts to theorise the nature of teacher learning and how professional practice can be changed in sustainable ways (e.g. Fraser et al. 2007). In drawing on the model, Christine Fraser and her colleagues make a distinction that we find useful between what is meant by ‘teacher learning’ and ‘professional development’:

> [T]eachers’ professional learning can be taken to represent the processes that, whether intuitive or deliberate, individual or social, result in specific changes in professional knowledge, skills, attitudes, beliefs or actions of teachers. Teachers’ professional development, on the other hand, is taken to refer to the broader changes that may take place over a longer period of time resulting in qualitative shifts in aspects of teachers’ professionalism. (pp. 156–157)

This distinction made by Fraser et al. has synergy with our interpretation of the work of Susan Loucks-Horsley et al. (2003), as these authors also refer to professional development in addressing broader issues of designing programmes, and to specific strategies for professional learning of teachers.

Besides clarifying their position on teacher learning and professional development, Fraser et al. incorporate the concept of teacher change, which they see as coming about through a process of learning that can be described in terms of transactions between teachers’ knowledge, experience and beliefs on the one hand, and their professional actions on the other. David Clarke and Hilary Hollingsworth (2002) also draw on both individual and professional aspects of learning in their account of ‘professional growth’; from a cognitive perspective, teacher growth involves construction of knowledge in the personal domain of the individual teacher, a perspective adopted in Shulman’s early work on pedagogical content knowledge (Shulman 1986), and from a situated perspective teacher growth is constituted through the evolving practices of the teacher (the professional domain). The need to conceptualise teacher learning from both perspectives is supported more widely in the literature; Hoban (2002) draws attention to the importance of both cognitive and situated perspectives in analysing teacher learning, by taking into account individual processes as well as social and contextual influences; Hilda Borko (2004), in taking what she terms a situative perspective, also emphasises the need to consider both individual teacher-learners and the social systems in which they are participants. The recognition of both cognitive and situated perspectives as important for understanding teacher learning in our view complements and builds on the work of Bell and Gilbert. We conceptualise teacher learning as a complex combination of the individual teacher's knowledge growth, the professional teacher practicing in a particular setting and the social teacher working collaboratively with others in that setting.

What Factors Help Teacher Learning?

In addition to a rationale for professional development based on perspectives of teacher learning is the need to consider how that learning takes place, for example, how the domains of Bell and Gilbert's model can progress, or how Clarke and Hollingsworth's 'growth' can be facilitated. Early studies undertaken by one of the authors enabled her to begin to identify the factors that can influence teacher learning. In the early 1990s, Shirley Simon undertook a study with Alister Jones, Paul Black and other colleagues called the Open-Ended Work in Science project, or OPENS (Jones et al. 1992). This project focused on how teachers, working alongside researchers, could make changes in their practice as they engaged in more inquiry-based activities in response to the new national curriculum in England. Working with a group of teachers we explored each existing situation to negotiate a starting point for development, planned the new approaches with the teachers who subsequently put these into practice, then reflected on and evaluated the changes and outcomes with the teachers. We found that teachers were so different in their individual needs and contexts that these features of existing practice, negotiation, reflection and evaluation were critical for change (Jones et al. 1992). Though the study was researcher dependent and did not follow through to gauge learning and sustained change, it alerted us to the need for establishing these features in a professional development context.

Some years later, Simon became involved in the professional development of teachers as part of a major innovation called Cognitive Acceleration in Science Education (CASE). CASE was founded by Michael Shayer and Philip Adey, drawing on a theoretical base derived from the work of Piaget and Vygotsky. Shayer and Adey set out to apply their analysis of students' reasoning in terms of Piaget's stages of development (Shayer and Adey 1981) and over many years established evidence for the effects of cognitive acceleration (Adey and Shayer 1994). They designed science curriculum materials to promote formal operational thinking (Adey et al. 1995), and a professional development programme to support teachers as they attempted to use the materials to promote cognitive conflict and social construction of reasoning. The development programme involved university-based workshops, in which teachers were introduced to the theoretical base, engaged in activities to experience cognitive conflict and construction, and shared with each other reflections on practice. These workshops were combined with in-school coaching (Joyce and Showers 1988), where ‘trainers’ observed lessons and gave individual or departmental feedback. Evaluation of professional development was not focused on individual teacher learning, but on sustained implementation by science departments. Collegiality and ownership of the innovation were seen as critical factors in helping to maintain its implementation, as evidenced in a study of ‘level of use’ conducted by Adey, Simon and others (Adey 2004). Factors influencing individual teacher learning became apparent through close contact with teachers, and included motivation to want to change, an understanding of the theoretical basis of the curriculum materials and teaching approach, and an appreciation of perceived benefits for students.

Our more recent work on research into professional development has drawn on the insights of Hoban (2002), who, in arguing for the notion of a professional learning system, identifies eight conditions that are needed to bring about teacher learning. These include:

- A conception of teaching as a dynamic relationship with students and with other teachers where there is uncertainty and ambiguity in changing teaching practice
- Room for reflection in order to understand the emerging patterns of change
- A sense of purpose that fosters the desire to change
- A community to share experiences
- Opportunities for action to test what works or does not work in classrooms
- Conceptual inputs to extend knowledge and experience
- Feedback from students in response to ideas being tried
- Sufficient time to adjust to the changes made

An evaluation of whether or not these conditions for learning are present in the context of an innovation can provide the basis for planning work with teachers. As Hoban points out, on its own, each condition is unlikely to sustain teacher learning; it is the combination of conditions that is important.

What Models of Teacher Learning Can Be Used?

In this section we look at ways in which factors and conditions for helping teacher learning have provided models for planning professional development. Models take different forms and we discuss some of the features of models that have informed our work with teachers.

Bell and Gilbert’s model (1996), which we have outlined above, included a key feature of progression in each of the three domains of development, personal, professional and social. The first stage of development occurs when teachers begin to see an aspect of their teaching as problematic (personal) and practicing in isolation as problematic (social), so they are motivated to seek out and try out new ideas in their practice (professional). As they progress in their development, teachers deal with feelings and concerns that come about as they behave differently, for example, loss of control, insecurity in subject knowledge, or uncertainty about how to intervene, and begin to change their ideas of what it means to be a science teacher (personal). They also begin to see the value of collaborative ways of working (social) and have confidence to develop their own ideas for classroom practice (professional). Progressing further in their development teachers feel empowered through increasing confidence (personal), they initiate or seek out collaboration (social) and eventually facilitate new kinds of professional development activities (professional). The notion of progression in this model can provide a basis for teachers to evaluate their learning within each domain, and how the three domains are intertwined. In an account of how particular teachers developed in the study, Bell and Gilbert identified the process of reflection as a key condition for progression. Reflection has become an integral part of many other models, either generating cycles of action, as in Jones et al.'s negotiated intervention (1992), or as a fundamental process for stimulating change, as in Clarke and Hollingsworth's Interconnected Model (2002).

Clarke and Hollingsworth built on Thomas Guskey's (1986) linear model for change and created a cyclic version with different entry points, where change is seen to occur through the mediating processes of reflection and enactment in distinct domains: the personal domain (teacher knowledge, beliefs and attitudes), the domain of practice (professional experimentation) and the domain of consequence (salient outcomes). In addition, the external domain provides sources of information, stimulus or support. The term enactment was chosen

> … to distinguish the translation of a belief or a pedagogical model into action from simply 'acting', on the grounds that acting occurs in the domain of practice, and each action represents the enactment of something a teacher knows, believes or has experienced. (p. 951)

The term 'reflection' originates from Dewey's notion of active, persistent and careful consideration where, for example, a reflection and re-evaluation of outcomes can lead to an alteration in beliefs and, hence, a reflective link between the domain of consequence and the personal domain. A further consideration of the Interconnected Model is the change environment, for example, being a member of a school community where colleagues can share the consequences of their experimentation. We have found this model particularly useful in mapping out changes we perceive over time in how teachers engage in an innovation. Teachers can be seen to be stimulated by external sources of ideas which prompt changes in practice (enactment leading to changes in the professional domain), they review their practice and re-evaluate what is important in their student outcomes (reflection leading to changes in the domain of consequence), begin to reconstruct their notion of teaching (the personal domain), which in turn leads to further enactment in the professional domain, a re-evaluation of outcomes and so on. Mapping progression using this cyclical model can form the basis of a dialogue between researchers and teachers, and amongst teachers, which enables them to recognise the continuous nature of their own learning and the processes through which it is mediated.

A useful analysis of different models is offered by Aileen Kennedy (2005), who presents a framework for looking at CPD (Continuing Professional Development) models in a comparative manner. The analysis focuses on the perceived purpose of each model, and Kennedy proposes a set of categories under which models of CPD might be grouped. These categories are organised along a spectrum that identifies the potential for transformative practice. The first set of models includes those that focus on training, such as the 1-day courses attended by teachers, usually off-site, deficit models that are underpinned by performance management, and cascade models where skills and knowledge acquired at training events are disseminated to colleagues. Kennedy identifies all of these models as being underpinned by transmissive views of teacher learning. These models can serve a purpose in terms of enabling teachers to become more informed, or broaden their knowledge and skills, but as they are essentially technicist in nature, they are unlikely to result in fundamental changes in pedagogy. The next set of models includes those based on coaching/mentoring and communities of practice, which Kennedy terms 'transitional' as they can support either transmissive or more transformative conceptions of teacher learning, depending on the nature of the relationships involved. Coaching could take the form of expert/novice partnerships or more collegial forms of peer coaching, whereas community of practice models would involve more than two people. Fundamental to successful CPD within a community of practice is the issue of power and the level of control over the agenda (Wenger 1998) exercised by the community. Models that can be transformative in bringing about sustained change would include those communities of practice where individual knowledge and experience is enhanced through collective endeavour. Shulman and Shulman (2004) provide models of learning communities that work through a shared vision or ideology that is realised through shared commitments supported by organisational opportunities for learning. Other transformative models include action research, where teachers analyse their own practice in order to make changes in a cycle of reflection and action, or include opportunities that provide links between theory and practice, reflection, construction of knowledge and autonomy involving a sense of empowerment. In our view, these models are most likely to bring about sustained change.

Practices for Teacher Learning and Professional Development

In designing professional development for science and mathematics teachers, Loucks-Horsley et al. (2003) identify six clusters of strategies for professional learning:

- The importance of aligning and implementing quality curriculum materials with opportunities to reflect on their use
- Collaborative structures
- Examining teaching and learning through action research and case discussion
- Immersion experiences where teachers benefit from engaging in activities designed for student learners

- Practicing teaching including coaching, mentoring and demonstration lessons
- Vehicles and mechanisms such as courses, workshops and strategies for 'developing professional developers'

In this section we draw on examples from our own practice of professional development to provide insights to the success of some of these and other strategies in setting up conditions for teacher learning and enhancing transformative aspects of professional development.

Curriculum Resources

The strategy of accessing good quality curriculum resources, embedding these within a scheme of work and having opportunities to reflect on their use was apparent in the CASE initiative. The materials produced by the CASE team (Adey et al. 1995) included detailed lesson plans for teachers that documented equipment needs, suggested timings and interaction strategies, and an abundance of student resources for each lesson. In the professional development programme, schools were encouraged to embed the 32 activities within the curriculum over a 2-year period, and to encourage all department members to adopt the scheme. Often this process worked well, as departmental implementation meant that all teachers could access the materials and were encouraged to teach the CASE lessons as part of an expectation to 'deliver' the programme for the school. However, many teachers had CASE foisted upon them without any sense of ownership, and much of the success of the innovation was determined by pioneering individuals who instigated the programme within their schools, convincing their senior management team of the CASE effects. When these individuals left the school to be promoted elsewhere, CASE often ceased to happen. However, the CASE approach of cognitive challenge and social construction became embedded within science teaching if it was valued, and it persisted either through the continued implementation of the CASE lessons themselves, or adaptations in different contexts that could be used to promote the same reasoning patterns.

Further experience of the power of good quality curriculum materials is evidenced in the argumentation projects undertaken by Simon since 1999. Simon worked with colleagues Jonathan Osborne and Sibel Erduran on a project called Enhancing the Quality of Argument in School Science (EQUASS). This project arose from concerns about extending the emphasis of school science to enhance reasoning (as with CASE), to help students develop their epistemological understanding (Driver et al. 1996), and to develop argumentation skills such as justifying claims using evidence in both scientific and socio-scientific contexts. The initial stage of this argumentation project involved a partnership with a group of teachers to design curriculum materials that would be aligned to their existing curriculum, thus addressing the requirements of the national curriculum. Individual teachers working on the project were provided with frameworks for argumentation activities (Osborne et al. 2004a) and either used them directly, adapted them, or designed new activities most suited to their school contexts and existing practice. Following the research phase that focused on teachers' changing practice (Simon et al. 2006), the team developed a set of resources comprising 15 lessons that included lessons aims, teaching procedures and student materials. This publication (Osborne et al. 2004b) formed part of a set of professional development activities called the IDEAS pack. The resources in the pack have proved invaluable in helping teachers new to argumentation to 'get started', in that the materials can be used as they are, or be adapted for use to match curriculum topics and classroom contexts. The resources have been the stimulus for the development of further activities by pre-service teachers (Simon and Maloney 2006) and practicing teachers engaged in a project of evidence-based professional development using portfolios (Simon and Johnson 2008). The IDEAS resources continue to provide a stimulus for ongoing work with teachers who are developing argumentation within whole departments in London schools; initial use of the actual materials has evolved to incorporate individual designs appropriate to curriculum needs and classroom contexts.

Recently, observations and conversations with teachers using IDEAS lessons have demonstrated the need to analyse more closely the design of the lessons and their implications for effective planning and teaching (Simon and Richardson 2009). The frameworks themselves, such as concept cartoons, competing theories or predict/observe/explain activities (Osborne et al. 2004b), do not provide a sufficient indication of how they will work in practice. The science contexts in which the lessons are set and the plan of how to put them into practice are critical factors, as are the teachers' interpretations, introductions within lessons and interactions with students. Presenting teachers with readily usable resources rests on an assumption that development comes from practicing specific processes. Our concern is with the question of *how* teachers construct activities from such resources that will enable students to develop their argumentation.

Immersion Activities

Immersion activities have become a feature of both CASE and argumentation professional development programmes. For example, in centre-based workshops of the CASE programme, teachers were provided with experiences to promote cognitive conflict, including student activities from the course materials. One example observed in CASE workshops included an activity where students had to blow into or tap tubes to make musical notes (Adey et al. 1995). The tubes varied in a number of ways; they were made of different materials and had different dimensions of width and length. Students were required to articulate their reasoning about which variables would make a difference to the pitch of the note, through designing combinations of tubes that would eliminate variables systematically. As teachers engaged in this activity they were encouraged to question each other about their reasoning, and enact the kinds of intervention that would stimulate conflict and social construction of reasoning with students. These immersion activities were a common feature of CASE workshops and helped teachers to discuss the essential features of the CASE teaching approach.

The IDEAS pack of argumentation lessons is accompanied by sessions designed to promote teachers' own rationale for argumentation, and pedagogic strategies for use in the classroom such as constructing arguments, group work, evaluating arguments, counter-argument and modelling argument. One immersion activity aims to help teachers consider that the evidential basis for scientific ideas is not easily articulated and, therefore, may not be explored in science teaching. Teachers are asked to decide what evidence there might be for some common ideas, for example, Day and Night are caused by a spinning Earth, plants take in carbon dioxide and give out oxygen during photosynthesis, living matter is made of cells, and we live at the bottom of a 'sea of air'. This activity helps teachers to think about the value of using argumentation activities to extend their teaching goals beyond a focus on content to include epistemic questioning about the evidential basis for scientific claims. Other immersion activities involve the use of group-work strategies, such as listening triads, to enable teachers to experience how such strategies might work with students. Triads are often used to explore the ideas within a concept cartoon (Naylor and Keogh 2000), where students express alternative ideas about a phenomenon, such as the rate of melting of a snowman with or without a coat. In the triad one participant takes on the role of explaining the ideas portrayed by the students in the cartoon, one takes on a questioning role and one a recording role. Immersion activities such as these, using the pedagogical strategies and IDEAS lesson plans together, not only enable teachers to think about their approach, but also provide a basis for them to analyse and become familiar with resources they can use with students.

Reflection and Sharing

We have seen that most models and perspectives of teacher learning include the notion of reflection. The idea of reflective practice became well established by Donald Schön (1983), who views the reflective practitioner as an expert performer capable of skilful action. Experienced practitioners acting in their everyday practice demonstrate the kind of knowledge, called 'knowing-in-action', that is tacit and which they depend on to work spontaneously. Schön sees knowing-in-action as the simplest component of reflective practice. In addition, 'reflection-in-action' is perceived as occurring during activity whilst the practitioner responds to the moment, resulting in constant adjustment to what is happening. A further component of reflective practice, 'reflection-on-action' involves thinking about an event after it has occurred. It is this component of reflective practice that is used in a general sense in the context of teacher learning. Many authors concerned with the nature of reflection have focused on different kinds of reflection on action, for example, Neville Hatton and David Smith (1995) and Lily Orland-Barak (2005) question what it means to be 'critically reflective'. Critical reflection can be contrasted to lay reflection (Furlong et al. 2000) or technical, descriptive and dialogic reflection (Hatton and Smith 1995). These levels of reflection are characterised by recounts of personal experience, whereas critical reflection reviews experience in the light of other forms of professional knowledge. Nona Lyons (1998) uses the metaphor of weaving and threading to illustrate how critical reflection can connect different experiences to bring into consciousness teachers' beliefs and values.

The role of reflection in the adoption of CASE, though clearly a feature of Adey's model (Adey 2004) and the CASE programme's intentions, was not structured into the work in schools outside of coaching by the developers, unless pioneered by the teachers themselves. In later cognitive acceleration programmes for younger children teachers were asked to write a log of their reflections, but few teachers found this useful (Adey 2004). Group reflections that took place between teachers who attended workshop days based at the teachers' centre were found to be more valuable. This model of building in reflective activity when teachers from different schools come together was adopted in all the argumentation projects undertaken since 1999. In the initial project, where individual teachers were implementing argumentation in isolation, reflection became an important component of centre-based days when they all met each other. Subsequent projects additionally involved teachers constructing written reflections in portfolios (Simon and Johnson 2008). The act of reflection was powerful, but the time for teachers to produce written reflections tended to be lost to other essential activities. The role of reflection has become more prominent as a mediating factor for teacher learning in ongoing research to develop argumentation practice in whole school science departments. Within each department teachers have embedded argumentation activities within the curriculum and meet once a month to reflect on their experience of teaching the activities. Over time the nature of shared reflection has changed from descriptive personal accounts of what went well or not, to more analytical observations of personal learning, effective practice and evaluation of student outcomes. Likewise in their analysis of teacher learning in communities of practice, Shulman and Shulman (2004) note the crucial role of shared meta-cognitive reflection, where teachers critically discuss their work with each other, and reflection is the central component of their model of teacher learning and development.

The act of reflection has great significance in the learning of pre-service teachers. For them the act of reflection is a prescribed process they have to demonstrate in their qualifying standards, and reflection on action is an important process for looking forwards when planning for the future. However pre-service teachers are limited in their ability to reflect meaningfully when they have little experience of theory and practice. The following account from Sandra Campbell's research on the process of reflection in pre-service teachers shows how the use of video can be a powerful strategy for enhancing reflective practice (Campbell 2008).

Video-Stimulated Discussions with Pre-Service Teachers

Pre-service teachers in England have to show evidence of reaching Qualified Teacher Status (QTS) by being assessed against standards produced by the Training and Development Agency for schools (TDA). A recent addition to these standards

(TDA 2007) requires pre-service teachers to 'reflect on and improve their practice and take responsibility for identifying and meeting their developing professional needs'. The standard presupposes that a teacher who is able to reflect on practice can learn from the knowledge and understanding gained from this reflective process, and can become a better teacher. But what is the nature of reflection for the inexperienced teacher?

The work of Chris Argyris and Donald Schön (1978) can be used to interpret and illustrate a pre-service teacher's reflections on practice. For Argyris and Schön learning involves the detection and correction of error. They suggested that when things go wrong, a starting point for many people is to look for another strategy that will address the problem while still working within their governing variables – these governing variables being their values that they are trying to keep within acceptable limits. In doing this they are not questioning goals and values, they are trying to find a way of working within the existing framework – what Argyris and Schön would term single-loop learning. An alternative response is to critically question the governing variables themselves, this they describe as double-loop learning. Such learning may then lead to an alteration in the governing variables and thus a shift in the way in which strategies and consequences are framed. The following scenario of a pre-service teacher learning how to teach practical science can be interpreted in this way. The teacher considered her first practical lesson as unsatisfactory because she had rushed the plenary session. On reflection she realised she had not given sufficient time earlier in the lesson for the students to carry out the practical work. In her subsequent lesson she laid out the practical equipment in a tray system to save time, which allowed more time at the end to consolidate learning. This new strategy became part of her repertoire, an example of single-loop learning. In a subsequent lesson, the teacher observed the students as they collected their equipment from trays and questioned whether this practice was limiting their autonomy and collective decision-making in practical work. She was now beginning to question the governing variables of her lessons and subsequently altered her strategies again, providing an example of double-loop learning where feedback from previous experience stimulates a questioning of assumptions previously taken at face value.

Pre-service teachers being asked to reflect on practice can thus be operating at different levels of criticality depending on their emergent professional knowledge. They are pressed to live up to the expectation that good teachers are reflective teachers (van Manen 1995), and yet they do not necessarily have adequate guidance as to how and when to reflect. Michael Eraut (1995) suggests that pre-service teachers may have neither the time nor the disposition to reflect because they need to develop habitual routines and become familiar with a wide range of situations; the imposition to reflect may be perceived as a threat. Reflection is difficult for novice teachers as their lack of experience limits their ability to meaningfully reflect during a lesson. Work undertaken with pre-service teachers suggests that if reflection on practice takes place in discussion with others, these teachers can find meaning where it was not initially obvious. In a study to explore ways in which pre-service teachers can be encouraged to reflect, Campbell (2008) conducted research into the use of video-stimulated recall of lessons, as video has been shown to provide a powerful means of stepping back and analysing practice when novice teachers engage in a dialogue about what is observed (Brophy 2004).

Working with three pre-service teachers studying for a Postgraduate Certification of Education (PGCE) at the Institute of Education, Campbell, who was their tutor, conducted video-stimulated recall (VSR) of in-depth interviews which took place in the week following her observation and filming of their lessons. A further interview was conducted a month later to ascertain whether the research had stimulated learning such that it impacted on practice. Campbell found that many initial comments were of a descriptive nature, for example, the pre-service teachers focused on how they were gesticulating with their hands whilst talking to the class, or how the students were behaving. Using Hatton and Smith's (1995) categories of reflective practice, she found that the most common kind of reflection was also descriptive. In some instances, the pre-service teachers reflected more deeply, stepping back from an immediate response to consider why they acted the way they had. Campbell calls this 'mulling reflection'. With some prompting and in discussion with their tutor two of the three pre-service teachers showed some instances of deeper, critical, reflection. As novices lacking experience this was not surprising. There was little unprompted discussion of subject pedagogy, with surface features such as the behaviour of the students tending to dominate the pre-service teachers' reflections. With prompting, more discussion of subject pedagogy took place, and guidance was needed to ensure that their reflection encompassed aspects of teaching and learning. The teachers in this small sample were aware of the drawbacks of having their lessons filmed, but did not believe that these drawbacks outweighed the benefits of the video. Through video-stimulated discussion they perceived advantages gained through talking about their lessons with a critical friend, and developed ideas for using the videos in a wider context.

Conclusion

In this chapter, we have drawn on international literature sources and our own experience in London to show how teacher learning can be conceptualised and professional development planned effectively. Teacher learning is a complex process, beginning with the pre-service teacher's experience and continuing throughout a teaching career. The motivation to learn comes from within a teacher as she or he reflects on the outcomes of practice, and perceives a need to change. Choices open to teachers who want to learn are often external courses they can attend, and though these can be beneficial and assist some aspects of learning, they are unlikely to initiate fundamental changes in how teachers view teaching and change practice. Increasingly, schools identify their own needs and initiate their in-house programmes of professional development, though change from within may be dictated from senior management rather than be part of a community of practice with a shared vision and commitment to change. Underpinning any approach to professional development is a perspective on teacher learning, and this perspective needs to be recognised and taken into account in the way in which the professional development is conceptualised. In a climate where teachers have to meet teaching standards and professional developers are subject to external demands that require particular models and content of professional development programmes, it can be a challenge to pay due consideration to the conditions, factors and mediating processes that promote learning. The analysis of teacher learning and professional development we have offered in this chapter shows the complexity of the task of those who, like the staff of Science Learning Centre London, have a role to play in making provision for professional development. Sharing our analysis of models of teacher learning and professional development that are based on clearly articulated views of learning helps to foreground the agenda of personal motivation, reflective analysis of practice and evaluation of salient outcomes that is at the heart of teacher learning.

Chapter 23
Developing Teachers' Place-Based and Culture-Based Pedagogical Content Knowledge and Agency

Pauline W.U. Chinn

Introduction

An emerging area of research in science teacher education centers on the role of place and culture in supporting science teachers' development of pedagogical content knowledge (PCK), a transdisciplinary concept developed by Lee Shulman (1986). PCK focuses on the interaction of content knowledge with a teacher's ability to represent it comprehensibly to students. The US Science Education Standards (National Research Council 1996) implicitly expect teachers to apply PCK as they "select science content and adapt and design curricula to meet the interests, knowledge, understanding, abilities, and experiences of students" (p. 30).

Susan Loucks-Horsley, Nancy Love, Katherine Stiles, Susan Mundry, and Peter Hewson (2003) wrote: "All educational changes of value require individuals to act in new ways (demonstrated by new skills, behaviors, or activities) and to think in new ways (beliefs, understanding, or ideas)" (p. 48). They encourage professional developers to "identify local needs based on analysis of student and other data" (p. 120) that incorporate "the community, policies, resources, culture, structure and history that surrounds it" (p. 265). Statements by policy makers and teacher educators recognize that science teachers are part of a social learning system in which teachers' competence can be assessed using two dimensions – knowledge of content; and knowledge of students' lives and communities.

Jean Lave and Etienne Wenger's (1991) view of learning as situated within communities of practice that are developing particular competencies, provides a rationale for developing teachers' PCK throughout their careers. The initial preparation

B.J. Fraser et al. (eds.), *Second International Handbook of Science Education*, Springer International Handbooks of Education 24, DOI 10.1007/978-1-4020-9041-7_23,

of secondary science teachers guided by courses of study and shaped by content area accrediting bodies, lays the groundwork for the development of science content knowledge. Developing pedagogical knowledge as knowledge of the process of teaching is guided by courses of study that are shaped by educational and learning theories. Cheryl Mason (1999) structured three secondary education courses to be team-taught by a science teacher, a content area professor, and a science education professor to provide preservice teachers with a “thorough understanding of the interconnectedness of content knowledge, learning theory and instructional strategies” (p. 279). However, Margaret Niess and Janet Scholz (1999) found that preservice teachers with science degrees who completed a Masters of Arts in Teaching designed to develop PCK did not always “possess well-formed or highly integrated subject matter or pedagogy knowledge structures” (p. 265); this finding is consistent with reported research. Teresa Greenfield-Arambula’s (2005) review of multicultural science education literature suggested that secondary science teachers’ understandings of science as objective and impersonal tended to impede their recognition of the impact of sociocultural factors on teaching and learning.

The 2-year (or even shorter) span of many science teacher certification programs thus presents challenges to moving aspiring science teachers beyond newcomer status either in science content or pedagogical knowledge. But, once in a school, new teachers are expected to demonstrate growing competence in cross-scale, transdisciplinary learning systems that span content, classroom, school, and community. PCK develops through teachers’ ongoing engagement and experiential learning in communities of practice (COP) relevant to their work. Etienne Wenger (2003) considers these the “basic building blocks of a social system” as these enable participants to “define with each other what constitutes competence in a given context” (p. 80). Increasingly, effective professional development of in-service teachers is recognized as fundamental to school success and teacher satisfaction (*Education Week* 2004).

A view of PCK as dynamic and affected by changes in multiple social systems suggests three driving reasons for taking an explicitly culture-based and place-based approach to professional development in science. The first addresses the twin goals of scientific progress and broad-based scientific literacy (NRC 1996) and responds to international evidence of declines in students’ interest in science and technology (Foster 2005; Organization for Economic Cooperation and Development 2006). The second, equity and social justice, centers on well-known issues of underrepresentation of females, minorities, indigenous, and economically disadvantaged students in science, technology, engineering, and mathematics (Malcolm et al. 2005; Aikenhead 2006). The third, sustainability, is driven by growing concerns over sustainability of resources, global climate change, and ecosystem and human health.

Robert Kates and Thomas Parris (2003) published two papers in the *Proceedings of the National Academy of Science* that emphasized the place-based nature of sustainability science and the role of education in a societal transition to sustainability. In the first paper, entitled Long-term Trends and a Sustainability Transition, they argued for place-based approaches: “Because sustainable development takes place locally rather than globally, an important task for a place-based sustainability science is to identify the specific trends most relevant to such places and the ways in which local populations can contribute to altering the trends that affect them" (p. 8066). In the second paper, entitled Characterizing a Sustainability Transition, they emphasized the role of education, teachers, and literacy in enabling a global transition to sustainability. A recognized need for teachers with place-based science literacy aligns with studies that show that the most successful professional development enables teachers to "deepen and contextualize their subject-area knowledge … to respond to individual student needs" (*Education Week* 2004).

The next section of this chapter provides a definition and historical overview of place-based science education and ends with the challenges and opportunities presented by programs that exemplify communities of practice that are not neatly compartmentalized into school subjects or schedules. The following section reviews the literature on place-based teacher education programs, by focusing on issues of science literacy, equity, and sustainability, and ends with challenges and opportunities for developing place-based PCK and agency. The final section identifies implications for place-based and culture-based science teacher education in the twenty-first century and suggestions for further research.

An Overview of Place-Based Science Education

Historical Development: Western Perspectives

Articles on place-based science education began appearing a few decades ago, but transdisciplinary, place-based education has a much longer history under the labels of service learning, progressive, experiential, and environmental education. At the end of the nineteenth century, in response to what was perceived as narrow, formalized schooling separated from learners' lives, educators in Europe and the USA proposed a more holistic, child-centered, community-based approach to learning that became known as Progressive Education. American educational philosopher John Dewey (1897) observed in *My Pedagogic Creed* that a rapidly changing world made it impossible to prepare students precisely for their future lives. Dewey strongly favored active learning, viewed individuals as members of historical social groups, and emphasized education for a democratic society. He criticized school science for presenting science in ways that seemed new, foreign, and disconnected from learners' lives. Progressive science educators were guided by Dewey's (1958) vision of student-centered, experiential, inquiry-oriented learning: "In modern science, learning is finding out what nobody has previously known. It is a transaction in which nature is teacher, and in which the teacher comes to knowledge and truth only through the learning of the inquiring student" (p. 152).

In the final decades of the twentieth century, ideological differences between mainstream science education's anthropocentric, economics-oriented approach and place-based science's ecocentric, sustainability-oriented approach began to crystallize.

David Orr (2004) cited the influences of Bacon (union of knowledge and power), Galileo (superiority of analysis over emotion) and Descartes (separation of self and object) in shaping education systems in which political and economic forces favored individualism and consumption. Orr connected urbanization to loss of knowledge of place, values, and practices that societies need in order to live sustainably. In the context of global climate change and threats to ecosystems, he held that education must enable students to understand the impact of knowledge on real people and communities and "must now be measured against the standards of decency and survival" (p. 8) instead of against standards oriented to competitiveness in a global economy.

Chet Bowers (1999) argued that teachers who "are not introducing students to [an] ecological way of understanding relationships … are socializing students to the current reformulations of the Industrial Revolution agenda of using technology to exploit and control the environment" (p. 167). David Gruenewald (2008) noted: "What needs to be transformed, conserved, restored, or created in this place … [could] provide a local focus for socioecological inquiry and action that, because of interrelated cultural and ecological systems, is potentially global in reach" (p. 149).

International and Indigenous Perspectives

Masakata Ogawa (1995) proposed a multiscience view that recognized the contributions of indigenous knowledge across a range of cultures. Indigenous science educators, Olugbemiro Jegede and Peter Okebukola (1991) and June George (2001), focused on the central roles that authentic, place-based and culture-based learning could play in increasing underrepresented, indigenous, and marginalized students' interest. Gregory Cajete (1999) noted that "American Indians understood that an intimate relationship between themselves and their environment was the essence of their survival and identity as a people" (p. 4). Knowledge and competencies valued to the community developed through learning through shared observation, practice, and experience. Cajete (2000) emphasized the potential for indigenous practices, values, and long-term knowledge of place for informing Western science in participatory research oriented to sustainability.

Oscar Kawagley and Ray Barnhardt (1999) identified four indigenous views that could contribute to science knowledge and science education by countering the specialized, short-term perspectives of many Western scientific and educational endeavors. Indigenous views included: taking a "long-term perspective" to emphasize the cross-generational nature of education, recognizing that the "interconnectedness of all things" also applies to knowledge, valuing "adaptation to change" to emphasize the dynamic nature of education, and maintaining a "commitment to the commons" that recognizes "the whole is greater than the sum of its parts" (p. 134).

A human-in-ecosystem view is shared by international science educators and natural and social scientists engaged in the emerging field of sustainability science education. This approach recognizes interconnected social and natural systems as "complex adaptive systems where social and biophysical agents are interacting at multiple temporal and spatial scales" (Janssen and Ostrom 2006, p. 1465).

Reviews of Place-Based Programs: Characteristics, Outcomes, and Challenges

A review of US and Canadian outdoor, environmental, and place-based curricular programs by Janice Woodhouse and Clifford Knapp (2001) noted the recent emergence of place-based programs shaped by Dewey's emphasis on learning that is grounded in students' lives. They differentiated place-based learning from environmental learning, which is often classroom-based, and outdoor education that connects classroom learning to the natural or constructed environment. They noted that the goal of place-based educators "to prepare people to live and work to sustain the cultural and ecological integrity of the places they inhabit" (p. 33) situated purposeful learning in students' cultural and historical places. They found that place-based programs possessed five essential characteristics that establish the unique, local nature of each program: (1) natural and historico-cultural content specific to place; (2) multidisciplinary approaches; (3) experiential and/or service learning; (4) a broader focus than preparation for a technological and consumer-oriented society; and (5) understanding of place, self, and community as part of a social-ecological system. They concluded: "One of the most compelling reasons to adopt place-based education is to provide students with the knowledge and experiences needed to actively participate in the democratic process" (p. 33). Knapp's (2007) reflections on his own instruction showed that place-based learning communities supported coteaching and learning.

Since 2001, the Place-based Education Evaluation Collaborative (PEEC) has evaluated the effectiveness of six place-based program spanning 12 states and 100 rural, urban, and suburban schools. The challenge of assessing unique, localized programs to meet the interests of state and national policy makers and funders is revealed in the range of qualitative evaluation methods: interviews of 800 adult and 200 students, surveys of 750 educators and 2000 students, document review, and on-site observations. The PEEC report *Benefits of Place-based Education* (2007) identified outcomes of: improved student achievement, stewardship, and connection to place; development of school, parent, and community partnerships; engaged and enthusiastic teachers; and shifts in school culture toward collaboration and adoption of the ideals of place-based education. (Evaluation reports can be viewed at http://www.peecworks.org/PEEC/PEEC_Reports/.) These outcomes mirror Robert Sternberg's (2003) findings that teaching students to think analytically, creatively, and practically like experts performing real tasks led to a greater diversity of successful students, while conventional instruction reduced diversity and produced pseudo-experts unable to transfer learning to real situations.

Elaine Loveland's (2003) report on schools in the US northwest and Emeka Emekauwa's (2004a, b) evaluations of NSF-supported place-based science programs in Alaska and Louisiana reported similar outcomes of improved student achievement, development of school-community partnerships and positive changes in the culture of schools. But issues of assessment of indigenous students persist, particularly with respect to cultural validity, with researchers, theories, methodology, questions, and reporting needing to be appropriate to the population being studied.

Sharon Nelson-Barber and Elise Trumbull (2002) emphasized the need for "research on new approaches to assessment design and use that consider the role of culture in learning and assessment" including "studies within specific Native communities" (p. 142).

Programs for Developing Place-Based and Culture-Based PCK

Given the importance of incorporating local contexts, professional development programs increasingly focus on developing in-service teachers' expertise relevant to particular schools and communities. Where science teachers and students differ significantly in language, culture, and values, place-based programs incorporate an explicitly culture-based perspective in order to situate teachers' learning in meaningful contexts focused on underrepresented learners' knowledge and experiences. Ray Barnhardt (2002) noted positive outcomes from the University of Alaska's field-based program aimed at preparing teachers for rural Alaskan schools that serve high proportions of Native Alaskan and American-Indian students. Field-based faculty integrated formal education with indigenous skills and knowledge to help preservice teachers to develop culturally responsive instruction appropriate to their communities. The highest impact on student academic performance, parent attitudes, and community support was evident when Native teachers became a majority of the teaching staff.

A 20-year collaboration between the village of Minto and the University of Alaska Fairbanks has provided teachers with a week-long cultural immersion in the daily activities of Old Minto Cultural Camp guided by Athabascan Elders (Kawagely and Barnhardt 2007). Esther Ilutsik (2003) describes the translation of this university-developed, field-based professional development model into district-level initiatives that provide new and out-of-state teachers with site-based, elder-led cultural immersions.

Eric Riggs (2004) and Steven Semken's (2005) research on essential components of geoscience education for Native American communities addressed issues of underrepresentation. Riggs found that

> …persistent and successful Earth science education programs … include active collaboration between local indigenous communities and geoscientists from nearby universities [while] successful Earth science curricula for indigenous learners share an explicit emphasis on outdoor education, a place and problem-based structure, and the explicit inclusion of traditional indigenous knowledge in the instruction. (p. 296)

Semken's list of five essential elements of place-based geoscience education went beyond Rigg's focus on knowledge and praxis to include personal meanings in order to "promote and support ecologically and culturally sustainable living in that place," "integrate or at least acknowledge, the diverse meanings the place holds for the instructor, students, and community" and "enrich the sense of place of students and instructor" (p. 152).

Semken's interest in assessing place-based teaching in order to increase geoscience literacy and the diversity of geoscience students led to research with Semken and Freeman (2008) that involved utilizing surveys to measure changes in 31 culturally diverse undergraduates' sense of place in an experimental geoscience course based on his indigenous geology course at a Dine (Navajo) tribal college. Place-based pedagogy included three extra credit, optional 2-h inquiry field trips and indoor learning that was structured to be "as evocative of the natural and cultural landscapes of Arizona as possible" (p. 5) through the use of local mineral and soil samples, visuals, handouts, and stories of place. They found significant increases in students' place attachment and place meaning and concluded that these and other methods measuring changes in learners' affective and cognitive sense of place merit further study as "authentic assessment of place-based science teaching" (p. 13).

George Glasson, Jeffrey Frykholm, Ndalapa Mhango, and Absalom Phiri (2006) studied a culture and place-based teacher education program for Malawian educators that included visits to a nature preserve. They found that teachers welcomed indigenous science and inquiry-oriented pedagogies as a way to engage students and develop ownership of local environmental issues. When Lynn Bryan and Martha Allexsaht-Snider (2008) studied two rural, Mexican elementary teachers whose classrooms served as sites for teacher education, they found that these master teachers situated student learning in community experiences in order to mediate among school, science, and community knowledge and discourse. Their findings emphasize the importance of familiarizing teachers with the discourse patterns and life experiences of culturally different students.

Pauline Chinn's (2006) 3-year study of *Malama I Ka 'Aina*, a year-long, team-taught, place-based and culture-based science curriculum course, found that 60 in-service, predominantly nonindigenous teachers learned to connect Hawaiian and Western science practices and knowledge in their lesson plans and instruction. A community-based, 4-day immersion with nights spent at campsites and schools allowed teachers to learn from indigenous Hawaiians, scientists, instructors, and peers' exemplary programs and sites. Written evaluations revealed the transdisciplinary and transformative aspects of their learning. A Part-Hawaiian teacher wrote:

> It made tying Hawaiian culture into lessons more of a norm than an anomaly. It got me in touch with the types of teaching I was doing and made me want to do more life-relating lessons. I did more hands-on activities and related things more to how they will affect the students. I'm applying Hawaiian values and lessons to teaching all subjects—asking questions like 'how did the Hawaiians do this?' (p. 393)

Chinn's (2007) study of a place-based education workshop involving 19 experienced secondary science and mathematics teachers and administrators from eight Asian nations and the USA showed that, prior to a presentation on indigenous Hawaiian practices oriented to sustainability, most Asian participants viewed indigenous knowledge and practices as inappropriate for inclusion in science curriculum. Following the presentation and small-group discussions, their writings indicated a shift in their thinking and included critique of national curricula for excluding local issues and indigenous knowledge and for interfering with intergenerational transmission of knowledge. Videotapes of teacher-developed lessons showed that most connected students' prior knowledge, places, or cultures to science and mathematics content. Three years later, a biology teacher had quit her teaching position and entered a graduate program because:

> I have a dream to become a teacher trainer, sharing knowledge, and creating a local, needs-based curriculum for rural areas in Indonesia … we don't have curriculum to develop the student skills about how to hatch fish, how to plant algae, etc. … And believe me you have a contribution. … I saw you guys spend a lot of time, making a field trip to the Hawaiian village, [to] learn their wisdom. (p. 1261)

Chinn's (2008) study focused on five Native Hawaiian women of the 11 teachers who cotaught *Malama I Ka 'Aina* over a 3-year period. Unlike the other six nonnative Hawaiians (mostly male secondary science teachers), four were elementary teachers and none were science majors. While all 11 teachers developed programs that cared for school or clearly bounded restricted lands, only the women engaged in caring for public lands that were open to all. The women drew on knowledge of place and community to develop transdisciplinary communities of practice focused on monitoring and restoring common areas – beaches, bays, and state lands. Even after the grant, professional and social networks continued to sustain interactions, reciprocity, and the exchange of different perspectives.

Rebecca Monhardt and Jon Orris (2007) noted the importance of culturally knowledgeable instructors and pedagogy in their review of a place-based earth science program for teachers in schools with high proportions of American-Indian students. Though most teachers evaluated the program as personally empowering and providing science content and experiences relevant to their students, Navajo teachers were offended by some displays of museum artifacts and put off by Western pedagogical formats that they perceived as pitting participants against each other. They strongly recommended that instructional teams represent the cultures of participants in order to facilitate effective development of teachers' place-based and culture-based pedagogical content knowledge (PCB–PCK).

Overall, a review of the literature suggests that thoughtfully designed place-based and culture-based teacher education empowered teachers to contextualize lessons and to teach in ways that support diverse learners.

Implications for Place-Based and Culture-Based Teacher Education

Social and natural scientists are beginning to converge around a view of teaching and learning that is place-based, active, personally meaningful, and ethical. Psychologist Albert Bandura (2001) wrote: "Efficacy beliefs are the foundation of human agency. Unless people believe they can produce desired results and forestall detrimental ones by their actions, they have little incentive to act or to persevere in the face of difficulties" (p. 10). Psychologist Sternberg (2003) suggested: "We may wish to start teaching students to think wisely, not just well" (p. 5). In his 2002 AAAS Presidential Address, Peter Raven noted:

> The kinds of grassroots activities that are promoting sustainability on a local basis have become a powerful force throughout the world: perhaps they are, fundamentally, only a re-emphasis of what has been traditional. … The people who are pursuing sustainability in a direct and personal way will hugely affect the shape of the world in the future. (p. 957)

Kenneth Kaneshiro, Pauline Chinn, Kristin Duin et al. (2005) described three sustainability science projects in Hawaii, including Chinn's teacher education program that nested science learning communities within a cultural stewardship framework. They think that these learning communities provided microcosms of social-ecological systems in which to "develop the underlying theories and principles of 'sustainability science,' based on an understanding of the fundamental interactions between nature and humans" (p. 349). This suggests that place-based and culture-based science teacher education could help to address the overarching goal of science education – scientific literacy for all citizens – by preparing teachers to form transdisciplinary learning communities focused on issues of science, technology, and society that are relevant to healthy and sustainable social-ecological systems.

Reviews of published place-based science programs suggest that situating science professional development in the context of place-based issues is meaningful to teachers, their students and communities, and is supportive of teacher expertise and agency. However, few institutions of teacher education provided explicitly place-based and culture-based science education courses as part of their regular, ongoing programs. The fact that most programs were funded by private donors or government agencies suggests that there is a challenge in institutionalizing transdisciplinary, place-based science teacher education programs while colleges and universities continue to be compartmentalized and discipline-based.

This gap suggests that research on place-based and culture-based teacher education programs might focus on longer-term studies of teacher learning, expertise, and agency in order to capture changes in teachers' place and culture-based PCK, communities of practice, and student learning. As instructional time devoted to place-based science lessons tends to conflict with classroom learning oriented to high-stakes tests, research is also needed on the quality, depth, and breadth of student science learning. Research on effective teacher education and professional development programs might provide insight into teachers' learning across their professional careers and models amenable to institutionalization.

In conclusion, envisioning science teacher education as participation in place-based and culture-based communities of learners which address meaningful and relevant science issues holds promise of a path toward educational equity and transdisciplinary science literacy for all learners. A focus on real places and concerns empowers teachers as local experts and curriculum developers who are able to contextualize learning in students' communities, practices, and cultural knowledge.

Chapter 24
Nature of Scientific Knowledge and Scientific Inquiry: Building Instructional Capacity Through Professional Development

Norman G. Lederman and Judith S. Lederman

Students' and teachers' conceptions of nature of scientific knowledge have been a concern since the early 1900s (Norman Lederman 2007). Similarly, students' abilities, and more recently their understandings of scientific inquiry, have been a concern within the science education community (National Research Council 1996). However, little research exists concerning the role of professional development in facilitating the desired change in students' and teachers' conceptions (i.e. how to help teachers to translate what they know into effective classroom practices). The existing literature reviews related to nature of science and scientific inquiry do not document the nature and impacts of sustained professional development in bringing about change. This chapter focuses on two large-scale professional development approaches (i.e. a localised teacher enhancement grant and a systemic change initiative) and a university-level programmatic effort in which our group has been involved in Chicago. Of particular importance are the relative impacts of these different approaches and the lessons learned that have impacted the nature of the professional development provided. Much debate permeates the literature on nature of science and scientific inquiry. Unfortunately, writers have not consistently considered the audience (i.e. K-12 students) of the desired instructional outcomes. In particular, it is important to consider the developmental appropriateness of stated instructional outcomes, empirical research related to students' and teachers' learning about inquiry and nature of science, as well the relevance of students' and teachers' understandings to the goal of scientific literacy. Consequently, using these criteria, it is important to clearly explicate our perspectives/views of the constructs of nature of science and scientific inquiry, as well the rationale for the importance of teachers' and students' understandings of nature of science and scientific inquiry.

What Is Nature of Scientific Knowledge?

At this point, there could be some confusion about our use of the phrase 'nature of scientific knowledge' versus 'nature of science'. Originally (during the 1960s), the phrase 'nature of scientific knowledge' was used to describe instructional outcomes related to the characteristics of scientific knowledge (Lederman 1992) that were directly derived from the way in which scientists develop scientific knowledge (i.e. scientific inquiry). However, during the 1980s, 'scientific knowledge' was dropped from the original label of the construct and 'nature of science' was used to refer to the same idea. Unfortunately, this change of language might have led to the consistent conflating of nature of science and scientific inquiry (Lederman 2007). A clear delineation between the two constructs is provided below.

When one attempts to answer the question, 'What is science', it seems clear that one valid answer delineates science into a body of knowledge, process/method and nature of scientific knowledge. The body of knowledge refers to the various concepts, laws, theories and ideas that are well represented in our various science textbooks. The 'process/method' refers to what scientists do to develop/construct the body of knowledge. Finally, nature of science refers to the characteristics of scientific knowledge that are directly derived from the process/method used to develop the knowledge. Clearly, one can elaborate on the categories used to answer the original question, but few would validly disagree with the three-pronged answer provided here.

With all the support that Nature of Science (NOS) has in the science education community, it might be assumed that all concerned individuals have adequate understandings of NOS. Even though explicit statements about the meaning of NOS are provided in well-known reform documents (e.g. NRC 1996), the pages of refereed journals are filled with definitions that run contrary to the consensus reached in the National Science Education Standards (National Research Council 1996) and other reform documents. Some would argue that the situation is direct support for the idea that there is no agreement on the meaning of NOS (Alters 1997). More recently, Hipkins et al. (2005) have expressed concerns about the lack of consensus about NOS in New Zealand curricula. However, counter-arguments by Michael Smith (Scharmann and Smith 2001; Smith et al. 1997) suggest that more consensus exists than disagreement. Others (Lederman 1998) are quick to note that the disagreements about the definition or meaning of NOS that continue to exist among philosophers, historians and science educators are irrelevant to K-12 instruction. At the level of generality concerning NOS that is targeted for K-12 students, little disagreement exists among philosophers, historians and science educators. Among the characteristics of scientific knowledge corresponding to this level of generality are that scientific knowledge is tentative (subject to change), empirically based (based on and/or derived from observations of the natural world), subjective (involves personal background and biases and/or is theory-laden), necessarily involves human inference, imagination and creativity (involves the invention of explanations), and is socially and culturally embedded. Two additional important aspects are the distinction between observations and inferences, and the functions of, and relationships between, scientific theories and laws.

What follows is a brief consideration of these characteristics of science and scientific knowledge related to what students should know. Although listings of the 'important' characteristics of NOS exist, the primary purpose here is to provide a frame of reference that helps to distinguish NOS from scientific inquiry and the resulting body of knowledge.

First, students should understand the crucial distinction between observation and inference. Observations are descriptive statements about natural phenomena that are 'directly' accessible to the senses (or extensions of the senses) and about which several observers can reach consensus with relative ease. Inferences are explanations about what is observed in the natural world, but are the result of human interpretation as opposed to being directly observed by the senses.

Second, there is a distinction between scientific laws and theories. Individuals often hold a simplistic and hierarchical view of the relationship between theories and laws whereby theories become laws depending on the availability of supporting evidence. It follows from this notion that scientific laws have a higher status than scientific theories. Both notions, however, are inappropriate because, among other things, theories and laws are different kinds of knowledge that do not develop or become transformed into each other. Laws are *statements or descriptions of the relationships* among observable phenomena. Boyle's law, which relates the pressure of a gas to its volume at a constant temperature, is a case in point. Theories, by contrast, are *inferred explanations* for observable phenomena. So, kinetic molecular theory is the inferred explanation for what Boyle's law describes. It is important to note, however, that theories are as legitimate a product of science as laws. They are simply two different types of scientific knowledge and one does not evolve into the other.

Third, even though scientific knowledge is, at least partially, based on and/or derived from observations of the natural world (i.e. empirical), it nevertheless involves human imagination and creativity. Science, contrary to common belief, is not a totally rational and orderly activity. Science involves the *invention* of explanations and this requires a great deal of creativity by scientists.

Fourth, scientific knowledge is subjective. Scientists' theoretical commitments, beliefs, previous knowledge, training, experiences and expectations actually influence their work. All these background factors form a *mindset* that *affects* the problems that scientists investigate and how they conduct their investigations, what they observe (and do not observe), and how they make sense of, or interpret, their observations. It is this individuality that accounts for the role of subjectivity in the development of scientific knowledge. Although objectivity might be a goal of science, subjectivity necessarily creeps into the development of scientific knowledge because humans do science.

Fifth, science as a human enterprise is practised in the context of a larger culture and its practitioners (scientists) are the product of that culture. Science, it follows, affects and is affected by the various aspects of the culture in which it is embedded.

Sixth, it follows from the previous discussions that scientific knowledge is never absolute or certain. This knowledge, including 'facts', theories and laws, is tentative and subject to change. Scientific claims change as new evidence, made possible through advances in technology, is brought to bear on existing theories or laws, or as old evidence is reinterpreted from a different perspective.

What Is Scientific Inquiry?

Although closely related to science processes, Scientific Inquiry (SI) extends beyond the mere development of process skills such as observing, inferring, classifying, predicting, measuring, questioning, interpreting and analysing data. Scientific inquiry includes the traditional science processes, but also refers to the combining of these processes with scientific knowledge, scientific reasoning and critical thinking to develop scientific knowledge. From the perspective of the National Science Education Standards (National Research Council 1996), students are expected to be able to develop scientific questions and then design and conduct investigations that will yield the data necessary for arriving at conclusions for the stated questions. The Benchmarks for Science Literacy (American Association for the Advancement of Science 1993) are a bit less ambitious as they do not advocate that all students be able to design and conduct investigations in total. Rather, it is expected that all students at least are able to understand the rationale of an investigation and be able to critically analyse the claims made from the data collected. Scientific inquiry, in short, refers to the systematic approaches used by scientists in an effort to answer their questions of interest. Pre-college students, and the general public for that matter, believe in a distorted view of scientific inquiry that has resulted from schooling, the media and the format of most scientific reports. This distorted view is called 'the scientific method' (i.e. a fixed set of set and sequence of steps that all scientists follow when attempting to answer scientific questions). A more critical description would characterise 'the method' as an algorithm that students are expected to memorise, recite and follow as a recipe for success. The visions of reform, however, provide no single fixed set or sequence of steps that all scientific investigations follow. The contemporary view of SI advocated is that the questions guide the approach and the approaches vary widely within and across scientific disciplines and fields (e.g. descriptive, correlational and experimental).

The perception that a single scientific method exists owes much to the status of classical experimental design. Experimental designs very often conform to what is presented as 'the scientific method' and the examples of scientific investigations presented in science textbooks most often are experimental in nature. The problem, of course, is not that investigations consistent with 'the scientific method' do not exist. The problem is that experimental research is not representative of scientific investigations as a whole. Consequently, a very narrow and distorted view of scientific inquiry is promoted among our K-12 students.

Scientific inquiry has always been ambiguous within science education reforms. In particular, inquiry is perceived in three different ways. It can be viewed as a set of skills to be learned by students and combined in the performance of a scientific investigation.

It can also be viewed as a cognitive outcome that students are to achieve. In particular, the current visions of reform are very clear (at least in written words) in distinguishing between the performance of SI (i.e. what students will be able to do) and what students know about SI (i.e. what students should know). Unfortunately, the subtle difference in wording noted in the reforms (i.e. 'know' versus 'do') is often missed by everyone except the most careful reader. The third use of 'inquiry' in reform documents relates strictly to pedagogy and further muddies the water. In particular, current wisdom is that students best learn science through an inquiry-oriented teaching approach. It is believed that students best learn scientific concepts by doing science. In this sense, scientific inquiry is viewed as a teaching approach used to communicate scientific knowledge to students (or allow students to construct their own knowledge) as opposed to an educational outcome that students are expected to achieve. With respect to the projects reported here, the primary focus is on knowledge *about* SI, because it is this perspective of SI that is most often ignored in classrooms and in methods of assessments. Specifically, the following understandings about inquiry are most germane to the projects reported here:

1. Scientific investigations all begin with a question, but do not necessarily test a hypothesis.
2. There is no single set and sequence of steps followed in all scientific investigations (i.e. no single scientific method).
3. Inquiry procedures are guided by the question asked.
4. All scientists performing the same procedures might not get the same results.
5. Inquiry procedures can influence the results.
6. Research conclusions must be consistent with the data collected.
7. Scientific data are not the same as scientific evidence.
8. Explanations are developed from a combination of collected data and what is already known.

As with NOS, these understandings about SI are not considered to be definitive or comprehensive. Rather, these understandings are considered to be developmentally appropriate for secondary students and have been shown in empirical studies to be understandable by secondary students.

Why Teach Nature of Science and Scientific Inquiry?

The goal of scientific literacy has been a perennial goal of science education since the 1970s (American Association for the Advancement of Science 1993; National Research Council 1996; Douglas Roberts 2007). In general, the scientifically literate individual has a functional understanding of science concepts and can apply this knowledge to making decisions about personal and societal problems. Two aspects of scientific literacy are an understanding of NOS and an understanding of SI. In addition to the goal of scientific literacy, understanding these two constructs is also presumed to facilitate understanding of subject matter and increase one's valuing of science as a human endeavour. At this point, there is scant evidence that understanding SI and NOS actually provides the benefits to learners as advertised. However, the emphasis on these two constructs remains as strong as ever, perhaps even stronger. Unfortunately, developing teachers' understandings of NOS and SI is no easy task. It requires a long and continuous programme of professional development. In addition, just because teachers have an adequate understanding of SI and NOS, it is not necessarily the case that they will be able to successfully develop these same understandings in their students. This chapter describes three large-scale professional development projects in Chicago that have been successful in developing teachers' understandings of SI and NOS and enabled teachers to promote the same understandings in their students: (1) Project ICAN (Inquiry, Context and Nature of Science); (2) High School Transformation project (HST); and (3) a programmatic model.

Project ICAN (Inquiry, Context and Nature of Science)

ICAN was a 5-year teacher enhancement project funded by the National Science Foundation. The project ultimately involved 238 teachers in Chicago and 23,500 students. Although the focus of ICAN was on secondary teachers (6–12), there were 12 elementary teachers included in the project. Approximately 50 teachers were recruited each year for participation in ICAN. Engagement with the project involved one full calendar year. During each academic year, Project ICAN was comprised of four stages: Summer Orientation; Academic Year Activities; Summer Institute; and Science Internship.

Summer Orientation

Project ICAN began with a 3-day orientation. The main focus of the orientation was to introduce ICAN teachers to aspects of NOS and SI by engaging them in NOS and SI activities (National Academy of Science 1998), watching relevant videos, and reading NOS- and SI-specific articles. Reflective questions, debriefings and discussions followed these activities to enhance teachers' familiarity with aspects of NOS and SI.

An example of an NOS activity is the tube activity (National Academy of Science 1998). Teachers were shown a mystery tube and its behaviours. They were then asked to infer the internal structure of the tube and design and construct physical models that behaved in the same way as the original tube. The discussion focused on elements of NOS such as how and why inferences differed although observations were the same, how human subjectivity led to different models, and the inconclusive nature of scientific models. This was followed by authentic examples from natural science, such as models of the atom and the centre of the earth.

Academic Year Activities

After the orientation, 10 full-day, monthly workshops took place from September to June. These workshops were centred on further NOS and SI instruction in the context of science subject matter, curriculum revision and assessment. The NOS and SI activities were intended not only for enhancing teachers' understanding of NOS and SI, but also for improving their knowledge of how to teach NOS and SI. An explicit/reflective approach, as described by Fouad Abd-El-Khalick and Norman Lederman (2000) was emphasised.

To help teachers to understand the explicit/reflective approach to teaching NOS and SI, Project ICAN staff presented model lessons. In the mitosis laboratory activity described by Norman Lederman and Judith Lederman (2004), for example, teachers were provided with two different teaching approaches for the same activity. First, teachers were given a brief review of the different stages of mitosis and how to categorise stages from pictures, and then teachers were asked to count the number of onion root tip cells in each stage of mitosis within a given field of view under high power. After the counts were entered as data in a table, they used the relative frequencies of stages to calculate the relative time required for each stage. In the second approach, teachers were given the same brief review, but this time teachers were asked to answer how they decided when one stage ended and the other began and how scientists made the same determination. A striking difference was that the first approach involved teachers in doing an investigation, but without any integration of NOS or SI. Unlike the first approach, the second engaged teachers in NOS and SI discussions involving careful selection and placement of reflective questions, followed by attention to certain aspects of NOS, such as tentativeness, creativity, observation versus inference, subjectivity and empirical basis. Attention to understandings about scientific inquiry was also included, such as the recognition of multiple interpretations of the same data set and the limitations of data analysis. In addition, curriculum evaluation and revision in terms of the teaching of NOS and SI were also emphasised. Under our guidance, teachers brought their own curriculum materials, evaluated them, and revised some topics in order to teach NOS and SI.

Teachers were also encouraged to apply what they learned through ICAN workshops in their classroom, and to bring examples of classroom experiences (verbally or via videotape) to the following ICAN workshop to share and discuss with each other.

Summer Institute

After the academic year, a 10-day summer institute focused on additional examples of curriculum revision and instructional activities focusing on SI and NOS. In addition, a major emphasis was placed on the assessment of students' understandings. Several model lessons integrating NOS and SI were also provided by teachers from previous years of ICAN.

Science Research Internship

During the academic year, teachers also participated in a science research internship with a practising scientist on the Illinois Institute of Technology campus or in surrounding community resources (e.g. zoos, museums). The teachers' primary role was as participant observers. They observed the ongoing investigations in the research settings and discussed specific research content and techniques with the scientists. Teachers kept daily journals, guided by focus questions about connections between the research experiences and the aspects of NOS and SI as presented in the project. In essence, this experience served as a 'reality check' for the perspectives of NOS and scientific inquiry presented in project activities.

Microteaching

During the third year of ICAN, we found that many of the participants' NOS/SI lessons were still characterised by implicit instruction. For this reason, we decided to assign three microteaching lessons to teachers in order to improve their pedagogical skills related to NOS and SI. Microteaching refers to a peer teaching presentation that mimics what teachers plan to do with their students. During the last 2 years of the project, three peer teaching lessons were also required during monthly meetings. These lessons were planned and delivered by teams of teachers. A teacher team consisted of three to four members who were voluntarily changed for each peer teaching assignment. Each lesson lasted for 45 min and afterwards there was a brief discussion of the aspects of NOS and SI addressed as well as ways in which the lesson could be further improved. Additionally, we provided written feedback to all teacher groups in terms of how to better integrate NOS and SI with their lessons.

Data Sources and Analysis

Teachers' Understandings of NOS and SI

Data addressing changes in teachers' views were collected during the summer orientation and the academic year. The summer orientation activities were preceded by pre-tests of teachers' understandings using Norman Lederman's Views of Nature of Science (VNOS) (Norman Lederman et al. 2002) and Views of Scientific Inquiry (VOSI) (Lederman and Ko 2003) questionnaires. These questionnaires were administered twice during the academic year.

The NOS aspects assessed included the idea that science is tentative, subjective, based on empirical observation and a product of human creativity. The distinction between observation and inference was also stressed. Aspects of SI targeted by the

VOSI include (a) multiple methods and purposes of investigations, (b) multiple interpretations of data being possible, (c) distinctions between data and evidence, and (d) data analysis being directed by the questions of interest and involving the development of patterns and explanations that are logically consistent. Additional data sources included journal reflections and revised curricular materials. Development of teachers' views was sought by comparison of profiles for each participant generated from VNOS-D and VOSI responses.

Teachers' Understandings of How to Teach NOS and SI

Teachers were required to provide videotaped lessons and lesson plans to illustrate their attempts to teach SI and NOS to their students. The reader is reminded that, during the last 2 years of the project, peer teaching lessons were also required during monthly meetings. Observation notes of videotapes and for peer teaching lessons were analysed along with instructional plans.

Students' Understandings of NOS and SI

The VNOS is an open-ended questionnaire that assesses views of the various aspects of nature of scientific knowledge. The VOSI is an open-ended instrument that assesses various aspects of scientific inquiry.

The VNOS-D and VOSI were administered to students at the beginning and the end of the academic year. Additionally, ICAN teachers were asked to submit samples of students' work completed during the NOS/SI-focused lessons, as well as test items related to these same topics. These data provided evidence of the impact on ICAN on students' understandings.

Before analysing all data sets, a 5% sample from each data source was used to establish inter-rater agreement. Agreement levels of 80% or higher were reached in all cases.

Results of the Project

Teachers' Understandings of NOS

Overall, over 70% of the participants showed enhancement in their NOS conceptions. The majority held informed views about four or more target aspects. Most significant were the changes in their views of the tentative, empirical, inferential, creative and subjective aspects of NOS.

As compared with 19% prior to instruction, 64% teachers had informed views about the tentative aspect of NOS. Teachers commonly stressed how new technology and discoveries play a role in developing scientific knowledge. For the post-test, 75% of the teacher participants (vs. 36% for the pre-test) exhibited informed views of the empirical aspect of NOS. For example, one teacher stated that 'they [scientists] could find evidence that might cause a change in what was previously thought and found'. The distinction between observation and inference was the aspect of NOS for which most participants (i.e. 82% vs. 32% for the pre-test) explicated informed views at the end of the programme.

About 69% of teachers (vs. 20% for the pre-test) demonstrated informed views about the role of imagination and creativity. Initially, around 65% of teachers held a limited understanding of the creative and imaginative aspect of NOS in analysing and interpreting data, stating that 'scientists use creativity in planning only, but creativity in observation and analysing data is a kind of lying. That is not science'. During the project, such a view was replaced by the notion that scientists involve creativity and imaginations in all the scientific inquiry activities including data analysis and interpretations.

Approximately 74% of teachers (vs. 25% for the pre-test) exhibited informed views of the subjective aspect of NOS. Prior to instruction, most of the teachers believed that scientists reach different conclusions because they have different data. A typical comment was that 'science is subjective in that each scientist has access to different data and evidence'. These responses changed appreciably during the programme. For example, one teacher believed that scientists disagree about what caused the extinction of dinosaurs even though they all have the same information because 'different people make different inferences based on their life experiences, education and cultural surroundings'.

Teachers' Understandings of Scientific Inquiry

ICAN teachers generally showed a significant improvement of their understandings of SI. For example, 40% began the programme with the view that SI consists of a set of steps that should be followed to obtain the correct answer. It was believed that these procedures are followed by objective scientists. They viewed the process as controlled, with the scientist being objective. At the end of the programme, few kept such views (i.e. 3%). They demonstrated major changes in their traditional view of the scientific method: they recognised that there is no universal step-by-step scientific method. Further, they came to recognise multiple methods for conducting scientific investigations and that scientists can have different methods for reaching conclusions. Some of them still described investigations as having steps, but they did not view these steps as a necessary part of doing an investigation.

Teachers improved in their understanding of multiple or alternative interpretations for a given a set of data. Nearly 80% of teachers understood that scientists are able to arrive at different interpretations of the same data because of 'scientists' creativity, culture, and differences' and that scientists often come into the process with prior conceptions, past experiences, beliefs and values that affects how they look, view and interpret things. As one teacher put it, 'even if scientists are working together, subjectivity can play a strong role in formulating one's theory and influence how results are looked at'.

Teachers' Understandings of How to Teach NOS and SI

Analysis of microteaching lessons indicated that there was a continuum of pedagogical content knowledge for NOS and SI instruction, from an implicit to a didactic and to an explicit/reflective approach. In the first microteaching session, more than half of the groups demonstrated an implicit lesson in which students were exposed to hands-on activities, but without any attempts to teach NOS and/or SI. Consistent with prior research of Fouad Abd-El-Khalick et al. (1998), Richard Duschl and Emmett Wright (1989) and Julie Gess-Newsome and Norman Lederman (1993), teachers did not consider aspects of NOS and/or SI when planning for microteaching lessons. All lesson plans for those implicit lessons included target aspects of NOS and SI, but most of them did not incorporate how to address those aspects of NOS and SI. Indeed, aspects of NOS were infrequently specified as outcome in their instructional objectives. The objectives pertained to doing science and/or only to science content.

Data analysis indicated that the failure of teachers to use an explicit/reflective approach to teaching of NOS and SI was associated with teachers' assumption that students can learn NOS and SI by *doing science*. In thinking about how to teach NOS, teachers intuitively treated NOS and understandings about SI as doing science.

But, by the final lesson, no implicit teaching was found and about 25% of the lessons were characterised as didactic; 75% of the lessons followed an explicit/reflective approach. The common features detected in explicit/reflective lessons are that the ICAN teachers explicitly addressed target aspects of NOS in the introduction of a lesson and intentionally guided students to situations in which target aspects of NOS were embedded. The explicit and reflective comments and discussions were identified not only at the end of the lesson, but also while students were exposed to the NOS/SI-specific situations. Indeed, in all explicit/reflective lessons, assessment pieces were developed and enacted for monitoring students' understanding of NOS and SI. Teachers provided students with written questions, a quiz, or homework assignments including assessment questions.

Analysis of student work and videotaped lessons indicated many more explicit/reflective attempts to teach NOS/SI in years 4 and 5 of the project than in previous years. About 85% of student work included NOS/SI-related questions to help students reflect on target aspects of NOS/SI and to assess their understandings of NOS/SI in the context of science subject matter, while approximately 75% of videotaped lessons followed an explicit/reflective approach.

It seems to be evident that the three microteaching experiences provided the ICAN teachers in years 4 and 5 of the project with important opportunities to reflect on their understanding of NOS/SI to develop pedagogical knowledge. The ICAN teachers planned and presented their microteaching lessons three times and had the opportunity to observe and discuss 20 peer lessons. The microteaching experiences familiarised the ICAN teachers with teaching NOS/SI and helped them reflect and develop their pedagogical content knowledge related to NOS/SI.

Students' Understandings of NOS and SI

Changing teachers' views is necessary but not sufficient for changing students' views. Teacher intentions and pedagogical skills for integrating NOS and SI into classroom practices are critical. The analyses of students' data indicated increasing success in changing students' views with each year of the project. By years 4 and 5, over 60% of the students (vs. 15% for the pre-test) held adequate views on over 80% of the aspects of NOS and SI that were focused upon.

Pre-test data indicated that overall the students demonstrated naïve views of NOS and SI. The most significant changes in students' views were with respect to the inferential, empirical and subjective aspects of NOS. In terms of SI, 37% (vs. 3% for the pre-test) of the teachers' students came to understand there is no single scientific method', saying that 'they [scientists] follow more than one method. For example, one method is investigating (observing) what birds eat and the shape of their beaks and the other method is doing an experiment involving chemicals'. Students also advanced in their knowledge of multiple interpretations of a set of given data; 46% (vs. 10% for the pre-test) of the students feel that 'if different scientists perform the same experiment, they might not all come out with the same answer. All these scientists have a different way to view things. They might have the same data but a different way in interpreting it'.

Conclusions and Implications

The data analyses indicated that Project ICAN was successful in helping teachers to improve their pedagogical content knowledge related to NOS and SI. Teachers initially tended to adopt an implicit teaching approach in which explicit/reflective questioning and discussion about NOS and SI were not planned. In helping teachers to understand and implement explicit/reflective NOS and SI instruction, the results of this study suggest that there are two critical changes that need to occur. First, teachers need to realise that explicit instruction is better than implicit instruction. Even though several explicit activities and explanations for the difference between explicit and implicit NOS and SI instruction were given to teachers before, in the first microteaching session, 62% of groups adopted implicit instruction. The teachers initially believed that students could learn about NOS only by *doing science*. They confused doing something with knowing something (e.g. Fouad Abd-El-Khalick et al. 1998). Extensive experience is needed for them to realise that they are adopting an implicit approach, which is not generally effective for teaching NOS and SI and to understand that 'doing' something is not necessarily 'knowing' something.

Second, teachers need to be aware that a student-centred approach to explicit/reflective is better than a didactic approach. Most teachers realised their implicit teaching of NOS and SI after the first microteaching session. However, discerning this implicit approach was not sufficient for some teachers for implementing explicit/

reflective NOS and SI instruction. They intended to teach NOS and SI explicitly, but failed to address target aspects of NOS and SI in the explicit/reflective manner advocated by Project ICAN. A short and didactic discussion for NOS was assigned at the end of a lesson rather than a reflective and interactive conversation integrated into the flow of the lesson.

Over the 5 years of the project, peer teaching experiences appeared to be an important professional development experience. In years 4 and 5 of the project, peer teaching became more prominent and provided teachers with opportunities to reflect on their understanding of NOS and SI and pedagogical knowledge related to NOS and SI. ICAN teachers planned and presented their lessons three times and had the opportunity to observe and discuss 20 peer lessons. These opportunities allowed teachers to become more familiar with teaching NOS/SI and helped them to reflect and develop their pedagogical content knowledge related to NOS and SI.

The development of teachers' pedagogical skills related to NOS and SI in years 4 and 5 was consistent with the analyses of student work and videotaped lessons, which showed much more improvement for teachers in years 4 and 5. This result implies that teacher education programmes should provide teachers with opportunities to plan and implement explicit NOS and SI instruction and to observe and discuss peers' lessons. Teachers will more readily adopt what they see that their peers do rather than what is modelled by professional developers.

Developing students' understandings of NOS and SI is not simple. It takes an extended period of time to develop students' understandings, as well as teachers' understandings and relevant instructional skills. It is important to note that short-term professional development activities are likely to meet with less success. It is also important to note that short-term attention to NOS and SI with students, typically through an introductory unit, is also not likely to yield success. NOS and SI are themes that must be developed through extended professional development and integrated throughout science courses and grade levels when dealing with K-12 students.

High School Transformation Project (HST)

The High School Transformation Project is currently a 6-year project (in its third year) funded by the Bill and Melinda Gates Foundation and Chicago Public Schools. Different from Project ICAN, the HST is a high school systemic change effort. For the most part, participating teachers in ICAN are individual teachers from different schools. There are some clusters of teachers from the same school, but this is not the norm. HST eventually engages *all* science teachers in the science department of participating high schools. Although HST includes NOS and SI as unifying themes, there is an equal emphasis on subject matter knowledge. Finally, HST primarily focuses on student outcomes, while Project ICAN focused primarily on teachers. Nevertheless, HST involves extensive professional development for teachers related to NOS, SI and subject matter. It is important to note that the lessons learned from

Project ICAN related to the delivery of professional development and the teaching of NOS and SI significantly informed the structure of HST.

HST has just completed its third year and currently involves all of the biology, chemistry and physics teachers in 20 high schools. There are currently 164 participant teachers and 24,652 students involved in the project. Each year additional high schools are added to the project, with the ultimate goal of having approximately 50 high schools by 2012. Schools are active in the project for a period of 3 years. All 9th grade science teachers in identified schools are involved in year 1; year 2 involves both 9th and 10th grade teachers, and year 3 involves teachers spanning Grades 9–11.

HST consists of three essential elements that are repeated, with some modification, during each of the 3 years of each school's engagement. These phases consist of (1) initial professional development for participating teachers, (2) monthly academic year professional development workshops (divided between the university and an informal education site and (3) on-site academic year support from science coaches. A science coach was assigned to each school to work closely with each of the teachers on a daily basis. Support ranged from observing lessons and providing feedback, co-planning lessons, team teaching or actually modelling instruction for the teacher. In addition, the science coach helped to coordinate science instruction by meeting with the science department as a whole each week. Science teachers in participating schools had a common planning time to facilitate this coordination. Participating schools and teachers received all needed materials, revised and developed new curriculum materials for each course taught, and daily support from a highly qualified science coach. Coaches are either teachers on leave from their school district or PhD students in science education. During professional development workshops, teachers experience a wide variety of 'model' lessons, directly derived from the curriculum content, that exemplify the inquiry-oriented instructional model advocated. Again, the overall focus of instruction is 'traditional' subject matter, scientific inquiry and nature of science by using an inquiry-oriented instructional approach. The primary goals of this systemic initiative are to:

- Enhance high school students' science achievement
- Enhance high school students' understanding of and ability to do scientific inquiry
- Enhance high school students' understandings of nature of science
- Enhance in-service science teachers' understanding of and ability to do scientific inquiry
- Enhance in-service teachers' understandings about nature of science
- Enhance in-service science teachers' ability to teach inquiry, about inquiry, and nature of science
- Enhance in-service teachers' ability to use informal education sites to enhance instruction and student science achievement
- Develop leadership skills in participant teachers so that they subsequently can work with other teachers in their school districts.

The aspects of NOS addressed in this project are that scientific knowledge is tentative, subjective, empirically based, socially embedded, and dependent on human imagination and creativity. Two additional aspects involve the distinction between observation and inference and the distinction between theories and laws (National Research Council 1996). The aspect of SI that was of particular interest was knowledge *about* scientific inquiry, because this distinguishing aspect of current reforms has been the most difficult to realise in classrooms. Specifically, the aspects of SI that were of interest were that: all scientific investigations begin with a question, but do not necessarily test a hypothesis; there is no single set and sequence of steps followed in all scientific investigations; inquiry procedures are guided by the question asked; all scientists performing the same procedures might not get the same results; inquiry procedures can influence the results; research conclusions must be consistent with the data collected; scientific data are not the same as scientific evidence; and explanations are developed from a combination of collected data and what is already known (National Research Council 2000).

Data Sources

Achievement scores were derived from standardised instruments developed for the project by the American Institute for Research (AIR). These instruments went through strict content validation procedures using multiple groups of subject-matter experts and educators. A level of agreement of 80% or higher was achieved for each item on each of the resulting instruments. Kuder-Richardson (21) reliability estimates exceeded 0.80 for each subject-matter test (0.82 for biology, 0.86 for chemistry, 0.83 for physics). As for previously described ICAN project, we used the VNOS and VOSI to assess students' views of nature of science and scientific inquiry respectively.

Results of Project's First 3 Years

Science Achievement

During each of the first 3 years of the project, pre-test and post-test data were collected on students' achievement. For Biology, 3 years of data exist because it is focused on the first year of school engagement and then continued in the subsequent 2 years; 2 years of data exist for chemistry and only 1 year for physics, at this time. For each subject area, correlated *t*-tests ($\alpha = 0.05$) were used to verify that students exhibited significant gains in achievement. Because instruction was provided to intact classes, the number of classes was used as the unit of analysis for each statistical test. Significant improvement in test scores ($p < 0.05$) was exhibited in each of the 3 years for biology, each of the 2 years in chemistry, and for the 1 year in physics. Although it is expected that significant gains would be exhibited across a year of instruction, these students on average were achieving at relatively high levels by the end of the academic year. That is, biology achievement reached 75% for the first year, 76% for year 2 and 78% for year 3. For chemistry, the average achievement score was 84% for year 1 and 85% for year 2. The physics achievement level was 85%. It is important to note that, for the chemistry and biology scores, the different years represent different sets of students.

Understandings of Scientific Inquiry

Both students and teachers were pre- and post-tested on understandings of scientific inquiry during each year of the project. If a student or teacher was part of the project for 3 years, he/she was assessed on understandings for each of those years. In short, teachers and students were assessed each year in which they participated in the project. Chi-square analyses ($\alpha = 0.05$) indicated significant improvements in each aspect of scientific inquiry addressed. Within the group of teachers, the greatest gains were shown with respect to understandings that there is no single scientific method and that scientists viewing the same data could arrive at different interpretations. As expected, teachers assessed in multiple years showed consistent improvement from year to year. The largest changes in students' views were related to an understanding that there is no single scientific method and that all science investigations must begin with a question. As with subject-matter understandings, the final understandings exhibited by students and teachers are more impressive than the fact that significant changes occurred from pre-tests to post-tests. That is, the 'final' understandings noted here are not commonly observed in student and teacher populations.

Understandings of Nature of Science

Teachers and students were assessed with respect to their understandings of nature of science as they were with scientific inquiry. Chi-square analyses ($\alpha = 0.05$) were again used to identify any changes in understandings from pre-test to post-test. Significant changes were found for all aspects of nature of science assessed within the group of teachers. Students did not show any change with respect to their understanding that scientific knowledge is partly a function of human creativity and imagination. As with subject matter knowledge and understandings of scientific inquiry, the 'final' understandings are more important than the significant changes from pre-test to post-test.

Comparisons Across Years of Engagement

Because HST is a multiple-year systemic change effort (with unifying subject matter themes such as inquiry and nature of science), it was logically assumed that both teachers and students would become more proficient in knowledge and skills with additional years of engagement in the project (i.e. students in the project for 3 years would become more proficient in science than students participating in the project for only 1 year). With respect to teachers, it was assumed that they would become more proficient in both knowledge and teaching ability with increased years of involvement. Although students involved for more than 1 year were taking different subject-matter courses (e.g. biology, then chemistry, then physics) comparisons of subject-matter improvement across years indicated that students' achievement levels increased from year to year. That is, students in the project for 3 years tended to achieve at a higher level in their physics course than in their chemistry course, and higher in their chemistry course than in their biology course. Students participating for 2 years consistently showed a greater level of achievement in chemistry than in biology. However, these data should be viewed with caution because the achievement levels are being compared across different subject matters. Still, the trend of increasing achievement levels from biology to chemistry to physics runs counter to students' typical performance in these different areas of science. That is, students usually do better in biology than chemistry. As was noted earlier, students consistently showed improvement in their understandings of scientific inquiry and nature of science from year to year.

Analysis of co-variance (ANCOVA) was used to assess student performance in the same subject matter area for teachers who participated in the project for more than 1 year. For example, for biology teachers who participated in the project for 3 years, their students' performance in biology was compared across the 3 years. The same analyses were undertaken for teachers involved in the project for 2 years. The ANCOVA tests ($\alpha = 0.05$), using the class as the unit of statistical analysis, indicated significant differences across years, with student achievement increasing with each additional years of teachers' experience. For example, if a teacher had participated in the project for 3 years, his/her students performed best in the third year relative to the second year or first year of involvement.

Conclusions and Implications

HST is a multi-year systemic change initiative that focuses on improving students' science achievement on standardised tests and knowledge of NOS and scientific inquiry. The design of the instruction and professional development for NOS and SI were directly derived from our work on Project ICAN. The project has completed its third year and so far has involved a total 20 high schools with instruction in biology, chemistry and physics. Furthermore, the project has involved 164 teachers and 24,652 students. Teachers are provided with extensive on-site and off-site instructional support. To date, it appears that the project has been quite successful with respect to improvement in students' subject-matter achievement and knowledge about scientific inquiry and nature of science. Single-year or short-term professional development efforts are often criticised for their inability to promote systemic change (Loucks-Horsley et al. 1998). Because systemic change requires intensive, frequent and long-term interaction with schools, teachers and students, there is an accumulated effect over time. The results of HST support this contention. The longer that students or teachers were involved in the project, the greater were the gains in their knowledge (for students) and knowledge and teaching ability (for teachers). With respect to teachers, it seems that the longer that they are involved with the project the more proficient they become in successfully enacting instructional materials and activities. Anecdotal data collected from the science coaches corroborate this assertion. Students improved because they benefited from the accumulated knowledge and perspectives provided by curriculum themes, as well as from the change in academic culture in a school that was very focused on systemic change. However, there is also another possibility at play. The formative assessments used within each instructional unit were designed to model the kinds of questions that students would encounter on the standardised summative assessments. Hence, it is quite possible that the students became more comfortable, with time, about answering such questions. This is not the same as learning test-taking skills or a case of teachers teaching to the test. Rather, students often do not do well on high-stakes tests because of their inexperience with the question types and formats as opposed to lack of knowledge. This issue needs further investigation and will be tracked in future years of the project.

Linking Knowledge of Nature of Science and Scientific Inquiry to Classroom Practice: A Programmatic Model

The previously described large-scale systemic professional development efforts clearly benefitted from external financial support. In addition, each of the projects had the luxury of engagement with teachers over multiple years. However, within the semester-to-semester reality of university in-service programmes, long-term and intensive professional development is not possible. The impact that one hopes to have on teachers' knowledge and practices must occur within approximately 450 hours of class contact and, with respect to NOS and SI, the impact might be limited to the content of just several courses. Thus, the desire to have teachers' classroom practice sustain itself after finishing a degree programme is a much more serious concern than with a funded project lasting for as much as 6 years.

Although previous investigations have attempted to develop teachers' understandings of NOS and SI, and the ability to teach these constructs (Randy Bell et al. 2000; Renee Schwartz and Norman Lederman 2002), there has only been limited success in getting teachers to continue attending to NOS and SI in an explicit manner during instruction. Various reasons have been cited by teachers for their lack of follow-through (e.g. time constraints, curriculum constraints, perceptions of what students can learn). Nevertheless, science classrooms are still not characterised by any concerted instructional focus on SI or NOS. At the Illinois Institute of Technology, we have been experimenting with the sequence of two courses (i.e. a course focusing on NOS and SI and a course focusing on advanced teaching strategies) within our in-service Masters Degree programme. In this investigation, a course on NOS and SI was taught concurrently with a course on advanced teaching strategies in an attempt to track the relationship between the development of teachers' understandings of NOS and SI and how this development was related to their ability to teach NOS and SI in an explicit manner within the context of a science lesson. The aspects of NOS and SI addressed in this investigation were the same as those addressed in Project ICAN and the HST.

Programmatic Design

The sample for this investigation comprised the 15 high school science teachers (9 females, 6 males) who were part of a Masters Degree leadership cohort for secondary mathematics and science teachers. Seven teachers were biology teachers, three were chemistry, and two were physics. These teachers ranged in experience from 3 years to 28 years, with an average of 8 years. The teachers were simultaneously enrolled in a course on NOS/SI and a course in Advanced Teaching Strategies. The teachers had previously completed courses in curriculum, assessment and evaluation, clinical supervision and action research, and they were currently completing an action research study that they had designed during a previous course. The course on NOS/SI was a discussion-oriented seminar focused around the reading of various books and classroom activities designed to develop teachers' understandings of the various aspects of NOS and SI. The course assumed no prior knowledge for the teachers and the instructional approach consistently expected teachers to reflect on both readings and activities with respect to how science was characterised. Instead of the teachers being provided with a list to memorise, the aspects evolved from class discussions. This course was taught by one of the researchers.

The Advanced Teaching Strategies course provided teachers with reform-based model lessons and the chance to practice instructional models that focus on student thinking (three 40-min peer-teaching lessons). The particular models stressed were the General Inductive Model, Concept Attainment Model and Inquiry Model described by Paul Eggen and Donald Kauchak (2006). During each of the three peer-teaching lessons, teachers were expected to follow the instructional model stressed and to include attention to at least one aspect of NOS and one aspect of SI. Teachers were free to choose the subject-matter focus of the peer-teaching lessons. All lessons were videotaped and followed by a 10–15 min debriefing class discussion. Teachers were also expected to watch their own videotapes and write self-critiques of the lessons. This course was team taught by two additional researchers.

Data Sources and Analysis

Multiple data sources were used in this investigation. Data collected during the NOS/SI course included pre-test and post-test administrations of the VOSI survey and the VNOS survey. In addition, teachers' book reports related to books read and reaction papers related to short readings were analysed. A total of two book reports and five reaction papers constituted the data set from the course. The data collected during the Advanced Teaching Strategies course included videotapes of lessons, teachers' lesson plans for their lessons, and teachers' self-critiques. Again, pre-test and post-test administrations of the VNOS and VOSI were used to assess changes in teachers' knowledge during the NOS/SI course, while the reaction papers and book reports provided a measure of the development of teachers' knowledge during the course. The data from the Advanced Teaching Strategies course also allowed documentation of the development of teachers' knowledge of SI and NOS, but were primarily used to correlate teachers' instructional development relative to their growth in knowledge during the course. Finally, a random sample of five teachers was interviewed to ascertain what facilitated or compromised their ability to explicitly address NOS and SI in their lessons.

The VNOS and VOSI were independently scored by two of the researchers. For each aspect of NOS and SI, each teacher was rated as 0 (unclear), 1 (naïve), 2 (transitional/mixed) or 3 (informed). The level of agreement for the VNOS was 0.88 and 0.92 for the pre-test and post-test, respectively. Levels of agreement for the VOSI were 0.91 (pre-test) and 0.94 (post-test). All disagreements were discussed and a consensus score was reached for all teachers. Data from the book reports and reaction papers were individually scored by one of the researchers and a chronological profile was created for each teacher's development of NOS and SI knowledge during the semester. All three researchers analysed the relationship between responses to the pre-test and post-test surveys relative to changes noted in the reports and reaction papers. With no exceptions, the views expressed in the surveys mirrored what was noted in the reports and reaction papers, lending confidence to the validity of the assessment of teachers' understandings.

The lesson plans and peer-teaching lessons from the Advanced Teaching Strategies course were analysed with respect to explicit references to aspects of NOS and SI. The two researchers who team taught this course analysed the data. Only explicit references were noted because the emerging research has indicated that students views of NOS and SI are significantly impacted primarily through explicit instruction, not implicit instruction. Specific attention was paid to what aspects of NOS and SI were targeted by the teachers, how well these aspects were addressed explicitly, and how the teachers' instructional development was related to the chronological profile of their knowledge development.

Results

As mentioned before, teachers' views were categorised as unclear, naïve, transitional and informed for both NOS and SI. These categorisations were based on analyses of VNOS and VOSI surveys, as well as other artefacts from the Advanced Teaching Strategies course and NOS/SI course.

Nature of Science

Teachers showed significant changes (pre-test to post-test) on all aspects of NOS using chi-square tests *($p < 0.05$)*. The largest changes occurred with respect to the creative and subjective aspects of scientific knowledge, with the smallest changes occurring with respect to teacher's understandings of the cultural embededness of scientific knowledge and the relationship between theory and law. By the end of the NOS/SI course, 73% (11/15) of the teachers exhibited informed views of all aspects of NOS.

Scientific Inquiry

As with NOS, teachers showed significant improvement on all eight aspects of SI investigated (chi-square tests, $p < 0.05$). The largest changes occurred with respect to the ideas that all scientific investigations begin with a question, but do not necessarily test a hypothesis, that there is no single set and sequence of steps followed in all scientific investigations (i.e. no single scientific method) and that scientific data are not the same as scientific evidence. The smallest changes occurred for the ideas that all scientists performing the same procedures might not get the same results, that inquiry procedures can influence the results, and that research conclusions must be consistent with the data collected. Overall, 80% (12/15) of the teachers exhibited informed views for each of the eight aspects of SI.

A clear relationship between the development of teachers' understandings of SI and NOS was evident when data from the Advanced Teaching Strategies course and the NOS/SI course (i.e. teachers' knowledge profiles) were analysed. In particular, during the first peer teaching lesson, teachers tended to teach NOS and SI implicitly, as opposed to explicitly as intended in both the NOS/SI course and Advanced Teaching Strategies course. That is, the teachers demonstrated a strong ability to design lessons that engaged students in investigations of scientific phenomena, but there was virtually no explicit attention to the NOS and SI objectives included in their lesson plans. This tendency was related to teachers' relatively superficial (i.e. transitional) knowledge of the various aspects of NOS and SI. As lessons from the second and third peer teaching lessons were analysed, which corresponded to teachers' possessing more informed views of NOS and SI, it was clear that teachers became more proficient at explicitly addressing NOS and SI (during instruction) as the courses progressed. In addition, teachers tended to include in their lessons those aspects of NOS and SI for which they had the most well-developed knowledge. In general, it appeared that, for most aspects of NOS and SI, teachers became more proficient at teaching each aspect of NOS and SI as their knowledge became more well-developed. Interviews with randomly selected teachers also indicated that they also selected for teaching those aspects of NOS and SI that seemed to fit most seamlessly with the topic of instruction.

There were some trends, however, that did not fit with what was noted overall.

Although teachers showed large changes with respect to their understandings that all scientific knowledge involves some level of human creativity and human imagination, the way in which this knowledge was manifested in lessons was distorted in an interesting way. Initially, it appeared that teachers were teaching ‘creativity’ in an implicit manner. However, as the Advanced Teaching Strategies course proceeded, it became clear that teachers instructionally interpreted ‘creativity’ to mean that students should be allowed to use their creativity during an investigation. Again, teachers approached instruction in this manner even though they had demonstrated through their survey responses and other artefacts that they understood ‘creativity’ to mean that all scientific knowledge is partly composed of human creativity and imagination. The five randomly selected teachers who were interviewed explained their instructional approach by stating that students could not understand that creativity was involved in scientific knowledge unless they were allowed to be creative. Interestingly, the teachers did not have this difficulty in translating knowledge into instructional practice when it came to addressing subjectivity in scientific knowledge.

Conclusions and Implications

Research over the past 2 decades has made it clear that the most effective way to teach students about NOS and SI is through an explicit/reflective instructional approach (Abd-El-Khalick and Lederman 2000; Lederman 2007). Although numerous studies have shown success in enriching teachers’ knowledge about NOS and SI, teachers continue to struggle in their attempts to translate their knowledge into effective classroom instruction. This investigation attempted to enhance the relationship between teachers’ understandings and their instructional practice in the relatively short time span of a professional Masters Degree programme. The results indicated a strong relationship between the progression of teachers’ understandings and their instructional practice. On the one hand, this finding is intuitive because a teacher cannot be expected to teach what he/she does not know. But, the relationship is not a simple one because teaching practice does not immediately follow the development of knowledge of NOS/SI and knowledge of how to teach both. It was clear that the progressive development of classroom practice lagged behind the progressive development of knowledge.

Prior to this investigation, researchers have been content to study teachers’ and students’ conceptions of NOS and SI using an ‘input–output’ model in which the primary focus has been monitoring pre-test–post-test changes during a carefully designed intervention. With respect to research on teachers, this approach to research has left us with the knowledge that we can enhance teachers’ knowledge about NOS and SI, but with little knowledge of how teachers’ knowledge progressively moves from naïve views to views that are consistent with current reforms. Other research efforts have clearly indicated that, although teachers might possess the desired views of NOS and SI and knowledge of how to teach NOS and SI, this knowledge is not automatically and necessary translated into classroom practice (Lederman 1999, 2007). This investigation has provided insights into the relationship between the progression of teachers' knowledge about NOS and SI and the progression of their instructional abilities related to these two constructs. It is clear that teachers' knowledge precedes their instructional ability. Our findings here are consistent with what was noted in the previously described projects. The teachers in these projects were not immediately successful at teaching NOS and SI as soon as their knowledge of the constructs developed. It seems that having the courses offered concurrently is not as effective as having the courses run consecutively. In addition, the relationship between knowledge and action is much more complex than simply meaning that teachers must know what they are expected to teach. Rather, after teachers develop in-depth understandings of NOS and SI and knowledge of how to teach it, there is a period of 'negotiation' during which the teacher needs to carefully consider how and where to best integrate NOS and SI into the existing curriculum. Consequently, recommendations for the integration of NOS and SI throughout the curriculum should be carefully considered in the light of the subject matter at hand (which provides an important context) and teachers' knowledge and instructional approach. Thus far, researchers have not considered the interaction between subject matter and the ability, or willingness, of teachers to address NOS and SI.

Professional Development and Teachers' Knowledge of Nature of Science and Scientific Inquiry: Lessons Learned

The previously described projects varied widely in terms of scope and logistical format. Project ICAN and the HST project were two large-scale professional development efforts that involved hundreds of teachers and thousands of students in the Chicago Public Schools. The third project is actually the in-service programme at Illinois Institute of Technology. Although the projects differ, they all focus on helping teachers to develop their understandings of NOS and SI and then translating this knowledge into effective instructional approaches. Consequently, the various projects do have some commonalities. That is, the views of NOS and SI promoted are consistent and the instructional approach, within the professional development activities and the approaches that the teachers are expected to use with their students, are all based on the research-supported explicit, reflective teaching approach (Lederman 2007). With respect to the focus of this chapter on professional development, we have learned several lessons through our work.

In each of the aforementioned efforts, we found that professional development needs to be long term, frequent and intensive (Susan Loucks-Horsley et al. 1998). In particular, in the large projects, we found that it was critical to meet with teachers throughout the academic year on at least a monthly basis. In addition, Project ICAN and the HST both included 'up front' intensive (i.e. 2 weeks or more) work during the summer and intensive capstone experiences during the summer following the academic year. These professional development activities involved knowledge development first, followed by attention to the development of instructional approaches. Teaching teachers about NOS and SI concurrently with teaching them how to teach NOS and SI simply did not work well. The cognitive demand seemed to be too great. In the organisation of the in-service programmes at the Illinois Institute of Technology, we found that courses addressing NOS and SI are best situated sequentially as opposed to concurrently with courses on the teaching of NOS and SI.

Microteaching opportunities have been shown to be crucial for success in all three of our efforts, regardless of scope. That is, our teachers benefitted significantly from opportunities to teach NOS and SI to their peers, as well as observe their peers, followed by 'friendly' but productively critical feedback. In each of the long-term efforts, it was obvious that the effectiveness of microteaching opportunities increased as trust developed among the teachers and our staff. It is also important to note that, in our in-service programme, this trusting environment was also critical and it was just developed prior to the two critical courses discussed here.

In terms of the decades of research on teaching and learning NOS, and more recently on the learning of SI, the overwhelming majority has focused on descriptions of teachers' and students' knowledge and on the development of isolated instructional approaches for developing teachers' and students' knowledge. The only long-term efforts focused on the development of science curriculum, but such efforts have not met with much success. The work reported here leads us to believe that the nature of the professional development efforts is more critical than the particular instructional materials. In addition, it appears that the intensive and prolonged work with teachers in two of the three reported projects is also successful in generating teachers' enthusiasm for teaching NOS and SI. This enthusiasm is critical if teachers are to continue addressing NOS and SI in their classroom practice after the completion of grants and professional development efforts.

Chapter 25
Mentoring in Support of Reform-Based Science Teaching

Thomas R. Koballa Jr. and Leslie U. Bradbury

As mentoring has grown in popularity as a means to support novice teachers, there has been an increase in the number of studies related to teacher mentoring. Early studies focused on the benefits of mentoring relationships, the needs of beginning teachers, and the possible roles that a mentor might adopt in a relationship with a new teacher (Gehrke and Kay 1984). More recent work has explored the content of conversations between mentors and novices and the impact that working with a mentor has on the classroom practice of the novice (Wang et al. 2008). While there is a great deal of research related to the topic of teacher mentoring, little of that is focused specifically on science teacher mentoring.

Consistent with teacher mentoring in general, the promise of science teacher mentoring has been associated with teacher retention and individual development, specifically directed at the satisfaction and practice of beginning science teachers (Coble et al. 2009; National Commission on Teaching in America's Future 2003). In this vein, mentoring has served as an important element of science teacher induction efforts (Luft 2003; Shore and Stokes 2006). Moreover, mentoring also has come to be viewed as a means of reforming science teaching (Koballa and Bradbury 2009). The ultimate target of this reform is the science learning experiences of students.

In this chapter, we review the research on science teacher mentoring. We first highlight the nature of mentoring and its influence on science teachers and their practice. Next, we discuss the professional learning that prepares mentors to support the work of science teachers and ways to position mentoring to facilitate science

education reform. We conclude the chapter with suggestions for future research on science teacher mentoring that are likely to promote a culture of reform-based science teaching and learning.

Nature and Influence of Science Teacher Mentoring

Numerous studies have demonstrated the potential for mentoring to influence the practice of beginning teachers in positive ways (i.e. Evertson and Smithey 2000). Studies of science teacher mentoring at the elementary and secondary levels indicate similar influences, suggest alternatives to the traditional model of mentoring, and underscore challenges to the success of mentoring as a vehicle for teacher professional growth and for the reform of science teaching.

Elementary Science Teacher Mentoring

At the elementary level, the focus of research has been the amount and quality of mentoring offered to pre-service teachers during their internship experiences. In a survey-based study of 331 pre-service elementary teachers in Australia, Peter Hudson (2005) found that less than half of mentors modelled a science lesson, helped the intern plan a science lesson, or assisted with evaluating the interns' performance in teaching a science lesson. Similarly, in a study of 54 undergraduates completing a field-based elementary programme in a large urban area in the USA, 39% of interns reported that they did not see any science being taught and the majority of those who did observe a science lesson did so on an infrequent basis (Travers and Harris 2008). While these pre-service teachers did not observe their mentors engaging in science teaching, the majority felt that the mentors supported them in their own efforts at implementing science lessons.

Factors contributing to the dearth of mentoring for elementary science teachers are the lack of subject matter knowledge and science teaching experience of mentor teachers (Jarvis et al. 2001). In a study of two pairs of mentors and student teachers who observed science lessons taught by each other, conversations focused on general issues of classroom management and lack of subject-matter knowledge, though all participants reported learning from the experience (Nilsson and van Driel 2008). To help mitigate the problem of mentors who reported a lack of confidence in planning, managing and assessing science lessons, Tina Jarvis and colleagues (2001) developed science-specific checklists to support the work of the mentors. These checklists provided guidance for novices as they planned science lessons and for mentors when they evaluated novices' performance. Both mentors and novices reported that the checklists were valuable and improved the quality of science lessons.

Concerns have been raised that pre-service elementary teachers do not have opportunities to observe experienced teachers engaging in science teaching and that they are being guided by mentors who do not engage in science teaching themselves

(Travers and Harris 2008). These concerns have prompted calls for increased education for those who serve as science mentors at the elementary level. Hudson (2007) advocated the use of a survey instrument for determining the extent and quality of science mentoring in order to facilitate the planning and implementation of mentoring programmes that address the needs of elementary science mentors.

Secondary Science Teacher Mentoring

At the secondary level, more studies focus on science teacher mentoring as one component of induction programmes that provide a variety of mechanisms of support for beginning science teachers. In a study that compared beginning teachers engaged in four different types of induction programmes, only half of novice teachers who met with their assigned mentors felt that the meetings were useful (Luft 2009). These beginning teachers wanted more assistance with locating materials for laboratory activities and more ideas to encourage their learning about science teaching. Addressing novice teachers' needs for science-specific teaching materials, equipment and other resources was the focus of the Exploratorium Teacher Induction programme (Shore and Stokes 2006). Here, the construction of *Teaching Boxes* by beginning teachers and mentors served as a focal point for discourse about science content and uses of materials and equipment to engage students.

Several studies involved the needs and experiences of people who enter science teaching through non-traditional routes. One example is the New Science Teachers' Support Network, a university–school district partnership that supports science teachers who enter the classroom before obtaining their certification (Frazier et al. 2008). New teachers are provided with an instructional coach who is a retired science teacher, a school-based mentor located at the same school as the novice, and access to coursework, web resources and other professionals. The instructional coaches served a vital role during the novices' first 2 years in the classroom in improving in their abilities to establish laboratory routines, pace laboratory lessons and plan for efficient assessment and detailed lessons.

Other studies emphasised the influence of mentor–novice compatibility on the success of the mentoring experience. In a year-long study of two student teachers, Leslie Bradbury and Thomas Koballa (2008) found that differing conceptions of science teaching and mentoring brought to the partnerships by mentors and novices contributed to tensions within each pair that negatively impacted on the relationships and learning of the novices. In a unique application of a Myers-Briggs type inventory, Lucretia Tripp and Charles Eick (2008) found that secondary science student teacher placements were most successful when mentor and student teacher were matched based on personality constructs measured by the inventory. Compatibility was reflected in the pedagogical approaches used by dyads and the mentoring skills employed by mentor teachers. Mentoring vignettes have also been tested as tools for ascertaining mentor–novice compatibility. Test results revealed that vignettes are useful in uncovering science teachers' beliefs about mentoring that can contribute to both harmonious and discordant mentoring experiences (Koballa et al. 2008).

Alternative Forms of Science Teacher Mentoring

Mentoring traditionally has involved an experienced teacher in providing support and guidance to a novice teacher. In this apprenticeship model, the experienced teacher shares expertise related to topics such as managing student behaviour and planning meaningful lessons. As the popularity of mentoring grows, new models are beginning to emerge.

Eick (2002) described a case in which two novice teachers were assigned to one middle school classroom and shared the responsibility for planning and teaching classes. The two novices provided feedback and support to each other. When they experienced particularly challenging situations, they sought out more experienced teachers at their school. While the two realised that they were not able to enact their ideal vision of science teaching, they felt that they benefited from having each other as sounding boards. Similarly, three early-career secondary science teachers participated in peer mentoring by observing each other teaching through videotapes and Internet videoconferencing, and then met once a month with a science education staff member (Forbes 2004). These participants reported that their confidence in trying new instructional approaches increased as a result of the support that they received in this collaborative environment. In another study of science teacher mentoring nested in induction experiences in five different countries, 'facilitated peer support', in which novices gathered and shared their own problem-solving strategies with support from more-experienced personnel, provided an important source of learning (Britton and Raizen 2003).

Mentoring to Reform Science Teaching

Mentoring is considered to be a vehicle for improving science teaching by emphasising reform-based teaching practices in mentor–novice interactions. When viewed through this lens, reform documents such as *The National Science Education Standards* of the National Research Council (NRC 1996) provide guidance for interpreting the phrase 'reform-based science teaching'. These documents call for science to be taught in a manner that emphasises the nature of science and how new knowledge is developed by engaging students in activities that allow them to generate and answer questions (NRC 1996). Deep understanding of science concepts by all students and their application to real-life contexts are central goals. While facilitating learning experiences in their classrooms, teachers should consider the culturally based beliefs that students hold, safety considerations in managing laboratory experiences, and appropriate strategies for assessing student understanding (NRC 1996).

Research into the experiences of novice teachers indicates that, although they might enter the classroom with reform-based ideas about teaching, when they are supported by teachers who value more traditional notions of science teaching, the guidance that they receive serves to constrain innovation and shapes the new teacher to fit the norms valued at the school (Trumbull 1999). In an analysis of mentoring conversations between two science teacher mentors and novices completing an internship in their classrooms, topics that were discussed only briefly or not at all included the nature of science, inquiry, issues related to scientific literacy and science in the community, which are all central components in reform-based science teaching (Bradbury and Koballa 2007). Instead, the majority of conversations focused on general pedagogical knowledge. However, when novice teachers participate in mentoring experiences that are nested in induction programmes that focus specifically on science teaching with an emphasis on reform-based practices, they are more likely to include a greater number of extended inquiry lessons in their teaching repertoire than those who participate in general mentoring or induction programmes (Luft et al. 2003).

Access to reform-based mentoring was the impetus for the e-Mentoring for Student Success (e-MSS) project (Jaffe et al. 2006). Through the application of a mentoring curriculum that brings attention to reform-based instructional goals and students' science learning, beginning teachers received support and guidance from experienced science teachers and scientists via an online mentoring network. While not concerned about access, other mentoring efforts also employed online systems to focus mentoring discourse on reform-based science teaching. One such effort employed the Video Analysis Tool (VAT), which allows for the application of a range of 'lenses' through which teaching episodes can be systematically identified, captured, coded and analysed. Use of the VAT by secondary student teachers and their mentors revealed increased attention to reform-based practices in their mentoring conversations (Koballa et al. 2005).

Professional Learning for Science Teacher Mentors

Mentors of beginning science teachers are teacher educators. They are called on to work with novice teachers at different levels of knowledge and development, support novices as they enact reform-based teaching practices, provide logistical assistance and model exemplary knowledge of science content and pedagogy (National Science Teachers Association 2007). Thoughtful and well-designed professional learning opportunities are essential for enabling mentors to fulfill these obligations (Britton et al. 2000). Educational opportunities in which mentors participate influence their behaviour and the teaching practice of the novices with whom they work (e.g. Harrison et al. 2005).

Professional learning opportunities for science teacher mentors should be developed in partnerships between the schools where novices and mentors work and the university to ensure that the needs of all stakeholders are met (Dunne and Newton 2003). These learning opportunities should be available to both school-based and university-based mentors. Appropriate topics include: the needs of beginning science teachers (Adams and Krockover 1997); strategies for observing and promoting reflective conversations about novices' lessons (Koballa and Bradbury 2009); and conceptions of mentoring and science teaching that participants bring to the relationship (Koballa et al. 2008).

Mentors are likely also to benefit from learning experiences that address the fundamental tenets of reform-based science teaching and from assistance with planning and implementing instruction that reflects these tenets (Luft et al. 2003). This is a particularly important aspect of the professional learning of veteran science teachers who agree to serve as mentors, but who might not be well versed in the tenets of reform-based science teaching. Professional learning opportunities for these mentors could involve the in-depth exploration of standards documents along with preparing, testing and discussing model lessons and assessments.

As facilitators design professional learning opportunities for science teacher mentors, the needs of adult learners must be considered as well as the differences in understandings and expectations that school-based and university-based mentors might hold. Adults learn most effectively when they have a clear purpose for their learning and the learning is situated in real-life contexts (Mundry 2003). Time must be provided for school- and university-based mentors to articulate their understanding about learning, teaching and mentoring and to negotiate expectations for novice teacher performance. Examination of such documents as the National Science Teachers Association Standards for Science Teacher Preparation (2003) can serve to inform these negotiations.

Moreover, science teacher mentors need opportunities to work productively on in-depth investigations that build on their experiences and that provide adequate time for reflection (Loucks-Horsley et al. 2003). Providing opportunities for discussion and case writing allows mentors to apply their knowledge in classroom-based contexts (Koballa et al. 2010). The use of video clips offers another productive site for learning, as mentors could view clips of mentoring conferences that incorporate a variety of mentoring strategies and discuss the potential benefits and drawbacks of each in their own work (Brennan 2003).

One other important consideration in developing professional learning opportunities for science teacher mentors is that the programme enables sustained contact between mentors (Dunne and Newton 2003). As mentors engage with novice science teachers, they need a place to which to turn for ideas and support when difficult situations arise (Bradbury and Koballa 2008).

Positioning Mentoring in Science Education Reform

Because of their recent experiences with education coursework that emphasises reform-based science teaching practices, pre-service and beginning teachers are in a unique position to function as agents of reform (Davis et al. 2006). The mentoring support that they receive can play a pivotal role in determining whether novices enact desired reform-based teaching practices and help spread these practices in their schools (Luft 2009).

For this reason, careful consideration must be given to the criteria used for recruiting and assigning science teacher mentors. A frequently used strategy has been to choose mentors based on their seniority and reputation as classroom teachers (Wang and Odell 2002). However, it is important for persons responsible for assigning mentors to remember that science is composed of multiple disciplines, each with its unique content and associated ways of thinking and investigation. Thus, the preferred mentoring match for a beginning biology teacher is likely to be an experienced biology teacher rather than an experienced physics or chemistry teacher. This consideration should not overshadow the importance of choosing mentors who model and support reform-based science teaching.

In this vein, it is important that science teacher mentors are attuned to the culture of schools in which they work and its potential influence on the success of mentoring experiences (Feiman-Nemser 2006). It is possible that mentoring that supports reform-based science teaching could run counter to the traditional culture of science teaching present in a secondary school science department or among teams of elementary or middle school teachers. In contrast to what might occur in a traditional teaching culture, science mentors whose goal is to encourage reform probably will engage novices in conversations that could be uncomfortable at times, but which encourage careful reflection about reform-based practice.

Edward Britton (2009) makes the point that the needs of novice science teachers that can be addressed through mentoring can be viewed as a continuum that ranges from science-specific needs to general needs. This view is important for science teacher mentors to adopt as they reflect on the guidance that they give to novices about reform-based teaching practices. For instance, mentoring focused towards the science-specific end of the continuum that supports reform-based teaching practices might highlight for novices unifying concepts and processes of science, such as evidence, models and explanation (NRC 1996), that might not be at the forefront of their thinking when planning learning experiences for their students. It is equally important that mentors recognise that even the general needs of novice teachers, such as those associated with classroom management, have science-specific aspects that call for special guidance when viewed through the lens of reform-based teaching. For example, classroom discourse requires a different teacher stance when students are engaged in scientific argumentation than when they are asked only to respond to teacher questions.

Additionally, those involved in the development and enactment of mentoring programmes for novice science teachers should think about mentoring models other than pairing one novice with one mentor. Increasingly, it is becoming apparent that a team mentoring approach is required to meet the needs of novice teachers as they learn to teach in reform-minded ways (Britton and Raizen 2003). For instance, a team mentoring approach could be particularly beneficial for science teacher novices coping with teaching assignments outside of their primary content field. These teams might include school and university mentors who can provide different kinds of guidance and assistance.

Future Research on Science Teacher Mentoring

The needs of novice science teachers are many. Increasingly, these needs are intertwined with matters of reform-based teaching. More research is needed to better understand the needs of novice science teachers and the relationship between their needs and the demands of reform-based science teaching. Research that addresses the needs of novice science teachers could provide insight about the influence of science teacher preparation on their needs and how their needs change over time.

Given the increasing awareness of the usefulness of multiple mentors to support novice science teachers, more needs to be known about the factors that influence this complex web of interaction. Peer group mentoring and mentoring teams, for which individuals assume different responsibilities, warrant further exploration as possible alternatives to the traditional one-on-one mentoring model. There is a need for research into from whom and how novice teachers seek guidance that informs their practice. Investigations with this focus also might provide guidance regarding the potential of different technologies for putting novice teachers into contact with mentors who are not at their schools, such as was done in the e-MSS project.

An increasing number of researchers (e.g. Roehrig and Luft 2006) have noted the influence of school context and other contextual factors on mentoring relationships, yet little is known about the many contextual factors that can enhance or constrain mentoring in support of reform-based science teaching. The influence of the school principal on the success of science teacher mentoring is one aspect of school context that warrants investigation. More also needs to be known about the influence of such contextual factors as school level, novice's science subject specialisation, and out-of-discipline teaching on the success of science mentoring conversations and novice teachers' reflection and reform-based practice. With mentoring experiences often nested within induction efforts, there is also a need to determine the influence of other induction programme activities on the mentoring received by novice science teachers.

In order to engage novice science teachers in conversations about reform-based practice, the learning experiences for mentors of elementary and secondary science teachers must address the tenets of science education reform and highlight tools that will facilitate their efforts to examine instructional plans, observe lessons and provide feedback. University staff who serve as mentors for novice science teachers also could benefit from professional learning experiences. More needs to be known about the needs of teachers and university staff who serve as mentors and the kinds of learning experience that will prepare them to guide novice teachers of science at all grade levels to engage in reform-based practice.

In some schools, the efforts of mentors to promote reform-based science teaching will place them in the role of change agents. The role of change agent can be challenging for mentors, especially when their efforts to support reform-based science teaching run counter to the prevailing school culture. Functioning as an agent of change also can lead to situations in which a novice teacher rejects the mentor's advice. This rejection could arise because of uncertainty about the mentor's practices and motives. Research is needed that will inform the professional learning experiences for mentors who take on the role of change agents in schools and how to work successfully with novice science teachers who might not value mentoring that focuses on reform-based practice.

The Alternative Support for Induction Science Teachers (Luft and Patterson 2002) and Mentoring in Middle School Science (Education Development Center 2003) are two projects for which mentoring practice is solidly based on tenets of reform-based science teaching. Results from these two projects are very promising, indicating an influence of mentoring on novice teachers' understandings and practice that reflect tenets of reform-based science teaching. Even with these successes, more research is needed to document the impact of different reform-based mentoring efforts on teacher thinking and practice. In particular, more needs to be known about the influence of science teacher mentoring that is nested within general induction programmes.

Some policy decisions seem to suggest that mentoring influences students' learning through influencing teacher practice. However, the causal relationship between mentoring and student learning in science is less than clear (Koballa and Bradbury 2009). Research is needed to test this causal relationship and to determine if and how mentoring in support of reform-based science teaching affects student learning. In addition to science content knowledge, students' understandings of unifying concepts and principles, the nature of science and the applications of science to daily life could be included in investigations into this relationship.

Overall, the research reviewed in this chapter demonstrates the potential of mentoring for supporting the professional growth of novice science teachers. It also reveals that much is still unknown about mentoring in support of reform-based science teaching, but that there are many possible directions for future research that potentially could inform our understandings of this important arena of teacher learning.

Chapter 26
Multi-paradigmatic Transformative Research as/for Teacher Education: An Integral Perspective

Peter Charles Taylor, Elisabeth (Lily) Taylor, and Bal Chandra Luitel

There's a crack in everything. That's how the light gets in.

Suddenly, or so it seems, we find ourselves in an age of great uncertainty; a new dark age, perhaps? The world is wracked by crises of unparalleled proportions, forcing us to rethink the fundamentals of our lives. Financial, climatic, health, resource and security crises are acting in concert to rob us with frightening speed of our confidence in the taken-as-natural primacy of our historic (Western) worldview. We are being forced to question our habituated ways of improving the material quality of our lives. Thanks to increasing public alarm it has dawned on us that for centuries our commitment to modernity, especially the seemingly unassailable drivers of science and technology, has fuelled unsustainable global exploitation. Prominent organisations such as UNESCO are lamenting the collapse of cultural, linguistic and biological diversity (Skutnabb-Kangas et al. 2003). The world's leading climatologists are warning that chronic pollution of planetary ecosystems, especially atmospheric carbon emissions, has created chronic damage to the planet's biosphere (Stern 2006). We are rapidly running out of time to curb our carbon footprint.

B.J. Fraser et al. (eds.), *Second International Handbook of Science Education*,
Springer International Handbooks of Education 24, DOI 10.1007/978-1-4020-9041-7_26,

Reflecting on how science education can contribute to resolving the problem of our survival on this planet we are inspired by Leonard Cohen's poetic notion in the epigram to this chapter, preferring to view this moment in human history optimistically as an unparalleled challenge and opportunity. We share Nobel Peace Prize nominee Ervin Laszlo's view that in order to avoid worldwide breakdown of social systems a macroshift is needed in the way we understand, respond to and reshape social reality. It is time to go beyond a narrow materialistic scientific view of reality and embrace a multidimensional world view of multiple interconnected realities in order to create 'a global civilization that possess[es] the will and the vision to achieve solidarity and translate it into international and intercultural coexistence and cooperation' (Laszlo 2008, p. 37). We understand that going beyond involves a transformation of consciousness to higher levels of awareness and understanding of self and other, and of the complex interconnectedness of all things. And so we advocate engaging science educators, especially those undertaking graduate research studies, in what Jack Mezirow (1991) calls 'transformative learning':

> … experiencing a deep, structural shift in the basic premises of thought, feelings, and actions. It is a shift of consciousness that dramatically and permanently alters our way of being in the world. Such a shift involves our understanding of ourselves and our self-locations; our relationships with other humans and with the natural world; our understanding of relations of power in interlocking structures of class, race, and gender; our body-awareness; our visions of alternative approaches to living; our sense of possibilities for social justice and peace and personal joy. (Morrell and O'Connor 2002, p. xvii)

How can graduate research students engage in transformative learning when to do so involves making their own (and others') subjectivities a key focus of their inquiries? Transformative research involves a process of examining critically our personal and professional values and beliefs, exploring how our life worlds have been governed (perhaps distorted) by largely invisible socio-cultural norms, appreciate our own complicity in enculturating uncritically our students into similar life worlds, creatively re-conceptualising our own professionalism, and committing to transform science education policy, curricula and/or pedagogical practices within our own institutions. How can research as transformative learning be represented in a doctoral dissertation and be legitimated as scholarly knowledge production?

Our purpose in this chapter is to address these questions. In doing so we draw on over 25 years of development in the field of qualitative social science research by pioneering scholars such as Norman Denzin, Yvonna Lincoln and Egon Guba whose scholarly work is well represented in the Sage *Handbook of Qualitative Research* (Denzin and Lincoln 2005) and the international journal, *Qualitative Inquiry* (http://qix.sagepub.com/). We start by considering the limitations of the traditional single-paradigm approach to educational research dominated throughout the twentieth century by hegemonic positivism and its derivative post-positivism. By the term 'paradigm' we mean a specific scholarly framework for conceptualising, investigating and communicating about the world; and, like Thomas Kuhn (1970), we recognise the incommensurability (but not incompatibility) of paradigms due to their contrasting ontologies (what is the nature of reality?), epistemologies (what type of justifiable knowledge can be generated?) and methods of investigation (how can we generate justifiable knowledge?).

We outline three research paradigms relatively new to science education – interpretivism, criticalism, postmodernism – and we consider the unique contribution that each is making to transformative research. In particular, we highlight the role of *new logics* for making new sense of personal experience of a complex and emerging world and *new genres* with which to investigate and communicate heartfelt concerns about the human condition. Drawing on recent graduate research in the field of cultural studies of science education we illustrate how multi-paradigmatic transformative research can be enacted. In closing, we adopt a perspective drawn from integral philosophy and generate a meta-theory about the compatibility of multiple research paradigms, justifying the transformative researcher drawing on all paradigms, including post-positivism.

Throughout the chapter we exemplify our arguments with reference to the nascent field of the cultural studies of science and mathematics education where graduate research students are exploring critically, reflectively and creatively their own cultural situatedness, excavating and re-honoring their indigenous cultural capital, generating authoritative voices with which to re-author their professional world views, and developing personal professional philosophies with which to generate seeds of liberation in the hearts and minds of their own students, many of whom are future teachers of science.

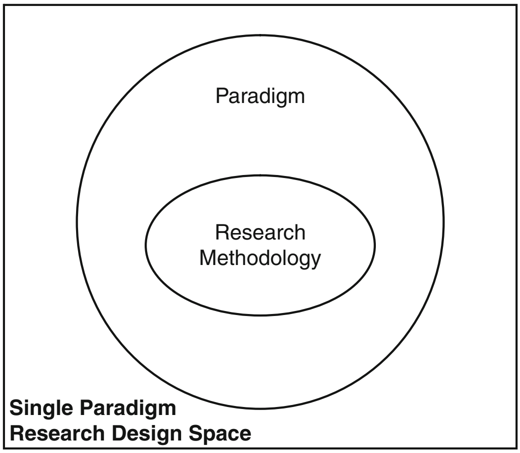
Single-Paradigm Research

Established for centuries as the standard-bearer of the scientific materialist world view, the positivist research paradigm has been, over the past 30 years, the subject of intense critique by philosophers of science and critical pedagogues (Kincheloe and Tobin 2009). Nevertheless, for historic reasons explained by Donald Schön (1983) and notwithstanding the rise in popularity of 'qualitative' research, positivism remains the dominant research paradigm in the social sciences, albeit in a 'softer' form called post-positivism. Jerry Willis (2007) gives an excellent account of all major research paradigms, describing post-positivism as directing a search for universal laws by employing an objectivist epistemology, a highly controlled, theory-testing methodology (or 'methodolatry'), and privileging academic research practice over the professional practices it purports to serve.

Our view of this research paradigm is mixed (Luitel et al. 2009). On the one hand, for reasons that we explain later in this chapter, we believe that it offers valuable methods for science education researchers. However, we are highly critical of its hegemonic stranglehold of graduate school research agendas inasmuch as it provides restrictive ways of thinking and writing that are not conducive to transformative learning.

The classical hypothetico-deductive logic of the post-positivist research paradigm comprises three powerful but restrictive logics, namely, propositional, deductive and analytical. Propositional logic entails reductionism that is exclusive of the ambivalence and uncertainties enshrined in our everyday realities, thereby ruthlessly reducing the notion of educational research to technical procedures. Whilst using deductive logic it is almost impossible to think outside of pre-existing laws and to deduce new truths. A narrowly conceived analytical logic promotes dualistic thinking, which can create unhelpful antagonisms between opposing attributes. Furthermore, positivism requires these logics to be expressed via the standard scientific genre of impersonal representation characterised by a neutral, passive, de-contextualised and distanced authorial voice. Although there is much to value in the standard logics and genre of the post-positivist paradigm, it is important to realise their limitations in accounting for and representing complex, non-linear, emergent and imaginative aspects of the thinking and actions of a transformative researcher.

Within a single-paradigm research design space framed by post-positivism the task of the graduate research student is relatively straightforward: to 'fill in the blanks' of a standard methodological template, ensuring that validity and reliability are the key regulators. In such restrictive scholarly conditions novice researchers, like the proverbial Chinese fish, may remain largely unaware of the epistemological 'water' in which they are immersed. Thus, when new research methods are encountered, especially in the absence of epistemological awareness, they are subordinated by the post-positivist paradigm under the seemingly inclusive label of 'mixed methods' research.



But our criticism is not directed at the single-paradigm model of research *per se*, rather we are concerned primarily with its restrictive nature, especially when it perpetuates uncritically and unimaginatively the prevailing tradition of post-positivism as the normative research paradigm. The problem is twofold. First, post-positivism privileges research that suppresses the subjectivity of the researcher, thereby failing to provide scholarly conditions for professional development as/for transformative learning, resulting in research serving largely to reproduce the prevailing research paradigm of post-positivism: an endless cycle of academia perpetuating its own existence. Second, the hegemony of post-positivism reproduces a narrow materialist scientific view of reality which reinforces the importance of learning uncritically a priori objective facts solely within a restrictive Western modern world view, to the exclusion of developing higher-order scientific literacy skills (Hodson 2008) with which to scrutinise the historical scope, philosophical boundary conditions and sociological limitations of this world view.

We believe that professional development of science teachers, especially via graduate research studies, should enable them to develop personally the transformative learning skills that they now are being called upon to develop in their own students, whether in school science or in college science teacher preparation courses. A pedagogy of transformative learning aims to raise students' critical awareness of the historic impact of science (and technology) on society, enabling them to develop ethical decision-making skills and a sense of personal agency for committing to make a difference, and fostering their empathic appreciation of alternative (ecological) knowledge systems embedded in other cultures (Settelmaier 2009). These transformative learning skills constitute essential components of the higher consciousness called for by Laszlo (2008) for combating the chronic crises threatening the planet's eco-cultural systems.

Multiple Research Paradigms

Critique of single-paradigm post-positivist research was precipitated by proponents of new research paradigms, two of which (interpretivism, criticalism) have become reasonably well-established in science education, whilst the third (postmodernism) is a relative newcomer still trying to establish a foothold.

Paradigm of Interpretivism

The interpretive research paradigm began to shape the thinking of science education researchers in the 1980s (Gallagher 1991). This paradigm is concerned primarily with generating context-based understanding of people's thoughts, beliefs, values and associated social actions. Its social constructivist epistemology foregrounds the researcher's unfolding subjectivity in shaping the process of the inquiry, especially the act of interpretation of the other's meaning perspective. Hallmarks of this paradigm are social constructivist standards of trustworthiness and authenticity (Guba and Lincoln 2005). Trustworthiness standards of credibility, dependability, confirmability and transferability are 'parallel to' the positivist standards of validity and reliability. Authenticity standards regulate the educative relationship between the researcher and his/her co-participants (or stakeholders) and include aspects of empowerment characteristic of the critical paradigm.

Interpretive researchers embrace an open-ended research design process that allows emergent research questions, emergent modes of inquiry and emergent reporting structure. The parallels with complexity scientists investigating emergent realities is quite striking (Horn 2008), leading us to speculate that interpretivist research might actually be scientific, in a post-Newtonian sense! The role of theory is quite different, no longer being entirely a priori, or situated at the front end of the inquiry. Theorising arises throughout the inquiry, the broader significance of which is supported by ongoing literature reviewing. Thus, the challenge for the research advisor is to find a way of resolving the perplexity of graduate research students indoctrinated into a post-positivist ideology as their entrenched objectivist epistemologies are challenged by this alien paradigm.

Culture studies of science education researchers employ interpretive research, especially ethnographic fieldwork methods, to understand the culturally situated nature of participants' beliefs and how they shape and are shaped by their normative social practices. For example, interpretive research has revealed how the everyday practices and communal artefacts of a Nepalese village community, living within a largely non-Western world view, have ethno-mathematics embodied informally and intuitively within them. This cultural knowledge was used to design mathematics curriculum materials for local schools to foster two-way border crossing between Nepali and Western world views (Kathmandu University 2008).

Paradigm of Criticalism

Science education researchers began to embrace the critical paradigm in the 1990s as a source of social values and transformative action (Kincheloe 2008). Central to this paradigm are concerns with social justice, bio-cultural diversity and sustainable ecosystems. Critical researchers employ ideology critique to understand how power imbalances serve as key sources of social injustice within normative social structures, especially how they give rise to and reproduce habituated behaviours of social groups (such as science curriculum writers, science teacher educators).

Critical researchers aspire to going beyond interpretive understanding of the social world to adopt an interventionst role and redress, for example, racial discrimination and climate change through advocacy and other forms of active engagement. One of these is a form of dialogical writing designed to engage the reader in reflecting critically on his or her own complicity in uncritically reproducing normative social values and practices; for educators, Max van Manen (1991) called this engaging the reader in pedagogical thoughtfulness.

Critical researchers strive to generate a professional praxis, that is, a practice aimed at social restructuring, at making a difference by, for example, working with socially and economically disadvantaged communities to foster their heightened social conscience, to develop their intellectual prowess, to enable them to envision a brighter future for their children, to empower them to unify around a heartfelt commitment, to project an articulate critical voice, and to hone strategic political skills in order to gain recognition and additional resources with which to transform their community and, ultimately, the broader society.

Critical science teacher-researchers use critical reflexivity (or critical self-reflective inquiry) as a self-study tool to help decolonise their own professional practices of hegemonic ideologies that serve asymmetric social interests; ideologies such as unabashed scientism and culturally de-contextualised (or 'pure') mathematics which, in industrially developing countries, can serve as vectors of neo-colonialism. Critical teacher-researchers aspire to help create emancipatory learning environments in which all students develop a critical conscience and civic mindedness. These advanced habits of mind enable students to engage in ethical decision-making about the impact on society of developments in science and technology, such as conflicting climate change policies, genetically modified food, human tissue transplantation, and euthanasia. Many graduates of emancipatory learning environments will become teachers of socially responsible science curricula.

Paradigm of Postmodernism

The postmodern paradigm is a recent arrival from the arts – critical literary studies, art and architecture, media studies – and has begun to exert an influence on science education researchers during the past decade (Taylor and Wallace 2007). Postmodernism elicits both fear and favour via its basic principle: 'be suspicious of all grand narratives' (including the 'grand narrative of postmodernism', respond its critics, not without irony). Forged in the fires of literary criticism, postmodernism (including post-structuralism, which metaphorically equates social life with text) has us constantly cocking an eyebrow, doubting the status of all universal knowledge claims – our own and others' – about the factual and moral truths of our empirical and ideational worlds, reminding us that every rational truth claim rests on a particular form of reason and is represented via a particular means of expression, none of which can rightfully claim primacy over others.

On the one hand, conservative science educators fear the 'slippery slopes' of a deconstructive postmodernism, which, by asserting a strong moral relativism, diminishes the long-established universalism of the Western modern world view. On the other hand, critical science educators, especially culture studies researchers, are embracing a constructive form of postmodernism with its central principle of pluralism. The power of constructive postmodernism lies in its opening the door into the multi-hued world of arts-based research (Eisner 2008), providing the transformative researcher access to powerful new logics with which to make new sense of and to act upon their personal experience of a complex and emerging world, and new genres with which to investigate and communicate their heartfelt concerns about the human condition (Luitel and Taylor 2007).

There are many new research logics; here we focus briefly on four. Firstly, dialectical logic allows the transformative researcher to hold contradictions together in creative tension so that, for example, *research as objective probing* (i.e. culture-free, disembodied) and *research as creative subjective envisioning* (i.e. culture-laden, embodied, emergent) can be given equal consideration without one denying the legitimacy of the other, just as the concept of light does not make sense without the concept of darkness (Luitel et al. 2009). In this chapter we signify a dialectical relationship by use of the '|' symbol.

Dialectical logic is often found in the company of metaphorical logic, which promotes open and embodied inquiry for exploring multiple facets of knowledge and knowing (Lakoff and Johnson 1999). Metaphorical logic enables the transformative researcher to engage in multi-schema envisioning, using elastic correspondence between conflicting schemas, in order to capture the complexity of a phenomenon. For example, an inquiry into transformative science teaching might explore the teacher's enactment of contrasting images such as *science as a body of knowledge*, *science as a process of inquiry* and *science as critical literacy* (Willison and Taylor 2006).

Narrative logic promotes thinking grounded in everyday life worlds (David 2006). Storied thinking enables transformative researchers to contextualise their knowledge claims within their personal, professional and cultural contexts (Clandinin and Connelly 1998). Narrative logic cultivates a diachronic vision, a means for conceiving the research process as a chronological evolution of emerging events, research foci and ideas. Diachronic vision helps make events intelligible in relation to what has transpired in the process of inquiry. Poetic logic enables the transformative researcher to experience non-real, envisioned and atypical reality, thereby reaching beyond the horizon of his/her conscious awareness towards the ineffable. Poetic logic can be useful for introducing non-linearity, silence, emergence, melody and meter, thus contributing to a holistic understanding of the world (Leggo 2004).

Amongst a plethora of new research genres we mention five. The first is narrative genres, which are used to speak from a lived, storied perspective bringing contexts, events and people to the textual space, thereby depicting richly the complexity of human experience. Many cultures bring forth storytelling traditions as a means of knowledge generation, depiction and transmission. Transformative researchers can use their natal cultures as a referent for structuring narratives to communicate research outcomes with their primary audience, articulating a dilemma, a moral tale, or a personal-professional story that paints a holistic sense of being and becoming (Cumming 2007).

Poetic genres help represent aesthetic-imaginative aspects of our knowledge claims through meter, rhythm, rhyme and playfulness (Christie 1979). Knowledge embedded in poetic genres evokes emotional, aesthetic, spiritual and interpretive responses. More so, a poetic genre is useful in transformative research to generate multiple, interactive and imaginative views of reality which help researchers to cultivate multi-perspectival envisioning of the issues under study (Glesne 1997). Within Eastern wisdom traditions there is a millennia-old truism that poetic eyes can reach further than the sun's rays.

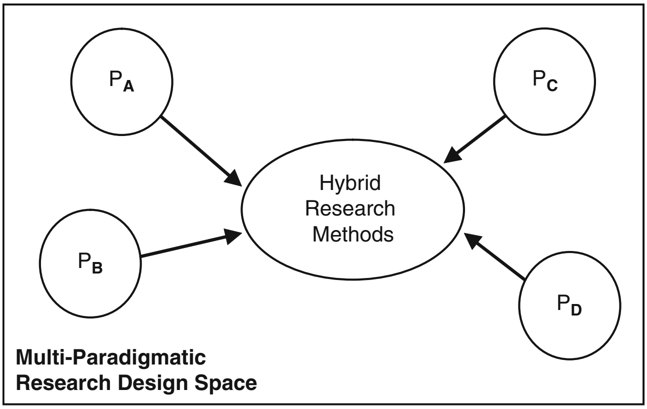
Performative genres such as plays or multi-voiced dialogue are designed to be acted out in professional contexts to stimulate transformative learning amongst an audience. A hallmark of performative research texts is that they are dialogic, embracing openness and uncertainties, thereby providing an interactive space for the audience. Transformative researchers construct performative texts in the form of ethno-dramas and ethno-theatre as means of generating resistance against repressive hegemonies (Saldaña 2005).

Non-linguistic genres – photographs, paintings, cartoons, collage, creative models – can represent knowledge claims otherwise unaccounted for by linguistic genres (Sullivan 2008). Transformative researchers use photographs and paintings to represent particulars, peculiarities and extraordinariness otherwise neglected in the mediative process of linguistic textuality. Cultivation of visual imagination can bring clarity to the articulation of knowledge claims, and can be achieved by juxtaposing linguistic and non-linguistic genres to foster pedagogical thoughtfulness in the reader/viewer (van Manen 1991).

Multi-paradigmatic Research

Thus, a new era of 'paradigmatic and methodological pluralism' (Paul and Marfo 2001) has emerged to create the necessary scholarly conditions for transformative research to flourish. Transformative research draws on the alternative research paradigms outlined above, particularly their new logics and genres, to conduct inquiries that are as much transformative of the researcher as they are of the participating other and of the social system in which self and other are embedded. Transformative research is a multi-paradigmatic approach as and for professional development of science educators: *as* a means of becoming change agents who wish to transform the policies, structures and processes of the teaching and learning of science, and *for* the purpose of ensuring that science (and technology) contribute to sustainable development, particularly of eco-cultural systems worldwide.

In the single-paradigm research design space considered earlier, post-positivism constitutes an ontological and epistemological framework within which students design their research methodologies. Methods of data collection (or data generation) introduced from beyond the borders of this framework are assimilated within this onto-epistemic space in accordance with the restrictive logics and genre of the post-positivist paradigm.



However, in the multi-paradigmatic research design space, it is essential to preserve the espistemic integrity of research methods drawn from various paradigms, and thus the pluralistic concept of referent (Tobin and Tippins 1993) replaces the restrictive concept of framework. The diagram represents a multi-paradigmatic research design space in which multiple paradigms (P_A, P_B, P_C…) serve as referential systems of knowledge production. The transformative researcher draws upon these paradigms, weaving together a hybridity of research methods with which to address complex research problems associated with the demands of their professional practice. Of primary importance is the need to ensure that appropriate standards of legitimation (i.e. quality standards or epistemic warrants) are used to regulate and justify different types of knowledge produced by the inquiry.

Culture studies researchers are currently working within multi-paradigmatic research design spaces, drawing on interpretive, critical and postmodern paradigms to create powerful hybrid research methods such as *critical auto|ethnographic inquiry*.

In critical auto|ethnographic inquiry, the autobiographical 'self' is set in dialectical tension against the ethnographic 'other', the researcher investigating critically his or her own cultural situatedness from the unique standpoint of both a cultural insider and border crosser, excavating the way in which his or her professional identity has been shaped (distorted) historically by hegemonic cultural, social, political and economic imperatives (Taylor and Settelmaier 2003). The autobiographical impulse directs excavation of the researcher's multiple life worlds by means of a variety of logics – metaphoric, dialectical, narrative – and seeks expression in a variety of genres – ethnodrama, poetry, imagery, dialogue, screenplay. Science and mathematics educators have reported successful critical and soulful auto|ethnographic studies of their own professional practices (Pereira et al. 2005).

In its many nuanced forms (evocative, soulful, critical), auto|ethnography has emerged as an exemplar of a hybrid research method for transformative research. Critical auto|ethnography enables culture studies researchers to explore their culturally embedded identities, to excavate and portray multi-hued accounts of their lived experiences, to generate critical reflexivity with which to deconstruct the hegemonic grip of their cultural history, to envisage with optimism, passion and commitment a culturally diverse and inclusive world, and to engage their readers in moments of pedagogical thoughtfulness.

Doctoral research completed by Mozambican science educators Emilia Afonso (2007) and Alberto Cupane (2008) combined post-colonial theorising and critical auto|ethnographic methods to develop professional philosophies of culturally inclusive teaching for Mozambique. As they examined their hybrid cultural identities (in colonial and post-colonial times) they generated auto|biographical memoirs, poems, stories, performance texts and images with which to explore and represent: (1) their lived experience as tribal indigenes who had since childhood crossed cultural borders into various hybrid spaces, especially the colonial space of Portuguese language and customs; (2) the mixed outcomes of their earlier professional struggles to render science education culturally diverse and inclusive; and (3) their vision as culture workers intent on transforming the professional practices of future generations of Mozambican school science teachers (Afonso and Taylor 2009). Thus, multi-paradigmatic research empowered Emilia and Cupane to transform their professional practices in accordance with a shared vision of creating culturally inclusive school science classroom environments wherein tribal children throughout

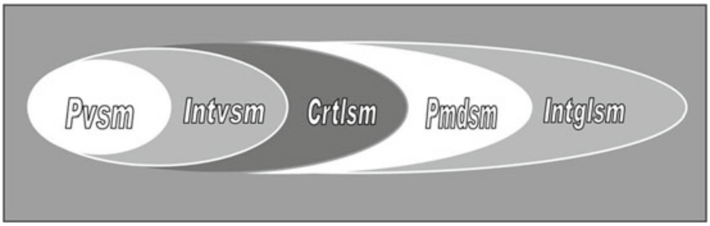
Mozambique can harness their cultural capital, especially their indigenous knowledge systems, and develop hybrid cultural identities with which to reconcile the tension involved in belonging simultaneously to pre-modern, modern and postmodern worlds.

An Integral Perspective

Thus far, our account of transformative educational research, which has drawn on multiple paradigms (interpretivist, criticalist, postmodernist) has all but excluded positive consideration of the positivist paradigm. In rejecting its hegemony and being critical of its restrictive methods, however, we do not intend to reject this paradigm because we recognise that it has great value for particular purposes. We turn to integral philosophy for an inclusive meta-theory of multi-paradigmatic educational research, utilising some of the new logics of the postmodern paradigm and its central principle of pluralism. In the process we propose an integral paradigm, which, we believe, is currently emerging from the postmodern paradigm, offering as yet largely unrealised ways of knowing for science educators to help address the global crises of the twenty-first century.

Integral philosophy – 'integral' meaning to integrate, to bring together, to join, to link, to embrace – can be regarded as a holistic philosophical referent characterised by the notion that it is not the individual mind that is celebrated but integral connectivity (Gergen and Gergen 2000). In the West, there is a common belief that if two opposites cannot be united, we try to either control or eliminate the oppositional pole of the bifurcation. An alternative strategy to this antagonistic Cartesian dualism is integration through dialectical logic: we attempt to transform both poles of a contradictory set of metaphors into a higher set of understandings where a higher level of synthesis is yet another departure point of further dialectic seeking (Slattery 1995). Integral philosophy uses dialectics to integrate dialectical systems by realising that all elements are interrelated and are reflections of an underlying unity. Applied to research, the dialectics of integralism allow for paradigmatic pluralism and for unity-in-diversity (Pallas 2001).

A key contribution of integral philosophy is that it helps us to understand the multiple research paradigms of the social sciences not as independent entities vying for legitimacy by pitting themselves against each other but as integral parts of a developing hierarchical system, each part (paradigm) building on its predecessor and giving rise to the next part (paradigm), and so on. What is distinctive about this system is the interdependence of the paradigms, best understood as the ongoing emergence of part–whole relationships in which each successive paradigm both transcends and includes its predecessor. It was the integral philosopher Ken Wilber (2000) who developed this theory of paradigm development. He drew on Arthur Koestler's (1976) view of naturally occurring hierarchies (called 'holarchies') in which each part (or 'holon') is itself whole and simultaneously a part of some other whole. The following diagram illustrates a holarchy of paradigms, with each paradigm emerging from (and including) earlier paradigms (from left to right) thereby creating a multi-paradigmatic system of knowledge production for social science research. This open-ended developmental process is driven by ongoing critical reflexive awareness of the inherent limitation of each paradigm to resolve significant social issues, leading temporarily to a state of chaos (a Kuhnian revolution) out of which emerges a more highly organised (or transformed) pattern of consciousness (i.e. a new paradigm) which can defuse earlier problems but which itself has inherent limitations, and so on.



The integral perspective, embodied in the integral paradigm, not only recognises the interconnectedness of multiple paradigms but also the 'moments of truth' in each of these distinctive knowledge production modes – each paradigm produces valuable knowledge – and accordingly it rejects attempts to privilege any single paradigmatic way of knowing. Thus, from an integral perspective, each way of knowing offers important but different and thus partial truths about the world, and all ways of knowing are equally legitimate and important. An integral perspective is not syncretism, where we would try to blend and homogenise differences into a whole. Pluralism respects differences residing across the variety of traditions without reconciling or integrating them. Unity-in-diversity and epistemological pluralism as proposed by an integral philosophy suggest that we have to learn to live with the ambiguity of difference which is a '…courageous practice, and engagement with the fact of diversity in our world' (Simmer-Brown 1994, p. 101). And is this not what Laszlo (2008) is calling for when he asks us to embrace a multidimensional world view of multiple interconnected realities in order to develop a synergistic global civilisation capable of cooperating to solve the planet's eco-cultural crises?

Cautionary Note

There is, however, a crucially important challenge for the transformative educational researcher who embraces the integral paradigm and attempts to integrate positivist research methods into the hybrid mix of methods drawn from other paradigms. History warns us that the long-established hegemony of the post-positivist paradigm lurks not out there somewhere (such as in research methods textbooks) but within the subconscious mind of most of us, for that is the legacy of our earlier science education, and that it will likely re-emerge to seize the methodology of the unwary researcher. Graduate research students are a primary target for post-positivism's subtle reassertion of its right to reify social reality and objectify understanding. Usually, the first sign is loss of authorial voice and sudden certainty about foretelling the long-term outcome of the inquiry. The antidote is for the transformative researcher to keep in touch with all of the epistemologies underpinning the inquiry (perhaps making wall charts of them). Criticalism will alert us to maintain a critical reflexive awareness of the power and scope of post-positivism's epistemological ideology, and to keep monitoring whose political interests are being served by the unfolding inquiry. Interpretivism will alert us to ensure that there is plenty of room for emergence of new research questions, new methods and new theorising, especially progressive development of our own subjectivity, and to keep making the familiar strange. But it is not only data collection and analysis methods of post-positivism that are a problem in this regard, its hypothetico-deductive logic and impersonal genre are especially worrying because they exert a subtly powerfully hold on our thinking. And thus we need also to remain mindful of the type of logic we are employing and to consciously allow plenty of space for exercising alternative logics and for allowing the constant process of writing narratively (and poetically, etc.) to actually constitute our unfolding inquiry (Richardson 2000). And once we have established these important habits of mind we can safely and profitably make use of the unique research tools that post-positivism has to offer. In this way incommensurable paradigms can become compatible and coexist peacefully (Watkins 1970).

Chapter 27
Teaching While Still Learning to Teach: Beginning Science Teachers' Views, Experiences, and Classroom Practices

Julie A. Bianchini

Sharon Feiman-Nemser (2001) described learning to teach as a lifelong process – as a continuum stretching from preservice teacher education, through induction, to participation in professional teacher communities. Beginning teachers, she continued, find themselves in the unique and difficult position of teaching while still learning to teach. Further, Julie Luft (2007) argued "that the induction years encompass a vital phase of science teacher development…. Beginning teachers are different from their preservice and in-service counterparts and deserve some undivided attention" by researchers and professional developers (p. 532). In response to these kinds of descriptions of teacher learning, science education researchers have begun to conduct more studies of beginning teachers so as to better understand the substance and structure of these initial years in the profession. The purpose of this chapter is to highlight what we have learned about the views, experiences, and classroom practices of beginning science teachers and to identify what avenues are in need of further investigation.

To begin, it is important to note that science education researchers do not share a singular definition of beginning, new, or early-career science teachers. I defined science teachers in their induction years – or beginning science teachers – as those employed during their first 3 years in the profession. I included those enrolled in internship or alternative certification programs if teaching full-time or part-time. I also included beginning elementary teachers – both generalists and science education specialists – when the subject matter under discussion was science. This definition of beginning science teachers differs in a number of ways from that offered by Elizabeth Davis et al. (2006): They included as new both preservice and early-career teachers, and defined early-career teachers as those in their first 5, rather than 3, years of practice.

What Do We Know About Beginning Science Teachers?

Because the last *International Handbook of Science Education* was published in 1998, research discussed here spans 1998 to 2010. A pervasive theme across these more recent studies of beginning science teachers is that learning to teach is a complex and demanding task. Challenges beginning science teachers face range from interrogating their own deeply held beliefs about teaching and learning, to filling gaps in their knowledge of students, science content, and instructional strategies, to overcoming inadequate support and resources in the schools in which they work. As a result of these and other challenges, Richard Ingersoll (2003) found that 29% of beginning teachers in the USA, including those in science, leave the profession after only 3 years. Although US science and mathematics teachers do not leave their jobs at higher rates than teachers in other disciplines, they are more likely to cite job dissatisfaction as their reason for leaving.

Research Bridging Teacher Education and Classroom Practice

Research on beginning science teachers is thought necessary both to improve the education of preservice teachers and to enhance the professional development opportunities for practicing teachers once in schools. Davis et al. (2006) argued that "if teacher educators [including induction professionals] do not understand their learners' needs, then their instructional approaches will be hit-or-miss" (p. 608). Dan Liston et al. (2006) emphasized that the identification of both quality teacher education and induction programs matters: Beginning teachers from quality programs manage personal and professional challenges more adeptly. Further, research is emerging but insufficient to determine the kinds of preservice education that is useful for learning to teach once in an induction context (Wang et al. 2008).

A pressing concern shared by teacher educators, induction professionals, and researchers is how better to support beginning science teachers in enacting reform-minded practices learned in teacher education. Definitions of reform-minded practices vary from student-centered, to constructivist, to conceptual change, to inquiry. Lucy Avraamidou and Carla Zembal-Saul (2005) provided a best-case scenario for learning to teach science as inquiry. They documented how a first-year elementary teacher, Jean, taught science as inquiry in ways that aligned with the goals and practices of both her teacher education program and the *National Science Education Standards* (National Research Council 1996). Jean was typical of a beginning elementary teacher in terms of her age and gender, but atypical in regards the depth of her university science coursework and the quality of her teaching internship. Researchers found Jean adeptly taught science as argument and explanation to her fifth-grade students. She provided students with rich and varied opportunities to give priority to evidence: to collect evidence, record and represent evidence, and construct evidence-based explanations.

Such success stories – however reform-minded practices are defined – are relatively rare in the beginning science teacher literature. More common are studies that document both connections and fractures between preservice education and classroom practice. Thomas Koballa et al. (2005), for example, constructed case studies of three beginning science teachers enrolled in an alternative certification program. They found that only one of these three teachers held views and practices aligned with the goals and instruction of the teacher education program – to teach science in ways that privileged the changing of students' science-related understanding. Similarly, Julie Bianchini et al. (2003) investigated three first-year science teachers' efforts to teach in contemporary and equitable ways. The three were graduates of the same fifth-year teacher education program in Southern California. Each teacher held some views and practices consistent with the goals of teacher education, for example, introducing students to the thought processes and investigative practices of science using open-ended investigations and/or projects. However, each struggled with ways to demonstrate the socially embedded nature of science, to incorporate the knowledge and practices of indigenous cultures, and to highlight connections between science and everyday life. Finally, Winnie So and David Watkins (2005) followed nine beginning teachers from their preservice experiences at one Hong Kong university through their first year of teaching science in elementary grades. They defined teacher thinking along four dimensions: conceptions of teaching and learning, planning, teaching practices, and reflection. As participants moved from preservice education to the classroom, they became more constructivist in their conceptions and practices, and were better able to reflect on their teaching. However, they also became more simplistic in their planning and less coherent across thinking dimensions.

Studies discussed above followed beginning science teachers from their teacher education program through their first year of classroom teaching; much rarer is research that documents beginning teachers' experiences across several years in the teaching profession. Because science teachers' views and practices are thought to evolve over years rather than mere months, such longitudinal studies are all the more important if we are to improve both teacher education and professional development opportunities. Deborah Trumbull (1999) followed six secondary biology teachers from the same US teacher education program through their first 3 years in the classroom. She examined their conceptions of learning, of biology, and of the nature of scientific inquiry. She found that most beginning teacher participants initially lacked subject matter knowledge and struggled to implement their planned lessons; over time, however, their understanding of science and of effective ways to promote student learning grew. In their third year of full-time teaching, most also became more reflective of their practice and critical of how they and others taught students.

Strengths and Weaknesses of Induction Programs

Researchers have also studied induction programs and how these early-career professional development opportunities shape beginning science teachers' views, experiences, and practices. Edward Britton and Senta Raizen (2003) provided one of the few descriptions of induction support received by beginning science and mathematics teachers outside the USA. They found France, Japan, New Zealand, Switzerland, and China exhibited a strong commitment to support beginning teachers and to help address their unique needs. Beginning teachers in New Zealand, for example, participated in a comprehensive induction program to promote early-career learning: to learn how to plan and implement lessons, assess student understanding, work with parents, and reflect on their practice. At their school sites, they were assigned an experienced mentor, participated in peer support meetings facilitated by a school induction coordinator, and sought the advice of a buddy teacher. In addition, New Zealand beginning teachers were given lighter teaching loads and less challenging classes.

In the USA, induction programs are available to some, but not all, beginning science teachers. Thomas Smith and Richard Ingersoll (2004) found that 8 of 10 beginning teachers in the USA participated in a formal induction program. In response to No Child Left Behind legislation and national standards movements, in recent years, such programs have shifted emphasis from concerns about socialization and emotional support to ways to promote teaching and learning consistent with standards (Wang et al. 2008). For beginning science teachers, science-specific induction programs appear more effective in promoting implementation of student-centered, inquiry-oriented instruction than general induction programs or no formal induction support (Luft et al. 2003).

From careful examination of the internal workings of an induction program, Gillian Roehrig and Julie Luft (2006) (see also Luft and Patterson 2002; Luft et al. 2003) found beginning science teachers' preservice training influenced both the kinds of support they derived from an induction program and the ways they taught science in classrooms. Beginning teachers from a teacher education program with strong methods courses and extended student teaching experiences held more student-centered beliefs and implemented more reform-minded practices than beginning teachers from other kinds of teacher education routes. This subset of beginning teachers also used their induction program for philosophical support rather than to expand and enhance their instructional repertoire. Roehrig and Luft cautioned, however, that their study did not shed light on ways school context shaped beginning teachers' learning during induction.

Julie Bianchini and Mary Brenner (2010) investigated both the influence of teacher education and of current school context on beginning teachers' induction experiences. These researchers followed two beginning teachers (one in science and one in mathematics) from different teacher education programs through a 2-year, K–12 induction experience. They focused their investigation on the teaching and learning of equitable instructional practices; they defined such practices as attention to students' experiences, instruction for English learners, differentiation, and reform-minded science or mathematics strategies. Researchers found that previous teacher education experiences and current school communities proved more powerful forces in shaping the ways in which beginning teachers taught science or mathematics to all students than did the induction program under study.

Missing from these and other accounts of beginning science teachers' induction experiences are rich descriptions of students and their learning. Researchers discussed above did not trace the influence of an induction program through changes in beginning science teachers' practices to effects on student learning. Indeed, Jian Wang et al. (2008) found no studies of induction programs did so – in science or in any other discipline.

Beginning Teachers in the Classroom: How School Context and Individual Agency Matter

A third major area of beginning science teacher research examines beginning science teachers in the classroom. Such studies can be divided into two groups: those that examine the influence of school context on beginning teachers and those that investigate the internal workings of teachers themselves. J. Randy McGinnis et al. (2004), for example, investigated the influence of school culture on the instructional practices of five beginning mathematics and science teacher specialists. These five beginning elementary and middle school teachers were expected to teach in reform-minded ways: to teach science for understanding, make connections between science and mathematics, use technology, and implement alternative assessments. Beginning teachers who thought school colleagues supported their efforts to enact reform flourished. In contrast, beginning teachers who worked in less supportive school cultures responded to institutional demands, affordances, and constraints in one of three ways: resistance, moving on to a new school, or exiting from the teaching profession.

Hugh Munby et al. (2000) went one step further in their examination of school context: They studied how school culture shaped not only a beginning science teacher's practices, but her development of professional knowledge as well. These researchers defined professional knowledge as including both practical and research-based competencies. Such professional knowledge, they continued, develops through a process of reframing a problematic situation to identify a new instructional solution. Researchers found that school science (science taught as a predictable process of uncovering new facts within a stable framework) constrained the ways this beginning teacher taught science, the kinds of problems she identified in her instruction, and thus, what she was able to learn from her own teaching practices.

Studies of beginning science teachers' internal workings – their self-efficacy, identity, and knowledge and beliefs – are more common than those of school context. A number of researchers have examined beginning science teachers' self-efficacy (Andersen et al. 2004; Mulholland and Wallace 2001). Ian Ginns and James Watters (1999) also investigated the relationship between beginning elementary teachers' self-efficacy beliefs and their efforts to implement a science program informed by constructivist views of learning. They found self-efficacy beliefs did not fully account for these beginning teachers' decisions to implement constructivist lessons; they noted the need to examine other factors such as volition, motivation to teach science, and the experiences of success. Along similar lines, Ken Appleton and Ian Kindt (1999) argued for the importance of attending to beginning teachers' sense of self-as-teacher. They studied nine elementary teachers who had graduated with high marks in their science education courses from one teacher education program in Australia. One of four factors found to shape their teaching of science was self-confidence. Researchers suggested beginning teachers' teaching of science might be related to positive or negative self-images of themselves as teachers.

Several other researchers (Proweller and Mitchener 2004; Varelas et al. 2005) have studied beginning science teachers' development of personal and/or professional identities. Maria Varelas et al. (2005), for example, explored how beginning science teachers' identities as practitioners of science and practitioners of science teaching were shaped by participation in a science research apprenticeship experience. Researchers found differences in beginning teachers' scientists and science teacher identities. They argued that the concept of hybridity allows such differences to be seen as opportunities for teachers to build bridges between their experiences in their lab and in their classroom to eventually challenge and reshape both kinds of practices.

Finally, beginning science teachers' beliefs and knowledge have also been investigated. Patricia Simmons and colleagues (Simmons et al. 1999) identified matches and mismatches between beliefs and classroom practices. Researchers found that many more first-year science teachers espoused student-centered beliefs than enacted student-centered practices. By their third year, many beginning teachers exhibited both teacher-centered beliefs and practices. In their study, Brenda Gustafson et al. (2002) examined the effects of a limited mentoring experience on the development of professional knowledge in 13 beginning elementary science teachers in Canada. Researchers found visits to and conversations with experienced teachers enhanced beginning teachers' general pedagogical knowledge; to a lesser extent, their curriculum knowledge; and to an even lesser extent, their subject matter knowledge, pedagogical content knowledge, and knowledge of learners. Rather than investigate beginning science teachers' beliefs or knowledge, Barbara Crawford (2007) chose to look at views. She defined knowledge as being empirically based, rational, and highly structured; beliefs, as subjective, connected to emotions, and embodying personal experiences. The use of the word views, she argued, highlights the interplay between a teacher's knowledge and his or her beliefs.

Possible Directions for Future Research

In the above discussion of existing research on beginning science teachers, two possible avenues for future study emerged. First, more studies that follow beginning science teachers from preservice teacher education through several years – rather than 1 year – of classroom practice are needed. Second, missing from the research literature are studies that trace mis/connections across induction training, beginning teachers' classroom practices, and student learning. Below, I describe in greater detail these and other possible avenues for strengthening research on beginning science teachers.

Theories of Beginning Teacher Learning

One way to strengthen research on beginning science teachers is to foreground the theory of teacher learning framing the study. Careful selection and explicit use of a theory of teacher learning should help researchers better align research purposes to methods used, findings presented, and/or implications identified. Liston et al. (2006) outlined four different frameworks researchers have used to investigate teacher learning. A stage theory of teacher learning describes teaching as beginning with survival during the first few months and ending with mastery achieved some time in the fourth year. Stage theories have been criticized, however, for presenting learning to teach as a linear process impervious to the influences of school contexts. A second, more recent framework presents teacher learning as adaptive expertise: Such expertise is conceived as existing along the two dimensions of efficiency and innovation. Progressive differentiation, a third framework, outlines five levels of knowledge drawn on by teachers as they learn. Finally, learning to teach can be conceived as a continuum where the central learning tasks for preservice, beginning, and experienced teachers differ. Such a continuum underscores that learning to teach takes place in different contexts with different supports. Indeed, such a continuum (Feiman-Nemser 2001) was used to introduce this chapter on beginning science teacher research.

In the science education literature on beginning teachers, explicit use of any of these four frameworks for learning is rare. More common are general theories of learning, for example, learning as socially constructed or culturally situated. In a recent study I conducted with a colleague (see Bianchini and Cavazos 2007), we described beginning teacher learning as both social and situated. More specifically, we employed Marilyn Cochran-Smith and Susan Lytle's (1999) definition of teacher learning as a process of generating knowledge of practice and identified three interconnected sets of opportunities beginning science teachers could use to learn to teach toward equity: from students, from inquiry into their own practice, and from teacher learning communities. This description of teacher learning emphasized learning as a means to improve teachers' own work and to eliminate school and societal inequities. It aligned well with the purpose of the study: to identify if and how beginning science teachers promoted equity and diversity in their own classrooms. It also provided the organizational structure for the study's findings.

A better sense of the kinds of insights generated from coherence across a theory of teacher learning, research purposes, and, in this case, research methods can be found in a study by Paul Adams and Gerald Krockover (1999). Their study was framed by George Kelly's (1955) personal construct theory of learning: This theory describes how recalled memories shape current teaching constructs. Their purpose was to help one biology teacher, Bill, enhance his implementation of constructivist teaching practices, such as the negotiation of key ideas with students, student-generated investigations, and multiple forms of assessment. To do so, researchers collected data using a constructivist-based observation instrument. Researchers asked: In what ways might this observation instrument stimulate recall of constructivist teaching practices advocated in Bill's teacher education experiences? How might these recalled experiences impact his teaching of reform-minded science? Teacher education programs, the authors concluded, must provide support and transition activities during the first critical years of teaching to help beginning teachers bridge the journey from a traditional student of science to a constructivist science teacher.

Varying the Grain Size of Studies

A second possible way to strengthen research on beginning science teachers is to more regularly vary the grain size of studies – to increase the number of participants included, diversify the kinds of teacher education routes examined, and/or lengthen the time the study is conducted. Most research discussed in this chapter presents qualitative case studies of one to several beginning teachers from the same teacher education program. These kinds of studies have an obvious strength: Researchers can clearly articulate mis/connections across the teacher education setting and beginning teachers' views and practices. Because the structure, goals, and experiences in one teacher education program can be thoroughly and comprehensively documented, researchers can ascertain how to better support beginning teachers both within and once outside their teacher education experiences. Limitations to these kinds of studies are also obvious. It is difficult to generalize the experiences of a few beginning teachers to many, for example. It is also impossible to compare and contrast the strengths and limitations of different approaches to the education of preservice or beginning teachers.

One way to vary the grain size of studies was already discussed above: following beginning science teachers across more than 1 year of classroom practice. A second possibility would be to increase the number of beginning science teachers selected for study. Annemarie Andersen et al. (2004) provide a rare example of a study with a large number of beginning science teacher participants: They administered three rounds of surveys to 39 (the initial sample size was 66) first-year elementary teachers in Denmark. Participants were graduates of the same teacher education program and had specialized in science. The researchers' purpose was to better understand how school context interacts with self-efficacy to affect the quality of science teaching. A study conducted by Gili Marbach and J. Randy McGinnis (2008) is a second exception: They surveyed 31 reform-prepared elementary and middle school science teachers from the Maryland Collaborative Teacher Preparation program to determine to what extent views and practices were maintained once teaching full-time in classrooms. The two researchers argued that more studies with larger numbers of participants are needed to understand if and how beliefs and practices introduced in teacher education are maintained and/or enacted once in the classroom.

Similarly, researchers might more often investigate beginning teachers from different teacher education institutions or induction programs. Roehrig and Luft (2006), discussed above, included beginning teacher participants from four different teacher education programs in their study of a science-specific induction program. They found a beginning teacher's teacher education program influenced both her/his implementation of reform-minded practices and the kinds of support derived from the induction experience. Simmons et al. (1999), also discussed above, included both a large sample size – 69 beginning science and mathematics teachers – and diverse teacher education programs – a total of nine – in their 3-year study. Unlike Roehrig and Luft, however, Simmons and colleagues did not separately examine beginning teachers from different teacher education programs.

What Is Missing? Connecting Beginning Teachers' Views and Practices to Student Learning

As stated above, at present, there are no studies of induction programs that include examination of student learning. Further, none of the studies of beginning science teachers discussed in this chapter examined mis/connections between beginning science teachers' views and practices and their influence on student learning. Examination of student learning appears a crucial but missing link in the literature on beginning science teachers. A few studies of beginning teachers do highlight the importance of attending to students without directly studying them. Helen Meyer (2004), for example, examined how teachers understand the concept of student prior knowledge and make instructional decisions based upon this understanding. She compared preservice and first-year interns' conceptions of learners' prior knowledge to those of expert teachers. What was unexpected was novice teachers' lack of strategies for finding out their students' prior knowledge. Novice teachers defined prior knowledge as learned science content, used activities to elicit what facts students knew, and then attempted to add on more information. Expert teachers, in contrast, focused on their students: They defined students' prior knowledge more broadly, intentionally designed activities that had students explain their prior knowledge, and then worked with their students' ideas by shifting between science content and life experiences.

Amira Proweller and Carole Mitchener (2004) used the theoretical lenses of race, ethnicity, and social class to explore relationships between beginning science teachers and their urban middle school students. As teachers discovered the diversity of experiences among their students, they found themselves rethinking the assumptions about who urban youth are and the kinds of lives that they lead that they had brought with them into the classroom. Beginning teachers came to understand that forging relationships with urban youth depended on learning about students' families and communities. They also discovered that science needed to be taught in personally relevant and socially contextualized ways to create powerful learning opportunities for students – opportunities for students to better understand themselves, others, and the world around them.

To repeat, student learning appears a crucial but missing piece of research on beginning science teachers. Because beginning science teachers are both teaching and learning to teach, it seems somewhat ironic that their students' learning of science does not figure more prominently in studies of their views, experiences, and practices. Ultimately, it matters little how successful a teacher education or induction program is in aligning beginning teachers' views and practices to the goals of science education reform if student interest in and understanding of science is not enhanced.

Chapter 28
Developing Science Teacher Educators' Pedagogy of Teacher Education

Amanda Berry and John Loughran

Science teacher education has been characterized as a technical-rational approach whereby science teacher educators deliver knowledge about teaching to prospective teachers in the form of theories and/or 'activities that work' (Appleton and Kindt 1999, p. 164). Underlying this approach is an assumption that knowledge about science teaching can be translated directly into practice and that prospective science teachers' professional knowledge can be developed independent of their experiences of teaching (Russell and Martin 2007). Exacerbating this situation, many prospective science teachers enter their pre-service programmes with strongly held beliefs about the nature of science knowledge as 'unproblematic … [whereby] [s]cientists are regarded as experts whose views have authority conferred on them by the power of the scientific method and its universal applicability' (Bencze and Hodson 1999, p. 522). Therefore, practices related to being a science teacher often carry 'a heavy reliance on didactic teaching styles' and a 'cookbook' approach to investigative work (p. 522) – a consequence of years of experience as learners of science. This situation presents a problem for science teacher educators: How can student teachers be stimulated to think about teaching and learning and science in ways that differ from a system in which they have been successful?

The job of the science teacher educator is complex. There is a need to challenge the image of teacher as technician in expanding prospective teachers' views of teaching (Clark and Lampert 1986). There is also a need to respond to the ongoing calls for science teacher education reform in ways that will positively impact the needs, concerns, beliefs and expectations of students. Doing so requires a sharper focus on the knowledge of teaching about science teaching and learning, that is, developing richer understandings of a pedagogy of teacher education (Korthagen 2001).

This chapter takes up the challenge to science teacher educators to pursue relevant, meaningful and applicable research so that learning about teaching science informs and enhances the experiences for all participants in the processes and practices of teacher education (Loughran 2007b).

Self-study

Self-study of teacher education practices (S-STEP) emerged partly in response to ongoing calls for teacher education reform and the hopes of teacher educators to be integral to such reform. Self-study is about teacher educators researching their teaching about teaching and their students' learning about teaching. With its genesis in action research, reflective practice and teacher research self-study grew and developed in ways that dramatically extended these fields through a teacher education context.

Despite the natural attraction of self-study, it is important that self-study goes beyond the self to genuinely impact on the work of teacher educators more widely. Through self-study, teacher educator practitioner research accounts of the dilemmas, issues and concerns germane to teaching *and* learning about teaching need to be available for public critique and scrutiny but need to inform knowledge of practice. This is critical to shaping what happens, how and why, in the work of other teacher educators and teacher education programmes.

It is this need for self-study to be more than 'just another story' (Loughran 2007a, p. 14) that matters to many self-study researchers (e.g. Berry 2007; Brandenburg 2008) and has been important in maintaining scholarly expectations in the self-study community. At the heart of self-study is an ongoing push for teacher educators to take seriously what they do, how and why, in their teaching of teaching so that their student teachers might become purposeful and professional educators. The expectation being that student teachers will understand teaching as problematic and feel comfortable working with the uncertainties of practice as they develop and extend their expertise in accord with that modelled by their teacher educators.

The development of knowledge is clearly important if there is to be progress in teaching and learning about science teaching. One aspect of knowledge development that self-study encourages is a teacher-as-learner stance and, many of the learning outcomes from research into such things as alternative conceptions (Pfundt and Duit 2000), prior views (Gunstone 1990) and engagement in science learning (Millar 2006) have been important in directing the focus of some science teacher educators' inquiries into their own practices.

Some self-study researchers have actively sought to examine the processes and practices of science teaching and learning in their own teacher education classrooms in an attempt to address the stereotype of school science teaching as the simple transmission of facts (Goodrum et al. 2001). This chapter offers an overview of some of this research as it is enacted in a pedagogy of teacher education (Russell and Loughran 2007) as developed through the work of science teacher educators who have adopted a self-study methodology.

Elementary Science Teacher Education

A feature of some self-study projects is related to the need for teacher educators to pay attention to their students in ways that offer insights into their own practice. This approach to learning about teaching has consequences as Cynthia Nicol (1997, 2006) discovered because there is a need to differentiate between 'listening for' and 'listening to' students, that is, 'listening for' those things that are only on the teacher's agenda in contrast to 'listening to' that which students say or imply (Nicol 1997, p. 112).

Azza Sharkawy confronted what it meant to really listen to her students in her early experiences of teaching elementary science methods classes. With a critical friend (an important aspect for many self-studies) she examined this experience.

> Listening non-defensively in a way that invites self-critique is difficult work. It is, after all, possible to identify tensions in teacher education without using them to inspire deep reflection and reframing that can help to work more effectively with the tensions. Recognizing the complexity of teaching and learning reinforces the fact that professional development and growth are processes that require time and systematic effort. (Sharkawy and Russell 2008, p. 290)

As the following studies demonstrate, listening, seeking critique on one's own practice and learning from those experiences demands a lot from a teacher educator. Self-study encourages listening in ways that can help teacher educators understand and respond appropriately to their learners' perspectives.

Teacher Educators Learning from Their Students

Andréa Mueller (2004) was drawn into self-study for reasons similar to those of many other elementary science teacher educators. As a beginning teacher educator, the experience of her first year teaching teachers highlighted for her that she needed to better connect with her students so she developed ways of accessing their reflection. As a consequence, she began to learn about her teaching of elementary science to her student teachers through their experiences and through their reflective accounts of those experiences. Through collaboration with a critical friend, she learnt to reconsider and refine her teaching of teaching in five specific ways. These included:

- Changing the design of her major reflective practice assignment
- Changing the nature of her responses to student teachers
- Taking more time for discussion in class

- Being explicit in classes about what she did as a teacher educator
- Allowing herself to make changes as the need arose

Her desire to better understand how to help her student teachers learn about teaching *and* learning science was the catalyst for her involvement in a study that impacted her practice. By examining her students' reflective accounts as data, not just as university assignments/tasks, she saw her own practice anew. This led her to reconceptualise her 'own teaching as problematic and [to] share this knowledge with preservice teachers and colleagues [which further helped] change [her] practice' (p. 151).

Focusing on student teachers' reflective accounts is a theme that is taken up by a number of beginning teacher educators. Brenda Capobianco wanted to learn about her students' experiences of her attempts to implement technology into her elementary science teaching programme, based on an inquiry-based approach (Capobianco and Lehman 2006). She found that 'as pre-service teachers make decisions about their own teaching, experience it, and reflect upon it in the context of their preparation programme, they are better able to construct educational understandings that are similar to those espoused by the teacher educators' (p. 143). As a novice science teacher educator she decided to share her personal reflections with her student teachers, which helped her begin to 'conceptualise the relationship between the modelling of reflective practice and its development in, and use by, preservice science teachers' (p. 290).

In a similar vein, Garry Hoban (1997), an experienced teacher educator, was also concerned to better understand his elementary science student teachers' learning about teaching in his classes. He adopted a much more personally confronting approach in his self-study. He sought direct and honest feedback from his student teachers about their experiences of learning science in his classes.

Aware that elementary science teachers are commonly uncomfortable in science practical classes because of their perceptions about their own lack of science content knowledge, Hoban asked his student teachers to use 'a journal to critique [his] teaching each week by recording and reflecting on their positive and negative learning experiences during the practical class[es]' that he organised and ran for them (p. 135). Hoban soon realised that there was much more to learn from inquiring into his teaching than he had previously anticipated. His learning was twofold: what his students learnt in terms of science content through class instruction; and, how they learnt that content, that is, their meta-cognitive processes in monitoring and analysing their own learning.

Hoban developed new ways of teaching about elementary science teaching and felt that he made certain breakthroughs around student teachers' perceptions of theory and practice. He was taken by the fact that through critiques of his own teaching, his student teachers came to better understand the 'complexity of learning and inappropriateness of "recipe" teaching approaches' (p. 146); something that the literature continually demonstrates is a paradox for the majority of student teachers and a source of frustration to many teacher educators. Through a focus on metacognition, some of his student teachers were able to move beyond the mental block they had developed towards science despite their negative attitudes about the subject from their previous schooling experiences.

Attitudes Towards Science Curriculum

Gilda Segal developed a three-part gender-inclusive learning and teaching model (Segal 1999) for 'alienated elementary teacher education students' (p. 24). She studied how both she and her students learnt about the science of refrigeration. The programme redesign included working from her students' prior views, stimulating them to embark on scientific enquiry and supporting their learning through cooperative group work. Her eyes were opened to many aspects of science teaching and learning that she might otherwise have overlooked had she only concentrated on the curriculum package itself.

Segal became 'much more sensitive to the nuances of how to entice students to make an initial plunge into contexts they might not find attractive' (p. 20). She found that the necessary equipment to conduct a practical enquiry can itself be a barrier to student engagement in the content and, in terms of pedagogy, that 'once students took their first tentative steps towards a context that held no initial attraction for them, [she] learned how slowly [she] should advance' (p. 20). There was also a reminder that relationships matter, including those between the learner and the science context and an ongoing need to address anxieties borne of previous science learning experiences.

Carol Mitchener (2000) also drew attention to the relationship between the learner and science content. She did this by seeing two aspects of the relationship simultaneously. One was that of the teacher–student relationship so common to thoughtful pedagogy; the other was the relationship between teaching and that which a learner makes with the content itself. Mitchener came to 'more fully recognize and feel the depth of [her] commitment to helping children develop a relationship with science, and not just knowing [science]' (p. 186) and this became a touchstone to her role as an elementary science teacher educator.

Integration: Taking Science Learning from Pre-service into Schools

Sandra Blenkinsop and Penelope Bailey (1996) confronted the concept of subject integration in their self-study. They were interested in challenging their students' initial 'foggy impressions of integration' (p. 224) in order to help them develop richer understandings of the ways in which 'various types of reading and writing could be used in the process of scientific inquiry' (p. 224). Not surprisingly, they found that, for many of their students, there was a washing out effect when they moved out into their school practicum internships; especially for those who did not have a strong commitment to 'hands-on inquiry science' (p. 224).

Their study led them to realise the importance of helping their students see that teaching reading and writing within the context of science is not a just an add-on or fun activity, but a central aspect of science teaching for meaningful science learning.

Similarly, Sandy Schuck and Gilda Segal (2002) became aware of the fading effect of their innovative pre-service teaching when they conducted a collaborative research project with their graduates. Their study highlighted a number of issues that impacted not only their understanding of beginning teaching, but also the manner in which they needed to reconsider what they did, how and why, in their teacher preparation programme:

> … most of the beginning teachers had embraced our socio-cultural views of teaching mathematics and science, and were keen to put into practice their beliefs about how mathematics and science should be taught. However, we observed some large barriers to the reforms. … tension between school realities and beginning teacher ideals often created a great deal of frustration for the new teachers … major difficulties that the beginning teachers mentioned related to school contexts with which we had not dealt explicitly in our subjects. These difficulties included specific dilemmas in classroom management, the requirement to teach from another teacher's program, and a lack of time for science teaching and hence little increase in expertise and self-confidence in science teaching. (p. 93)

Learning with and from elementary teachers was also a theme in the examination of students' science learning interests through the School Museum Integrated Learning Experiences in Science Project (Pressick-Kilborn et al. 2006). Again, understanding the self and how that self is shaped by previous teaching and learning experiences stood out as important. In particular, and in accord with Schuck and Segal above, self-confidence and independence are crucial to fostering teaching that supports learner-centred approaches to science.

These accounts of researching practice demonstrate that there is a clear need for science teacher educators to experience and understand learning about science teaching *and* learning in ways that challenge their existing taken-for-granted assumptions about practice. Science teacher educators' learning appears to impact not only the way they teach their student teachers but also the way their student teachers think about their own teaching of science to their students. That is an important outcome that creates a genuine challenge to the status quo in elementary science teacher education. What it means in secondary teacher preparation programmes is explored in the next section of this chapter.

High School Science Teacher Education

Science teacher educators are often drawn to self-study through the dilemmas and challenges they face in understanding and managing the relationship between their students' learning to teach science and their own efforts in supporting that learning.

Many science teacher educators are themselves former science teachers, so their transition from teacher to teacher educator often highlights that their experiences of teaching science is, in itself, insufficient as a basis for a pedagogy of science teacher education. Teaching about science teaching is different from classroom science teaching, and knowing what to do and how to do it is far from clear or straightforward.

Shawn Bullock (2009), a newly appointed physics teacher educator, found his transition experiences more challenging than he anticipated as his identity as a physics teacher did not serve him in the way that he had hoped. While Bullock believed in the importance of providing opportunities for learners to develop and trust their own voice, he found that this was not so easy for him to live as a teacher educator as student teachers wanted him to tell them what he knew about teaching physics. While initially he felt an urge to fulfil their need to be told, he learnt how to enact an alternative approach that was more consistent with his beliefs. Through recognising particular aspects of his teacher educator behaviour, Bullock drew parallels between his experiences of classroom teaching and teacher education that helped to better inform his developing pedagogy of teacher education.

> There was an awkward moment in class today when one of my teacher candidates, who is working toward certification as a science teacher, asked me what I thought about doing a lab at the end of every week over the course of a unit. Her logic was that students would 'get more' out of the lab if she was sure that they clearly understood the concepts beforehand. …. I was horrified when I realized that I wanted to plainly disagree with her. I wanted to tell her the 'right' answer. (Personal Journal, September 2006)
>
> Fortunately, I was able to hold my tongue and suggest that she try a variety of approaches to teaching laboratories over the practicum. I was surprised at how much I wanted to tell someone how to teach. The experiences reminded me of how I struggled with the differences between telling students about physics and teaching students about physics early in my career. That moment in class helped to frame my future learning as a teacher educator. (p. 296)

As a beginning science teacher educator, Rebecca Cooper learnt that even though she was prepared to share her considerable expertise as a science teacher with her student teachers, they did not take on board her ideas in the ways she anticipated. Simply telling them what she knew did not impact their practice. As a consequence of her self-study (Cooper and Keast 2008), she came to realise that her interpretations of her student teachers' needs was different from the needs they expressed for themselves: 'I had to be willing to engage in discussion that began from where my students were at rather than from my own needs as an experienced teacher' (p. 80).

Peter Chin (1997) pursued deeper understandings of his practice as a chemistry teacher educator through articulating his core beliefs and investigating how these beliefs played out in his practice. He learnt that student teachers needed to have opportunities to experience and make sense of what he sought to help them understand, but that just providing such opportunities was not enough. He came to recognise that student teachers also needed to experience some dissatisfaction with their current ways of thinking for them to consider, or try out, the alternative approaches to teaching that he was promoting.

> Even if pre-service teachers recognise the intelligibility, plausibility and potential fruitfulness of the teaching approaches I advocate in the science methods course, my efforts are fruitless unless they are personally dissatisfied with some facets of their current conception of teaching. (p. 122)

In many ways, Chin was developing a pedagogical stance that was based around the need for his own practice to model a constructivist approach. He concluded, 'learning about teaching best occurs through shared experiences and critical discussions' (p. 123), a view that stands in stark contrast to more traditional science teacher education approaches that are commonly reported as comprising the status quo. Facilitating a constructivist perspective is then one way of challenging the existing position.

Facilitating a Constructivist Perspective

A dominant theme across science teacher educators' self-studies is a concern to incorporate a constructivist perspective into their teaching about science teaching. This is typically developed through an emphasis on promoting opportunities for student teachers to experience self-directed learning and problem solving in order to promote 'a more authentic view of science and scientific practice' (Bencze and Hodson 1999, p. 521). In this way, science teacher educators hope to encourage their student teachers to learn about their students' experiences of grasping the science content, and as a consequence, to organise experiences in their own classrooms to help their students develop other and better ways of understanding the content (Trumbull 2004).

Karen Goodnough (2003), a teacher educator responsible for the preparation of middle and high school science teachers, sought 'to foster, in [pre-service science] students, an inquiry-based approach to teaching by modelling constructivist approaches in [her]… own teaching' (p. 18). She explored the use of problem-based learning (PBL) as an instructional approach in her science methods class in order to provide her students with opportunities to construct richer understandings of science concepts through specific science problem scenarios.

Through developing their understanding of the nature and use of PBL by experiencing it, Goodnough anticipated that it might help her student teachers make stronger links between science content and pedagogy, and in the process develop student teachers' (and her own) pedagogical content knowledge (PCK). As a consequence of her self-study, Goodnough found that her knowledge base for teaching about PBL changed, but not in the way she had expected. She came to learn more about how she organised the experiences of learning through PBL, and what she did or did not do, to enhance student teachers' learning opportunities:

> In retrospect, I should have started with one small problem before introducing several in my course. When I collaborate with teachers, I always tell them to start small when trying something new. I did not heed my own advice. (p. 3)

Embarking on a self-study helped her to see differences between what she advocated for others and what she did in her own practice. This is an important realisation that is central to facilitating change in a teacher educator's practice.

Peter Aubusson (2006) also used a project based teaching approach similar to PBL with his pre-service secondary science teachers as a means of modelling more authentic approaches to science learning. In order to help his student teachers examine their experiences of this open-ended approach, Aubusson modelled the use of metaphor and analogy as a tool for analysing and communicating their thinking along the way. He encouraged class members to share and comment on each other's analogies and metaphors, including his own.

Although familiar with the use of metaphor and analogy as a means of 'inform[ing] personal analysis of ideas about teaching' (p. 102), he was taken aback by his students' responses to his metaphors. This experience led him to view aspects of the teaching/learning relationship as problematic in ways that he had not previously recognised or considered. Although he had not expected to be the learner himself, it was he who most benefited from the chosen approach.

> I had entered into the task lightly; being familiar with metaphor use, the modelling did not seem threatening. Strangely as a researcher I was aware that metaphorical analysis serves to reveal the unknown but as a teacher I had not anticipated that it might reveal things that I did not already realise. (p. 107)

Through genuinely engaging in the learning experience with his students, Aubusson's understanding of the problematic nature of engaging in an inquiry approach was greatly enhanced.

Deborah Trumbull (2006) used a reflective approach to teaching her student teachers about the uncertainties and complexities of science teaching. Through sharing entries from her teaching journal with her pre-service maths and science teachers, Trumbull intended to model 'the kinds of attitudes of a reflective teacher' (p. 68) and provide insights into 'what engaged [her], as a teacher and as a person' (p. 68). She hoped that her student teachers might be stimulated to think more deeply about what engaged them as teachers through offering access to her thinking about teaching processes.

Her self-study evolved over several years and involved a systematic exploration of student teachers' responses to her journal. Her data revealed a surprising finding: her student teachers did not comment on her reflections about her science content knowledge. Through her self-study, she came to realise that if she wanted student teachers to engage in discussions of science content with her (and each other) then she needed to develop more purposeful ways of inviting them to do so. Her insights led her to: be more directed in the selection of reflections to share with her students; be more explicit about what she asked her students to comment on with regard to her reflections; and provide opportunities to make reflection a shared, public activity rather than something private and individual.

These studies illustrate how some science teacher educators have come to a position whereby their need to articulate what they are doing, how and why matters not only for the development of knowledge about science teacher education, but also because of the underlying value of doing so for enhancing the science education experience of student teachers. Articulation of practice and purpose is at the heart of a pedagogy of teacher education.

Articulating a Pedagogy of Teacher Education

Tom Russell, an experienced physics teacher educator, was concerned to understand how to make his knowledge of teaching physics more accessible to his student teachers in ways that could prompt them to reconsider their views of physics and physics teaching (Russell 1997). He recognised that many student teachers entered their teacher preparation programmes with traditional views of teaching as telling; where physics teachers were holders of 'the right answers' (Russell and Martin 2007, p. 1173), and physics teaching was concerned with the delivery of facts.

Russell modified his physics methods programme, using teaching approaches such as Predict-Observe-Explain (White and Gunstone 1992), which were consistent with his ideas of actively engaging students in constructing their understanding of physics concepts. As a consequence of his self-study he came to recognise the powerful influence of the way he taught, compared with what he taught in his physics method classroom: '*How* [author italics] we teach must be a major focal point for all who are concerned with teaching and learning science and how individuals learn to teach science' (Russell and Martin 2007, p. 1173). Based on analysis of his journal entries as well as feedback from students and colleagues, Russell was able to articulate the frames that guided his practice, and to reframe understandings of practice as his experiences in the physics methods classroom led him to understand his practice differently. Across the range of self-studies he has published, there is an ongoing focus on his learning as a consequence of exploring his own and his students' understandings of learning to teach physics in ways that inform and shape his practice in the physics methods classroom. In so doing he actively develops and articulates a pedagogy of teacher education.

John Loughran was also concerned with challenging traditional approaches to science teaching as the transmission of propositional knowledge. He sought to offer 'alternative experiences of being engaged in science' (Loughran 1997, p. 57) to his student teachers. By '[p]lacing student teachers in a genuine learning about teaching context … us[ing] [his] own learning about a concept to drive [his] teaching about teaching – [he] actively consider[ed] (and reconsider[ed]) how [he] learn[t] and came to understand content knowledge - so that it directly influence[d] how [he taught] that content knowledge' (p. 66). This experience led him to see the need to be able to articulate his principles of practice based around the themes of: relationships (trust, independence); purpose (engagement/challenge); and, modelling (reflection, risk taking) – themes that resonate with many of the studies reviewed in this chapter.

Loughran's own involvement as a learner in teacher education significantly impacted his understanding of the teaching/learning relationship. He came to recognise the value for learners of science teaching (including himself) to experience the teaching procedures being advocated in order to more deeply understand their potential for learning particular science content (learning through modelling). For instance, through developing and participating in a role play with his students about the relative movements of the earth and its moon, Loughran experienced the powerful effect of making the abstract concrete (a problem commonly experienced in science teaching) and that there is so much more to role play than simply playing a role (a problem in the use of this procedure in science teaching):

> Suddenly I got what it meant to be involved in a role-play. Suddenly I saw a number of important pedagogical insights. Suddenly content matter started to take new shape as a developing understanding slowly emerged. Suddenly, our class became alive with learning; and I was part of it. … After the class I mused over the episode again. …[W]hat I knew – or thought I knew – before the experience was dramatically different to what I knew after the experience. Being involved in the experience was different to directing it for others. Abstracting the learning from this experience to other situations was intellectually challenging and engaging. What I saw in my students' approach to learning about teaching was new and different. What I began to see in teaching about teaching was a revelation. What I previously knew, I now understood. (Loughran 2006, p. 26)

An important aspect of this development of a pedagogy of teacher education is in the dual role of teacher and learner and how that plays out in the way student teachers learn about science teaching. Teacher education is then a context in which teacher educators and student teachers together can begin to examine some of the assumptions and problems of practice and to begin to think more deeply about what that means for quality in the teaching *and* learning of science. This point is developed further through Amanda Berry's research.

As a biology teacher educator, Berry identified a set of seven tensions regularly experienced by teacher educators as they learn to recognise and manage differences between their needs and concerns as teacher educators and those of their student teachers (Berry 2007). For example, one of these tensions, resonating through the studies reported in this chapter, is that of 'telling and growth' (p. 45): the competing feelings experienced by teacher educators of wanting to tell their student teachers about teaching through the transfer of experience or propositional knowledge, and providing opportunities for student teachers to grow through self-directed experience and personally constructed knowledge.

Berry's extensive self-study, conducted over 1 year with her biology methods classes, drew on data from colleagues, students and her own reflections about her teaching and her students' learning from these classes. Conceptualising her practice as tensions to be managed, she was able to recognise fundamental differences between the concerns of teacher educators to develop student teachers' understandings of practice, and student teachers' personal concerns (at least initially), to satisfy their need to know about technical aspects of practice. As a consequence of being able to articulate her understandings of her practice in this way, Berry was able to recognise and effectively build on a pedagogy of teacher education.

While many of the self-studies reported by science teacher educators concern their experience in their university context, a small number of self-studies have been conducted by science teacher educators returning to teach in schools.

Experienced Science Teacher Educators Return to the Classroom

Jeff Northfield (Loughran and Northfield 1996) returned to the classroom after 20 years as a teacher educator, and undertook a year-long examination of his teaching with a class of year 7 (first year of high school in Australia) students. With the support of a critical friend, he analysed his experiences of his teaching and his students' learning in science and mathematics, as a means of trying to better understand and inform his, and others', teacher education approaches. However, as he quickly discovered, simply doing teaching in a different context is not the same as learning about teaching and so he came to question some of the underlying assumptions about the mantra of recent and relevant school teaching experience:

> … the connection between school experience and improvement in teacher education is not clear. Although we would argue that greater opportunities should exist for teacher educators to work in schools and classrooms, the experience alone is not sufficient. Certain conditions for learning about teaching and teacher education need to be established to make the effort worthwhile. (p. x)

Northfield's experiences were important in shaping how he came to reconceptualise and articulate his teaching as derived from his learning about teaching in a school context. This learning through experience was also evident in the work of Russell who similarly chose to return to high school science teaching to inform his pedagogy of teacher education.

Tom Russell returned to the high school physics classroom after a long absence in order to better understand what his physics method students were learning to do and to test his abilities against the current realities of physics teaching (Russell 1995). Like Northfield, Russell also 'made [him]self a data source for [his] continuing study of teachers' development of professional knowledge' (p. 95). He came to recognise that his '[r]eal professional learning' emerged as a consequence of 'the intense often chaotic experiences of the first year' (p. 107). As a consequence of his experiences he came to recognise anew the importance of listening to his own voice and learning from experience.

Both Russell and Northfield experienced their first year (back) in school as chaotic and intense, and that dramatically informed what they did, how and why with their student teachers in their university-based teacher education programmes. Russell went on to a second year of high school teaching and found that his learning really began to flourish as he was able to analyse his experiences more effectively; all of which he found enhanced his teaching of science teaching. Northfield pursued his professional knowledge development through a deep and rigorous analysis of his data with a colleague that led to a book about his experience. Importantly, both Russell and Northfield learnt that 'learning about teaching cannot be conducted alone' (Loughran and Northfield 1996, p. 139).

A major learning outcome from both of these studies is in the importance of articulating knowledge of practice – regardless of the setting. For Northfield, the change in teaching context dramatically highlighted: 'the types of tacit knowledge that teachers develop as part of their teaching role … [These] tacit experiences must be made explicit if we are to consider alternative frames of reference that may lead to a deeper understanding of teaching and learning' (p. 140).

Making the tacit explicit, building the knowledge of science teaching and learning practices in ways that are accessible and useable by teacher educators and their student teachers is fundamental to a pedagogy of teacher education and is a meaningful response to the calls for science teacher education reform.

Conclusion

Research on the development of science teacher educators' pedagogy of teacher education is a relatively new and growing field. The studies reviewed in this chapter illustrate that the development of understanding of teaching and learning about science teaching is an individual and evolutionary process that tends to focus on teacher educators examining the ways in which their beliefs and values might (or might not) be enacted in their practice. At the same time, while this work is often deeply personal and context bound, it is also a 'big-picture enterprise' (Russell 2007, p. 190) as the knowledge of teaching and learning about science teaching that is developed is articulated and portrayed in ways that seek to impact the work of others.

In our view, developing a pedagogy of science teacher education requires educators to be awake to, and aware of, the complex and problematic nature of science and of teaching, as well as having a preparedness to create and engage in experiences that enable genuine learning to take place for all participants in the learning to teach process. In this way, possibilities for developing and enacting approaches to science teaching that can seriously challenge taken-for-granted models can be encouraged to develop so that real alternatives for learning that is meaningful and applicable in school science will emerge.

Chapter 29
Using Video in Science Teacher Education: An Analysis of the Utilization of Video-Based Media by Teacher Educators and Researchers

Sonya N. Martin and Christina Siry

There is an increasing trend toward incorporating video[1] and multimedia into teacher education for both K—12 pre- and in-service teachers of science. Our purpose in this review chapter is to examine the trends involving video usage in science teacher education and science education research that we have noted in the literature, both recent directions as well as early uses of video. We begin by tracing some developments in video technologies and exploring examples of the ways in which video/multimedia have been utilized in the education of science teachers. We also focus on some of the web-based technologies and software that enable educational researchers and teacher participants to edit video content (both from their own classrooms and others) and then author and share their analyses of the video with a larger teacher or educational research community. We note a growing emphasis in science teacher education toward having preservice and in-service teachers developing electronic portfolios, including video vignettes of teacher practice with reflections as evidence for development as critical practitioners. We conclude by offering implications and raising questions for future research on the utilization of video and multimedia technologies in the preparation and professional development of science teachers.

[1] In our discussion of video, we use the term video in reference to recorded images and sound. When we make a distinction between videotape and digital video, it is to denote the method used to store and access recorded images and sound.

Video Technologies and Teacher Education

Over the last 50 years, technologies for recording, storing, and showing video have become more affordable, portable, and accessible for general consumers as well as educators. Currently, digital video cameras no larger than a box of crayons can be purchased for about US$100 (e.g. FlipVideo http://ca.theflip.com/), which record 60–120 min of video that can be transferred immediately via a USB connection to a computer for instant digital editing and analysis. The availability of such inexpensive videography equipment for the everyday consumer is rapidly changing the ways in which people interact with video in their lives, especially through image, video, blog, or social network hosting/sharing sites such as Flickr, YouTube, Blogger, MySpace, and Ning. However, the implementation of new technologies in science teacher education often trails behind technology use in the consumer market. This lag-time between when new equipment, software programs, and applications of media become available and when these technologies are introduced into K—12 classrooms can be attributed to policies that make access in K—12 schools complicated and also because of a considerable lack of professional development for current and future teachers on how to integrate technology in the classroom.

In a historical overview spanning nearly 40 years, Miriam Sherin (2004) argues that major advances in video implementation in teacher education programs have been driven by both technological innovations and prevailing theoretical frameworks in teacher education. Sherin cites the evolution of learning theories from primarily behaviorist models where teaching was viewed as a "well-defined activity consisting of a set of skills to be practiced and learned," to the growth of cognitive psychology models of learning to teach where "researchers and teacher educators began to focus more on the ways in which teachers *think* rather than the ways in which teachers *behave*" (p. 5). As a result of these theoretical shifts, Sherin notes that teaching began to be seen as a more complex activity, from which emerged the utilization of video to help novice teachers develop practical teaching knowledge by observing and analyzing the actions of veteran teachers. Early video use focused on reviewing episodes of microteaching or analyzing/coding of teacher actions in video (e.g., via the Flanders (1970) method) to identify, discuss, and emulate specific teaching actions characterized as behavioral aspects of classroom teaching practices. Notable among early research using video for strategy analysis was Russell Yeany's (1977, 1978) training of preservice science teachers to analyze and code videos of science teaching using observational guides to help new teachers gain awareness of different classroom teaching practices. Following this training, teachers would engage in peer-teaching of a science lesson that was designed to model some of the same practices identified via the strategy analysis training. These lessons were videotaped so that the teachers could self-analyze their lesson using the same strategy analysis techniques to determine how faithfully they had implemented the observed teaching practices.

This early approach to teacher training was grounded, as Sherin (2004) observed, in a behaviorist model of learning to teaching where students acquired specific skills to implement in classrooms. Behaviorist theories of learning tended to see teaching as a set of knowledge and practices that can be acquired and directly transferred to any classroom. Such theoretical perspectives were quite common in teacher education during the 1970s, as teaching was seen as a set of behaviors to be learned. Yeany's work on strategy analysis heavily influenced some of the early studies involving video as a means for modeling certain teaching strategies, such as student-centered activities, and became an impetus for other studies using video to examine the relationship between science teaching strategies and student engagement and achievement. For example, Linda DeTure (1979) employed video to analyze interaction patterns between teachers and students in science classrooms, and in particular she used video to capture classroom interactions and then used these data in her work as a teacher educator. DeTure's use of video as an ethnographic tool for capturing and analyzing classroom interactions was relatively novel in itself; however, she then re-purposed the video to model for preservice teachers the strategy of extending the "wait-time" after teachers ask questions of students before responding to, or calling on students to respond, as a way to promote increased dialogue among students.

In the 1980s, researchers began to use video not only as a means to conduct classroom research, but also to produce video cases to model teaching strategies for preservice teachers. Several researchers in the late 1970s and early 1980s were active in developing video cases of science teaching, which were shared with prospective teachers as a means to engage them in controlled teaching experiences where they analyzed video and teacher narratives in an effort to reflect on their own beliefs about science teaching. In the sections to follow, we expand on these ideas and trace the development of the ways in which video and multimedia are currently being utilized in science teacher education. In the next section, we detail the organization of our analytic process and describe our approach to examining the literature on video in teacher education.

A Layered Approach to Analysis

What we have learned and describe in this chapter emanates from an extensive review in which we conducted an interpretive, comparative analysis of the literature around general uses of video/multimedia in teacher education (Martin and Siry 2008). Given that our own research involves the creation and analysis of primary source video in K—12 science classes, the evidence we have collected results from a multimodal inquiry and synthesis of literature in the field of teacher education combined with findings from our own research. We focus our analyses on the science teacher education literature, presenting trends that can be considered in structuring experiences for teachers to interact with video and multimedia as they learn about teaching and learning science at a variety of levels, and we begin by describing how we identified research for the initial review and then present our analysis of the literature.

Literature Review Approach

Stemming from a review of over 100 publications from journals, book chapters, and books, we categorized and analyzed the different ways in which video has been utilized, in an attempt to characterize the uses and reported efficacy of video in teacher education. Our analysis included sources focused on video and multimedia usage in preservice and in-service education as well as for research purposes. In this chapter, we are considering both the use of video as well as multimedia programs that generally include video clips as one part of the media component. We use both terms within the chapter, but attempt to distinguish for the reader how video is utilized in each context. In our discussion of video, we use the term video in reference to recorded images and sound. When we make a distinction between videotape and digital video, it is to denote the method used to store and access recorded images and sound. Initially we conducted several levels of analyses of these literature to describe differences in the intended purpose of video implementation, and the targeted audience for the video usage. From the first level of analysis, we developed six categories of video implementation, including (1) video cases, (2) hypermedia/multimedia presentations of video, (3) video for self/individual analysis, (4) tools/programs for analyzing video, (5) video utilized in electronic portfolios, and (6) conferencing facilitated by virtual/video interaction.

Once we categorized the literature according to usage, a second level of analysis demonstrated that video has been utilized in teacher education programs for a variety of purposes. We identified four main reasons, including: (1) to demonstrate "best practices" of specific teaching strategies, (2) to document growth or development in teaching and learning practices as an evaluation of individuals and/or programs, (3) to promote reflective practices, and (4) to record classroom events for educational research. The findings that follow emerged from this categorization and analysis. This synthesis and review is by no means exhaustive of all the research being done in science teacher education with video technology, but is meant to provide readers with a historic overview of seminal earlier works, as well as an understanding of the emerging and innovative research using video in the field of science teacher education. The implications we outline provide suggestions as to the ways in which video and multimedia can be utilized by science teacher educators and researchers.

Video Implementation and Uses

Video Cases

Teacher educators often tout case methodology as a powerful tool for creating a bridge between theory and practice. The literature offers many instances of studies and descriptions of programs where teacher educators use pedagogical dilemmas, both in the form of written case as well as video case studies. Video cases take a variety of forms, including commercially made video as well as cases created by science teacher educators to represent what they consider to be exemplars of teaching and learning situations. Case method instruction offers pre- and in-service teachers with models of how to approach pedagogical dilemmas and is thought to help bring the complexities of classroom activities into focus by allowing teachers to connect the theories being discussed at the university with real-life scenarios from K—12 classrooms. Also of great importance, case methodology is cited as a cost-effective and logistical solution for circumventing issues related to field experiences – either not having time in program schedules for extended field placements or not having suitable placements for preservice teachers to experience classrooms where teachers enact "best practices." Although some researchers have raised questions about the efficacy of case methods (e.g., Copeland and Decker 1996 for a critical examination of video/case study), proponents of case methodology laud the potential to support the development of teachers to become reflective practitioners and be able to analyze classroom interactions effectively and develop decision-making skills.

Most of the research on case studies in teacher education has focused on the use of text-based cases (e.g., Koballa and Tippins 2004, for examples of analyses of text-based cases designed to promote reflection on learning to teach science). In addition to these text-based cases, there is currently a growing body of work using video and multimedia to develop case studies. James Watters and Carmel Diezmann's (2007) research provides a good example of how video cases are used with preservice teachers to depict teachers and students engaged in various science activities. Enriched by a suite of multimedia resources, Watters and Diezmann created video cases depicting teachers and students engaged in various science activities. Designed to "make visible" the pedagogical practices and assumptions of teachers and the actions of students, these cases were shown to teachers who were then asked to reflect upon the cases and real classroom interactions and consider how these experiences inform their own teaching. As a frame for promoting discussions among teachers as they analyze and reflect on the classrooms depicted in the video, many studies invoke the work of Donald Schön (1987). In their study, Watters and Diezmann noted the need to situate teacher learning in "real" contexts, citing Lee Shulman's (1992) research on the importance of providing preservice teachers with "images of the possible" and a need to support in-service teachers to develop pedagogical content knowledge to improve their science teaching.

Case studies have clearly become the primary use of video for many education programs, and this seems especially true in the areas of K—12 math and science teacher education. Researchers using video cases in science teacher preparation often cite the lack of classrooms that incorporate inquiry-based science teaching (e.g., Yung et al. 2007) and note that video case studies provide authentic examples of classroom practice that become accessible to wider audiences. Videos of classrooms can be broad based, as with the Third International Mathematics and Science Study (TIMSS), and its follow-up study (TIMSS-R), providing an opportunity to examine classrooms across the 41 countries that participated. In this sense, teachers can gain a window into classrooms from other cultures, and consider the similarities and differences in the teaching of science and math. Writing about the use of these videos for learning about teaching, James Stigler et al. (2000) present the use of a video survey, which combines video with large-scale probability sampling and suggest that such a hybrid approach provides a support for researchers, as well as an opportunity for incorporating analytic approaches of teaching into professional development.

Sandra Abell, Lynn Bryan, Maria Anderson, and Katherine Cennamo have been pioneers in the use of video cases in science teacher education (e.g., Abell and Cennamo 2004). Abell et al. (1998) suggest that video cases provide prospective teachers with "virtual worlds" within which one can think about science teaching and learning. Abell and her colleagues developed what they termed, "integrated media (videodiscs controlled by hypermedia) cases of elementary science classrooms' which they used in an elementary science teacher education program to promote a reflection orientation in their preservice population. This group designed several structured prompts to promote discussion and reflection among preservice science teachers around a shared experience of viewing the same video vignettes as part of the case studies (e.g., Abell and Cennamo 2004). This early work has been very influential on the work of other researchers as evidenced by the many times the studies have been cited by science teacher educators who use video in courses.

Other examples of uses of video case studies in science teacher preparation include the work of Larry Bencze and his colleagues (2003), who created a set of cases based on video from seven lessons. In this study, the use of video cases led to a contextual understanding of the issues in teaching a science and technology lesson to children, and the authors recommend cases of this type as a way to incorporate authentic science observations into teacher preparation and professional development. More recently, Benny Yung, and his colleagues (2007) conducted a study in which preservice science teachers in Hong Kong were asked to watch the same two videos of exemplary science teaching three times during one academic year. The researchers found that progressive viewing, analysis, and reflection on the same videos over a period of time provided a supportive structure from which to scaffold these novice teachers' evolving understandings of science teaching during their preservice education.

Today, there are many examples of video cases being utilized in teacher education (e.g., see Barnett 2006, for an example of a web-based professional development system for pre- and in-service science and math teachers using video cases to develop an appreciation for and understanding of inquiry-based teaching (http://ilf.crlt.indiana.edu/). In fact, reports on the development and challenges of implementation of video cases were the most common papers we were able to access for our review. Terri Kurz et al. (2004) provide a comprehensive review of challenges associated with creating video cases for preservice science teachers and discuss recommendations for other educators and researchers. Despite reported challenges, video cases have become a critical component of many multimedia resources now available for science teacher education, as we elaborate on in the following section.

Hypermedia/Multimedia Presentations of Video

In the late 1980s, advances in technology allowed digitized video segments to be "hyper" linked to text and graphics which could be accessed on the Internet or using programs, such as HyperCard. The ability to provide *hyper* links to additional materials, such as lesson plans, samples of student work, audio interviews, or photos of classroom activities, all offered teacher educators and researchers a means to provide a richer social context for their video cases of exemplary teaching practice. Due to the hyperlinking of additional materials to one central site, location, or text/image/video, this technology was initially called hypermedia, but is now most commonly referred to as multimedia. While the terms are often used interchangeably in the literature when referring to mixed media applications connected to a central component, we refer to all hyperlinked media as multimedia.

Multimedia technologies are generally more cost-effective to develop than analog videos, offer increased functionality for users, and due to web-accessibility these products can be utilized with a wide audience. As a result of these technological advances, the majority of publications in both the late 1990s and currently, examine the role of video cases within the context of various multimedia resources. Multimedia presentations of video for science teacher education generally include different web-based activities available in classrooms, including scientific visualizations, simulations, virtual reality, animations, video clips or still images, and distributed information sources (Bodzin and Cates 2003). Watters and Diezman (2007) report on the development and use of multimedia materials that demonstrate professional practices and their data support the value of multimedia material for explicitly representing particular parts of practice and providing a shared experience for discussion, debate, and reflection. They suggest that the use of such multimedia can improve the experiences of distance/on-line learners, enhance field experiences by illustrating authentic classroom science teaching for comparison and discussion, and result in an increased willingness among future teachers to adopt technology within their classrooms as a result of positive experiences interacting with technology as a "mind resource" in their own education (p. 369).

The Multimedia in Science & Technology (MUST)-project in the Netherlands combines interactive video linked to comments by teacher educators and prospective teachers, context description, curriculum and lesson plans, and justification for video cases focusing on outdoor activities in science education (Van den Berg et al. 2004). Another example of multimedia resources used in science teacher education includes materials from Knowledge Media Laboratory (KML) of the Carnegie Foundation where users can access a free web-based program called KEEP Toolkit, which enables K—12 teachers to share "snapshots of practice" from their own science classrooms which pre- and in-service teachers can both view. Described as a "living archive of practice," users can then engage in reflective analysis and interactive discourse with one another. Emily Van Zee and Deborah Roberts (2006) describe this project and provide an evaluative discussion as related to science teacher education. The Gallery of Teaching and Learning (http://www.cfkeep.org) provides a venue to view an exhibition of faculty, teacher, and student-developed studies in science and technology education. Reflecting a science teaching and content perspective, the eSTEP and Knowledge Web projects offer a digital library of video linked to a hypertext book. These programs provide pre- and in-service teachers a variety of content developed to offer windows into K—12 science classrooms that engage participants in design experiments structured to develop cognitive theory, sociocultural understandings about classrooms, and science pedagogical content knowledge (Derry et al. 2002).

The development of new software and video-web sharing sites that provide users the ability to edit existing archives of video or to edit and post their own video for discussion within a larger teacher education community is a significant trend to consider. Video annotation tools provide interesting possibilities for enabling individuals to capture and analyze video of personal teaching as well as review, analyze, and synthesize examples of their own teaching for viewing by others. In Peter Rich and Michael Hannafin's (2009) recent review of video annotation tools, they urge educational researchers to consider the potential of utilizing video analysis programs, such as Transana (www.transana.org), DIVER (diver.stanford.edu), and Constellations (orion.njit.edu) not only for their data-mining capabilities, but also as tools for analyzing instructional decision-making processes and participant interactions in classrooms. Additionally, they call for expanded research agendas to examine not only the utility of these tools for promoting reflection practice, but also the impact, effects, and risks associated with using these technologies in educational research. Roy Pea (2006) argues that ethical and legal restrictions preventing researchers from sharing original data sources for reanalysis by other researchers obscures connections between evidence and argument, impedes research, and as such, discourages researchers from utilizing video as data. Noting the proliferation of digital video recording in the contexts of social sciences research and learning technologies, Pea and Robb Lindgren (2008) call for the creation of *video collaboratories*, in which researchers from around the world and in differing disciplines would access virtual repositories with video files and associated metadata to develop a community to share "video data sets, metadata schemes, analysis tools, coding schemes, advice, and other resources, and build video analyses together, to advance the collective understanding of behaviors represented in digital video data" (p. 236).

Advances in video technologies such as these provide unique pathways for the educational community to engage in cutting-edge research on how people learn to teach. We have found that the majority of the information about these innovative projects and sites are not available as publications. That these technologies are available as free access websites expands opportunities for changing the roles and responsibilities of teachers in research. We discuss the issue of autonomous video use by science educators and researchers in greater detail in the following section.

Video Used for Self/Individual Analysis

Proponents of video usage in teacher education often reason that teaching occurs in isolation from peer support, and that sharing video of one's teaching with others offers an opportunity to not only see oneself in the act of teaching, but also provides a convenient "window into a classroom" where others can view and discuss the teaching and learning that has been documented. Video serves as a lasting record, which can be reviewed and analyzed over and over from different perspectives, with different people, and over long periods of time. Advances in technologies have now made it possible for teachers, students, and researchers to not only view video, but to also rewind, fast forward, and advance the video frame by frame to analyze classroom interactions. This can support careful consideration of participant actions and discourse around pedagogy and content, and provides a focus on interactions at the micro level. In this way, the use of video by classroom participants and researchers mediates becoming consciously aware of the unconscious practices that are not generally available to us when social life unfolds in real time. Indeed, watching oneself and other teachers has become common practice in teacher education and promises to become more so as video continues to be an important means of evaluation and instruction in education programs around the world.

The ability to digitize video has contributed to the most significant technological advancement shaping the way in which video is being utilized in education today. Sherin (2004) attributes current developments to the fact that now video can be explored in a nonlinear fashion, no longer restricting users to sequential viewing of recorded actions, but enabling viewers to move through time, rewind actions, and jump to different segments of recorded interactions. We have found that this change in user dynamic has not only influenced the ways in which educators and researchers have implemented video playback in teacher education programs, but that these advances have begun to shape theories of how people learn to teach using these technologies. Indeed, many of the papers published within the last 5 years have begun to consider not only *what* teachers are learning about teaching via multimedia interactions, but also *how* teachers are learning from these experiences. Researchers are beginning to raise both theoretical and methodological questions about how tasks should or could be scaffolded to support learning as users choose to move through these multimedia materials in unstructured, nonlinear pathways. Our review suggests that there is a growing shift away from using predeveloped video cases and supporting multimedia resources in teacher education towards involving teachers in the construction of their own video cases, either by editing pre-captured video of classrooms or by capturing and editing their own teaching for the purpose of critical reflection with others about how to improve science instruction.

Interesting examples of how teacher educators and researchers are introducing the concept of autonomy and videography in teacher education include utilizing programs that enable teachers to annotate, edit, and share video with others for the explicit purpose of constructing meaning from the perspective of the individual, to then be shared with a larger community of educators, both in face-to-face and on-line education courses, teacher-led professional development groups, and for educational research. One example, called *video clubs*, engages in-service teachers and a facilitator (often a university researcher) in regular school-based meetings to watch and discuss excerpts of one another's teaching. Researchers Elizabeth van Es and Miriam Sherin (2008) note that video clubs provide a forum for teachers to effectively discuss pedagogy, content knowledge, and student learning where video plays a pivotal role in providing a shared experience from which teachers frame discussions. Using desktop video editing software (e.g., iMovie), Randy Yerrick et al. (2005) found digital video editing an effective tool for helping promote reflection in preservice elementary science teachers. These researchers found that the cyclical process of engaging students in editing, producing, and sharing personal science teaching vignettes through digital video editing extended participant engagement with their own teaching, helping them to make “mature and insightful shifts in their thinking about science, teaching, and even their own science experiences as children” (p. 369).

Described by Linda Beardsley et al. (2006), VideoPaper is a presentation of text and video side-by-side, where authors annotate digital video and upload still images captured from video (e.g., offprints of facial expressions of students), scanned content (e.g., student work), or other digital images. VideoPaper allows users to choose to read text and play video as originally intended by the author of the content, or select to interact with the raw data (in the form of video, text analysis, etc.) as the reader chooses, without needing to advance through the material in a linear fashion. Used primarily with in-service teachers and in conjunction with educational researchers, VideoPaper is a good example of programs currently being developed and used to provide teachers with opportunities to perform research on their practice by choosing video episodes to (re)construct and (re)present for others in order to share their understanding of the moment (see http://vpb.concord.org/about/ to access VideoPaper Builder).

These are just three examples of some of the ways in which video can support pre- and in-service teachers to consider new aspects of their practice. By providing access to tools that allow for individual and shared editing, viewing, and discussion of classroom events captured on video, teachers and researchers are able to engage in more complex and innovative uses of video technologies to improve teaching and learning. As these technologies continue to evolve, they offer a more cost-efficient means for evaluating teaching practice via greater distances, and thus, reduce the need for on-site teacher supervisors and mentors. Examples of this trend include the utilization of video-mediated communication [VMC] by veteran teachers to supervise/mentor preservice teachers (Ardley 2009) and the utilization of video-enabled, web-based computer-mediated communication [CMC] for supervisors to provide feedback to prospective teachers while engaged in a teaching practicum course (Lee and Wu 2006). More and more districts and teacher education programs are beginning to implement video as a tool for conducting program and individual teacher performance assessments. In the following section, we discuss video in the context of the assessment and evaluation of teachers as well as explore implications for changing practices in educational research.

Video Utilized for Evaluative Analysis

There are a variety of ways that video recordings have been used for evaluative analysis in teacher education. One way is for video to be used by teachers as part of electronic portfolios to document individual growth and development for evaluation purposes. A study that documented the use of web-based portfolios by preservice elementary teachers found that the use of such portfolios supported teachers as they developed their understandings of the ways in which children learn science (Zembal-Sual et al. 2002). In this project, preservice teachers authored hypermedia as they constructed their own portfolios. This was based on the assumptions that a web-based portfolio can place more emphasis on the process of constructing a portfolio, rather than the product itself. Further, the authors suggest that it is a more effective way of documenting the complex nature of teaching and learning. As teachers created "multidimensional and interconnected representations of learning" (p. 289), the research considered the types of representations that teachers included as well as the ways in which the portfolios revealed their understandings of science teaching. This study revealed that the web-based portfolios were successful in supporting critical reflection, enabling preservice teachers to make connections between their course work and children's learning using a nonlinear approach to documenting learning. Furthermore, some states, as well as the National Board Certification program, are now requiring video as evidence of effective teaching to be submitted as part of certification or certificate renewal processes (Park and Oliver 2008).

A less common, but seemingly increasing, use of video in science teacher education is for program evaluation. A current study (Ruggirello and Pitts 2009) situated at the University of Pennsylvania's Science Teachers Institute (Penn STI), explores the ways in which the creation of electronic portfolios, which include videos, provides a medium to promote teacher reflection. It has been reported that through the use of video in e-portfolios, researchers were able to gain insights into participant practices, thus documenting and demonstrating evidence of growth in areas that met the goals of the University's teacher education program and evaluation. In the next section, we take up the issue of video usage in research in science teacher education, providing examples from the literature as well as examples for our own research.

Research

Our work using video in research and science teacher education is what prompted us to review the literature, and our experiences with video provided a lens to interpretation. Our approach to research on learning to teach science involves collaborating with pre- and in-service teachers and students to discuss and analyze shared classroom events as recorded on video. Thus, we use video to capture events in the classroom, and replay this video to reexamine moments in time and analyze classroom interactions. By working directly with teachers and students to examine video, we seek to develop a reflexivity that goes beyond reflecting on past events. In our research, reflexivity implies that participants are reflecting upon what occurred, from their own standpoints, with the explicit intention of considering ways to improve practices moving forward. In this way, video helps us to develop a polysemic approach to understanding teaching and learning.

From an analytic perspective, the uses of video with participants are vast. In addition to simply replaying classroom events (either events at which all were present or not), video can be used in ways that manipulate the perspectives of time. Video can be sped up or slowed down to examine particular features of classroom interactions, and gesture analysis can be added through successive offprints (e.g., see Roth 2005, p. 234, for examples of how to create gesture diagrams and offprints from captured video for empirical analyses). Further, video provides an innovative window from which to examine the role of emotions in the learning of science, and a variety of micro-analytic approaches have been utilized to examine the ways in which emotions mediate the teaching and learning of science. Examples include the analysis of prosodic features of participant voices, facial expressions, gestures, and body language (e.g., see Roth and Tobin 2010 for utilization of video and audio to identify aligned and misaligned prosodic episodes between teachers and students and their effect on conflict and solidarity in an urban science classroom). Consequently, the use of video can be a valuable tool for teachers and researchers as they investigate learning to teach science.

In Jennifer Adams' (2009) collaborative research with preservice urban teachers, participants work together in cogenerative dialogue groups to discuss their student teaching experiences. In the cogenerative dialogue groups they then share selected video vignettes from their host classrooms and co-analyze them during the research meetings. In this way, the preservice teachers, as research participants, have central roles in data collection and analysis. In our own experiences, as in Adams' work, the ability to replay classroom events with varying speeds allows a research group to focus on interactions and to examine moments that may have passed unnoticed in teaching, and provides a forum for individuals to share their classroom experiences with others. We have learned that if teachers are in control of the videoing, have a voice in what gets videoed, and how the video is viewed, edited and interpreted, then the process becomes more transparent, and is less anxiety-ridden.

Thus, collaborative research between teachers and researchers is one way to mediate the anxiety surrounding the use of video. Much of the research we have reviewed indicates that teachers benefit as practitioners and researchers with expanded access to forums where they experience autonomy with regards to the capture, editing, annotation, analysis, and (re)presentation of themselves in video that is used for educational research purposes. Advances in video technologies are expanding the roles that teachers and their students play in research, making it imperative that we recognize and pay attention to ethical concerns associated with classroom research. In the following sections, we begin to address some of these issues and raise questions for teacher educators and researchers to consider.

Challenges of Implementing New Technologies

Simply making technology available, such as placing computers in K—12 classrooms, does not typically enhance or transform classroom instruction, as the technology is likely to be utilized to support existing teaching practices (e.g., replacing "chalk and talk" lectures with PowerPoint enhanced "point and click" lectures). This includes both K—12 classrooms, as well as classrooms in teacher education programs, where research, such as that by Jon Pedersen and Randy Yerrick (2000), has shown implementation of changing video technologies also lags behind the consumer market. Based on results from a broad-scale survey, Pederson and Yerrick found that even while science teacher educators report they use technology themselves and think it is important for teaching science, the majority are not integrating technology into their instruction of future science teachers. Acknowledging the same disconnect in science teacher education and implementation of technology that other researchers have found in K—12 science classrooms, these researchers urge the science teacher education community to address the need to programmatically improve the preparation of future teachers by addressing this disparity of belief and practice in their own courses. Additionally, there have been instances of school policies that limit the technology that could be available to educators, like accessing the vast database available on video sharing sites, such as YouTube, which have been blocked by many public schools in the USA, the UK, and in some states in Australia, all of which cite concerns about inappropriate content on the website. Thus, preservice teachers are often not exposed to implementing innovative uses of video technologies in their preparation at the university level or in the classrooms in which they observe.

One possible reason science teacher educators may not be informing prospective and current science teachers how to implement technology for science instruction is that the publishing process for research papers takes a considerable amount of time, leading to publications about the uses of video technologies in teacher education lagging behind current cutting-edge trends in technology. For example, some of the most widely cited work on the use of video cases with preservice science teachers stems from a project beginning in the late 1980s and early 1990s, involving laserdiscs as the delivery format for viewing video cases of exemplary science teaching in an elementary science methods course (see Abell and Bryan 1997). At the time, this research was cutting edge, but the laserdisc, like VHS tapes and even CD-ROMs, have become virtual dinosaurs in the everyday lives of most students and teachers. In a more recent publication referencing the papers from 1997 and 1998 (Abell and Cennamo 2004), this research group indicated they have transferred the video cases from the laserdisc format to an updated web-based media site, but this work raises important considerations about the timeliness of publication and implementation of these technologies. One of the dilemmas we have found in the literature is that the information published about advances in utilization of video technologies in teacher education is far behind the general consumer's use of video, but the use of video technologies in teacher education is also out of sync with current advances in video technology. With the proliferation of web-based journals, perhaps there will now emerge additional reliable, valued means of disseminating research and information about advances in technology and potential impact on practice, which can be accessed sooner than traditional journal publications.

In addition to the issue of lag-time in new practices and technological advances, the majority of the publications we have analyzed are mostly descriptive in nature, focusing often on the process of developing a video/multimedia product to be used with pre- and in-service teachers or describing the implementation of a product with a sample population of teachers. In other words, while many authors have exciting new uses for video or multimedia, there is not much evidence as to what purposes these tools actually serve toward learning about science teaching. Many of the studies we reviewed, including those more than 30 years old, highlighted the same problem. For example, Fuller and Manning in their *Review of Educational* Research publication from 1973, chided authors for commonly providing descriptive accounts of ways in which they used video in their teaching, evaluation, and supervision, and research without sufficiently explaining theoretical and methodologically sound frameworks for data collection and analysis for the widespread application of video in teacher education (e.g., for extensive review and critique of early literature focused on "confrontation of self" through video playback, see Fuller and Manning, 1973). Thus, while there has been much innovative work done on developing and implementing specific materials, there is a need for researchers to also consider the ways in which people are interacting with video-based media, and to ground their work in theoretically and methodologically sound ways that reflect the researchers' perspectives and foundations.

Implications

Our analysis for this chapter has focused on how video and multimedia have been utilized specifically in the education of science teachers and we have offered examples of some of the contexts in which teacher educators and researchers have implemented these tools in the education of K—12 teachers. We have drawn attention to advances in video and multimedia technologies which continue to offer new potential in the realms of educational research and teacher preparation through the adaptation of video technologies for learning about and improving teaching. We have found a wide range of rationales for using video in teacher education, and found that research studies and professional development efforts utilizing video vary considerably, depending on the ways that video has been adapted for particular instructional or research goals of a specific program or study. In this way, we can be flexible in our uses of video while continuing to expand our understanding of how these technologies inform teaching and learning.

While we have found much literature around the development and implementation of specific video technologies, there is not much that has been published about how these technologies can mediate the teaching and learning of science. We are left with important questions to consider in the field of science teacher education. In particular, we wonder, what role can science teacher educators play in transforming science teaching practices through video technology implementation? Further, we ask, how can/do pre- and in-service teachers use video technologies to reflect upon their own science teaching and science learning experiences?

As more educators introduce video and multimedia resources as teaching tools into their courses and as more programs require electronic portfolios with integrated video analysis, there are implications for what is being asked of teachers and how video/analysis and supporting resources are being used. Additionally, on-line teacher education programs are proliferating as communities become more multimedia savvy and as education programs extend their services to educate teachers in remote areas or those with few resources. The expansion of on-line education options greatly increases educational opportunities for people around the world. While this may be a positive direction for education, it raises many new questions about the role of technology in teacher education. As researchers, we must question how to effectively integrate video/multimedia in these programs to promote teacher reflection and we need to develop new evaluation methods to assess the effectiveness of these new learning technologies. Research also needs to be done to determine how to make these programs more effective given that the future will continue to include many new technological advances in video and other areas, and educators at all levels need to continue to engage in "cutting-edge" research to meet the needs of future teachers and learners.

Chapter 30
Professional Knowledge of Science Teachers

Hans E. Fischer, Andreas Borowski, and Oliver Tepner

Nathaniel Gage (1964) points out that teaching, like all other classroom activities, embraces far too many different kinds of processes, behaviors, or interactions for it to be described by a single theory. Even then he was suggesting that the concept of teaching and learning should be analyzed in the light of teachers' types of activities, educational objectives, and learning theories. Therefore, estimating the quality of a lesson is inseparably combined with teachers' professional activities in the classroom and it can, for example, be controlled by assessing students' learning outcomes at the cognitive and emotional levels. As a consequence, research on teaching and learning at school deals with the question of the quality of instruction from at least three different angles, which include certain perspectives and facets of teachers' personalities, their professional knowledge, and its application under classroom conditions. During the last 40 years, research on the professional knowledge of teachers has been mainly conducted using three paradigms: the teacher personality paradigm; the process-product paradigm; and the expert paradigm. In the following section, these paradigms and their relations to the professional knowledge of teachers are discussed.

Jacob Getzels and Philip Jackson (1970) investigated the extent to which teachers' personalities influence their students' learning outcomes. Personality may be viewed as a dynamic organization of those traits and characteristic patterns of

behavior that are unique to an individual (Callahan 1966). The major features of effective teaching identified by Milton Hildebrand and Robert Wilson (1970) are: (1) clarity of organization, interpretation, and explanation; (2) encouragement of class discussion and the presentation of diverse points of view; (3) stimulation of students' interests, motivation, and thinking; (4) manifestation of attentiveness to and interest in students; and (5), manifestation of enthusiasm. In addition, a large number of different characteristics of teachers' personality were also identified in many studies but these characteristics turned out to be not useful to effective teaching. All the profiles relating to personality turned out to be partly trivial or too complex to investigate, and consistent effects of at least some features of the teacher's personality on students' behaviors, emotions, and learning outcome in classrooms were not found (Bromme 1997).

Following the process-product paradigm, some aspects of teaching and learning have been studied and found to be highly correlated with certain facets of students' performance, interests, and attitudes. More than thirty years ago, Barak Rosenshine (1979) summarized corresponding aspects of the quality of instruction from this perspective using the notion of direct instruction which is taken as a reference in many studies to this day (see also Brophy 2000; Weinert et al. 1989). Rosenshine concludes that most researchers agreed time on task, having explicit goals, organizing lesson content using reasonable units, offering sufficient training opportunities, and controlling students' learning progress, are the main characteristics of quality of instruction. Most of the characteristics of direct instruction are related to the teacher's ability to act under classroom conditions. According to Jacob Cohen (1988), medium effect sizes could be identified in those studies on classroom conditions (Wise and Okey 1983; Fraser et al. 1987). In different but comparable studies, correlations could be found among the mentioned unique features of the quality of instruction by developing more or less elaborated structured models. Thus, Marten Clausen et al. (2003) developed a systematic model of quality of instruction and Andreas Helmke (2003) published a framework called the opportunity-use model, characterizing some aspects of the relations between teaching and learning in a classroom. Recently developed models and approaches to improve the quality of instruction also include features of teachers' professional knowledge as a main element.

As a synthesis of the personality paradigm and the process-product paradigm, Rainer Bromme (2003) proposed analyzing lessons of teachers identified as successful. To describe these teachers' expertise, a model was used by referring to Lee Shulman's (1986, 1987) notion of teachers' professional knowledge. To distinguish between experts and novices, teachers are selected by measuring variables like the students' improvement in learning or the teachers' professional experience (Bromme and Dobslaw 2003). In addition, there are some studies on the correlation of subjective theories, or teachers' beliefs, as they are called today, and teachers' classroom activities (e.g., Peterson et al. 1989; Staub and Stern 2002) without assessing students' learning outcomes. There is also a study on the relation between professional knowledge and students' performance measured with the PISA tests for mathematics but without investigation of classroom activities (Baumert et al. 2010).

Professional Knowledge in General

As mentioned, professional knowledge of teachers, discussed as an essential precondition for successful teaching, is therefore linked to the discussion about teachers' competencies in general and standards for teacher education in particular. Models of professional knowledge have been more or less explicitly included in all attempts to describe the quality of instruction. In parallel with these developments, the standards of teacher education have been developed and summarized, for example, in a report of the AERA Panel on Research and Teacher Education (Cochran-Smith and Zeichner 2005) and in the program of the National Academy of Education (NBPTS; Darling-Hammond and Bransford 2005; Oser and Oelkers 2001), to give perspectives on and to analyze their effectiveness in teacher education. All these proposals are normative and describe a set of competencies considered as general preconditions for good teaching. Walter Herzog (2005) points out that there is only a poor connection between those competencies and theories; that is, the choice of competencies is characterized as open and subject to change. James Calderhead (1996) describes six elements of the teacher planning process: planning occurs differently for different time spans (Shavelson and Stern 1981) and units (Clark and Peterson 1986); planning is mostly informal; planning is creative; planning is based on knowledge of subject matter, classroom activities, children, teaching, school conventions, and so on (Clark and Yinger 1987); planning allows for flexibility; and, planning occurs within a practical and ideological context. The line of the development of a theory on teachers' professional knowledge to act under classroom conditions can be tracked from Lee Shulman (1998) to Franz Weinert (2001), and to the five core propositions of the NBPTS (2002). These propositions are: (1) teachers are committed to students and their learning; (2) teachers know the subjects they teach and how to teach those subjects to students; (3) teachers are responsible for managing and monitoring student learning; (4) teachers think systematically about their practice and learn from experience; and (5) teachers are members of learning communities. Symptomatically, all those general attempts do not explicitly contain statements on subject-specific pedagogical competences, which are in non-English-speaking countries called *didactic of the subject* and described as strategies of teaching the content of a certain subject. Even proposition (2), only refers to knowledge about subject matter and not explicitly to knowledge of how to reduce or reconstruct content knowledge for certain situations in the process of teaching and learning under classroom conditions.

To describe the effect of teachers' professional knowledge, most recent research projects use distal indicators like state certifications or marks to correlate with indicators of the quality of instruction or students' learning outcomes. For example, Suzanne Wilson and Peter Youngs (2005) report positive correlations between teachers' certificates and their general pedagogical knowledge and students' increase of knowledge in a certain subject. Most of those studies contain the inconsistency of using general pedagogical knowledge as a measure but they mostly do not consider the conditions of lessons of specific subjects. Therefore, Marylin Cochran-Smith and Ken Zeichner (2005) emphasized that it is now necessary to develop measures and variables to reliably and validly capture data on professional knowledge in all facets, to correlate with learning outcomes regarding different subjects. According to Shulman (1986, 1987), professional knowledge can be divided into seven categories that seem to influence teachers' behavior in the classroom: (1) content knowledge; (2) curricular knowledge; (3) pedagogical content knowledge; (4) general pedagogical knowledge; (5) knowledge of learners and their characteristics; (6) knowledge of educational contexts; and (7), knowledge of educational ends, purposes, and values. In recent research, reduced models of Shulman's concept are mainly applied using only content knowledge (CK), pedagogical content knowledge (PCK), and pedagogical knowledge (PK) (Baumert et al. 2010).

In some models, subject matter is included in PCK (Fernandez-Balboa and Stiehl 1995; Marks 1990). In most investigations, different test instruments are applied to assess the three dimensions of professional knowledge independently without integrating them. For example, content knowledge and alternative concepts are analyzed from different perspectives (e.g., Harlen 1997; van Driel and Verloop 1999). Marissa Rollnick et al. (2008) deal with relations between pedagogical content knowledge and subject-matter knowledge, or Pernilla Nilsson's (2008) study reveals pedagogical content knowledge as an amalgam of subject-matter knowledge, contextual knowledge, and pedagogical knowledge. Up to now, a connection between CK and teaching practice has been analyzed mainly using case studies, based on which it is generally agreed that positive connections exist between CK and supportive teaching, but such connections are only restricted to the cases being studied (Gess-Newsome and Lederman 1995; Newton and Newton 2001). Pedagogical content knowledge as transformation of subject-matter knowledge into forms accessible to the students (Geddis 1993) has also been described using different theoretical frames, for example, by Onno de Jong and Jan van Driel (2001), and analyzed in greater detail regarding different facets like concepts on teaching and learning, various subjective theories, beliefs, and attitudes by others (see also Loughran et al. 2001; Porlán et al. 2004). Finally, pedagogical knowledge – as knowledge of teaching, learning, instruction, classroom-management, goals of Bildung – is seen to be subject-independent and general. Facets of PK regarding science teaching were investigated by David Treagust (1991) and Anat Zohar (1999) also by means of case studies. A model for professional knowledge based on the reduced version of Shulman's concept already exists for mathematics teachers, and at least CK and PCK and interdependencies are assessed by correlating CK and PCK with students' performance in large-scale assessments (Baumert et al. 2010; Organisation for Economic and Cultural Development (OECD) 2003). High CK and PCK of teachers of mathematics are seen as a necessary precondition for good performance of their students but only if the lessons are cognitively demanding. Up to now, the influence of PK on teaching and learning or quality of instruction has not been connected with students' competencies regarding science subjects. In addition, effects on motivation and interest are not sufficiently investigated.

According to Jürgen Seifried and Detlef Sembill (2005), learning has to be seen as a complex process not only focusing on cognitive performance but also on emotional, motivational, and interest-related elements (Kunter 2005). Therefore, besides professional knowledge of teachers, students' cognitive development and lesson activities, motivation, and interest of students and teachers should be considered when analyzing teaching and learning at school (Weinert 2001).

Professional Knowledge of Science Teachers

As already pointed out, the debate about teacher knowledge in science education mainly highlights the three areas: content knowledge (Krauss et al. 2004), pedagogical content knowledge (Baumert et al. 2010), and pedagogical knowledge (Bromme 1997, 2001), as being relevant for teaching and research (Wilson and Floden 2003). Therefore, standards for professional knowledge of teachers describe mainly expected competencies in those dimensions. Like the standards for student education and those for teacher education, all standards contain goals of a society for certain subjects in general (Oser and Oelkers 2001; NBPTS 2002), and the specific biology, chemistry, and physics standards, respectively (Sekretariat der Ständigen Konferenz der Kultusminister der Länder in der Bundesrepublik Deutschland [Secretary of the Standing Conference of the Ministers of Education and Cultural Affairs of the Länder in the Federal Republic of Germany] 2005a, b, c), are necessarily normative (Klauer and Leutner 2007) but can be used for developing and empirically validating models to measure teachers' competencies (see Kauertz et al. in this handbook). In a cyclical process, on the basis of the results of student performance in respective tests, the underlying standards can be adapted to develop the standards for professional knowledge of teachers. In addition, establishing a correlation between professional knowledge, lesson activities and students' learning outcomes also contributes to modeling the quality of instruction. In a first attempt, the notion of professional knowledge refers to all kinds of theoretical knowledge learned during teacher education but also skills as a result of systematic in-service teacher training and teaching practice (Clandinin and Connelly 1995). Furthermore, personal characteristics, like attitudes, beliefs, and emotions, are also seen as elements or correlates of professional knowledge (Barnett and Hodson 2001; Moallem and Moallem 1998). Therefore, the professional knowledge of teachers is more than a fixed taxonomy of well-defined elements of knowledge clearly distinguishable and applicable to all possible situations in the classroom. But, not all knowledge of a teacher is unrestrictedly relevant for action because only some parts are applicable to regulating classroom teaching activities (Dann 1994; Fischler et al. 2002). With a model of instructional quality that takes into account not only instructional characteristics and their influence on outcome criteria but also framework conditions on classroom, school, and system levels, the gap between normative approaches in teacher education programs and process-product approaches, as stated by Barak Rosenshine and Norma Furst (1973), can be closed.

Content Knowledge

Content knowledge is seen as a necessary precondition for successful teaching (Ball et al. 2001; Shulman 1986, 1987). Nevertheless, most empirical research on instruction did not show this relationship, which may be due to the fact that pedagogy cannot be used to investigate the influence of teachers' content knowledge on instruction or even students' learning outcomes. Furthermore, difficulties with developing applicable test instruments for assessing teachers' content knowledge and their willingness to take part in these assessments lead to an unsatisfying quality of tests. Instead, content knowledge is often operationalized indirectly using teachers' certifications, their marks on reports or the number of seminars completed successfully by them. In contrast, Jürgen Baumert et al. (2010) defined and analyzed four different kinds of content knowledge: academic research knowledge, a profound mathematical understanding of school knowledge, school knowledge after some teaching experience, and the everyday mathematical knowledge of adults, which are available already after having passed some time teaching at school. Within the COACTIV-study, teachers' mathematical content knowledge is assessed immediately and mathematical content knowledge of teachers is understood as background knowledge of school content (Brunner et al. 2006a). Successful teaching is dependent on the depth of the teachers' exploration of lesson content including the structure of the content and theoretical modeling (van Driel and Verloop 1999). Deborah Ball et al. (2001) distinguished between this kind of background knowledge from university knowledge and considered these respectively as common knowledge of content and specialized knowledge of content, although they were not able to identify the postulated parts of their model by means of factor analysis (Hill et al. 2004). The results of the COACTIV-study showed high correlations between test results of the German students in the PISA 2003 study (OECD 2003) and their teachers' PCK and CK as well as strong connections between CK and PCK. CK was also found to be a necessary but insufficient precondition for PCK.

Pedagogical Content Knowledge

In contrast to CK, PCK represents knowledge that enables teachers to provide opportunities for students to learn certain content. Shulman (1987) describes PCK as a special amalgam of content and pedagogy that corresponds to a fusion of CK and PK. Accordingly, it seems difficult to distinguish the three kinds of knowledge: CK, PCK, and PK. Jan van Driel et al. (1998), and Soonhye Park and Steve Oliver (2007) combine different attempts for describing PCK regarding science instruction; and van Driel et al. (2002) agree on knowledge about learning processes, students' concepts, teaching strategies, and forms of presentation as central elements of PCK. Ineke Henze et al. (2008) use similar facets for describing PCK but reveal two qualitatively different types of PCK. Stefan Krauss et al. (2004) add a new facet by differentiating between teaching mathematical content, students' cognition regarding mathematics and the cognitive potential of mathematics tasks to represent all three sides of the didactic triangle: (1) the teachers and their subject-specific interventions, (2) the students and their subject-specific concepts, and (3) the subject matter with a certain cognitive potential (Cohn and Terfurth 1997). Knowledge on all three aspects is understood as a requirement for the creation of learning opportunities which allow students to be cognitively activated and thus to support their learning as far as possible. An adequate cognitive activation of students leads to an active use of learning opportunities and therewith to successful learning (Brunner et al. 2006b). Therefore, an adequate level of the teacher's or the task's requirement is indispensable. Already Lev S. Vygotsky's (1987) notion of the zone of proximal development has pointed out that cognitive activation of students should demand adequately but not to overtax their ability. Therefore, cognitive activation should consider pre-knowledge and so-called misconceptions as well as conceptual change as teaching strategies, which are seen especially as being necessary for learning sciences (Duit et al. 2007; Treagust and Duit 2008). Eunmi Lee and Julie Luft (2008) explored a PCK model consisting of seven aspects and suggested that knowledge of resources should be explored to determine whether it should be considered a component of PCK. Rainer Wackermann et al. (2008, 2009) report effects of an intervention to support teachers' ability to organize problem solving, learning by experience, and concept development in physics lessons using video analysis, test medium effect sizes, and acceptable correlations between the an appropriate structure of the lesson and students' motivation and interest. In addition, some important qualitative features, like the complexity of the levels of teachers' questions and the levels of their students' responses, could be linked to the lesson structure as well as teachers' self-reported experience in pacing and monitoring processes of the analyzed lessons.

Viewing PCK from a meta-level and using it as a heuristic device, John Loughran et al. (2008) refer to positive effects on student-teachers preparing lessons by using the Content Representation (CoRe) and Pedagogical and Professional-experience Repertoire (PaP-eR) for teacher training. Jürgen Baumert et al. (2010) report PCK and CK as separate factors as a result of a factor analysis but also an increasing integration of both constructs with increasing expertise. PCK itself shows a positive correlation to an effective instruction and students' achievement (Ball et al. 2005; Brunner et al. 2006b). General quality criteria that account for effective instruction have already been identified (Fraser et al. 1987; Wang et al. 1993). It is expected, however, that these general quality criteria must be complemented by subject-specific criteria (Helmke 2007). Sandra Abell (2007) summarizes the research perspective regarding CK and PCK as follows:

> The research in both SMK [CK] and PCK has predominantly been at the level of description. In the current area of standards-based education and accountability for student learning, science education researchers should make more efforts to connect what we know about how teachers bring to bear on science teaching, we know little about how teacher knowledge affects students. Answering this question will require more work in classroom settings of all kinds (…) and more complex research designs. The ultimate goal for science teacher knowledge research must not only be to understand teacher knowledge, but also to improve practice, thereby improving student learning. (p. 1134)

Accordingly, some of the recent case studies are describing science teachers' PCK qualitatively as being oriented to modeling content when talking about teaching the solar system (Henze et al. 2008). Lee and Luft (2008) also describe PCK of four teachers using semi-structured interviews. They found seven components of PCK: knowledge of science, goals of students, curriculum, organization, teaching, assessment, and resources. Again in a case study (but as an intervention), John Loughran et al. (2008) investigated the influence of an explicit teaching of elements of PCK to some preservice science teachers. As case studies with only small samples and descriptive attempts, most do not provide generalizable results but generate a picture of what can be expected when teaching PCK to science teachers. Up to now PCK is rarely measured directly using valid test instruments. One reason may be that PCK mostly refers to specific situations and proofs of the effectiveness of certain measures are difficult to carry out. For a detailed overview on PCK in science education see Julie Gess-Newsome and Norman Lederman (1999).

Pedagogical Knowledge

According to Shulman (1986), pedagogical knowledge includes knowledge of general principles of classroom organization and management. In more detail, Krauss et al. (2008) describe it as declarative and procedural knowledge to facilitate a trouble-free and effective course of a lesson and to establish a social climate supportive for learning which is tightly connected with knowledge about measures and strategies of class guidance as well as to effectively use the available learning time (Seidel and Shavelson 2007; Wang et al. 1993). Alexander Renkl (2008) summarizes effective class guidance as: (1) establishing an efficient system of rules, (2) avoiding no-load operation phases, (3) controlling disturbances, (4) outsourcing non-instruction activities, (5) consequent flow of lessons, and (6) clarity and adequate requirement levels. These principles include strategies to prevent disturbances in the classroom as well as corrective activities when disturbances occur but Thomas Good and Jere Brophy (1997), and Jacob Kounin (1976) attach a stronger effect to prevention. Pamela Grossmann (1990) and Shirley Magnusson et al. (1999) add also knowledge on general principles of instruction, learning processes, and personal characters relevant for learning and on teaching goals. Knowledge on general principles of instruction includes knowledge on numerous instruction forms that can use teaching methods regarding curricular content and teaching goals (Kunter et al. 2005; Seidel and Shavelson 2007) and adequate characteristics of the learner (Brophy 2000; Klauer and Leutner 2007). Knowledge on learning processes covers knowledge on different learning theories and its applicability in different situations (Blömeke et al. 2008). Knowledge about teaching goals, learning processes, and principles of instruction are seen as a necessary precondition for adequate cognitive activation (Kunter et al. 2006).

Because PK does not refer to a subject, it is seen as a general precondition for a high quality of instruction. Focusing not only on declarative but also on procedural knowledge PK includes knowledge on instructional measures and strategies and the conditions of their effective use under classroom conditions. Thus, PK can be seen as a necessary but not sufficient precondition to use CK and PCK for enhancing subject-specific learning processes.

Conclusion

Research on professional knowledge of teachers and its consequences for teaching and learning science have not been sufficiently developed. There are some well-established attempts in research on pedagogy describing PK but the relation between PK and subject matter, its structure, its transformation and operationalization for classroom conditions are not well known and only poorly investigated. Most of the research on CK and PCK, which are the most important facets of professional knowledge regarding science education (didactics of science or didactics of the different science subjects), still remains on a descriptive level. Moreover, recently conducted studies do not sufficiently refer to each other which lead to a deficit regarding reliability and validity of their results. Studies and models are needed that consider a combination of at least three main components of professional knowledge – CK, PCK, and PK and its correlations to student learning – and, most importantly, their effects on instruction to draw conclusions for teacher education and to develop quality of science instruction. Therefore, more studies are needed that investigate the correlation between variances of teachers' professional knowledge, and quality features of classroom interactions and of student learning outcomes in different subjects to find subject-dependent differences but also common features of professional knowledge and to connect teachers knowledge, teaching and learning processes, and students' knowledge and competences.

Chapter 31
Science Teaching Efficacy Beliefs

Jale Cakiroglu, Yesim Capa-Aydin, and Anita Woolfolk Hoy

During the last few decades, educators have placed increasing emphasis on the scientific literacy in science education programs. Scientific literacy is based on a premise that all students should have the opportunity to learn and do science. In an effort to better prepare students in science, the science teacher is considered one of the most influential factors in increasing the quality of students' learning processes and outcomes. However, previous studies have indicated that many preservice and in-service teachers demonstrate a low confidence in their abilities to teach science and help students learn. Teachers who do not believe in their ability to teach science effectively, that is, teachers with low science teaching efficacy beliefs might avoid teaching difficult concepts in science or tend to spend less instructional time on science. For that reason, efficacy beliefs are one of the most powerful variables predicting both teachers' behaviors in science classrooms and student achievement in science.

The chapter begins with the theoretical foundation of self-efficacy, including origins, definition, and distinctive features of self-efficacy beliefs. Then we provide a brief explanation of teachers' sense of efficacy, including its conceptual framework and critical measurement issues. Next we focus on science teaching efficacy beliefs by summarizing major findings. Finally, we propose an agenda for future research.

Meaning of Perceived Self-efficacy

Self-efficacy, which stands at the core of social cognitive theory, has generated a growing body of literature in psychology, medicine, education, and business administration since the publication of Albert Bandura's (1977) article Self-efficacy: Toward Unifying Theory of Behavior Change. Perceived self-efficacy refers to personal beliefs about one's capabilities to perform actions at designated levels (Bandura 1997). Self-efficacy beliefs can influence human functioning in numerous ways. They "influence the courses of action people choose to pursue, how much effort they put forth in given endeavors, how long they will persevere in the face of obstacles and failures, their resilience to adversity (Bandura 1997, p. 3). These subsequent performances are influenced by self-efficacy, whereas the self-efficacy beliefs are affected and altered in turn by how individuals interpret the results of their performance attainments (Pajares 1996).

The definition of self-efficacy is sometimes clouded by similar or related constructs such as self-concept, self-esteem, and locus of control. However, Bandura (1997) points out that although all other self-constructs are self-referential, self-efficacy is clearly different from each of them in that self-efficacy involves judgments of capabilities specific to a particular task. On the other hand, self-concept is a more global construct that contains many perceptions about the self, including self-efficacy. Self-esteem refers to perceptions of self-worth and does not include judgments of capabilities. There is no preset relationship between individuals' beliefs about their capabilities and whether they like or dislike themselves. For example, a man may judge himself as inefficacious in a given activity but not suffer any loss of self-esteem.

Although self-efficacy and locus of control often are viewed as the same construct, they correspond to entirely different phenomena (Bandura 1997). Originally developed under the umbrella of Julian Rotter's (1966) social learning theory, the locus of control construct refers to the degree to which an individual believes the occurrence of reinforcement is contingent on his or her own behavior as opposed to under the control of others. The factors involved with reinforcement expectancy are labeled internal and external control, respectively.

Bandura (1997) stated that locus of control is an outcome expectancy that could be defined as "a person's estimate that a given behavior will lead to certain outcomes" (p. 193). High locus of control does not necessarily indicate a sense of efficacy. For example, students may believe that high academic grades are entirely dependent on their performance (high locus of control), but feel hopeless because they believe they lack the skills to produce those superior academic performances (low self-efficacy).

Although other self-referential constructs may be more global (e.g., self-esteem, self-concept), self-efficacy is defined and measured as specific to behaviors in specific contexts or situations (Bandura 1997). Therefore, Bandura (1997) cautioned researchers assessing self-efficacy beliefs that they should use assessments that correspond to the specific task and the domain of functioning being analyzed. Otherwise, the resulting omnibus-type instrument would not only create problems of prediction, but also be unclear about what is being assessed.

Teachers' Self-efficacy Beliefs

Considering the task-specific nature of self-efficacy, Megan Tschannen-Moran et al. (1998) defined teacher self-efficacy as "teacher's belief in his or her own capability to organize and execute courses of action required to successfully accomplish a specific teaching task in a particular context" (p. 233). In their review paper, Tschannen-Moran et al. proposed a model suggesting that teacher self-efficacy is produced as a result of the interaction between analysis of teaching task in context and analysis of personal teaching capabilities. The resulting efficacy beliefs influence the teachers' professional goals, their effort expenditure, and their resilience when faced with difficulties.

The model also refers to the sources of efficacy information described by Bandura (1997): mastery experience, vicarious experience, social persuasion, and physiological states. Among these four sources of information, Bandura proposed that enactive mastery is the most influential source. A sense of efficacy to teach is enhanced when accomplishments are present in a person's history of teaching and particularly when these past successes are attributed to the individual's own efforts and abilities. Opportunities to observe a model's (colleague or mentor) accomplishments might be a source of vicarious experience that supports the efficacy judgments. Social (or verbal) persuasion refers to the specific positive talk about teaching performance from an administrator, colleague, mentor, or a student. Finally, physiological or affective reactions to a teaching task also add to the efficacy information, depending on how the arousal is interpreted. For example, if seen as anxiety, the arousal may lower efficacy expectation, whereas interpretations of excitement and readiness may raise efficacy expectations. These four sources of efficacy information are cognitively processed, that is, they are "selected, weighted, and integrated into self-efficacy judgments" (Bandura 1997, p. 79).

This process of selecting and weighting efficacy information differs for each individual as different factors may influence each person. Elizabeth Labone (2004) proposed that factors such as preexisting self-schema, task difficulty, and effort invested may influence the extent to which enactive mastery would enhance efficacy judgments. The cognitive process is considered as essential in the Tschannen-Moran et al. (1998) model because such processing will impact how the analysis of teaching task and personal competence interact with each other to form future efficacy beliefs.

Measurement of Teachers' Self-efficacy Beliefs

Two theoretical frames have shaped the measurement of teachers' sense of efficacy, Rotter's locus of control and Bandura's self-efficacy theory.

Rotter

Under the influence of Rotter's article published in 1966, the RAND Corporation included two efficacy items in their examination of teacher characteristics and student learning (Armor et al. 1976). Those researchers defined teacher efficacy as "the extent to which the teacher believes that he or she has the capacity to affect student performance" (McLaughlin and Marsh 1978, p. 84). In these studies, teachers were asked to respond to the two 5-point Likert-type items. Two items used to measure teacher efficacy were designed to measure the degree to which teachers consider environmental (external) factors as overwhelming any power that they can exert in schools or accept personal (internal) responsibility for what happens to them (Guskey and Passaro 1994). See Table 31.1 for further information. After this, other instruments with more items were developed such as Responsibility for Student Achievement (Guskey 1981), Teacher Locus of Control (Rose and Medway 1981), and The Webb scale (Ashton et al. 1982). Despite the important implications of these studies for teacher efficacy research, several researchers tried to expand the construct of teacher efficacy, and to develop longer and more reliable measures (Tschannen-Moran et al. 1998; Woolfolk Hoy et al. 2009).

Bandura

Patricia Ashton and Rod Webb (1986) expanded the Rand methodology by using Bandura's social cognitive learning theory, in which they made a distinction between outcome expectations and efficacy expectations. They believed that outcome expectation was assessed in the first Rand item, whereas efficacy expectation was captured in the second Rand item. Sherri Gibson and Myron Dembo (1984) developed a 30-item instrument called Teacher Efficacy Scale (TES) based on these two dimensions and later reduced it to 16 items. Through factor analysis of 208 elementary teachers' responses, they reported a 2-factor model that accounted for 28.8% of the total variance. Gibson and Dembo noted that Factor 1 represented a teacher's sense of personal teaching efficacy, and corresponded to Bandura's self-efficacy dimension. On the other hand, the second dimension stood for a teacher's sense of teaching efficacy, and corresponded to Bandura's outcome expectancy dimension. These two dimensions are now referred to as personal teaching efficacy (PTE) and general teaching efficacy (GTE), respectively. Gibson and Dembo presented alpha coefficients of 0.78 for PTE, and 0.75 for GTE. They recommended the use of the revised scale of 16 items for further research. Other instruments were adapted based on TES for specific subject matters. For example, Iris Riggs and Larry Enochs (1990) developed the Science Teaching Efficacy Belief Instrument (STEBI) to measure efficacy of science teaching and Larry Enochs et al. (2000) developed a similar instrument to measure efficacy of mathematics teaching.

John Ross (1998) reported that TES (or adaptations of TES) has been used in almost half of the studies performed up to 1998 to assess teacher efficacy. Despite its common use, there are both conceptual and statistical problems

Table 31.1 Measures of teacher self-efficacy

Instrument	Developers	Characteristic	Sample item
The RAND measure	Armor et al. (1976)	• Based on Rotter's theory • Two 5-point Likert type items	When it comes right down to it, a teacher really can't do much because most of a student's motivation and performance depends on his or her home environment. If I really try hard, I can get through to even the most difficult or unmotivated students.
Teacher Efficacy Scale	Gibson and Dembo (1984)	• Based on Bandura's theory • 30-item 6-point Likert scale • Two subscales: personal teaching efficacy (PTE) and general teaching efficacy (GTE)	I have enough training to deal with almost any learning problem. (PTE) Teachers are not a very powerful influence on student achievement when all factors are considered. (GTE)
Teachers' Sense of Efficacy Scale	Tschannen-Moran and Woolfolk Hoy (2001)	• Based on Bandura's theory • 24 items on a 9-point rating scale • Three subscales: efficacy for classroom management (CM), efficacy for instructional strategies (IS), and efficacy for student engagement (SE)	How much can you do to control disruptive behavior in the classroom? (CM) To what extent can you use a variety of assessment strategies? (IS) How much can you do to get students to believe they can do well in schoolwork? (SE)
Science Teaching Efficacy Belief Instrument A and B	Riggs and Enochs (1990) Enochs and Riggs (1990)	• Building on Gibson and Dembo's work • Two subscales: personal science teaching and science teaching outcome expectancy • STEBI-A: 25-item 5-point Likert scale • STEBI-B: 23-item	I am typically able to answer students' science questions. (STEBI-A) I will typically be able to answer students' science questions. (STEBI-B)
Self-Efficacy Beliefs about Equitable Science Teaching and Learning (SEBEST)	Ritter, Boone, and Rubba (2001)	• Based on STEBI • 34 items • Two subscales: personal efficacy (PE) and outcome expectancy (OE)	I will have the ability to help children from low socioeconomic backgrounds be successful in science. (PE) Good teaching cannot help children from low socioeconomic backgrounds achieve in science. (OE)

(Henson 2002; Tschannen-Moran et al. 1998). Some researchers stated their concerns particularly regarding the second factor, GTE (Guskey and Passaro 1994; Henson et al. 2001). For example, Thomas Guskey and Perry Passaro (1994) noticed that there are some biases in the wording of the items. Items measuring personal efficacy used the referent "I" and were positive; while items measuring teaching efficacy used "teachers" and were negative. For that reason, they changed the wording of the items in order to have balanced characteristics throughout the instrument (both positive and negative "I" items and both positive and negative "teachers" items).

When Guskey and Passaro administered this balanced scale, their results confirmed internal and external dimensions instead of personal and teaching efficacy dimensions. This categorization stems from locus of control theory rather than self-efficacy theory. Tschannen-Moran et al. (1998) discussed this theoretical distinction in detail, drawing upon the findings of the Guskey and Passaro study. Based on a reliability generalization study, Henson et al. (2001) concluded that use of the GTE subscale as a measure of teacher self-efficacy is questionable not only because of conceptual problems but also for measurement error problems. They suggested not using the GTE subscale.

Another commonly used teacher self-efficacy instrument is the Teachers' Sense of Efficacy Scale (TSES) developed by Tschannen-Moran and Woolfolk Hoy (2001). Taking Bandura's suggestions for constructing a self-efficacy scale (Bandura 2006) and using the Tschannen-Moran et al. model as a base, they developed an instrument assessing teachers' beliefs about their abilities to accomplish a variety of teaching tasks. After different validation studies, they generated a short form with 12 items and a long form with 24 items. Analyses of both forms indicated that the TSES could be accepted as a reliable and valid instrument for assessing the teacher efficacy construct. Both versions supported a 3-factor model with high subscale reliabilities. The factors were named efficacy for student engagement, efficacy for instructional strategies, and efficacy for classroom management. The authors argued that TSES could be used for assessment of either three domains of efficacy or of one generalized efficacy factor. The instrument was adapted to other languages such as Turkish (Capa et al. 2005), Greek, Korean (Klassen et al. 2009), and Chinese (Kennedy and Hui 2006).

Correlates of Teacher Self-efficacy Beliefs

Researchers have consistently found a strong relationship between teacher efficacy, teacher classroom behavior, and student achievement. For example, teachers with higher levels of self-efficacy tend to be open to new ideas, demonstrate greater levels of planning and enthusiasm, and are committed to their profession (Tschannen-Moran et al. 1998). Furthermore, higher levels of teacher self-efficacy have been related to positive classroom behavior management (Emmer and Hickman 1991). Further, efficacious teachers tended to be less critical of students when they made errors and worked longer with struggling students (Gibson and Dembo 1984).

In addition to the teacher variables, teacher efficacy is also linked to students' affective growth, student motivation, student self-esteem, and achievement (Midgley et al. 1989). Findings related to the relationship between teacher self-efficacy, and both teacher and student outcomes were discussed in Ross's (1998) article reviewing 88 teacher efficacy studies.

Science Teaching Efficacy Beliefs

Reinforcing Bandura's definition of self-efficacy as both subject-matter and context-specific construct, Riggs and Enochs (1990) developed the Science Teaching Efficacy Belief Instrument (STEBI) to measure efficacy of science teaching. Building on the Gibson and Dembo work, the authors identified two uncorrelated factors within STEBI, which they named personal science teaching efficacy (PSTE,13 items) and science teaching outcome expectancy (STOE, 12 items). The PSTE refers to teachers' belief in their ability to perform science teaching, whereas the STOE refers to the teachers' belief that effective science teaching can change student behaviors (Riggs and Enochs 1990). The original 25-item STEBI Form A was developed for in-service teachers in a 5-point Likert-response format (Riggs and Enochs 1990). Enochs and Riggs modified STEBI-A to a 23-item questionnaire suitable for preservice teachers (STEBI-B) by rewording the items to the future tense to reflect the anticipatory nature of preservice teachers.

By extending the level of specificity and using STEBI as a base, other subject-matter-specific instruments were developed including STEBI-CHEM (Rubeck and Enochs 1991) assessing chemistry teaching efficacy, the Environmental Education Efficacy Belief Instrument (EEEBI; Sia 1992) assessing efficacy beliefs in environmental education, and Self-efficacy Beliefs about Equitable Science Teaching (SEBEST; Ritter et al. 2001) assessing the self-efficacy beliefs of preservice elementary teachers with regard to science teaching and learning for diverse learners.

Studies with In-Service Teachers

Numerous studies investigated the construct of teacher efficacy and found that efficacious teachers tended to use activity-based science instruction and spent more class time teaching science (at the elementary level). They also used inquiry approaches, small-group learning, cooperative learning, and more student-centered instructional approaches. In contrast, teachers with low efficacy beliefs tended to utilize teacher-centered instructional methods and whole-class instructional techniques (Enochs and Riggs 1990). Considering the fact that student-centered approaches have gained importance in recent years in science education field, researchers have focused on how to improve teachers' self-efficacy beliefs. However, research findings are contradictory regarding the enhancement of different dimensions of STEBI. For example, some interventions have produced significant enhancement of teachers' PSTE, some in teachers' STOE or some in both.

To illustrate these contradictions, in a 32-week professional development program, Tracy Posnanski (2002) found that PSTE was significantly enhanced but their STOE was not. However, Ian Ginns et al. (1995) found significant changes only in STOE. In her study, Posnanski suggested that components of the professional development model positively impacting PSTE were the presence of long-term training, support from colleagues, experimenting with new strategies through practice, and innovative science instructions. The nonsignificant change in STOE was attributed to its stability and/or its measurement problems. In another study, specific to the field of chemistry education, Claudia Khourey-Bowers and Doris Simonis (2004) explored the influence of specific professional development design elements (e.g., instruction in fundamental chemistry concept, modeling the learning cycle, and guided discussion of learning theories). Their results indicated that professional development enhanced both participants' PSTE and STOE. Similar findings were obtained in a 3-year longitudinal study in which both PSTE and STOE increased as a result of participating summer workshops (Chun and Oliver 2000).

There is some evidence suggesting that finding significant increases in efficacy requires that participants enter with lower levels of teacher self-efficacy beliefs. For example, results of a study with 330 science teachers participating in an in-service program that varied from 2 to 6 weeks indicated that in-service interventions had the greatest impact on the efficacy of teachers who began the program with the lowest level of efficacy beliefs. The researchers suggested there was not much room for the growth in self-efficacy for the teachers with high levels of PSTE (Roberts et al. 2001). Consistent with this result, Riggs (1995) reported that teachers who began training with low scores on both PSTE and STOE made gains in PSTE while STOE scores remained constant.

Studies with Preservice Teachers

A large body of research has examined preservice teachers' science teaching efficacy beliefs because once efficacy beliefs are established they appear to be somewhat resistant to change (Woolfolk Hoy et al. 2009). Teaching experiences, courses, and other interventions have produced mixed results regarding teacher efficacy beliefs. Many of these studies have used the STEBI-B as the primary instrument for data. For example, Judith Mulholland et al. (2004) found that the number of science classes completed at the high school level was positively related to preservice teachers' PSTE but not to their STOE. Robert Bleicher (2004) presented similar findings. In addition, he found that age, ethnicity, and teaching experience showed no relationship to either PSTE or STOE. Tarik Tosun (2000) emphasized the importance of preservice teachers' quality of past experiences in shaping their science teaching self-efficacy. Using both quantitative and qualitative data, Watters and Ginns (1995) found that beside their previous experience, a supportive learning environment in teachers' training programs enhanced their teaching efficacy.

Authors suggested that positive self-efficacy stemmed from experiencing exciting, hands-on practical activities. In addition, they attributed the improvement in participants' STOE to experiences with teaching science to young children.

Science Content Knowledge

A few authors have studied science content knowledge as a factor that has been linked with increased self-efficacy of elementary teachers. For example, Kenneth Schoon and William Boone (1998) found that preservice teachers who held fewer numbers of alternative concepts in science had significantly higher efficacy levels. These alternative conceptions act as fundamental barriers to fully understanding scientific phenomena presented in science courses and thus preservice teachers feel less able to teach science to others. However, Patricia Morrell and James Carroll (2003) claimed that science content knowledge alone is not sufficient to improve self-efficacy. In their study, they found that students enrolled in the science methods course showed significant gains in PSTE.

Methods Courses

David Palmer (2006a) also examined the retention of efficacy beliefs after a science method course. He reported that positive changes were recorded for both PSTE and STOE over the period of the course itself and after the delay period. A mixed-method design study by Bleicher and Lindgren (2005) explored the relationship between changes in levels of science teaching self-efficacy and participation in a constructivist oriented science methods course for preservice elementary teachers. Results showed that preservice teachers demonstrated significant increase in conceptual understanding, PSTE and STOE. Consistent with Watters and Ginns (1995), hands-on activities, minds-on activities, and discussion were effective in increasing teaching self-efficacy. Similarly, Posnanski (2007) found that preservice teachers' efficacy beliefs improved more in a constructivist-based science content course than in a traditional one. This constructivist-based course included a nature-of-science aspect and means to mediate self-efficacy beliefs such as vicarious experiences and a positive emotional tone. Regarding the sources of self-efficacy in a science methods course, Palmer (2006b) found that the main efficacy source for preservice teachers was cognitive pedagogical mastery in accordance with Bandura's (1997) assertion that enactive mastery is the most important source of efficacy information.

Discussion and Implications for Further Research

Since its inception in 1977, teacher efficacy has been extensively described and interpreted in the literature as a strong indicator of the teacher's ability to be productive and successful. Not only in science teaching, but also in teacher efficacy research in general, quantitative studies are dominant. Although many quantitative studies assessing science teaching self-efficacy have been conducted, methodological limitations persist regarding the characteristics of the scales that are used. A common concern raised by the researchers regarding teacher self-efficacy scales is the unrealistic optimism of teachers who rate themselves above the average, that is, most preservice and in-service teachers avoid the lower end of the scales and tend to select only the higher values. This presents a problem in intervention studies. Significant changes were observed only for teachers with low self-efficacy at the entry level. Hence, statistical analysis suffers from low variability and ceiling effects.

The STEBI is the most commonly used instrument assessing science teaching efficacy. Henson et al. (2001) stated that the problem of more measurement error in the outcome expectancy (or GTE) sub-dimension also occurred in the STEBI, as it was developed from the TES. In addition, concerns about the construct validity of TES (Tschannen-Moran et al. 1998) also apply to the STEBI as well. A promising instrument, the TSES, was developed based on a model of teacher efficacy. However, the study of science teaching efficacy still suffers from psychometric issues. Considering the well-grounded arguments, we echo the need for a new or revised measure(s) that would reliably assess science teaching efficacy and its components. Ignoring these arguments and going with the already existing measures would suppress the advancement of science teaching efficacy research. More investigations employing qualitative or mixed method designs would help better understanding of this elusive construct (Labone 2004).

Because efficacy beliefs are shaped early, it would be useful to better understand factors that support the development of a strong sense of efficacy among preservice and novice teachers. Future research is warranted to determine possible ways to develop stronger efficacy beliefs by focusing on the sources of self-efficacy beliefs: enactive mastery, vicarious experiences, social persuasion, and arousal. We recommend conducting follow-up longitudinal studies of the science teaching efficacy beliefs of preservice teachers as they progress through the teacher education program and of science teachers at different career stages – early, mid, and late career. It would be desirable to monitor how these beliefs are formulated and sustained throughout the teaching career. Such knowledge would enable teacher educators to modify courses and field experiences to enhance preservice teachers' efficacy beliefs. Several studies have demonstrated that well-designed science methods courses are quite effective in improving science teaching self-efficacy. Courses that are structured to be inquiry based, constructivist in nature, and include use of hands-on activities and group investigations could be beneficial in bringing about appropriate change. In addition, these courses should provide such experiences for preservice teachers as microteaching, cooperative learning, good role models, and a supportive learning environment. Of course, the final question to explore is if these changes in methods courses lead to improvements in teaching efficacy and finally to increases in the science literacy of students in the teachers' classrooms.

Extending the notion of teachers' sense of efficacy, Hoy, Woolfolk Hoy, and their colleagues have discussed the importance of "academic optimism" at the school

(Hoy et al. 2006) and individual teacher levels (Woolfolk Hoy et al. 2008). At both the collective school and individual teacher levels, teacher's sense of efficacy, teacher trust in parents and students, and academic emphasis combine to form a single, strong second-order factor – teacher's academic optimism. Teacher efficacy is a cognitive aspect of academic optimism, the thinking and believing side; teacher trust in students and parents is the affective and emotional side of the general construct; and teacher academic emphasis is the behavioral side, that is, the enactment of the cognitive and affective into actions. Academic optimism has been related to teacher beliefs about instruction and management and to student achievement. Much remains to be done in examining academic optimism and its associations with other variables, particularly in science education field.

Chapter 32
Context for Developing Leadership in Science and Mathematics Education in the USA

James J. Gallagher, Robert E. Floden, and Yovita Gwekwerere

Leadership is an important component of any field of endeavor; the field of science and mathematics education is no exception. Little is known, however, about leadership in this field, about who become leaders, what skills are required, and how leadership develops. To answer some of these questions, the National Science Foundation supported a project at Michigan State University to advance understanding of the context of leadership in science and mathematics education. The project addressed the following research questions:

- What are the characteristics of current leaders who influence science and mathematics education in crucial arenas of educational activity?
- What educational and professional experiences led them to their positions of leadership and influence?
- What has been the role of leaders in influencing the direction and quality of science and mathematics education?
- Where will the next generation of leaders come from, and what kind of preparation will they need?

The study consisted of three parts including a review and analysis of existing literature and databases, interviews with a sample of current leaders in the field, and an examination of a sample of doctoral programs that serve as training grounds for new

leaders in the field. The study was conducted during 2001–2003, with data analysis continuing to the present time; 68 recognized leaders in science and mathematics education, with at least 15 years of experience in the field, were interviewed. Also, 20 doctoral programs (ten each in science education and mathematics education) were studied through document review, questionnaires, and interviews with program deans, faculty members, and recent graduates at the doctoral level. A conceptual model was developed to guide the study, and later modified based on the findings.

Research Design

Literature Review and Analysis of Databases

Literature related to leadership in science and mathematics education was examined along with literature on leadership in other professional fields. Relevant databases were identified and examined for information that could aid in understanding leadership and its development.

Interviews with Current Leaders

A plan for interviewing approximately 80 recognized leaders in science and mathematics education was devised, with ten leaders to be interviewed in each of eight subfields including curriculum, assessment, undergraduate and pre-college teaching, doctoral programs, teacher education, professional development, research, and educational policy. Leaders to be included in this part of the study were identified by project staff, starting with lists of people on editorial boards, involved with major projects (e.g., development of national standards), serving as organizational leaders, and so on. Further nominations were solicited from some of those so identified as leaders and from our national advisory board. Those to be interviewed were selected from this larger pool with advice from the project's national advisory panel. The sample selected spanned the variability in the field along several dimensions, including perspectives about the goals of science and mathematics education, position (leaders by virtue of holding office vs. others who have not held "official" positions), function (to include idea generators, implementers, collaborators who can catalyze others, etc.), and status (leaders who have received awards for their work, and leaders who have been less visible but highly effective).

An interview protocol was developed that focused on background information and three episodes from early-career, mid-career, and recent events that highlighted the development of leadership. The interview protocol was tested and refined by project leaders in face-to-face and telephone settings. A project leader contacted each interviewee and a time for an hour-long telephone interview was established as soon as consent was gained. Interviewers, including both project faculty and graduate students, were trained to conduct the interviews by telephone. All interviews were recorded, and selected quotations from interviews were transcribed. Data were then entered into Filemaker Pro, which was used to support individual- and cross-case analyses.

Examination of Selected Doctoral Programs

Data on production of doctorates in science and mathematics education in recent years were collected from several sources, including Dissertation Abstracts and surveys conducted by the National Center for Educational Statistics. For both mathematics education and science education, a sample of programs was selected to include well-known, visible programs that have produced large numbers of mathematics and science education PhDs over several years. Other programs were included to ensure some variability in geographic location, program structure, and distinguishing features such as success in the production of graduates from minority groups.

We selected ten doctoral programs in science education and ten in mathematics education for study. Project leaders contacted a key staff member in each program to explain the study and secure necessary permissions. Telephone interviews were conducted with the dean who oversaw the program, at least one key faculty member in the program, and two recent doctoral graduates, between 2 and 7 years after completion. Tape recordings of the interviews were summarized as a first step in data analysis. Three additional sources of information were requested from the program faculty members: (1) written responses to a questionnaire regarding specific data on the faculty, the student body, courses included in the program, and support that faculty and students received from varied sources; (2) program plans for five recent graduates, and (3) sample syllabi for key courses in the program. These data were analyzed to provide additional evidence about the experiences graduates received in their program.

Findings

Literature Review and Analysis of Databases

Initial reviews of literature on leadership pointed to difficulties in studying leadership because its dimensions and definitions are not clear and the variety of social influences that affect it remain poorly defined (Pfeffer 1977). One factor that further complicates the study of leadership in science and mathematics education is that leaders in the field may or may not hold formal positions of leadership, whereas most other leaders, such as those in business and government, hold a position with a title and other publically recognized attributes that clearly identify them as leaders. In science and mathematics education, recognition as a leader is often achieved as a result of the creativeness and utility of individuals' ideas, which guide their research, developmental work, and publication.

Further complications arose because there had been little, focused, prior study of leadership and its development in this field. Willard Jacobson, who examined 50 years of science education research, helped us to understand one component of leadership within the science education community (Jacobson 1975); 20 years later, Paul Joslin and Karen Murphy added to that work in a report that was recently published (Joslin at al. 2008). George DeBoer's (1991) work on the history of science education also described the evolution of the field and many of its key players. Robert Yager and James Gallagher's (1982) study of the nation's 35 largest doctoral education centers in science education showed a deficiency in the number of younger professors.

A recent book by two prominent leaders in the field, *Inside Science Education Reform* (Atkin and Black 2003), offers important insights about leadership in science education. These two leaders each give a personal history of their professional development over half a century. Their pathways to leadership differ from one another, highlighting features that were helpful in designing interviews and data analysis for the proposed research. In a complementary work, Kenneth Tobin and Wolff-Michael Roth (2006) compiled an anthology of brief autobiographies of leaders in the field of science education. This autobiographical genre holds promise in delineating varied pathways to leadership and characteristics of leaders in the field.

Research on leadership is also sparse in mathematics education. A study undertaken by Carmen Batanero et al. (1994) concluded that increased availability of formalized graduate programs in mathematics education in universities indicated the consolidation of the academic discipline of mathematics education and its recognition as a field of research. Robert Reys et al. (2001) produced a status report on doctoral programs in mathematics education, providing information about trends in doctoral preparation over the past 20 years. Part of their study addressed the faculty members working in mathematics education in doctorate-granting institutions. They found that 79% of current faculty in such institutions would be eligible for retirement within the next 10 years, signaling an impending major shortfall of available faculty.

Other studies of mathematics and science education leadership, such as those done by Reys (2006), Peter Hewson (2001), and Michael Battista (1994), helped us to refine our conceptualization of "leadership."

In addition to literature reviews, we used data from national surveys. Dissertation Abstracts and the NCES Integrated Postsecondary Education Data System gave us information about numbers of doctoral degrees being granted; the NCES School and Staffing Survey gave us limited information about assumption of leadership roles by teachers and other educational personnel. The National Research Council's

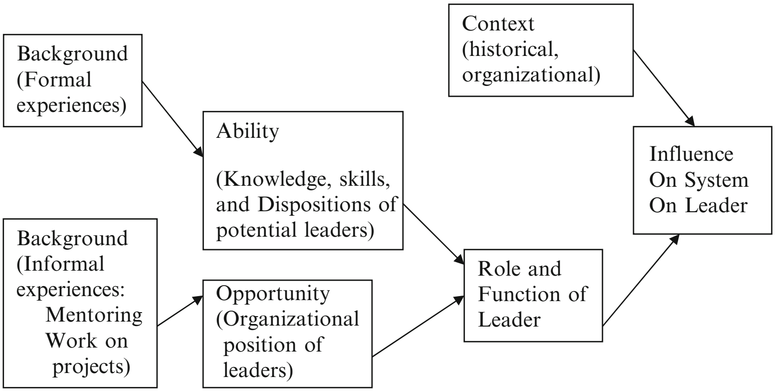

Fig. 32.1 Leadership development model

studies of graduate education (e.g., NRC 1999) were useful sources both for data and methodology.

As anticipated, we found difficulties in interpreting the data that were routinely collected because of imprecision in definitions used for the data. For example, data from Dissertation Abstracts provide an inflated picture of the number of potential leadership personnel for science and mathematics education, as well as the number of potential faculty members who are capable of, and interested in, the routine work in the field. The problem arises because dissertation writers can classify their theses as they wish. As a result, many people in reading and educational psychology who study science or mathematics learning or teaching for their dissertation research may be classified as science or mathematics educators, even though they may not have expertise that qualifies them as professionals in those fields. This inaccuracy of classification does not diminish the importance of their research to the field, but it does give a false picture of the number of people willing and able to engage in science or mathematics education as a career, in teaching methods courses, in providing subject-specific staff development, in developing curriculum and assessment resources, and in contributing to educational policy specific to mathematics or science education.

Conceptual Model for the Project

To clarify the process of leadership development in mathematics and science education, we used the above conceptual model (Fig. 32.1) to guide our investigations and interpretation of data from them. Based on prior research on leadership development, we included factors such as leaders' personal and professional background, motivation, and knowledge related to the eclectic field of science or mathematics education. We also felt that the special abilities and energy that leaders possessed were important factors in leadership in a professional field, and we hoped to learn about the genesis of opportunity, responsibility, and influence through this study.

Interviews with Current Leaders

Several findings emerged from the interviews and are highlighted in the following pages relevant to each research question.

What are the characteristics of current leaders who influence science and mathematics education in crucial arenas of educational activity?

- Interviews were completed with 68 leaders in science and mathematics education with 15 or more years of experience. For leaders with 25 or more years of experience, 69% of the sample was male; for leaders with between 15 and 24 years of experience, the gender balance shifted to a slight majority of females.
- In this sample, 40% of the leaders had earned doctoral degrees in science or mathematics education; 25% held doctoral degrees in science; 3% in mathematics; 24% in measurement or psychology; and 8% in education. Nearly half of the leaders interviewed earned a Bachelor's degree in science and 38% held a Master's degree in science.
- Leaders in the field exhibited important personal qualities including high levels of commitment, tenacity, energy, enthusiasm, confidence, and humility. The majority of the leaders interviewed were altruistic, visionary, entrepreneurial, open to new ideas, and scholarly in their approach.
- Nearly all had high energy and tended to work long hours. Workweeks of 60 or more hours were commonplace. Of equal importance, leaders knew their field well and were able to bring relevant ideas together in framing research questions or solutions to specific problems.
- Most leaders were charismatic, able to excite others with their enthusiasm. Interpersonal skills were complemented by skills in writing and public speaking.
- Several leaders spoke about their "passion" to improve teaching and students' learning in an area of science or mathematics.

What educational and professional experiences led leaders to their positions of leadership and influence?

The data showed that pathways to leadership were highly varied. While leaders of a particular age-range often traced the early development of their careers to experiences in National Science Foundation summer institutes for teachers, an important feature in many of the leaders' developmental scenarios was "taking advantage of opportunities" to play a significant role in a project. At the time the opportunity arose, the leader often felt unsure about his or her capacity to succeed in the new role, but having accepted the opportunity, was able to perform well. Further, success at one leadership task led to more opportunities, and more confidence, to exercise leadership.

The following points highlight additional key findings from the interview data:

- In spite of their energy, background, and confidence, several leaders faced a steep learning curve with their early career positions. Crucial skills and knowledge for "retooling oneself" for new developments in the workplace were needed, such as interacting in new discourse communities, working effectively with professional colleagues, and dealing with new research methods, subject matter content, and proposal writing.
- Particular leadership opportunities were strong influences in career paths. Nearly two-thirds of the leaders identified a specific role that had been significant in their career development, influencing their thinking, visibility, reputation, networks, and future opportunities.
- Nearly all of the leaders interviewed had an apprenticeship period with a mentor, who supported their development as leaders.
- A "norm of collegiality" enabled most leaders to benefit from mentors and many said that mutual learning was common for both mentor and mentee.
- Factors influencing the professional work of leaders were quite varied, ranging from their own dissertation research, prior experiences and understandings, research-based principles and theories, particular research skills, their own philosophy and interests, and practices learned from other societies or cultures.

The range of responses about ideas and experiences informing the leaders' work was surprisingly broad, yet highly informative. This range underscores the individual and creative character of research and development in science and mathematics education.

What has been the role of leaders in influencing the direction and quality of science and mathematics education?

Interviews provided evidence that leaders had exerted a large influence on the character and directions of the field during their careers, which range from 15 to more than 40 years. Moreover, it appeared that their claims were not overstated, as a tendency toward humility, seemingly engendered by the awesome responsibility of educating teachers and developing curriculum and policies that affect large numbers of children for many years, overshadowed any excesses in statements.

Leaders had influenced the field in many ways through their individual and collaborative efforts, including:

- New research questions, methods, paradigms, and centers of excellence for research and development in the field that have strengthened and advanced the nature and quality of research in the field.
- New, broader, more socially appropriate goals and standards for the field, as well as new curricular and assessment resources to support improvements in teaching and student learning.
- High-quality programs in teacher education and staff development for prospective and practicing teachers that are grounded in research, and reflect new educational goals and standards.
- Educational policies that are contributing to improvements in research, curriculum, teaching, teacher education, and students' learning.

- A better understanding of learning, teaching, and the connections among goals, assessments, teaching models, and learning activities, which resulted from research and scholarship.
- Larger, more active professional organizations, and improved professional journals that support a scholarly atmosphere in the field.

Overall the leaders in this study described their work, and its outcomes, in positive terms. They had seen the field of science and mathematics education change substantially over their professional careers. Each also felt that his or her work had an influence on some part of a massive, complex educational enterprise.

Where will the next generation of leaders come from, and what kind of preparation will they need?

In the design of the study, we sought to shed light on this concern, with special emphasis on what preparation will be required by potential leaders in the field. Thus, we chose to explore perceptions of the challenges and issues that confronted the field, at the time of the study and in the near future.

Interviewees, including deans and faculty members involved in doctoral programs, identified several challenges to the field. The most frequently cited challenge facing the field was the need for new leadership. This was in recognition of the aging of current leaders and the shortage of new people at mid-career levels over the past decades, for reasons identified earlier in this chapter.

A second challenge identified by interviewees was the gulf that exists between science and mathematics educators and two key sets of colleagues – teachers in schools and faculty in science and mathematics departments. Part of the difficulty is that the eclectic nature of science and mathematics education is not well articulated as a strength. Instead, academic colleagues frequently perceive it as a weakness. A major difficulty is that the field lacks an integrated conceptual framework to guide its work. As a result, the field frequently is influenced by fads, which critics perceive as ineffectual both from a scholarly and practical standpoint.

Other challenges and issues that were perceived as confronting the field, according to the leaders, included:

- Assessment-based accountability programs, such as No Child Left Behind, which appear to be driving instruction away from understanding and higher-order thinking, toward low-level learning emphasizing factual recall.
- Teacher education seen as failing novice teachers, while requiring large investments in professional development for reeducating practicing teachers.
- The gap between researchers and practitioners regarding the value of theory and research.
- Inconsistent policies and fluctuating support for research and development from the federal government and other agencies.

An implicit assumption underlying deans' and faculty members' views of present-day challenges is that doctoral education needs modification. Existing programs have not attracted sufficient numbers of students, student diversity is too limited and new knowledge and skills are needed to address the challenges facing the field. Therefore, existing doctoral programs should (1) give more emphasis on meeting these challenges, (2) modify program requirements so that graduates have the knowledge and skills to better address the learning needs of science and mathematics teachers and their students, and (3) increase attention to recruitment of students, including minorities.

One added finding from the interviews of deans and doctoral program faculty members was the lack of emphasis on leadership development in their thinking and program structures when the topic was raised in our interviews. Many said that they had not given leadership development much thought prior to its mention in the interviews. Further, all agreed that it was an important, but overlooked, dimension of doctoral-level education.

Examination of Selected Doctoral Programs

Data reported in this section of the study refer to ten science education doctoral programs in our sample. The programs studied were those at the following universities: Michigan State University, Montana State University, North Carolina State University, Purdue University, Teachers College-Columbia, Texas A & M University, the University of Georgia, the University of Texas at Austin, the University of Wisconsin at Madison, and the joint program at San Diego State University and the University of California at San Diego. Two of the programs were less than 10 years old, whereas the others had been in operation for over 40 years. Programs also differed in their location within the university structure. The varied organizational patterns show that there are multiple "models" for science education doctoral programs in the USA; this is also reflected in the diversity of courses offered and program requirements. Only one program was discipline-centered, focused on chemistry education; the others all dealt with education in all of the sciences.

In these ten programs, there were 84 faculty members at the time of the study in 2003, with 52% full professors, 26% associate professors and 20% at the assistant professor level; only two faculty members in these ten doctoral programs were not part of the tenure stream. All tenure stream faculty members held doctoral degrees.

These 84 faculty members earned their doctoral degrees at 44 different universities, though six universities had produced 26 (31%) of the faculty working in the programs we studied. Doctoral specializations of the program faculty were as follows:

- 51% science education
- 24% science (physics, biology, etc.)
- 17% reading, psychology, adult education, feminist theory
- 4% in history of science
- 4% technology education

In 2001, 232 doctoral students were enrolled in the ten programs, with the following demographic characteristics:

- 80% of these students were US citizens
- 20% international students
- 37% female
- 81% White, non-Hispanic
- 9% African-American
- 7% Asian-American
- 2% Hispanic-American
- <1% Native-American
- Two-thirds were full-time

The mean number of students enrolled at each of these programs was 23.2. Considering that students typically are enrolled for 4–5 years for doctoral study, the average number of students entering per year was about 5, with an average of about 3 people per program completing their degree programs each year. Compared to the number of open vacancies in this field, these ten programs do not seem to be producing an adequate number of students to meet the needs of the job market. The shortage of faculty for US programs is made more pronounced because about 20% of enrolled students are foreign, with most returning to their home countries on program completion. Another notable feature about enrollment at the ten science education programs is the low representation of minority students, which will continue the limited cultural diversity within the field.

Doctoral Program Requirements

Doctoral programs studied vary considerably in requirements for admission and graduation, and level of student financial support. However, all programs require an extensive dissertation, with graduate level courses to prepare students for this research and to become working members in the discourse community that carries out research, development, and teacher education in science. While assistantships provided financial support for students at all institutions, only one program claimed that all students received support every year. In several programs, availability of assistantships depended on variations in the university's available budget and external funding.

The ten programs exhibited wide variation in number and kinds of courses or credits required for completion of doctoral study, ranging from 14 to 36 courses or the equivalent of 36–90 credit hours for both coursework and dissertation in science education. Different degrees of flexibility in program requirements also were found among the ten programs. That is, some programs have specific course requirements while others allow students and advisors more choice in program planning, depending on interests and career aspirations. Five of the programs do not have specified course requirements in science, but there is an expectation that, on completion of the doctoral program, students will have a strong background in science that approximates a

Master's degree. In these programs, candidates may enter with a Master's degree in science or they may enrich their background during the program.

Other emphasis areas identified by faculty include multicultural science education, technology, teaching strategies, cognitive science, and research. Three of the ten science education programs strongly promote multicultural science education. Most programs have some requirement for application of technology in teaching.

Research courses in both qualitative and quantitative methods are a part of all programs, although emphasis varies from three to ten courses, with a median of four.

While the researchers in this study knew that doctoral programs in science education differed, the degree of difference among these ten was quite surprising. Perhaps the field needs to address standards for doctoral level education.

Interviews with Recent Graduates

As part of our study we interviewed 20 recent graduates from the ten science education doctoral programs, asking for their perceptions of the program and of their preparation for their present career.

The recent graduates interviewed in this study were generally positive about their doctoral preparation. The vast majority valued program components such as assistantships, mentoring from advisors, dissertation, and other research experiences, as well as opportunities to make presentations at professional meetings. These opportunities were mentioned far more frequently than formal courses as important preparation for their current and future jobs. Recent graduates indicated that the collegial atmosphere in their doctoral programs was an important, positive aspect in their professional development. Unfortunately, not all had the opportunity to serve on projects or university committees, which limited their enculturation into the science education community.

Most of the recent graduates felt that they were treated as partners in this work, and this engendered confidence for their first postdoctoral positions. In contrast, while most recent graduates were pleased with their assistantships, nearly a quarter of them expressed concerns that this entailed "doing the professor's work for them." Perhaps, faculty members could be more explicit about the role of assistantships as part of professional development in the overall doctoral program, making the essential place of specific work more clear.

Most recent graduates said they had the opportunity to copresent research papers with their professors or present their own papers at professional meetings, to meet other members of the science education community, and join professional associations. As they entered their first postdoctoral positions, the graduates felt they were well prepared to write papers and present at conferences; they have continued to write and present.

When asked, all the recent graduates indicated that the idea of having coursework prior to dissertation research was useful in introducing them to new ideas that supported development of conceptual frameworks for their dissertation research, teaching, and other professional work. Although most had teaching experience, many lacked practical understanding of how schools work and how reforms come about. The recent graduates also appreciated learning theoretical constructs on learning, teaching, schooling, qualitative and quantitative research methods, critical thinking, and skills related to educational applications of technology, that influenced their dissertation research, and which they carried with them into their careers. Also, experience in writing grant proposals, and teaching science methods and other science education courses, ranked high regarding preparation for their careers.

In contrast, four out of the 20 recent graduates interviewed did not feel that they were well prepared for their current positions as professors in science education, because they had little or no coursework on pedagogy during their doctoral studies. These sentiments came from graduates from programs that are either content focused or located in departments that are isolated from the Colleges of Education. These recent graduates felt that they could have benefited more from interacting with and taking courses from science education professors. These four also felt that they did not have adequate mentoring as potential leaders during their doctoral programs. Because this represented 20% of the sample, it is cause for concern.

When recent graduates were asked about doctoral programs as preparation for leadership, responses were mixed. About half were confident that their programs prepared them to be leaders in the field, whereas the other half thought they had not been helped to develop as leaders. The majority of individuals who thought they were prepared to be leaders felt that the programs themselves were not meant to prepare leaders. These people said they made an individual choice in favor of assuming a leadership stance. The majority of recent graduates who perceived that they had emerged as leaders attributed the development of this quality to their programs, and specifically to professors who were not "out for their own glory," but supported and believed in their students.

On the other hand, the recent graduates who did not perceive their programs prepared them to be leaders fell into two categories: The first are those who now see themselves as potential leaders in the field; the second say they never aspire to be leaders of any kind. Some of those who see themselves as potential leaders thought that their programs taught them to be more thoughtful, but faculty did not encourage them to write, publish, or present at conferences. Two students described tension that existed between faculty members who differed in their encouragement of students to publish and present papers.

Conclusion

Based on the findings of this study, a revised, more elaborated conceptual model of leadership development in science and mathematics education was constructed that includes emphasis on the personal qualities of leaders and how leadership develops throughout a career in response to forces within the professional community and the larger society. This model is shown as Fig. 32.2.

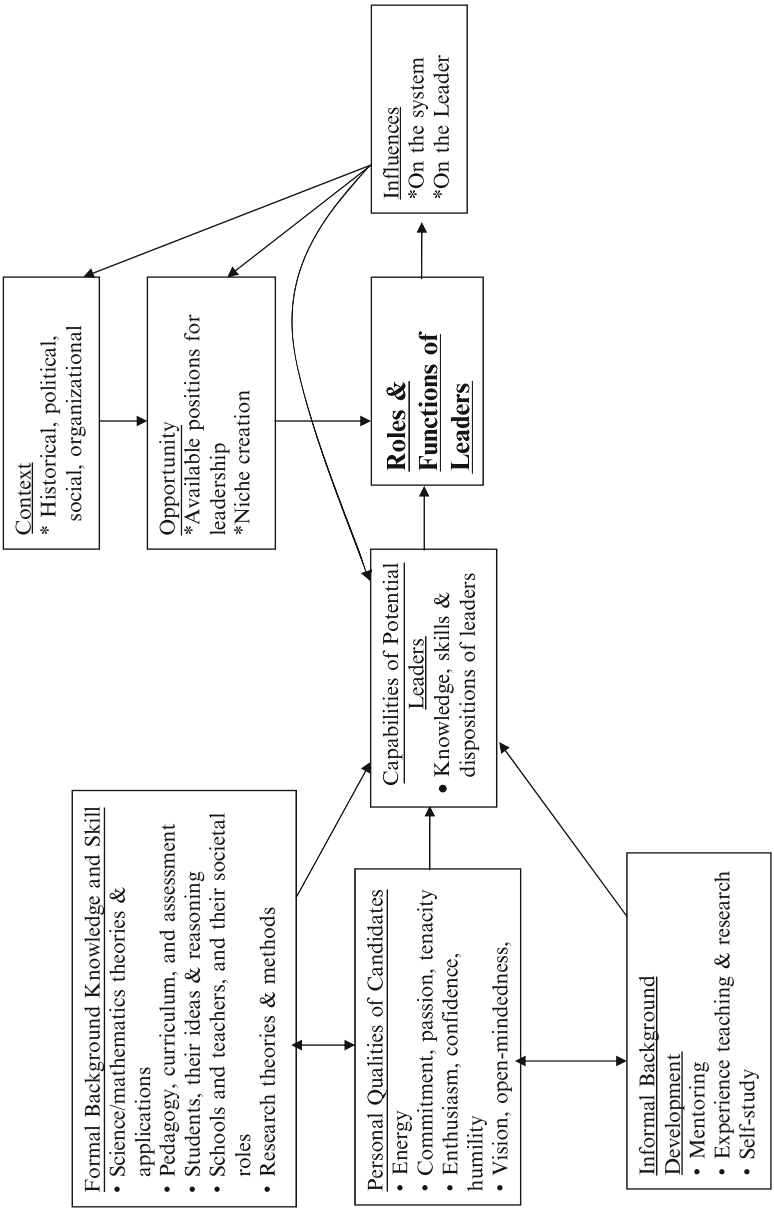

Fig. 32.2 A revised model of leadership development

It is our strong recommendation that deans, doctoral program faculty, and those who influence educational policies give attention to strengthening doctoral programs in science and mathematics education to improve both the number and quality of graduates, including adding leadership development as a program goal. In addition, because continuing high-level support for doctoral programs, and for research in the field, is essential to maintain quality programs and a steady supply of personnel to carry on the work of the field, we also strongly recommend that universities, foundations, and governmental agencies provide more stable funding for doctoral programs in science and mathematics education, and for research in these fields.

Acknowledgments The project was supported in part by a grant from the National Science Foundation (NSF Award No. ESI-0101110). Chapter 33
Research on Science Teacher Beliefs

Lynn A. Bryan

In the mid-1980s, the confluence of the publication of the three landmark documents [*A Nation Prepared: Teachers for the 21st Century* (Carnegie Commission Task Force 1986), *Handbook of Research on Teaching*, (3rd ed., Wittrock 1986), and *Tomorrow's Teachers* (The Holmes Group 1986)], advances in cognitive psychology (particularly as it pertained to teaching), and the increasing popularity of qualitative approaches to educational research propelled research in the domain of teacher thinking in a new direction. Researchers saw promise in examining and understanding the mental constructs and thought processes underlying teacher behavior as a way to yield meaningful changes to practice. A marked shift occurred in how teacher education research was framed – from a *training* perspective that identified and examined the most effective instructional approaches for preparing teachers to perform specific behaviors to a *learning* perspective that sought to understand teachers' knowledge development. Teacher educators began to examine teachers' knowledge and educational beliefs, how knowledge and beliefs change over time, and how teachers' translate knowledge and beliefs in to classroom practices. Research began to focus on the integral relationship between beliefs and actions in order to develop a complete and useful understanding of teachers' thought processes (Cochran-Smith and Fries 2005). Concomitantly, new reform initiatives were emerging in science education, particularly in the USA, calling for the implementation of widespread, diverse, and substantial innovations in science classrooms. Hence, the need to examine teachers' beliefs in relation to their decision making about classroom practices became paramount.

More than two decades later, the field of science education has amassed a literature base on teacher beliefs that establishes that teachers are creative, intelligent decision makers who hold complex systems of beliefs that influence how they view students,

themselves, and science. Science education research has moved from simply describing beliefs and practices toward developing explanations for how beliefs influence practices and vice versa (i.e., why teachers do what they do in the science classroom). This review of international studies on science teacher beliefs attempts to depict the most salient themes that have emerged from more than 25 years of science education research on teacher beliefs. It is not an attempt to report an exhaustive review of literature, but instead provide a survey of informative studies in the field from an international perspective. In addition, this review primarily focuses on research that examines teachers' epistemological and pedagogical beliefs, and does not include large subsets of research literature related to science teacher beliefs such as teacher knowledge, attitudes, and self-efficacy beliefs.

Defining Beliefs

As research on teacher beliefs has gained attention in the science education literature over the past two decades, it is well noted that there is not one consensus definition of beliefs consistently used in the literature. Pajares (1992) referred to the problem of defining beliefs as "at best a game of player's choice" (p. 309), noting that one may find numerous aliases for the construct of beliefs in educational literature. Nonetheless, several works have emerged as being influential in the conceptualization of beliefs as a guiding construct for contemporary teacher thinking research. Among the most prominent scholarship cited in science education research are the works of Milton Rokeach (1968) and Thomas Green (1971), Jan Nespor's Teacher Belief Study (1987), and Frank Pajares's review of teacher belief research (1992). Reviews and analyses of this literature contribute to a consensus that beliefs are part of a group of psychological constructs that describe the structure and content of human thought that is presumed to drive a person's actions. In addition, keeping with the traditional philosophical literature, the term belief implies a construct different from knowledge. Green (1971) stated that while knowledge and beliefs are remarkably similar, the difference between them "seems to lie in the truth condition" (p. 69). Similarly, according to Pajares (1992) the most commonly, albeit "artificially," used distinction between beliefs and knowledge is: "Belief is based on evaluation and judgment; knowledge is based on objective fact" (p. 313). In other words, knowledge carries a kind of epistemological assurance that beliefs do not. Furthermore, from this research a number of fundamental assumptions that characterize beliefs can be derived:

- Beliefs do not exist in complete independence of one another, but are structured into an "internal architecture" of systems that are psychologically, but not necessarily logically organized.
- Not all beliefs are of equal importance to the individual. They are prioritized according to their relationship to other beliefs or other cognitive and affective structures.

- Beliefs are held along a continuum of centrality – some are more central, core, or primary, than others. It follows that the more central a belief is, the more resistant to change that belief will be.
- When a belief is changed, the centrality of that belief has repercussions for the entire belief system.
- Beliefs are far more influential than knowledge in discerning how individuals frame and organize tasks and problems and are stronger predictors of behavior.

Finally, there is a complex relationship between beliefs and actions. Rokeach (1968) argued that what a person espouses as a belief may or may not represent accurately what the person truly believes. He suggested that beliefs cannot be directly observed, but rather beliefs "must be inferred as best one can, with whatever psychological devices available, from all the things the believer says or does" (p. 2). In this vein, what a teacher does in the classroom is representative of his or her beliefs and should not be taken as a separate entity from a teacher's belief system.

Regardless of the limitations or concerns about the definition of beliefs, we do know that beliefs are personal constructs that may provide an understanding of a teacher's practice, and the nature of that relationship, while not simple, is becoming better understood and described in science education research.

Methods for Ascertaining Beliefs in Science Education Research

Science educators have employed numerous methods for ascertaining and reporting on teacher beliefs. When investigating teacher beliefs, most researchers make a distinction between espoused beliefs and beliefs as they are inferred from practices.

Espoused Beliefs

Espoused beliefs are self-reported claims about the way things are or should be. In other words, espoused beliefs are what we say, but not necessarily what we do. Interviews, questionnaires and Likert-style surveys are commonly employed to determine teachers' espoused beliefs. Many researchers design their own context-based instruments such as semi-structured or structured interview protocols and theoretically grounded surveys based on characteristics of a specific national curriculum or intervention programs. Within the last decade, several standardized protocols and validated surveys have been disseminated through the science education literature, including *Attitudes and Beliefs About the Nature of and the Teaching of Mathematics and Science* (McGinnis et al. 2002), *Context Beliefs About Teaching Science* (Lumpe et al. 2000), *Inventory of Scientific and Pedagogical Beliefs* (Porlán 1989 as cited in Porlán and Martín del Pozo 2004), and *Teachers' Pedagogical Philosophy Interview* (Richardson and Simmons 1994 as cited in Simmons et al. 1999).

While quantitative survey instruments and questionnaires such as those described above assist in the comparison of teachers' espoused beliefs (particularly over large populations and between studies), they often veil the details of teaching–learning interactions and the contextual nature of teachers' beliefs. To uncover the idiosyncrasies and contextual nature of teacher beliefs, several studies have employed methods that require teachers to respond to various prompts such as classroom scenarios. One such methodology is the repertory grid technique based on Gregory Kelly's (1963) personal construct theory. Examples of studies that used this technique include the works of John Olson (1981) and Hugh Munby (1984).

Additionally, science educators have used critical incidents, metaphors, and case-based approaches to educe a more detailed portrait of teachers' beliefs. For example, Nam Hwa Kang and Carolyn Wallace (2004) used critical incidents as a tool for identifying teachers' epistemological beliefs. Ken Tobin and colleagues have used metaphors as a vehicle to elicit teachers' beliefs about teaching and learning (e.g., Tobin and LaMaster 1995). Sandra Abell et al. (1998) ascertained teachers' pedagogical beliefs using video cases and a series of reflective prompts in which teachers responded to video case scenarios of other teachers' instruction.

Beliefs Inferred from Teachers' Actions

Espoused beliefs may or may not be consistent with the actions carried out by an individual. Hence, many studies in science education examine teachers' beliefs-in-action: the beliefs that implicitly guide and are inferred from teachers' actions. Methods used to examine teachers' beliefs as inferred by their actions include prolonged field observations documented in field notes, observational protocols, and videotaping. For example, over the past several years, science educators have begun to use digital editing tools to help teachers build "cases" of their own teaching not only for research purposes but also for facilitating teachers' reflection upon and refinement of their beliefs and practices. The *Video Analysis Tool* is a web-based resource that has been used in several teacher belief studies while also serving as a robust and flexible pedagogical resource for teacher education courses (Bryan and Recesso 2006). Randy Yerrick and colleagues (2005) have used *iMovie* for similar purposes. Within the last decade a few standardized rubrics for gathering observational data for teacher belief research have been disseminated through the science education literature including the *Secondary Teacher Analysis Matrix* (Gallagher and Parker 1995 as cited in Simmons et al. 1999) and *Science in Schools Component Mapping* (Tytler et al. 2004).

Salient Themes in Science Education Research on Teacher Beliefs

Many significant contributions to understanding teacher beliefs have been made by scholars in the field of science education. This research presents a portrait of both prospective and practicing teachers who hold deeply entrenched beliefs about teaching and learning, their students, and subject matter. Many studies profile teachers' beliefs in a "snapshot" of time, portraying espoused beliefs as congruous or incongruous with teachers' actions in the classroom. This research is unquestionably important, but should not be construed as implying that beliefs cannot change. Indeed, beliefs are strongly held and relatively static in nature (Rokeach 1968); however, they can be provoked to change. Studies that examine change in beliefs over time often occur within the context of a teacher education program or an intervention aimed at facilitating teachers' refinement of beliefs and actions to be congruous with reform initiatives. Finally, there is a small but emerging set of studies that examine the complexity of teacher beliefs and belief systems.

Congruity Thesis

A number of studies have concluded that s*cience teachers possess beliefs about teaching and learning that influence their classroom practices.* This subset of beliefs literature demonstrates a congruity thesis – that is, the findings depict congruity between a teacher's espoused beliefs and classroom practices. The congruity thesis especially seems to hold true for teachers who espouse empiricist/positivist views about science and behaviorist/transmissionist beliefs about learning.

In her seminal case study, Nancy Brickhouse (1990) examined the nature of science beliefs and teaching practices of one US beginning middle school teacher and two US veteran high school science teachers. The two veteran teachers' understandings of the nature of science and how students learn science formed a consistent set of beliefs for guiding their classroom practice. However, many obstacles prevented the beginning teacher from implementing instructional strategies that were congruous with his beliefs. Brickhouse concluded that teachers' beliefs about the nature of scientific theories, the nature of scientific processes, and the progression and change of scientific knowledge influenced not only their explicit lessons but also an implicit curriculum about the nature of science.

Teacher beliefs about themselves and students as knowers of science have also been shown to influence teachers' classroom practices. Bernard Laplante (1997) reported on the profound influence that the epistemological beliefs of two Canadian elementary teachers had on their choice of teaching strategies. The teachers viewed themselves as consumers of science knowledge (as opposed to inquirers of science) and science as a body of knowledge (as opposed to a process of inquiry). Their teaching reflected these beliefs – the use of teacher-centered strategies in which students engaged in closely controlled activities and were cast as receivers of decontextualized knowledge transmitted by the teacher.

A system of reinforcing beliefs that included traditional positivist-empiricist beliefs and a belief about control of the classroom were found to be particularly influential in driving the practices of a 14-year veteran Mexican high school biology teacher, Maria. In their in-depth case study, Janet Verjovsky and Guillermina Waldegg (2005) concluded that Maria possessed a strongly held system of beliefs that was markedly coherent with her practices. This belief system served as a powerful filter through which Maria unconsciously interpreted new models of teaching and learning and resulted in difficulties in establishing a collaborative learning environment.

The congruity thesis has been demonstrated among prospective teachers as well. In a study of 74 secondary student teachers at the University of British Columbia, Jose Aguirre and colleagues (1990) examined student teachers' beliefs about the nature of science, science teaching, and science learning. Nearly 50% of the student teachers held a belief about teaching as knowledge transfer from sources of authority (such as the teacher's mind and textbooks) to the students "empty" minds. Correspondingly, nearly 50% of student teachers viewed learning as the intake of knowledge. They concluded that holding a positivist-empiricist view of science may be a significant disposition leading student teachers to adopt a more transmissive approach to teaching.

While the majority of studies that demonstrate congruity between beliefs and practices focus on empiricist/positivist views about science and behaviorist/transmissionist beliefs about learning, notably there are a few studies that portray teachers whose classroom practices are congruous with their espoused constructivist epistemological beliefs. For example, in a study that examined teachers' beliefs about the nature of science, Larry Bencze et al. (2006) found that Canadian teachers' espoused beliefs about science, whether positivist or constructivist, broadly corresponded to their tendencies to control student knowledge building or promote student-centered, open-ended scientific inquiries. Specifically, the pedagogical repertoire of teachers who believed that science involves highly systematic methods that lead to conclusions matching reality tended to include teaching practices such as lectures, multimedia presentations, whole-class guided questioning, text reading, and completion of worksheets. On the other hand, when teachers held beliefs that were congruous with a social constructivist view about science, they utilized practices that enabled students to engage in student-directed, open-ended scientific inquiry projects in which students designed their own methods to develop and evaluate knowledge claims.

Similarly, Maher Hashweh (1996) found in a study of Palestinian teachers who held contrasting epistemological beliefs that constructivist teachers used multiple strategies to facilitate students' learning of new conceptions including the elicitation of alternative conceptions and facilitating cognitive restructuring. They had a richer repertoire of teaching strategies. On the other hand, empiricist teachers used presentation of information, explain-and-convince methods, and repetition strategies more often. Hashweh concluded that the effects of teachers' epistemological beliefs are strong and stable across teachers' field of expertise in science and the education level at which they teach.

Influence of Teacher Beliefs on Science Curriculum Implementation

The studies described so far have examined the congruity of teachers' beliefs vis-à-vis their classroom practices so as to establish the influence that beliefs have on teachers' practice. Another set of studies that have demonstrated the influence of science teachers' beliefs on their practices are those conducted in the context of implementation of curriculum innovations and science education reform initiatives. In these studies, the teachers' beliefs and practices, while congruous, typically were in direct contrast with important reform-oriented elements and goals of the innovations. The predominant findings in these studies portray teachers who translated reform-oriented initiatives to "fit" with teaching practices that were strongly supported by their espoused beliefs. These studies document the critical relationship between teachers' beliefs and instructional decisions and demonstrate that *teachers' beliefs mediate the curriculum implementation process.*

For example, one of the earliest studies examining science teachers' beliefs in the context of reform-based curriculum implementation was conducted by John Olson (1981). In this study, Olson examined the beliefs and practices of eight Canadian teachers who participated in the implementation of the English Schools Council Integrated Science Project (SCISP). Utilizing the repertory grid technique, Olson elicited "a picture of [the teachers'] thinking about classroom activity, and particularly about relationships with the students" (p. 262). Olson found that when the teachers attempted to implement the innovative curriculum, they confronted dilemmas as they became aware that how they wanted to proceed with implementation was at odds with the project goals and "doctrine." In the end, teachers either ignored important elements of SCISP that were not resonant with their beliefs, or transformed the curriculum to align with their traditional beliefs about the teacher's role in the science classroom which entailed controlling the direction and goals of the lessons.

Linda Cronin-Jones' (1991) naturalistic case study of two US middle school science teachers portrayed a similar influence of teacher beliefs on curriculum implementation. She found that teachers' beliefs about how students learn, teachers' role in the science classroom, the ability levels of students, and the relative importance of science topics strongly influenced teachers' translation of the intended curriculum. Although certain components of the teachers' belief structures facilitated implementation, on the whole the teachers significantly altered the curriculum to be more congruous with their existing belief structures, which were incongruous with the underlying philosophy of the intended curriculum.

Framed in terms of cultural myths, Kenneth Tobin and Campbell McRobbie (1996) examined the beliefs about teaching and learning of an experienced chemistry teacher, Jacobs. Jacobs made sense of his teaching based on four cultural myths concerning transmission of knowledge, efficiency, rigor in the curriculum, and assessment. The myths related closely to one another and were grounded in two core beliefs: (a) knowledge exists separate from the knower, and (b) the teacher should have power in enacting curriculum. The myths led to classroom practices consistent with the two core beliefs but in clear contrast to the type of instruction advocated in science reform initiatives.

These studies provide examples of the influence of teachers' beliefs on their practices in the context of curriculum reform. Specifically they paint a detailed portrait of how, when teachers' beliefs are incompatible with the philosophical underpinnings and advocated practices of reform-based curricula, implementation of reform initiatives is compromised. On the other hand, since the publication of the *National Science Education Standards* (National Research Council [NRC] 1996) and the resultant shift in emphasis of science education toward more inquiry-centered classrooms, studies have emerged that show a more positive influence of teacher beliefs on the process of reform-oriented curriculum implementation. For example, in a study by Karen Levitt (2001), it was found that the majority of the 16 US elementary teachers from two school districts involved in a local systemic science education reform initiative (called ASSET) held beliefs and demonstrated practices that were consistent with recommendations for teaching and learning science as described in the *National Science Education Standards* (NRC 1996) and facilitated curriculum reform. Moreover, Levitt concluded that in the process of implementing a program of science education reform, beliefs and practices changed in a reciprocal way; that is, not only did teachers' beliefs have a positive influence on curriculum implementation, but the process of implementing the reform-based practices of the ASSET program had a positive influence on some of the teachers' espoused beliefs.

Similarly, Barbara Crawford (2007) found that the US prospective teachers in her study who exhibited the firmest beliefs aligned with a goal of engaging students in inquiry were able to enact those views in their practice, even in the face of "the rough and tumble of practice" (p. 613). She concluded that prospective teachers' belief systems, including epistemological beliefs about science, may well serve as the most critical factor influencing his or her ability and intentions to teach science as inquiry, even more influential than cultural obstacles (e.g., resistant student, mandated curriculum).

The Role of Context and Teacher Beliefs

The role of science teachers' beliefs is significant to curriculum implementation and cannot be overlooked or minimized in the process of curricular change and innovation. However, as many studies suggest, there inevitably exists contextual factors that have a mediating influence on teachers' beliefs in the process of curriculum implementation. As science education studies have documented the influence of teacher beliefs on curriculum reform, studies also have emerged that focus on the role of contextual constraints and demands on teachers' beliefs, practices, and implementation of reform-based curricula (e.g., Haney and McArthur 2002). The context of the teacher includes how the teacher perceives his/her world as well as the teaching conditions that teachers must negotiate on a daily basis. Specifically, these studies have shown that teaching practices associated with positivist/empiricist epistemologies resonate with a number of external teaching conditions that rarely challenge teachers' epistemological beliefs: strict accountability, a culture of time efficiency, mandatory curricula, state and national assessments, teacher socialization. Randy Yerrick and colleagues (1997) asserted that these external conditions may influence teachers to the point that they simply resist thinking about content and teaching in any other way. Even when teachers hold private, individual beliefs that align with constructivist-oriented epistemologies, such conditions often become the mediating factor in teachers' decision making. In these cases, teachers face a difficult conundrum in reconciling what they believe about science teaching and learning with the powerful influence of the constraints that they encountered in the school culture.

"Incongruity" Thesis

Just as there are studies that support the influence of teachers' espoused beliefs on their practices, a competing set of studies exist that demonstrate that *teachers' espoused beliefs do not necessarily influence their actions.* These studies by and large portray teachers who espouse beliefs that are congruous with philosophical underpinnings of reform but are incongruous with their observed teaching practices.

In one of the most comprehensive and long-term studies on science teacher beliefs to date, researchers from nine different US institutions in the Salish I consortium conducted a 3-year investigation of the beliefs and practices of 116 beginning teachers as related to their philosophical beliefs about teaching and their content pedagogical skills. One report from this study (Simmons et al. 1999) focused on 69 participants and showed that overall beginning teachers' espoused beliefs were incongruous with their teaching practices. Specifically, beginning teachers espoused student-centered beliefs and described their teaching practices as very student-centered. However, observational data portrayed a set of teaching practices that starkly contrasted with the teachers' beliefs.

Kang and Wallace (2004) profiled the epistemological beliefs and practices of three US experienced secondary science teachers and concluded that beliefs do not necessarily have a direct causal bearing on teachers' actions. They found that while two teachers who held naïve epistemological beliefs tended to practice in ways that resonated with those beliefs, one teacher who held sophisticated epistemological beliefs about science did not demonstrate instructional practices clearly connected to those beliefs. While the teacher espoused a view of "real science as scientists' tentative explanations validated through rigorous inquiry processes; truths of scientific explanations depend on contexts" (Kang and Wallace 2004, p. 148), he completely separated "real science" from school science and the science teaching context, and therefore did not fully apply his sophisticated epistemological beliefs to his teaching practices.

Vicente Mellado (1998) also found that there is not a clear and direct correspondence between teachers' beliefs and practices. He examined the beliefs and practices of two prospective primary teachers and two prospective secondary teachers who completed their studies at the University Extremadura in Badajoz, Spain. Mellado found that while their espoused beliefs reflected an apparent constructivist orientation toward learning, their observed teaching practices reflected little to no correspondence to these beliefs. In one of the cases in particular, the teacher, Ana, espoused beliefs that were not completely recognized in practice predominantly because her espoused beliefs were epistemologically naïve.

The underdeveloped, naïve nature of teachers' beliefs is a recurring theme in science education literature on prospective teachers' beliefs, particularly in those who espouse beliefs regarding a discovery approach to students' ideas. These teachers tend to believe that children's ideas are valuable simply because they are the children's ideas (Mellado 1998). When prospective teachers espouse beliefs about the active learner roles in which students express their ideas, their beliefs often lacked the attention to the role of students' ideas in reasoning, explaining, and making sense of science phenomena. For example, in a recent study by Yesdan Boz and Esen Uzuntiryaki (2006), 12 Turkish prospective secondary teachers espoused beliefs about chemistry teaching and learning that included a belief that group work and interaction among students in chemistry lessons should involve students in the learning process. However, when asked to describe specifically how students would be involved in the learning process, the teachers' explanations were limited to vague statements about understanding what students think, allowing students to express their views, and learning from each other.

Change in Beliefs: The Influence of Teacher Education Programs on Prospective Science Teacher Beliefs

Research has shown that prospective science teachers' beliefs are formed from years of experience as a science learner, an observer of the profession, and a participant in education courses, as well as from limited experiences as a science teaching professional (e.g., teaching in a practicum, tutoring). Through years of these experiences, prospective teachers have encountered and consumed implicit and explicit messages and images from which they form beliefs that influence their future practice – beliefs about the nature of science, how students learn, what constitutes effective science teaching, the teacher's and students' roles in the science classroom and various other aspects of schooling (Eick and Reed 2002). Prior to their teacher education, many prospective science teachers often have not been exposed to more contemporary educational theory that promotes a view of learning as generative and revisionary in nature. However, as teachers have been entering preparation programs over the last two decades, they have been confronting their largely empiricist, transmission, and absorptionist beliefs vis-à-vis constructivist epistemology and teaching. Nonetheless, conflicting findings have been reported about the influence that experiences in teacher education programs have on teacher thinking and learning to teach science.

For example, in one of a set of studies conducted by a group from the University of Wisconsin-Madison (UWM), Helen Meyer and colleagues (1999) examined prospective elementary teachers' beliefs about science, learning science, and teaching science, and how these beliefs developed over the course of a teacher preparation program that emphasized conceptual change teaching. The three teachers profiled in the study entered the program espousing beliefs about learning in which the learners' role was to receive knowledge presented from other sources. All three teachers made progress in revising their beliefs in the direction of the goals of the program.

However, their progress was dependent upon their individual beliefs about science and science learning. Furthermore, the progress that they made in developing practices that aligned with the program was found to differ among the prospective teachers. In one case, the teacher was hampered by her lack of knowledge of alternative teaching approaches and not having a solid content knowledge base. In another case, there was a mismatch between the teachers' espoused beliefs and classroom practices that reflected her ongoing struggle during the year as she reconciled the tensions between her beliefs and the reality of her teaching.

In another study conducted by the UWM group, John Lemberger et al. (1999) reported on three prospective secondary teachers' beliefs and practices through their teacher preparation program. The prospective secondary teachers entered the program with positivist beliefs about science and transmission beliefs about science teaching and learning. In addition, they believed that the overriding responsibility of the teacher was to ensure that students left instruction with the correct scientific answer, a belief that aligned with their empiricist view of science as an authoritative set of facts. These initial views of teaching science remained a "high-status" conception for the teacher throughout the program. Nonetheless, as the teachers completed the teacher education program, they demonstrated elements of more student-centered beliefs about science teaching and learning. The researchers noted that as teachers exited the preparation program, they were still struggling with the conflict between positivist beliefs about knowledge and transmission beliefs about teaching versus conceptual change teaching.

Keith Skamp and Andrea Mueller (2001) found that 12 Canadian preservice science teachers' beliefs about learning science at the entry of the program were characteristic of discovery learning and process teaching approaches. That is, they believed that students learn by engaging in science instruction, but the nature of that engagement was often limited to working with physical manipulatives ("hands-on" science). Handling concrete materials, in turn, would lead to something that the student would discover and remember. Furthermore, despite the constructivism emphasis of their 2-year postgraduate science teacher education program, the prospective teachers did not change their discovery learning framework of beliefs about science teaching and how students learn, and even slightly expanded those beliefs. The researchers noted that these findings were similar to an earlier study of the beliefs of nine Australian student teachers conducted by Skamp (1995). While student teachers indicated that additional beliefs about effective primary science teaching emerged, they overall maintained their entry beliefs about teaching and learning.

The Maryland Collaborative for Teacher Preparation (MCTP) is an example of a program that reported a significant positive influence on prospective teachers' beliefs about science and science teaching. In a study conducted by Randy McGinnis and colleagues (2002), the attitudes toward and beliefs about mathematics and science of more than 200 prospective teachers were traced over a 2.5-year period. The landscape of teachers' beliefs that evolved over the MCTP program showed that their beliefs moved substantially and significantly in the direction compatible with the guiding principles of the MCTP program, including "mathematics and science for all, the use of cooperative learning, the use of technology to enhance instruction, the fundamental importance of problem solving, and the view that the disciplines are human endeavors open to revision" (p. 719).

Change in Beliefs: The Influence of Professional Development on Teacher Beliefs

The slow pace of reform in science education has been attributed to a fundamental characteristic of teacher beliefs: beliefs are stable and highly resistant to change (Haney et al. 1996). Numerous studies have demonstrated that despite a range of professional development experience – from short summer courses to intense and sustained professional development efforts – the process of facilitating revision and change of teacher beliefs and practices is complex and not always successful. For example, in a study by Yerrick et al. (1997), teachers overall did not shift in their beliefs about the nature of scientific knowledge, teaching, and assessment, despite participating in a professional development program whose goals aligned with tenets of reform. Instead, teachers assimilated "new messages" into their initial set of fundamental beliefs. The researchers concluded that the teachers' "unshakable" beliefs kept them from understanding the merit of present-day scientific inquiry and realizing the tenets of reform.

The difficult process of facilitating teachers' change in beliefs and practices through professional development also was reflected in a study by Jari Lavonen and colleagues (2004). Finnish physics teachers who participated in a 1.5-year In-service Training for Physics Teachers (ITPT) professional development program aimed at enhancing their use of laboratory experiments developed an improved awareness of the goals of classroom experiments. In addition, the teachers reported more attention to using experiments consciously to help students construct meaning. However, while their beliefs seemed to move toward those advocated by the ITPT program, only approximately 20% of the participants enhanced their use of experiments in conjunction with the goals of the program.

Several studies have shown that specific design elements of professional development programs in science education are crucial in facilitating teachers' changes in beliefs and practices. For example, Julie Luft and colleagues (2003) examined teacher beliefs in the context of variations on traditional in-service professional development programs. Beginning secondary science teachers who participated in a *science-focused* support program held more conceptual and constructivist beliefs about student learning, implemented more inquiry-based or students-centered lessons, and felt fewer constraints in their teaching than did teachers in no induction program or a general induction program. These findings support teacher education research that has shown that subject matter focus and sustained contact are necessary for effective professional development.

Mentoring and coaching relationships have been shown to significantly and successfully facilitate the revision and refinement of science teachers' beliefs and practices, particularly in the context of participation in studies in which the teacher and science educator were coresearchers. For example when beginning teachers participated as coresearchers in studies with Ken Tobin, they refined their beliefs and practices through iterative cycles of analysis and reflection upon what happened in their respective classrooms and ways to improve student learning (e.g., Tobin 1993). In these studies, metaphors served as an organizer for beliefs and practices and became a critical tool in facilitating the teachers' change in beliefs. While such a process was difficult, labor-intensive, and required considerable reflection on practice, the teachers noted that they became empowered and accountable for their classroom practice in the process of educational reform.

Complexity of Beliefs

Within the last decade an increasing number of studies have surfaced that focus on the complexity of beliefs. The major assertion of these studies is that when beliefs and practices are found to be incongruous, the relationship between beliefs and practices may not be so simple. These studies have demonstrated various aspects of the complexity – beliefs as clustered, nested, and competing.

Derek Cheung and Pun-Hon Ng (2000) studied the curriculum beliefs of 810 integrated science, chemistry, physics, and biology teachers in Hong Kong. One of the significant findings reported in the study indicated that science teachers' beliefs about curriculum design were held in clusters and had a hierarchical structure. They found that five curriculum orientations (academic, cognitive process, society-centered, humanistic, and technological) clustered together to form a superordinate curriculum meta-orientation. Hence, it was possible for a science teacher to hold several competing orientations. Furthermore, they asserted that the clustering effect may explain the varying degrees of incongruity between teachers' beliefs and practices seen in research.

The complexity of teachers' beliefs has also been characterized in terms of "nestedness." In an interview study of 37 Taiwanese teachers, Chin-Chung Tsai (2002) investigated teachers' espoused beliefs about science teaching, learning science, and the nature of science as traditional, process, or constructivist. He found that most science teachers held traditional beliefs across the three belief categories. Only two of the 37 teachers espoused totally divergent beliefs. Furthermore, more than half of the teachers demonstrated close alignment between their beliefs about science teaching, learning science, and the nature of science, forming a belief system that Tsai termed "nested epistemologies." Similarly, Stephen Waters-Adams (2006) found that the complex relationship among sets of beliefs influenced four English primary teachers' practices, specifically the nested nature of teachers' espoused beliefs about the nature of science and their beliefs about education, teaching, and learning.

While nested epistemologies found in Tsai's and Waters-Adams' studies tended to be experienced teachers, Lynn Bryan (2003) found substantial nesting characteristics in the belief profile of a US prospective elementary teacher. The prospective teacher held a highly complex set of beliefs that included foundational beliefs and dualistic beliefs. One nest of beliefs was based on her vision of science teaching and reflected a student-centered, discovery approach to teaching. This nest consisted of espoused beliefs to which she developed a commitment in her teacher preparation course, but with which she had very little experience enacting in a classroom. The other nest of beliefs was well-developed, supported by years of educational experiences, and reflected a transmission view of teaching and learning. This nest of beliefs had a stronger influence on her practice during student teaching as it was resonant with her foundational beliefs about the nature of science and control in the classroom and created a strong, consistent, and self-reinforcing belief system. The nested and competing nature of beliefs described in this and other studies is resonant with psychology literature in that beliefs within a system that are incompatible or inconsistent with one another may remain so, as long as they are not examined against one another (Rokeach 1968).

Direction for Future Research

Upon reflecting on the international representation of the studies in this chapter, it was somewhat surprising that very few studies addressed the sociocultural dimensions of science teacher beliefs. As the world's population becomes more globalized and populations become more mobile, the demographics of today's classrooms are changing. Classrooms around the world are becoming more diverse. Hence, it seems incumbent upon science educators to consider the sociocultural dimensions of teacher beliefs, particularly as they come to bear on equitable science instruction, or "science for all." For example, what is the relationship between teacher beliefs about culturally diverse students, teachers' decisions and actions, and equitable science learning opportunities for students? What science teacher beliefs are likely to predict successful teaching of culturally diverse students? How do science educators facilitate teachers' change or refinement in beliefs in ways that will assist them in developing science curricula that empowers students from culturally diverse backgrounds?

One series of studies by Okhee Lee and colleagues (e.g., Lee et al. 2007) has been examining such questions, in particular elementary school teachers' beliefs and practices regarding science instruction in linguistically and culturally diverse classrooms. Overall these studies showed that changing teachers' beliefs and practices to incorporate students' cultural and linguistic experiences into science instruction is a gradual and challenging process – regardless of whether or not the teachers shared elements of their students' language and culture. Furthermore, these studies illustrate the complex and nuanced relationships among culture, language, and science learning.

Another line of research for the field of science education to consider relates to the influences of teachers' personal cultural beliefs (e.g., beliefs related to the social norms, customs, values, and social practices associated with a group of people) on science teaching decisions and actions. One example of such a study is Ping Wang's (2004) investigation of the influence of traditional Chinese cultural beliefs on science teachers' assessment practices. Wang described how in a long course of historical development, the Chinese people have developed several cultural bond characteristics. He illustrated through an analysis of multiple cases how the unique concept of "face" and keeping face in the Chinese culture influenced teachers' decisions to implement certain assessment practices. He discussed how cultural beliefs strongly motivated the decisions and practices of the Chinese teachers, even in the era of science education reform:

> Chinese slangs, "Chu Tou De Chuan Zi Xian Lan" (the rafters that jut out rot first—one who wants to be in the fore will get into trouble) and "Shu Da Zhao Feng" (a tall tree catches the wind—a person in a high position is liable to be attacked), to name but a few, reflect the characteristic of Chinese people to fit into the crowd…. A practical representation of the above characteristics in Chinese school system is a collective mode of teaching. [Teachers] are expected to teach with the same approach and at the same pace. (pp. 103–104)

Unquestionably, all cultures have some characteristics and beliefs that distinguish them from others. An interesting and necessary line of research entails uncovering the tacit and taken-for-granted sociocultural aspects of teachers' beliefs and development of knowledge for teaching science. Specifically, what is the relationship between teachers' culture, beliefs, and practices? What are the implications of this relationship on teacher learning?

Concluding Remarks

If teachers' are expected to revise and refine their beliefs and practices, science education instruction must provide ample opportunities for teachers to articulate and confront beliefs vis-à-vis their practices and the philosophical underpinnings of reform. Both teacher educators and students of teaching need to view teaching as a process of inquiry, and view tensions as a necessary stimulus for developing professional knowledge about teaching and learning. Adopting the view that learning to teach science is analogous in many ways to learning science means taking into account that (a) teachers should engage in experiences that contribute to constructing their knowledge about teaching and learning, rather than passively receiving and accepting information; and (b) revising and refining beliefs and practices entails reflection in and on practice (Schön 1983). Science teacher educators must also recognize not only that teachers may hold beliefs that are incongruous with the philosophical underpinnings of reform initiatives, but also that they may not have well-developed knowledge to enact those beliefs (i.e., knowledge of how to use the approaches advocated in reform), as they may not have learned science themselves through the use of instructional approaches guided by these learning principles. Hence, it is essential that as science teacher educators design professional development experiences, they take into account that teachers may need to reflectively consider or reconsider principles of learning derived from research, as well as how to facilitate learning in their classrooms based on these principles.

Science teacher educators also must keep in mind that experience for the sake of experience, is not in and of itself educational. Research has shown the most educative experiences are those that provide substantial support of teacher learning: ongoing assessment and evaluation, time and opportunities for reflection, administrative and community support, and opportunities for observing and being observed. The goal of science teacher education should be to facilitate teachers' disposition to inquiry and to systematically reflect upon their beliefs, practices, and developing knowledge. Teachers at all stages of their career trajectory must continue to challenge and refine their ideas about teaching and learning science and learn how to learn from experience. Learning to observe and analyze teaching; learning to isolate, frame, and reframe problems of practice; and learning to take action and interpret that action are skills that take time and practice to develop. Moreover, teachers' interpretations are fundamental to the process. Rather than confronting teachers with alternative conceptions and administering prescriptions for improving practice, teachers should share responsibility in their learning.

Finally, the complexity studies reviewed suggest that science teacher educators should consider addressing the system of beliefs, rather than targeting individual beliefs. Reform efforts advocate teaching science such that there is a weaving of science knowledge, the nature of science, and science processes in science instruction. Likewise, teacher educators should consider targeting prospective teachers' systems of beliefs about science knowledge, the nature of science, and science processes.

Science education reform in countries around the world advocates a view of learning science that places more of an emphasis on understanding scientific concepts and developing abilities of inquiry, using evidence and strategies for developing or revising an explanation, attending to students' active engagement and learning needs, and acknowledging that students perceive their world through the knowledge and beliefs that they hold. This view of the science classroom means not simply new sets of teacher practices, but a revised and contemporary way of thinking about science and the teaching and learning of science. The success of these reforms indisputably depends upon science teachers' capacity to integrate the epistemology and practices of reform with their beliefs and extant practices. Whether it is a process of refinement or complete revision, it is a matter of learning. Research on science learning tells us that learning begins with the existing beliefs and knowledge of learners. If gains are to be made in terms of reforming science teaching, then teacher educators must tailor instruction to address the beliefs and knowledge of those who are expected to enact the changes. Ignoring or marginalizing the role of teachers' beliefs in the process of improving science education is essentially the same as ignoring the role of students' existing beliefs and knowledge in the process of learning science.

Part IV
Equity and Social Justice

Chapter 34
Still Part of the Conversation: Gender Issues in Science Education

Kathryn Scantlebury

Recent studies and policies suggest that teachers, researchers, students, parents, and policymakers no longer need to consider gender as one of the constructs when examining issues in science education such as students' learning, achievement, attitudes, participation, career trajectories, teachers' perceptions and practices, curriculum, and assessment. For example, in the USA, the major policy impacting K–12 education in the twenty-first century, the *No Child Left Behind* act, requires accountability for students' achievement in mathematics, reading and language arts, social studies, and science disaggregated by race and students with learning disabilities. But because the perception from policymakers and educators is that the education inequities between students attributable to gender are no longer salient, it is optional for state agencies to report achievement data by gender (Kahle 2004). Science education researchers acknowledge that studies focused on gender issues, while ignoring the possible mediation of students' ethnicity, race, religion, sexuality, and/or class, are limited and in some cases can produce misleading results. And there are few studies that have taken into consideration gender, race/ethnicity, religion, sexuality, and/or class when analyzing data and inferring conclusions (Scantlebury and Baker 2007). One reason for the disinterest in continued gender studies in science education may be because researchers have noted for several decades that the differences within a gender are larger than those that exist between genders. A study from the American Association of University Women (AAUW) reported that gender differences between girls and boys have decreased and in some subjects no longer exist. But the analyses typically do not examine students' achievement data broken out by girls' and boys' ethnicity and/or social-economic status (Corbett et al. 2008). The lack of detail in the achievement differences within and between groups of students by gender has limited researchers' understandings of the issues that mediate students' achievement, attitudes, and participation in science.

B.J. Fraser et al. (eds.), *Second International Handbook of Science Education*,
Springer International Handbooks of Education 24, DOI 10.1007/978-1-4020-9041-7_34,

For example, in the USA, the executive summary of the 2005 National Assessment for Educational Progress (NAEP) science results described achievement trends across the grade levels, making comparisons with 1996 and 2000, and examining differences attributable to race. There was an increase in the gap between 12th grade White and Black students. Gender was not reported in this overview chart or at the 8th grade level. At 4th grade level, there was a 4-point gap in favor of boys, but this finding has little practical significance. For 12th grade students, males had significantly higher scores than females, and overall girls' achievement results were the same in 2005 as they were in 1996 and 2000. In the same time period, males' achievement declined. However, the report did not provide further analyses of the factors influencing students' achievement. Is there a difference between the achievement of Black, Latina, Asian, and White girls and if so why? If there are achievement differences between these groups, are those differences influenced by socioeconomic status? Do male and female students within racial, socioeconomic, and religious groups have similar science achievement, attitudes, and participation rates?

The latest study from AAUW focused on the participation of women in science, technology, engineering, and mathematics (Hill et al. 2010). Three major themes emerged from the report. First, there remains a strong perception that males are inherently better at mathematics, and thus more likely to succeed in science and mathematics than women. Based on this perception, US society attributes gender differences in students' participation to their cognitive abilities ignoring the influence of the sociocultural context. However, the report noted that the cultural context accounted for the changes in girls' mathematics participation over the past three decades. Second, girls and women are not interested in science. Third, balancing work and life demands differentially impacts females and males, and women are more likely to leave, or underachieve in science than their male peers (Hill et al. 2010). The report did provide participation and achievement data for various racial groups; students' socioeconomic status was not included in the analysis. And the authors noted that much of the data and studies reported were based upon the experiences of White females. Further research is needed; for example, do the perceptions about students' ability in mathematics change because of race, socioeconomic status, and other social factors? Are our perceptions that African-American, Latina, and Asian girls will have similar success in science? Are there differences in students' interest in science because of race, socioeconomic status, and other social factors? Further, the report showed how few women from African-American and Latina cultural backgrounds pursue and succeed in science; what are the barriers these females face? What are the external, nonwork-related factors that influence women to leave science careers or career paths? What work-related factors contribute to women leaving science? How do the factors differentially impact women from different racial, socioeconomic, religious, and language groups?

In addition to gender researchers ignoring critical questions about the influences that students' gender, ethnicity, race, religion, sexuality, and/or class may have on their learning, achievement, participation, and persistence in science, there are also critical research areas in science education that have ignored, or have not seriously addressed, gender issues. Feminist research has clearly documented the salience of gender, along with other social factors such as race, socioeconomic class, religion, language proficiency, and/or sexuality, yet these factors are not considered in most conceptual change research on how students learn science (Scantlebury and Martin 2010). Conceptual change research has dominated science education journals for the past three decades. However, there are few studies that address how females and males may come to know science differently because of their experiences, let alone consider how other sociocultural factors may combine with gender to ameliorate students' in- and out-of-school experiences.

Within gender studies researchers have often missed the opportunity to further explore nuances. For example, Hanson's study (2009) focuses on African-American girls and science but did not examine other sociocultural factors; the girls were treated as a homogeneous group. While this study provided a counterbalance to the preponderance of research focused on White girls, the opportunity for a deeper examination of the science experiences of African-American girls in various cultural contexts – urban, suburban, and public or private schools – was lost. This is particularly unfortunate if one considers the differential impact that African-American culture has on girls and boys. For example, the role of "othermother" (being responsible for child care for nonbiological children or children from the extended family) mediated girls' continued access to education and their practices within the classroom (Scantlebury 2007). African-American girls have positive attitudes toward science, learn self-reliance, and attain a level of independence that their Latina and White peers do not (Hanson 2009). In contrast, urban African-American boys have lower academic aspirations and higher truancy rates compared with their sisters.

While African-American girls may have higher education aspirations compared to their male peers, their science achievement is below girls from other racial groups. Yet gender research has yet to explore why girls' and boys' socioeconomic status has more influence on their achievement than their race and the role of gender in that finding. For example, an examination of students' achievement on NAEP reading and mathematics showed that girls had higher scores in reading than boys, and boys from low-income families had the lowest reading scores. Similarly in mathematics, boys outscored girls but girls in a high socioeconomic bracket outperformed boys from a low socioeconomic group. But we do not have studies examining girls' and boys' science achievement that consider race along with socioeconomic status. Future research could examine if there are any differences between the science (or mathematics) achievement of high-income African-American, Latina, Asian, and White girls and boys. Other questions may include: Does the low, middle, or high socioeconomic status of African-American, Latina, Asian, and White girls and boys differentially impact their science (or mathematics) achievement? If there are different achievement patterns associated with students' socioeconomic status, race, and/or gender, are these patterns consistent in different cultural settings?

Review of Gender Issues in Science Education

In the mid-1990s, Jane Kahle and Judith Meece (1994) critiqued the deficit view of girls and women that initially framed research in gender issues. Intervention programs focused on "fixing" girls, rather than critiquing science curriculum or science itself. Kahle and Meece recommended that researchers focus on sociocultural aspects of learning. In particular, they noted the role of teachers with regards to encouraging and engaging students in science through their pedagogical practices and curricular choices. Dale Baker (1998) reiterated that view and also included a historical perspective to the low number of women and minorities in science compared with White males, citing the influence of home, how cultural issues can act as barriers to females' science participation, and the impact policy could have on those barriers. A decade later, Kathryn Scantlebury and Dale Baker (2007) noted that science education research had examined broader gender issues, including how heteronormativity impacted science curriculum (i.e., textbooks) and the use of queer theory to critique science teacher education. But overall, the field had produced few studies that examined issues of gender with race, ethnicity, class, religion, and/or sexuality. Further, studies that focused on teachers' attitudes toward gender roles and practices were still needed, as classroom-based research continued to document a range of micro-inequities between girls and boys ranging from access to human (i.e., teacher) and physical resources (equipment), to perceived learners', parents' and teachers' expectations of students' abilities in science which impacted students' science self-esteem and self-efficacy.

Recently, Jennie Brotman and Felicia Moore (2008) classified published science education articles on gender issues for K–12 from 1996 through to 2006 as having a focus on equity and access, curriculum and pedagogy, reconstructing the nature and culture of science or identity. In equity and access, they noted that girls prefer biological sciences and boys continue to be more interested in physical sciences than girls. This issue regarding students' science preferences has remained consistent for over 40 years of research in science education. Researchers have suggested that girls relate better to biological topics, while the cultural influences on boys emphasize more aggressive interests. That is, boys are encouraged to explore and play games that are more aligned with physical sciences (e.g., shooting firearms, explosions that involve loud noises, and other extraneous energy transformations). Students have strong stereotypes that view the physical sciences as masculine and the biological sciences as more feminine. Boys receive more out of school science experiences than girls. Girls' interests in science begin to decline during middle school. However, we do not understand how these general trends are nuanced by race and other sociocultural factors. Thus, science education researchers could begin to examine these data from multiple perspectives.

Brotman and Moore (2008) found that curriculum that builds from students' interests and preferences engaged more students. They also classified researchers' approaches to revising science curriculum as either girl-friendly, gender-balanced, and/or gender-inclusive. Although these terms have slightly different meanings and interpretations, girl-friendly science curriculum evolved in the 1980s in response to various feminist studies of science education. Researchers proposed that science curricula failed to engage girls' interests and suggested revised, "girl-friendly" science curricula. Girl-friendly curricula introduced science topics that girls either stated that they wished to learn or that researchers and teachers thought would interest girls. A key aspect of "girl-friendly" science curricula included the contributions of women to science. Gender-inclusive curriculum attempted to include the interests of girls and boys. Another aspect they highlighted was the importance of engaging teachers with a critical review of the curriculum, and the pedagogy used – especially when these two aspects could reinforce the marginalization of students from under-represented groups, and girls in particular, from science. Their final theme looked at the role of gender in students' identity, especially a science identity. In particular, this area of research has moved away from analyzing data from a female/male binary perspective and argued that others' aspects also shape students' identity – such as, racial background, socioeconomic status, and/or religious affiliation.

Angela Calabrese Barton (2008) introduced three concepts to define critical science agency. Those concepts are intersectionality, counter-knowledge, and solidarity. Calabrese Barton (2008) used examples from ecological feminism to describe how science education could broaden its ideology to produce an education that would resonate with students and provide opportunities for them to embody science as part of their identity. Intersectionality acknowledges the multiple dimensions of one's identity and the complexity of social relations and establishes that women's experiences are multilayered, contextual, and overlapping, and thus subject to society's hegemonic forces and power dynamics. Counter-knowledge expands on those ideas by foregrounding the knowledge and experiences of those who have lived on society's margins. In ecological feminism, women through their activism challenged to improve living conditions for their families and communities. Through environmental activism, groups of women demonstrated solidarity in their voicing of concerns for the health and well-being of their families and their commitment to improving the community's living conditions. Overall, gender research in science education has yet to utilize intersectionality and researchers could explore its potential for providing the new insights into how gender may shape science education students' science education. Further, we could examine how the students typically disenfranchised by science education could become engaged through curriculum focused on local environmental issues. For example, students could become engaged in local environmental impact studies, where they could collect and analyze data about water and air quality, levels of pollutants, and/or biotic and abiotic factors that may influence the quality of their lives and those of their community.

Focusing their discussion on gender issues in the USA, Jasna Jovanovic and Ruchi Bhanot (2008) noted that differing gendered expectations for girls by their parents, teachers, peers, and themselves continue to limit girls' opportunities to learn and succeed in science. They suggested that societies are moving away from gender stereotyping; however, the perception of science as a masculine endeavor has remained a strong image for several centuries. One future direction for gender research in science education could examine why science's masculine hegemonic structures have remained so entrenched.

While the number of girls and women that are participating in science has increased over the past three decades, recent research suggested that student attitudes and perceived value of the subject have remained static and in most countries students' interests in science continue to decline (PISA, Organization for Economic Coordination and Development, OCED 2009). The next section addresses gender issues in science student achievement and attitudes toward science as reported by two international studies, the Program of International Student Assessment (OCED 2009) and the Third International Mathematics and Science Study (TIMSS) (Gonzales et al. 2008).

Students' Achievement and Attitudes

PISA (OCED 2009) provided three reasons for studying gender differences – to identify inequalities, to examine student performance, and to increase an understanding of how students learn. The 2009 report focused on examining gender differences across various subjects for 15-year-old students and found small gender differences in students' science achievement. The three areas on the PISA test were *identifying scientific issues, explaining phenomena scientifically*, and *using scientific evidence*. Males scored better than females on *explaining phenomena scientifically.* Females had higher scores than males on *identifying scientific issues.* Research conducted in science classrooms may offer some explanation of these results. Boys typically offer, and are called upon to answer, questions more often than girls (Scantlebury and Baker 2007). Also, teachers tend to ask boys more conceptually challenging questions. Thus, boys may have more experience explaining scientific phenomena. Girls could identify and understand the features of a scientific investigation that may rely on a student's reading comprehension. Also, their ability to identify variables and identify what other information may also relate to their language skills. Girls have higher reading and comprehension skills than boys. In physical and earth science, males performed higher than females. This pattern has remained consistent throughout the decades of gender studies, and has been explained by girls' preferences for learning about humans and other living things rather than physical science phenomena.

Achievement scores had minimal gender differences and different outcomes depending upon the country. Turkish and Greek girls scored higher than boys, while boys from the UK, Luxembourg, Denmark, the Netherlands, Mexico, and Switzerland scored higher than their female peers. The OCED report categorized countries into one of three groups. First, there were insignificant gender differences in science on the three scales, *identifying scientific issues, explaining phenomena scientifically*, and *using scientific evidence*, and this pattern held for school-level analyses. Thus, regardless of students' geographic location (rural, urban, or suburban) or school size, female and male students performed at the same level on the science scales. A second group of countries had insignificant gender differences at the national level but differences between girls and boys occurred at the school level. OECD (2009) further examined this pattern and found that in Australian and Belgian schools where students had a higher socioeconomic status, boys were more likely to outperform girls. But in Austria, gender differences decreased between students of higher economic status. Also boys from lower socioeconomic standing were more likely than their peers or girls to drop out of school. These variances on student performance have policy implications for school funding and the practices that may reduce gender differences in one country or group of students may not be successful in other settings. Possibly, in Australia and Belgium, students in the higher socioeconomic group might have a stereotyped attitude that may influence student achievement: that science is more suitable for boys than girls. A third group of countries, namely, UK, Luxembourg and Denmark, had significant gender differences overall and at the school level. These results in achievement may be connected to students' attitudes toward science because in those countries, males had more positive attitudes toward science than their female peers (OECD 2009). These results do not provide insights into whether there are gender differences in students' achievement that relate to socioeconomic status and school. Identifying the reasons for these different patterns is another area where gender researchers could conduct studies.

Two attitudinal areas were tested: *interest in science* and *support for scientific enquiry*. PISA used effect sizes to examine students' attitudes toward science on subscales that included *self-efficacy, self-concept, interest in science, enjoyment of science, instrumental motivation to learn science, career intentions, awareness of environmental issues, optimism regarding environmental issues*, and *responsibility for sustainable development.* Males scored higher than females on the *self-efficacy* scale in Japan, the Netherlands, Iceland, Korea, and Taiwan. Previous gender research in Japan found that males studying science in high school and college viewed females as having less science ability than males and science as an inappropriate career for women. Female Japanese students reported that women had the ability, confidence, and interest but there were structural barriers to their participation in science (Scantlebury et al. 2007).

In a majority of the countries there were no gender differences on the *self-concept, interest in science, enjoyment of science*, and *instrumental motivation to learn science* subscales. However, there were slight gender differences in favor of males on *the intent to have a career in science*. When asked about their future careers in science, 15-year-old girls predicted they would become involved with nursing, but only 2% of girls aspired to a career in computing. For countries who are concerned with the numbers of students studying science at college and then continuing into science careers, the continued gender differences between high school males and females regarding pursuing a science degree poses an ongoing and long-term problem. The transition from high school to college and onto a career in science is an area where gender researchers could plan longitudinal studies to examine students' career trajectories to identify strategies for expanding students' participation in science.

The PISA study also addressed the influence of single-sex schools on students' achievement. While there were gender differences favoring males, when researchers controlled for the school's socioeconomic status single-sex versus mixed-sex schooling did not make a difference. In previous gender studies on science career trajectories, researchers documented that many women scientists had experienced a single-sex environment at some stage during their formative years. The single-sex experience could have been in formal education either in high school or college or in their personal lives through being only children or only sisters as siblings. Some researchers investigating the culture in classrooms suggested that girls would benefit by having a single-sex education experience in science and/or mathematics. But the PISA results infer that students' socioeconomic status rather than experiencing single-sex education is more likely to contribute to the differences in science achievement. Moreover, in England and Wales, girls in mixed-sex schools were as likely as their peers in single-sex schools to study physics, although girls in single-sex schools reported a stronger sense of belonging and higher self-esteem than their peers in mixed schools (Murphy and Whitelegg 2006).

The 2007 Third International Mathematics and Science Study (TIMSS) reported gender differences favoring girls at 4th and 8th grades (Martin et al. 2008). Fourth grade girls scored higher on reasoning, physical sciences, and life science but boys performed better on earth science questions. At the 8th grade girls had higher scores in biology and chemistry, and the three cognitive domains of *knowing, applying*, and *reasoning*, while boys scored higher in physics. In 4th, for students with a high self-confidence, girls' confidence was significantly higher than their male peers. The reverse was the case for students with lower self-confidence; girls in this group had a lower self-confidence in science compared to boys. In general, girls receive higher grades in school than boys, as they perceive education as an opportunity. While low-achieving boys, especially those from African-American and Latino backgrounds are more likely to drop out of school, and have less interest in their grades. The different results regarding gender differences from the TIMSS and PISA studies may in part be attributable to the different test styles. TIMMS emphasizes more factual and less interpretive assessments (Kahle 2004). PISA questions are placed within a context, which is preferred by girls. There is also more reading required in the PISA assessments, and as a group girls score higher on reading tests than boys.

There remains a consistent pattern regarding gender differences in students' attitudes toward science, whether the studies are conducted at international, national, regional, or local levels. Attitudes toward science decline for males and females as they remain in school; however, the decline is greater for girls than for boys. If high school girls are educated about discriminatory practices, their self-efficacy and attitudes toward the relevance of science increases; however, their interest in the subject did not increase (Weisgram and Bigler 2007). In particular, students report little interest in physics and girls cite its lack of relevance to their lives (Murphy and Whitelegg 2006). While a group of US female students reported that studying high school physics enhanced their college applications, but they had little interest in the subject (Carlone 2004).

A Hong Kong study examined the interaction effects of grade level and gender on students' attitudes toward chemistry on four subscales: (1) *theoretical chemistry lessons*, (2) *laboratory classes*, (3) *importance or usefulness of chemistry*, and

(4) *behaviors toward learning chemistry*. Significant single and interaction effects were found for gender and grade level. Males had a more positive attitude than females toward theoretical chemistry lessons in lower high school grades. And while males' attitudes on this subscale declined during high school, girls' attitudes improved. Males' attitudes towards lab work declined over their high school years, thus teachers may want to use different pedagogical approaches to maintain girls' and boys' interests in chemistry (Cheung 2009).

Science's perceived lack of relevance to females' lives also remains a reason why women choose not to participate in science at the tertiary education level. For example, undergraduate women of color reported that they disliked large lecture classes, asking and answering questions in class, and engaging in research as undergraduates. Moreover, this study identified that these female students had a negative response to the representation of science as a meritocracy uninfluenced by gender, ethnicity, or race and the presentation of college level science as decontextualized (Johnson 2007).

For the past 30 years, researchers have examined gender differences in students' science achievement, attitudes, and career trajectories in science. Small gender differences exist which may be attributable to students' classroom experiences. However, OECD's study found that gender differences in science achievement varied depending upon the country, the type of school students attended and students' socioeconomic status. The report did not examine these results by students' race. Researchers could begin to examine why there is variance in the gender differences in science depending upon country. In particular, what are the practices and policies in countries where there are no gender differences? Does this pattern hold if achievement and participation data are examined by students' gender, race, socioeconomic status, and other cultural factors?

Restructuring Science Education for Inclusivity

The research provides examples of successful instances when students, and in particular girls, become engaged with, and enjoy science. When ethnically and linguistically diverse, low socioeconomic kindergarten students participated in a 5- or 10-week science program that used inquiry, they had more motivation than a comparison group of students not involved with the program. More importantly, there were no gender differences for the project's students but in the comparative group kindergarten boys liked science more than their female peers (Patrick et al. 2009).

Middle school is a critical time for students because their attitudes toward school and in particular science decline, often along with achievement. Several classroom studies have noted the importance of generating hybrid spaces for girls to construct their science identities (e.g., Calabrese Barton & Tan 2008). When given the opportunity, urban Latina girls produced scientific artifacts such as songs, puppets, posters, and magnets through their ability to incorporate school science into their funds of knowledge. Through these experiences the girls played with their identities in a lighthearted manner that reflected their enjoyment and engagement with science and began negotiating their science roles. These practices formed a third space in which, over time the girls reconstructed their identities to include being a "scientist."

Another strategy that teachers are using to enhance students' ability to form science identities is through the introduction of cogenerative dialogues (cogens). Teachers and students have used cogens as a research and pedagogical tool in urban settings to understand the local cultures of their science classes (e.g., Bayne 2008). "Girls only" cogens with urban African-American girls resulted in the young women restructuring their teacher's perceptions of what it means to "do science," and changing her teaching practices to align with the girls' learning needs and preferences. The girls' science practices began to reflect a hybridity of gender schema that generated science identities, and also utilized cultural practices such as "othermothering" to care for and engage each other in science (Scantlebury 2007).

In another study, girls involved in an after-school science program showed a hybridity of practices (Rahm 2008). Similar to the girls who engaged in cogens together, Sabrina and Tehara used their female friendships as an avenue to construct a hybrid identity that incorporated images of themselves as people who learned, did, valued, and owned science. Findings from this research demonstrate that the informal setting can provide the space and opportunity for students who had previously never constructed "being a scientist" as part of their identities to develop a sense of achievement and science competence and knowledge through the completion of research on topics of their own choosing. The girls in the after-school program constructed their learning space, as did the girls who participated in cogens. By working in a hybrid space to construct their science identities, the girls produced a set of practices and schema that reflected those of "scientist."

Teachers' Gendered Perspectives and Strategies

There are few gender studies that examine science teacher background, attitudes, practices, and career trajectories. However, Shwu-Yong Huang and Barry Fraser (2009) reported gender differences between 818 Taiwanese female and male science teachers' perceptions of the school environment using a survey instrument (STSEQ) with nine subscales*:* Teacher–Student Relations, Collegiality, Principal Leadership, Professional Interest, Gender Equity, Innovation, Resources and Equipment, Staff Freedom, and Work Pressure. Female teachers had more positive attitudes than their male colleagues on Collegiality, Professional Interest, and Gender Equity subscales. While male teachers had a significantly higher score on Principal Leadership and Staff Freedom compared with their female peers. There was a significant difference for the effect size between the two groups on *Work Pressure*, and teachers' gender, school level, subject taught, and the number of years of teaching at current school contributed to these results. Women teachers felt more pressured to complete their work than their male colleagues, but they had more positive attitudes toward their professional relationships. However, a critical finding in the study is of concern to gender researchers, namely, that male science teachers reported that science is a subject more for boys than girls and that these teachers reportedly gave boys more encouragement in science. Female science teachers viewed the subject as equally important for both student groups.

Smaller-scale studies have used qualitative approaches to examine teachers' attitudes toward gender equity. A consequence of the policymakers and recent documents in science education ignoring gender, is that teachers who are in primary positions to challenge and change inequities no longer view equity as it pertains to gender as an issue. Working with a group of 15 science teachers using a case study approach, Kristine Andersson et al. (2009) found that introducing gender theory as the lens for interpreting the classroom events allowed teachers to deepen their reasoning and produce new interpretations of the impact of gender stereotypes on their teaching and students' science participation. The study did not extend to exploring the impact of gender theory on teachers' practices and this is another avenue where the research could emerge.

When examining a female science teacher's pedagogical practices, Maria Zapata and Alejandro Gallard (2007) uncovered tensions for the teacher between her views about science, the production of knowledge, and her pedagogical practices. The teacher in their study, Laura, noted she left the girls in her class to engage with science while she managed her male students. However, the girls could possibly interpret this action as their teacher having less confidence in their science ability than the boys. Laura's unconscious practices toward her female and male students reinforced cultural norms regarding gender stereotypes in students' academic abilities, attitudes, and behaviors.

These studies have highlighted teachers' perspectives and attitudes about gender issues in science education impact their practices and interactions with their students. Moreover, these studies emphasize the need for further research to examine the interplay of teachers' gender and race with those of their students. Introducing teachers to gender theory and also engaging them with the generation of local theory through the use of cogens are possible approaches to meet these challenges. Additionally, researchers and teachers could analyze video of classroom dynamics to uncover unconscious practices that lead to inequities in science teaching (see Martin and Siry 2011).

Rethinking Feminist Science Education

The factors identified above are symptomatic of a larger concern raised by Angela McRobbie (2008), namely that the societal gains made for/by women and girls through 30 years of activism rooted in feminism is being undone through disarticulation and displacement. Disarticulation assumes there is no longer a need for groups to focus on a particular issue and often negates the reasons for forming the group. An example of disarticulation occurs when feminism is portrayed as a movement of angry women who hate men, rather than a group using feminist theory to examine and critique societal structures that impact women and girls. A consequence of disarticulation for feminist perspectives in education is an assumption that as gender gaps in student achievement scores have decreased, "gender issues" are no longer an important issue to consider. For example, in the USA, the *No Child Left Behind* act does not require states to report test results by gender, and there is no disaggregation of data by gender and race/ethnicity. While results of international studies suggest that level of income is also an important contributor to students' achievement, those data are not gathered in the USA.

In a recent US study of over 400 projects focused on gender issues in science, technology, engineering, and mathematics funded by the National Science Foundation, researchers did not report basic demographic data such as participants' gender and race (AAUW 2004). Yet, Western education systems are becoming more diverse as immigration patterns introduce new challenges for stakeholders. For example, in the USA, English Language Learner (ELL) students, or students who are not fully proficient in English, are the fastest growing segment of students in K–12 education and the nuances that impact their learning associated with gender, race, socioeconomic status, sexuality, and religious categories have yet to be explored (Garcia et al. 2008). Another concern regarding gender studies in science education is, apart from a series of studies in the early twenty-first century, Lesbian/Gay/Bi/Transgendered (LGBT) issues have "vanished" from the published literature in science education.

Various racial and socioeconomic groups produce gender differently but as yet, science education has not fully examined how these variations in gender identities impact how students learn and participate in science or their teachers' approach science teaching and learning. Thus, the challenge remains with gender research in science education to produce studies that examine patterns and contradictions associated with gender across social categories such as race, ethnicity, social class, sexuality, and religion. How gender combines with power, identity, and intersectionality should remain part of the conversation in science education and educational researchers are to expand our knowledge about the ways in which gender impacts teaching and learning in science.

Research has shown that girls prefer life science topics, while boys focus on the physical sciences. As science research becomes more interdisciplinary, the gender divide between life and physical science may disappear, but it has been consistent for four decades, and across cultures. Yet the field has not provided definitive explanations for these patterns and studies are needed to examine how students develop their science identities and the influence sociocultural factors, in and out of school experiences, and personal expectations have on achievement, participation, and career trajectories in science.

Another consistent pattern is how teachers' attitudes and practices toward students are influenced by gender, and in this area, there are some studies that address race. The challenge for researchers is to articulate how preservice and in-service educators could improve teacher education to address these issues, given that in many Western countries the teaching populations are becoming increasingly feminized, White, and middle-class. There is a need for ongoing studies that examine gender within the context of social factors, how structures impact gendered social interactions, whether institutional and interactional levels can produce changes in gendered social contexts, and can interactions between individuals be sites for change (Deutsch 2007)? Cogens are successful in helping teachers and science educators to generate local knowledge and theories to improve teaching and learning. However, the call to action for researchers is to examine how those local examples of agency could change education and science's gendered structures because gender remains part of science education's conversation.

Chapter 35
Respect and Science Learning

Adriane Slaton and Angela Calabrese Barton

What Is Respect and Why Is it Important?

Respect is often used, cited, and highly regarded, but there is little in the research literature describing its complexities or the relationship between how teachers and students co-construct respect in classrooms. Notions of respect are intimately connected and vital to the work done in science classrooms. With this chapter, we construct a working framework for understanding respect as a practice as well as to trouble traditional notions of respect focused on respect as static or absolute power and authority.

We put forth the idea of *practices of respect*, or context-specific actions individuals take to publicly appreciate or develop understandings of others and their value. Applying this framework of respect is important if we want to understand how and why participants seek to engage in science learning opportunities as well as to help us consider issues of identity development. With this paper, we make the case that looking at classrooms via *practices of respect* contributes to the field a new working sociocultural framework for observing science classrooms. This framework allows for understanding respect as a practice, troubling traditional notions of respect focused on respect as static or absolute power and authority. Notions of respect are intimately connected and vital to the work done in science classrooms: When teachers and students collaboratively author practices of respect, opportunities to learn are expanded for all students.

Forms of Respect in Literature

Respect has been a part of the lexicon of educators for more than four decades. However, a close analysis of the work on respect shows several different orientations for thinking about the nature or function of respect within school settings. While earlier work tended to focus more on respect as a quality or possession, more recent work has focused on respect as dynamic and situationally contingent. It is with this latter body of literature that we consider respect more deeply. The work on respect can be grouped into two categories: Respect as commodity (something that can be earned, given, or exchanged) and respect as a relationship (something that is enacted between people to define their position vis-à-vis one another). We draw upon aspects of these two orientations to respect to make an argument for the value of framing respect as a practice.

Respect as a Commodity

By respect as a commodity we refer to respect as something that can be given, earned, or exchanged. Early work in this area suggests that one can give respect to another if they assess or appraise the other as having qualities worthy or respect, such as their character traits, abilities, and perseverance (Darwall 1977). This kind of respect, which is also referred to in this earlier work as "appraisal" respect, positions the giver of respect with the power to make the decision about whether respect is worthy to be given.

More recent work focused in urban environments has looked at respect as a commodity that can be exchanged as forms of social capital. Instead of the power to give respect, sociologist Elijah Anderson (1999) examines the power to *earn* respect. Specifically, after chronicling life in high-poverty neighborhoods, he argues that students earn respect through their public image: dress, jewelry, expensive possessions, fighting abilities, and family image:

> In the inner city environment respect on the street may be viewed as a form of social capital that is very valuable, especially when various other forms of capital have been denied or are unavailable. Not only is it protective, it often forms the core of the person's self-esteem, particularly when alternative avenues of self-expression are closed or sensed to be … a people's law based on a peculiar form of social exchange that is perhaps best understood as a perversion of the Golden Rule. (1999, p. 66)

How a commodity is understood or valued depends upon the network of actors present to exchange the commodity. Respect as a commodity does not exist on its own. In this sense, respect as a commodity is situated within relationships, a point we take up in the next section. However, we wanted to call attention in this section to the importance of respect as a resource or tool for gaining access to other forms of capital or even for expressing agency. Elmesky and Tobin (2005) draw out this point in their work where they demonstrate, how, in science classrooms, respect can act as forms of social capital that can be used and exchanged (notably, for science cultural capital):

> Respect … can be conceptualized as a form of symbolic capital or a means by which one's status or the identity others attribute to you can be built, lost, or exchanged for other forms of capital (e.g., social and/or cultural). This symbolic capital can be exchanged for social capital; for example, group membership. … We have gained deep insights into understanding respect as a highly valued form of currency in inner-city classrooms. (p. 814)

Elmesky and Tobin sought to understand how such practices constructed meanings (images, practices, symbols) of respect. They considered how, when students and teachers coauthored curriculum, students were afforded opportunities to build the social capital of respect and how this social capital could then be exchanged for science cultural capital. Further, we thought it of great importance to see how the creation of this capital involved listening to voices, often traditionally marginalized in science. We were intrigued by notions of respect as capital and respect as a tangible good that can be exchanged in beneficial ways in a science classroom.

Respect as commodity challenges us to think about who and what is valued in classroom learning communities and the role of teachers and students co-constructing that value. Respect as commodity also helps us to see how such commodities are tied to social contexts, the resources available there, and the roles individuals play in those contexts. We now turn to respect as relationship to interrogate more directly how and why respect is contextually negotiated.

Respect as Relationship

Respect as relationship offers a lens for thinking about the contextual, relational nature of respect and refocuses the conversation from a *commodity* that is exchanged into one that foregrounds respect as a negotiated *stance* toward another. In other words, while respect as a commodity may be negotiated within relationships, in this section we examine what it means to look at respect *as* a relationship.

Respect as relationship is a dialogic, requiring a deep understanding of the other and a sharing of authority. Respect as relationship also draws our attention to how issues of power are connected to respect: respect "create[s] symmetry, empathy, and connection in all kinds of relationships, even those, such as teacher and student … commonly seen as unequal" (Lawrence-Lightfoot 2000, pp. 9–10). From this stance, respect arises from "efforts to break with routine and imagine other ways of giving and receiving trust, and in so doing creating relationships among equals" (Lawrence-Lightfoot 2000, p. 10). In her book, *Respect*, Lawrence-Lightfoot uses the story of Kay Cottle, a classroom teacher as an exemplar to illustrate the uncertain territory a teacher must navigate in regarding respect as relationship: risk, questioning (of both her authority and the content of the class), and "interweaving ideas" from students. The story of Kay is a story of a teacher enacting respect as relationship. We see a teacher sharing authority, making connections, and questioning. Kay is not "given respect" because she is a teacher and in a position of authority; respect is negotiated.

This greatly pushed us in thinking about respect as being constantly renegotiated by participants and contexts.

For our research we needed a way to conceptualize how individuals enact respect as relationship and how students engage in such a practice. We therefore focused on the concept of respect as "expressive performance" acknowledging others for the value they bring to a situation (Sennett 2003, p. 260). Yet respect as relationship is slippery, for operationalizing how one engages in these expressive performances is amorphous. This is where the work on caring offers useful insight.

What is it about teachers like Kay who are willing to navigate the uncertain waters of respect? We believe the answer lies somewhere in the construct of caring. To better understand the relationship and differences of caring and respect, we turned to the idea that caring is a relationship between the one-caring and the cared-for that is neither contractual nor based on rules, but rather is contextual, involving "a constellation of conditions that is viewed through both eyes of the one-caring and the eyes of the cared-for" (Noddings 2003, p. 13). Further, caring relationships develop by promoting respect and building respect from cultural norms and practices (Valenzuela 1999). Yet the question can be asked as to how these relationships are negotiated amidst power and difference. Engaging in "caring" and "respectful" relationships are often the objects of oppression that youth struggle against:

> Less obvious to caring theorists are the racist and authoritarian undertones that accompany the demand that youth … "care about" school. The overt request overlies a covert demand that students embrace a curriculum that either dismisses or derogates their ethnicity and that they respond caringly to school officials who often hold their culture and community in contempt. Misunderstanding about the meaning of caring thus subtract resources from youth by impeding the development of authentic caring and by obliging students to participate in non-neutral, power evasive position of aesthetic, or superficial, caring. …The definition of authentic caring that evolves in this work thus expands on caring theory to include a pedagogical preoccupation with questions of otherness, difference and power that reside within the assimilation process itself. (1999, p. 25)

Lawrence-Lightfoot's notions of authority and questioning and Valenzuela's introduction of power, otherness, and oppression are extremely helpful when thinking about how respect can reinforce or break down issues of power and authority in the science classroom. Respect as relationship highlights how respect is always an act of positioning and criticality. How one orients himself or herself to care for others while recognizing power dynamics that structure those relationships makes respect possible.

Analytic Lens: Respect as Practice

Based on the scholarship around respect as commodity, as relationship and caring, we put forth a framework to help us think about the dynamics of respect in science classrooms. *Practices of respect* are context-specific actions individuals take to publicly appreciate or develop understandings of others and their value. Thinking about respect in this light operationalizes respect as commodity and respect as relationship. By considering the actions one takes, we can think about how individuals construct respect in the classroom. Further, this lens can help us to understand how and why participants seek to engage in science learning opportunities as well as to think about issues of identity development. We hope to bridge the concepts in the literature of "respect as commodity" and "respect as relationship" into thinking about how (1) practices of respect value traditionally marginalized resources and identities and (2) how practices of respect acknowledge that authority and power dynamics are in constant renegotiation by participants.

Science, although biased and socially constructed, does not have to be a *prejudiced* entity. Yet in the science classroom, and in the scientific community, reality tells us that many perspectives and discursive practices are marginalized (Aikenhead and Jegede 1999). Several theorists advocate the transparency of "Western modern science" (WMS) through postcolonial, critical, feminist, and postmodern theories and further call for multicultural science education that deconstructs what it means to learn and becomes enculturated into WMS (e.g. Carter 2004). Science is not objective or value-free – and it certainly is not objective or value-free in the science classroom.

These critical orientations remind us that science education has the potential to legitimize various forms of knowledge, ways of speaking and relating to the world. Deconstruction of power and authority in the science classroom opens the sciences up for all to reconceptualize, providing participants opportunities to make sense of and value the different perspectives, experiences, and histories each other has to offer. Elizabeth Moje (Moje et al. 2004), among others, refers to this kind of hybrid discourse space as "third space," or a "space of cultural, social, and epistemological change in which the competing knowledges and Discourses of different spaces are brought into 'conversation' to challenge and reshape both academic content literacy practices and the knowledges and Discourses of youths' everyday lives" (Moje et al. 2004, p. 44).

Teachers can create such third spaces that value multiple perspectives and experiences by activity leveraging students' funds of knowledge, sense of place, and ways of knowing (e.g., Calabrese Barton and Tan 2009; Lim and Calabrese-Barton 2006). Yet, it is not just the "presence" of these varied perspectives, experiences, and ways of knowing that make possible such third spaces. It is in how such cultural resources are made *to matter* in the classroom – or in other words, how and why they are legitimized in a science discourse community. One way to think about this process is through practices of respect. In this dialogue, it is important to recognize that this type of pedagogy is not possible without sharing authority, co-constructed learning spaces, caring and legitimizing all perspectives.

Authority, or power to persuade others, exists within all relationships: interpersonal relationships with others, our relationships with text, science, and politics. Authority is often seen as a good teacher characteristic, one that allows classroom management and daily classroom routines to function smoothly. Yet, we know that this imbalance of power can undercut relationships. Sharing of authority calls into question the power given to scientific text and scientific critique as well as questioning who has power in the scientific community and science classrooms (Tan and Calabrese Barton 2007). Respect as practice helps to make teachers more accessible to students, adopt teaching practices that include listening to students, and reconceptualize education as collaborative work. For students, it empowers and motivates (Cook-Sather 2002). For purposes of this chapter, we focus on the constructs of teacher–student shared authority for respect.

We present two classroom vignettes to highlight what we mean by each of these points. We conclude by describing how, together, they offer a framework for practices of respect.

Vignette #1: Rankings

Students in Ms S's seventh grade science classroom were just beginning a unit on forces and motion. Ms S taught at a fairly diverse school, where the students are 43% African-American, 37% Caucasian, 15% Hispanic, and 5% Asian/Pacific Islander; about 67% of students receive free or reduced-fee lunches. Ms S is very well liked by her students and the other teachers, and students often spoke to her in confidence about their problems and issues.

Our first vignette, Rankings, describes an activity in which students ordered animals and objects based on speed. The activity was an introductory activity created through the university partnership. The objectives of the lesson aimed at introducing velocity as connected to distance and time. A lab followed this introduction in which students determined their own velocities doing several different activities (running, skipping, hopping) in which the distance was predetermined and they had to calculate time. Notice throughout the transcript if and how answers are accepted, challenged, or questioned. The transcript begins with one of the students reading the directions for the class in which students are asked to predict the rankings of fastest to slowest animal or object; these animals/objects include 13 items: running turtle, deer, fast walker, attacking hawk, mile a minute, Olympic sprinter, fastball pitch, race horse, lightning bolt, jet plane, fox, car moving at 50 miles-per-hour, running cheetah. Students work on these lists individually and after several minutes, Ms S opens the discussion for students to share their rankings.

1	Ms S	Alright guys. Which one do you guys think was the fastest one? Raise your hand. Yvette?
2	Yvette	The lightning bolt.
3	Ms S	The lightning bolt. Does anybody agree with Yvette with the lightning bolt?
		(*Several students raise their hands, including Fergie*.)
4	Ms S	Alright. Fergie, why do you think the lightning bolt is the fastest one?
5	Fergie	I don't know.
6	Ms S	Who, Why did you put number one next to it? What made you think the lightning bolt had to be faster than the rest of them?
7	Fergie	He told me. He told me. (*points to Joey, who is seated beside her*)
8	Ms S	Cause you listened to Joey. Why would you listen to Joey?
9	Ms S	Alright, Veronica why did you put lightning bolt?
10	Veronica	Because it's fast and it goes real quickly it goes down and then back up (*moves her hand in sync with the words showing it going down and up*)

11	Ms S	So you've seen it before? (*Veronica shrugs her shoulders*)
12	Ms S	Okay. Anybody else? Shawn?
13	Shawn	'Cause lightning travels faster than anything.
14	Ms S	So he's saying light travels faster than anything. How did you know that?
15	Shawn	'Cause I listened in science class last year.
16	Ms S	Alright. Thomas?
17	Thomas	'Cause it's just energy.
18	Ms S	'Cause it's energy. Kay. What about this energy? Explain Thomas.
19	Thomas	I don't know.
20	Ms S	You just think 'energy' when you think of lightning bolts and that just seems fast to you.
21	Yvette	I've seen it. It'd just be like (slices her right hand horizontally across the air and purses her lips as though about to make a "whoosh" sound)
22	Ms S	Say it again Yvette. Why did you think lightning bolt was fastest?
23	Yvette	'Cause I've seen it!
24	Ms S	You've seen it. You've seen lightning bolts before. (*later in the discussion*)
25	D'Angelo	We always compare everything to lightning. When we talk about speed they always say "moves as fast as lightning".
26	Ms S	Yeah! You guys have all heard that saying before. D'Angelo's right. You always hear, "So-and-so's fast as lightning" or "This thing is as fast as lightning." So he's taking that little quote and saying, "Well then, lightning must be pretty fast then if everything's being compared to it." Okay? That's good.
27	Ms S	Yeah, Evan?
28	Evan	Because everything else on the list has to start off slow then go fast, but lightning doesn't.
29	Ms S	Okay. So he's saying that everything else on here kinda starts off slow and then has to build up speed to become fast, right? While lightning is just kind of quick all the time.
30	Thomas	No.
31	Ms S	That's what he's saying. It's okay. Do you think something different Thomas?
32	Thomas	Yeah, it's fast, the fastest one on the list but as it hits something it slows down.
33	Ms S	Okay. As it hits something it slows down. (*Ms S later gives the students the 'correct' rankings.*)

This transcript helps us to both unpack and also make problematic what it means to engage in practices of respect in a seventh grade science classroom.

On the one hand, Ms S designed an activity and conducted a classroom conversation meant to help students elicit their own experiences and stories to open up a conversation on velocity: moving from student to student, allowing all answers into the discussion, using popular culture and personal observation as evidence. Further, each student was given the opportunity to share his or her ideas – this can be interpreted as actions demonstrating appreciation for others. In this transcript we see many students engaging in the activity. These actions, on the part of Ms S, provided entry points into the science for students – allowing them the floor to try out new ideas and possibly new scientific identities. It is important to note, for example, that some students spoke in this episode with ideas and with excitement who rarely spoke in other class periods. While many teachers jump at the "correct" answer or the answer that neatly aligns with their ideas, Ms S allowed the conversation to move in the directions dictated by student ideas. Though we see Ms S's enthusiasm for some ideas over others (as evidenced by questioning and her exclamatory remarks), she still invites in all student ideas. Through accepting and valuing responses all students' responses, she provides the space for students to participate.

On the other hand, Ms S appears to be valuing all students' responses regardless of their scientific validity or their connection to students' own experiences. Two different dynamics seems to be going on in this class session. First, students appear to draw upon each others' ideas to raise their own and to ask questions, which aligns with Ms S's goal to elicit more student participation and interest. In the discussion of "what is fastest," we see students using each other's ideas in the space created for this discussion. We also see how students are using evidence to support their thinking and what is valued as evidence. For D'Angelo, lightning is fastest because of an expression. For Veronica and Yvette, lightning is fastest because they have seen it (and use dramatic action to share the experience). For Shawn, he relies on content from last year's science class. For Fergie, she is listening to another student, Joey. For Thomas, it is because it is energy. For each of these different responses, each is given the floor by Ms S and their ideas are invited into the discussion. While some are traditionally valued evidence in science classrooms like Shawn's, we also see the use and validation of nontraditional evidence by the students and teacher as well. Second, Ms S seems to privilege student participation as "doing the work" of school rather than trying to develop deeper understandings of others' ideas or of the science involved. We explain these points below and use our respect as practice framework to challenge our understanding of this episode.

But a closer look at the transcript reveals that while Ms S is valuing her students' responses publically and legitimizing their wide range of resources, including how the students co-gesture the speed of lightening, she may be working toward respecting their identities as good students and worthwhile people rather than also supporting them in engaging deeply in science. Look what happens when one student, Thomas, tries to challenge another student's claim (line #30). What is particularly interesting in this is twofold: (1) Ms S stands up for Evan, telling Thomas "That's what he's saying, it's okay" and then asking him for his opinion. Again, we see that all student ideas and opinions are given equal value – all are accepted as valid. (2) Thomas disagrees with this notion that lightning is, as Ms S states, quick all the time. His disagreement, that lightning is quick all the time, is not necessarily disagreeing with his peer, Evan, but the way Ms S paraphrased it. While this statement is not discussed as a large group, Ms S does validate and accept it: "Okay, as it hits something it slows down." Throughout this discussion, students state an idea and all ideas are accepted, regardless of student challenge. Ms S has privileged contributing ideas over asking questions. Further, in doing so she potentially privileges the wide range of resources that her students bring to learning about velocity. We use the phrase potentially because while the discourse in the classroom is one where Ms S uses her authority to create the space to allow these resources to become public tools for all to use, she also truncates the space because she does not further support students in taking up these tools to reason more critically about velocity.

If practices of respect move toward also supporting student learning, then teachers and students need to have the space to try on new identities in the classroom that might be at odds with traditional identities for the classroom. Here, Thomas seems to be trying to engage the science. In this sense he is asking to be respected for his science thinking. In this vignette, as Ms S pushes against Thomas's questioning (not valuing Thomas' effort to try out scientific reasoning) in defending Evan's idea (valuing the story that Evan brings to the classroom), she also cuts off opportunity for dialogue among the students – in a sense keeping identity development in check. As such, practices of respect in the classroom seem to reflect what it means to be a good student and even possibly a worthwhile person (that is, one with good ideas), without really considering science learning. A student like Thomas would need the space to challenge a claim (not necessarily fitting a "good student" identity in this class, but allowing for learning). The question then becomes, how are practices of respect negotiated in these classes where such space is created?

Science education has the potential to legitimize various forms of knowledge, ways of speaking and relating to the world. This is where practices of respect enter. As both teacher and student conceptualize what "counts" in science, we believe many marginalized voices may be heard. If we open up how students might initially "talk" in science, then this values the individual as an important contributor and coproducer of scientific thinking, rather than a student who has only the ability to share the right or wrong answer. It is important to recognize that this type of pedagogy is not possible without sharing authority, co-constructed learning spaces, caring, and legitimizing all perspectives. Both teacher and student must enter this dialogue practicing respect.

As we see here, entering into a science discussion in a nontraditional way does not necessarily mean that the student will learn science or gain more meaningful access to science trajectories or science talk. Thus we see the complexities within practices of respect tangled up in social structures, expectations, and positions of power. This vignette also challenges us as we think about authority and sharing power. On one hand, we can see the invitation of student ideas and a conversation that breaks away from more traditional forms of science discussion. Yet we are also reminded that the teacher ultimately holds the power and reminds students verbally as she shuts down Thomas' questioning.

Vignette #2: Rules

In the second vignette, we are allowed access to some of the community's values in terms of its discursive norms and activity. The previous day, the students engaged in their favorite lab of the unit in which they hopped, skipped, jumped, ran, and walked to determine various velocities. The day of the "rules" vignette, they were talking about the reference points and velocity students experienced, witnessed, and calculated the day before. About 20 min into the class period, the teacher stops the discussion and tells students to take out books and start working from the textbooks. In this classroom, bookwork was seen as a punishment. The teacher then tells the students

> I just don't think you guys in sixth hour are getting the message at all. I called parents twice, sent people out to the office, given you detentions. What is it I can do to help you? I'm serious. Raise your hand. There's something I can do, something that would work better.

A student raises his hand and is called on. "Everyday, split the class up with the kids who talk and the kids who don't talk on one side, the kids who do talk on the other … and with the kids who talk on one side, just give them homework. 'Cause then you could tell who's talking." The teacher replies that she wishes she could and that she has considered it. Another student later recommends a similar idea "…You give the kids that aren't doing what they supposed to bookwork and all the other kids do like the experiments and work on computers and stuff instead of punishing everybody." The teacher then asks the entire class to stop what they are doing and write down two rules they would like implemented,

> What do you think the two most important rules should be in this class? Here's a couple questions to think about. What would make you guys more successful in this class? Are there some rules that would help that? What would make you feel more safe, or more comfortable, in this class? Are there some rules that would help that? We said this before, science is supposed to be fun, hands-on, talk to everybody as a group, talk about your evidence, your experiences, your reasonings. The things that go around on the world around you. Are there rules that could help that happen?

As students are writing, Ms S comments: "Obviously there's some disconnect between you and I, or you guys and each other, the class and Ms. P. I don't know. There's some sort of disconnect and we need to figure it out. This isn't a punishment right now. We're just trying to figure out how things should run in here." Students suggest and discuss the following ideas: (1) don't talk when teacher's talking during lesson, (2) less work, (3) raise your hand to talk, (4) everyone should pay attention to the teacher, and (5) do our work.

In the end, the teacher summarizes the class rules:

> It really all comes down to, or at least what you guys are showing me and telling me from all of these rules and suggestions, it's really coming down to one word "respect." Okay? Respecting yourself, respecting me, respecting Ms. P., respecting your other classmates. We know sometimes you guys have your days and you're not gonna be perfect everyday. But today, would most of you guys agree that you were being pretty ridiculous?
>
> (*No student seems to respond.*)

> Off-task, talking, not paying attention, not respecting your classmates, not respecting me, not respecting yourself, because that's what you're here to do is to get an education. You're not respecting yourself when you're not trying to do that.
>
> (*She later repeats this summary*.)
>
> Alright, so overall you guys would agree that we need to respect each other. That's our big number one rule, right? There are some sub-rules we can add to that like "Make sure you're listening when somebody else is talking," right? Alright, does anybody disagree with Thomas and, like, Sean's suggestions about splitting the kids up?
>
> (*Students were separated by teachers at a later date, utilizing two of the student's suggestions*.)

In this vignette we see what discourses and activities are privileged in this science classroom. First, according to Ms S, science is "fun, hands-on, talk to everybody as a group, talk about your evidence, your experiences, your reasonings" and, as such, bookwork (reading and answering questions from the book), are seen as punishment and not "good science." Students take up and reinforce this idea by suggesting that students who are not behaving appropriately should be given bookwork, but students who are behaving appropriately should be able to do experiments and work on the computers. There seems to be an underlying idea that, according to students, all students should have access to science, even if being punished with bookwork (vs. being asked to leave the classroom). Second, we see how the teacher connects classroom management and rules to access to science. For her, the teachers and students must remedy this "disconnect" in order to engage in science. This is so important, in fact, that she asks the class to stop the bookwork and punishment and write two rules. As a beginning teacher, we can understand the difficulties and frustrations of "managing" a classroom. As punishment for not doing "school" right, Ms S removes access to science. Third, we begin to understand, how the teachers view respect: through courtesy (raising hands, listening to teacher, students doing work); and respecting oneself and others is how one gets an education. One can also see the teacher making an attempt to reach out and listen to student input.

Looking back to our framework, one could consider this an action the teacher is taking to publicly appreciate or develop understandings of others and their value, through trying to share authority, negotiating spaces (rules), legitimizing comments of students, and by trying to remedy the perceived disconnect between teachers and students. The students coauthored this practice by offering their own rules for how to remedy the disconnect and explaining to their teacher that they valued all students having access to science, even if the "talkers" only had access to "bad science" (i.e., book work).

The difficulty in looking at this scene may illustrate several instances of practices of respect that emerge when one considers issues power and privilege. For example, how is it problematic for a teacher to accept and enact a student-suggested rule that recommends splitting and labeling the students in a classroom? Similar to the Rankings vignette, we see the teacher still is safely positioned with the power and authority despite outward attempts to share this power. In one light, one can see a teacher taking up a student suggestion, on the other hand, one can see the implementation of this rule as troubling. Another way to trouble this scene is by thinking about nature of the conversation as procedural and management-based.

This vignette leaves us with several questions as we consider the contradictions and intricacies embedded within practices of respect. Could this conversation move to one about how students relate to material, connect the science in their lives to classroom science, or to think about deconstructing science? If we know that students are thinking about science in complicated ways, how can teachers elicit these conversations? Thinking of Valenzuela's discussion of caring as one that "include[s] a pedagogical preoccupation with questions of otherness, difference and power that reside within the assimilation process itself," we wonder how this conversation could really push on the ideas and boundaries of practices of respect. In what ways was the teacher engaging in a practice of respect and in what ways was she not? In what ways do practices of respect influence student engagement in a science classroom?

CODA

Neither science education nor our students exist within a vacuum. In very complicated and nuanced ways, teachers and students must deeply understand the dynamic nature of context in order to engage in respect. Learning is situated; it is "a process in which outcomes and goals are shaped by learners as well as by other historical, political, social, cultural, and physical factors" (Calabrese Barton and Brickhouse 2006, p. 223). Building on this idea, the authors describe the embodied nature of science and help us to think about how learning science goes beyond learning content and facts but involves learning how to participate in scientific communities and discussions. This learning has to be contextual: it is necessarily historical, political, and cultural and because of its humanity, requires us to think about the people (students) involved in the science classroom. Here we see that both science context and identity development are dynamic. The recognition of science as contextual and dynamic allows for practices of respect to be co-constructed.

Practices of respect call into question the idea that science teaching and learning is a neutral process. What and how students learn is deeply situated within a sociocultural and historical context and embracing such contexts makes possible a teacher's or student's ability to engage the other in thoughtful ways. "Unpacking" or "making sense of" the contexts (and the power dynamics therein) that shape context is an important part of the process of understanding others. If, for example, the way we teach science in schools leaves silent the sociocultural features that surround the "making of a scientific fact," then how students learn to value each other as users and producers of science is also made silent. Respect is important for how students and teachers engage in the class in that it increases both teacher and student engagement. Further, practices of respect help us question *who* is allowed to learn and *what* students are allowed to learn.

Chapter 36
Science Education in Rural Settings: Exploring the 'State of Play' Internationally

Debra Panizzon

The existence of the *Journal of Research in Rural Education, Education in Rural Australia, Rural Educator* and the *Rural Society Journal* reflects that rural education is a clearly defined area of research. Reviewing the articles represented in these publications highlights (a) a broad diversity of topics pertinent to the research area (see Arnold et al. 2005 for a recent synthesis) and (b) an apparent dichotomy around the focus of the research. For example, at one end of the spectrum, studies emphasise what Mary Jean Herzog and Robert Pittman (1995) refer to as a 'deficit model' of rural community and lifestyle as they explore the issues and challenges experienced by schools situated in these locations. Debra Holloway (2002) provides an extensive synthesis of this literature as she discusses the variety of concerns facing teachers working in rural communities in the USA. At the other extreme, research accentuates the high rate of success underpinning education and schooling in rural areas (Haller et al. 1993; Alspaugh and Harting 1995; Arnold 2001; D'Amico and Nelson 2000). Joyce Stern (1994) particularly acknowledges the early 'pioneering' role of rural teachers in the USA by implementing strategies around multi-grade teaching, cooperative learning, interdisciplinary studies, peer tutoring and block scheduling, which are now commonplace in classrooms across the globe.

This dichotomy is also evident in the science education literature, although the pool of available studies with a focus on rural settings is considerably fewer. The most recent publication by James Steve Oliver (2007) is a book chapter entitled *Rural Science Education* in which he addresses four broad aspects. First, he considers the many difficulties around defining 'rurality' and attempts to identify characteristics of rural schooling that are 'universal'. Second, he provides a historical perspective on research in science education from the 1960s to the 1990s that

describes the condition of rural science teaching during the period. While focused predominantly on research conducted in the USA, the findings are pertinent to other countries facing similar challenges. Third, he outlines the Rural Systemic Initiative Movement in Science, Mathematics and Technology Education (RSI) in the USA and six drivers to use as "guideposts or standards about which the progress of systemic reform could be measured" (2008, p. 357). Finally, he discusses the ramifications and implications of these findings for teacher education programs. This is a critical component if educational authorities are to devise policy around the provision of challenging, relevant and opportune pre-service and in-service professional development to address the needs of rural science teachers.

The work of James Steve Oliver (2007) and others begins to unravel the apparent inconsistencies in the research data for rural settings. This chapter attempts to develop the area further by exploring the following questions. What is the extent of the impact of a rural location on student achievement in science internationally? What can we extrapolate from the existing research around rural education that helps to explain the dichotomy in the findings? Considering the research findings more holistically, what direction for science education in rural settings emerges for the future? Subsequently, rather than critique a range of individual research studies around science education in rural settings (given that this already exists), this chapter identifies the major themes emerging from this prior research and attempts to provide a broader and holistic perspective upon which to consider future directions.

Student Achievement in Rural Settings

In considering the research available around science education in rural locations, student achievement is often a prime area of focus. This is one area where inconsistencies in the data proliferate, with some studies suggesting that students in rural areas achieve more highly than their peers in urban centres (Fan and Chen 1999) while other research suggests that the reverse is the case (Canadian Council on Learning [CCL] 2006; Panizzon 2009). What is most interesting from a research perspective is when these discrepancies occur *within* the same country. For example, in the case of the USA, Frank Beck and Grant Shoffstall (2005) found that rural students in Illinois attained higher results for the Illinois Standards Achievement Test (ISAT) than their urban peers. Alternatively, Vincent Roscigno and Martha Crowley (2001) identified that students in rural areas exhibited lower levels of achievement than urban students using National Longitudinal Education Study (NELS) data. Clearly, one issue emerging here is that comparisons within or across countries are difficult given the lack of a common metric or standard upon which to base the evidence. This is complicated further by the alternative definitions of rurality used in particular studies (Kannapel and Young 1999 for the USA; Lyons et al. 2006 for Australia). However, data from the Programme for International Student Assessment addresses both issues and provides a common metric and consistency around a definition of ‘rurality’. For PISA, geographical locations are defined solely around population size:

1. Village, hamlet or rural area with fewer than 3,000 people
2. Small town with between 3,000 and 15,000 people
3. Town with between 15,000 and 100,000 people
4. City with between 100,000 and 1,000,000 people
5. Close to centre of a city with over 1,000,000 people (OECD 2006)

To facilitate a comparison across participating countries, mean scores for science from PISA 2006 were reviewed along with their standard errors (*SE*). This measure expresses variation around the mean, with a lack of overlap of *SE*s suggesting significant differences between the individual values. Results of this analysis for selected countries are summarised in Table 36.1.

In reference to Table 36.1, three broad patterns in relation to location are identifiable including countries in which the:

- Mean score for rural students is considerably lower than urban students’ scores
- Mean score for urban students is lowest when compared to all other locations
- Mean score variation across geographical locations is minimal, suggesting a high degree of homogeneity

Considering the first set of countries, the relatively low *SE*s across PISA categories for Australia, Canada and to a lesser extent New Zealand is indicative of potential significant differences. The extent of the ‘rural versus urban’ divide in student achievement for these countries is supported by research including Lyons et al. (2006) for Australia, the Canadian Council on Learning (2006) for Canada, with Panizzon (2009) reporting initial evidence of a gap in New Zealand. The data for Korea suggest a clear gap between the rural students (i.e. PISA categories 1–2) and students in more urbanised areas (i.e. PISA categories 4–5), even though the *SE*s are high for a number of these categories. Germany is interesting in that students in small towns and cities (i.e. PISA categories 2–4) achieved more highly than both highly rural and urban students (i.e. PISA categories 1 and 5, respectively). However, the high *SE*s for three of these categories indicate that the differences might not be significant, thereby explaining why this gap is not documented in the literature.

In contrast to this first group of countries, results for the UK and the USA suggest that rural students achieve higher mean scores than their urban peers. While little research is available to corroborate the results for the UK, as discussed earlier, there is considerable research data from the USA that provides conflicting results about student achievement according to geographical location. It is interesting to note that, in the USA, the highest mean score is for PISA category 3 representing centres with populations of 15,000–100,000 people. Clearly this raises the issue about how ‘rural’ is defined, which goes part of the way in explaining some the inconsistencies in the data for the USA. This aspect is discussed in detail later in the chapter.

The final pattern of countries including Denmark and Ireland suggests a high degree of homogeneity with minimal differences in the achievement of students in

Table 36.1 Patterns of science means for PISA 2006 based on geographical locations

Pattern across geographical location	Examples of countries	PISA category	*M*	SE

		4	513	13.23
		5	516	8.36

[a] Different pattern from other countries in the group

relation to location evident from the data. Hence, neither country is likely to be represented in the rural education literature, which does appear to be the case.

Subsequently, this broad analysis of data patterns indicates that the gap between the achievement of rural and urban students appears to be an international issue for a number of countries that participated in PISA 2006. However, other examples are evident in the literature with Adebowale Akande (1990) highlighting a gap for Nigerian students; Christine Liddell (1994) within the South African context; Harold Stevenson and colleagues (1990) for Peruvian students; and, finally, UNESCO (2003) for students in South American countries. Critically, only a small proportion of these countries is represented in the research literature.

In an attempt to explain this particular outcome, it is important to recognise the need for higher-level statistical analyses to ensure that confounding variables do not mask the impact of location. An excellent study that demonstrates the importance of statistical procedures being applied and implemented in this manner is provided by James Williams (2005) in a detailed study of PISA 2000 mathematics results. A number of the aspects raised by Williams are discussed in the following section.

Reflecting on Rural Science Education Findings

An audit of the science education research literature for rural settings highlights a wide diversity of topics impacting rural schools including teacher recruitment and retention (Holloway 2002), teacher subject knowledge (Carlsen and Monk 1992), teacher qualifications (CCL 2006), teacher preparation and the quality of ongoing professional development (Holloway 2001; Oliver 2007), accessibility to resources (Truscott and Truscott 2005) and teacher expectations of students (Gilbert and Yerrick 2001). Again, there are often contradictions about the extent to which these aspects impact on rural schools. To help explain some of these discrepancies, Wang Fan and Jin-Quan Chen (1999) highlight four potential limitations in relation to the research findings including: (a) inconsistent and unclear definitions of rurality; (b) the potential for ethnicity and the school sector to act as controlling variables; (c) issues around school selection and the research sample; and (d) socio-economic status (SES) as a confounding variable.

Potential Limitations of Previous Studies

1. *Definitions of rurality*. Implementation of different criteria across and within country comparisons make comparative studies meaningless because population size (OECD 2006; Stern 1994), school size (CCL 2006; Huang and Howley 1993; Simpson and Marek 1988) or the area served by a school (Liu and Brinlee 1983) are used to categorise rural and urban localities. Complicating this further, students live in what can be defined as urban locations but they choose to travel

to rural schools. This increased mobility makes it even more difficult to define 'rurality' (Gilbert and Yerrick 2001).

2. *Ethnicity and the school sector as controlling variables*. Fan and Chen (1999) suggest that ethnicity varies markedly across geographical locations, although, historically, there was greater homogeneity in rural areas (Nachtigal 1982). Given that links between ethnicity, poverty and socio-economic status are identifiable in the broader research literature, researchers suggest that ethnicity needs to be considered as a confounding variable in any analysis of rural settings (Biddle and Berliner 2002; Truscott and Truscott 2005). Similarly, few studies differentiate between public and private school sectors in their designs, even though significant differences in student achievement between the school sectors are evident in the research data (Fan and Chen 1999). This aspect is elaborated upon in relation to the research sample.
3. *School selection and research sample*. James Williams (2005) and James Oliver (2007) raise the issue of relying on convenience or local samples of schools that do not provide appropriate representation. In their view, most rural research merely incorporates rural schools because of convenience, with few research studies actually seeking to understand the 'rural-specific issues' relevant to the context. As quoted by Mary Jean Herzog in Topper Sherwood (2000, p. 161): 'People will do a study in a rural area and think this makes it a rural study; but they aren't necessarily the same thing'. This aspect was explored by Michael Arnold et al. (2005) through a detailed audit in which they filed studies into two possible categories. *Rural-specific studies* focused on issues in rural schools and were indicative of 66% of papers. In contrast, *rural-context studies* explored generic issues in rural school and accounted for 34% of the literature. Such representation is positive although Fan and Chen (1999) suggest that, without a non-rural setting for comparison in any rural study, it is impossible to discern generic teaching-related issues from those that are rural-specific. Importantly, comparative studies across urban and rural settings are rare in the science education literature.
4. *Socio-economic status (SES) as a confounding variable*. There is already a strong correlation demonstrated between student achievement and socio-economic status in the literature (CCL 2006; Howley 2003; Khattri et al. 1997; Williams 2005). In many countries (e.g. Australia) rural settings tend to have lower socio-economic status than urban areas so that any analysis that does not control for this variable hides the actual impact of locality on student achievement in science (Lyons et al. 2006). For example, in a large-scale study of rural Australian students in science, Diedre Young (1998) used multi-level modelling techniques to control for SES to highlight that students were not disadvantaged by location but by differences in relation to their self-concept. In her view, student variability in science achievement was influenced more at the level of student and classroom than by geographical location. To explain this result further, Williams (2002) suggests that, while Young (1998) considered community-level SES, it is critical to distinguish this from school-level SES, which is overlooked in the majority of research studies.

Attempting to Address These Research Limitations

A number of these limitations were addressed in a large-scale national study conducted in Australia around science, mathematics and information and communication technology (ICT) education (Lyons et al. 2006). The study consisted of five questionnaire surveys designed for primary teachers, secondary science, ICT and mathematics teachers and parents. Essentially, the science teacher surveys sought views around the availability of: (a) qualified science teachers in schools; (b) material resources and support needs; (c) accessibility of professional development; and (d) the availability of science learning experiences for students.

Schools in the study were categorised using the MCEETYA Schools Geographic Location Classification based upon population size and accessibility to a range of facilities and services to produce four main categories: Metropolitan Areas, Provincial Cities, Provincial Areas and Remote Areas (Jones 2004). Surveys for secondary science teacher were distributed to 1998 secondary departments or faculties (i.e. high schools) in all provincial area and remote area schools (i.e. rural schools) across Australia, along with a stratified random sample of 20% ($n = 291$) of metropolitan secondary departments. Responses were received from 580 secondary science teachers representing 334 secondary departments.

A number of analytical strategies were implemented including chi-squared tests on categorical data, principal components analysis on Likert Scale items, and MANCOVAs for comparing the component scores across various respondent categories (e.g. sex, indigenous populations). The MANCOVAs also controlled for the effects of school size and the socio-economic background of the school location. Some of the major findings were:

- Science teachers in different locations reported significant differences ($p < 0.001$) in the annual turnover rates of staff and the difficulty in filling vacant science teaching positions when compared with teachers in metropolitan schools.
- Science teachers in provincial cities and areas were twice as likely, while those in remote areas were four times as likely, as those in metropolitan areas to identify that it is ‘very difficult’ to fill vacant science teaching positions in their schools.
- Science teachers in provincial areas were twice as likely, and those in remote areas were about three times as likely, as those in metropolitan areas to teach a science subject for which they are not qualified.
- Science teachers in provincial and remote areas demonstrated a significantly ($p < 0.001$) higher unmet need than teachers in metropolitan areas for professional development opportunities that provide help with teaching targeted groups of students (e.g. gifted and talented, indigenous and special needs). In contrast, teachers in metropolitan schools had a lower level of unmet need for *every* professional development and resource item (e.g. laboratory consumables) included in the survey.

Incorporation of a representative sample of rural and non-rural schools in this study facilitated the comparisons necessary to identify significant differences between the needs and experiences of secondary science teachers across geographical locations in Australia. Strengthening the emergent findings from this study was the controlling of school size and socio-economic status, thereby addressing some of the limitations identified in previous research (Arnold et al. 2005; Fan and Chen 1999; Williams 2005). Another positive outcome of the study is that it provided an opportunity to compare the findings across secondary science, mathematics and ICT teachers given that similar but separate surveys were implemented with each group of teachers (see Lyons et al. 2006 for the full report).

However, one of the constraints of the national study was the focus around issues already evident in the literature (i.e. retention, resources, professional development). So, while it provides substantive evidence for Australian educational authorities about prevailing concerns around the teaching of science in rural settings when compared to other geographical locations, it did not allow other factors not yet identified in the literature to be investigated.

Clearly, much is known about the types of factors that influence the effectiveness of science teachers in rural communities, even though the data are somewhat inconsistent. The discussion of potential limitations of previous research goes some way in explaining some of these ambiguities but not all. Another key component to recognise is the diversity that exists among schools and communities that are designated as rural. For example, Mike Arnold (cited in Sherwood 2000, p. 161) suggests that 'there is poor "rural" and wealthy "rural". There's "rural" with no minorities, and "rural" with high minorities'. Similarly, Jerry Horn (1995, p. 3) states: '[T]he simple fact is that rural people, rural communities and rural conditions are so diverse that one can find evidence to support nearly any characterization'. Hence, it is recognition of this variation within rural settings that helps to explain further the discrepancies in the data around student achievement and the impact of schools in not only rural but also urban education. This component is explored in more detail in the final section of the chapter.

Future Directions for Rural Science Education Research

In 'stepping back' from the literature, alterative perspectives emerge that compel us to consider science education in rural settings in a more holistic fashion. Before exploring this avenue further, it is imperative to recognise what Alfred Schultz referred to as a 'life-world' (Schultz and Luckmann 1973) around rural communities that must be understood to appreciate the complex and highly dependent interactions that exist between rural schools and the communities in which they reside (Barley and Beesley 2007; Harmon et al. 2003; Howley et al. 2005). Critically, this life world is very different from that of an urban setting, which explains the importance of specific science education research for rural and urban settings. However, given this premise, it is possible to identify similarities across the two spheres that 'unifies the cause' (Truscott and Truscott 2005). For example, Howley et al. (2005, p. 3) suggest that:

> [r]ural education research simply must ask what sort of schooling rural kids are getting, why they are getting it, who benefits, who gets injured in the process, and by what mechanisms?

Surely, the same questions are pertinent to research around urban schooling? Perhaps finding an alternative way of conceiving the research area will help to overcome some of the difficulties experienced by researchers in their attempt to develop a coherent research framework around rural science education (Kannapel and DeYoung 1999; Lyons et al. 2006; Oliver 2007). As expressed by Topper Sherwood for the US context (2000, p. 164):

> Researchers have tried to establish a 'rural education research agenda' at least since 1984, but no effort seems to have been dynamic enough – or well funded enough to capture the research community as a whole. Successes in rural research have been as isolated as some rural communities.

Diane Truscott and Stephen Truscott (2005) provide a radical exemplification of an alternative lens by suggesting the replacement of the rural–urban antagonism with a 'high-need versus resource-rich school' perspective (p. 1). In their view there are four critical factors that impact on the quality of education received by students regardless of location.

1. *Catering for increasing diversity*. Truscott and Truscott note that, over the last decade, there has been an increase in ethnic and racial diversity in many rural communities in the USA as people migrate away from urban centres in search of work. Subsequently, there is no longer the ethnic homogeneity assumed in much of the early rural education literature (Nachtigal 1982).
2. *Overcoming childhood poverty*. One of the most ubiquitous challenges for all schools is that poverty is linked not only to ethnicity but also to lower student achievement and self-efficacy (Biddle and Berliner 2002; Teachman et al. 1997; Young 1998). Quite simply, 'poor children fare worse in school and are less likely to graduate from high school' (Truscott and Truscott 2005, p. 2). This statement is supported by research evidence that recognises poverty as an issue in both rural and urban schools, with traditional generalisations about the wealth of rural communities in the USA being no longer applicable (Michael Arnold cited in Sherwood 2000; Horn 1995).
3. *Lack of adequate financial resources*. Biddle and Berliner (2002) suggest that having inadequate resources aligns strongly with poverty because schools with a higher proportion of poor students often receive less government funding. While urban or metropolitan areas are known for poverty and a lack of adequate resourcing (Calabrese Barton 2007), Truscott and Truscott (2005) allude to the high levels of poverty in many rural communities in the USA where science teachers constantly struggle to obtain the funds needed to maintain school laboratories. Similar findings around resources emerged for research involving Australian secondary science teachers (Lyons et al. 2006).
4. *Recruiting and retraining 'good' quality teachers*. While often alluded to in relation to rural settings (Barrow and Burchett 2000; Holloway 2002), many urban schools also struggle to recruit and retain qualified science teachers (Calabrese Barton 2007).

Collectively, these factors encompass the notion of *equity* and the recognition that some schools, because of their clientele, geographical location, SES or community context, require more support if they are to provide their students with educational opportunities equivalent to those in the 'resource-rich schools' referred to by Truscott and Truscott (2005). Exploring this area further, Angela Calabrese Barton (2007) discusses an *equity metric* for science and mathematics developed by Jane Butler Kahle (1998) for implementation in urban schools. The resource-based indicators (e.g. course enrolment, quality of courses, teacher expectation, instructional quality, out-of-school experiences) used to assess the degree of equity in urban schools are equally appropriate for rural schools.

Similarly, Steve Oliver (2007) identifies six drivers guiding systemic reform in rural education in the USA that are relevant to schools in urban areas: (a) a standards-based curriculum; (b) consistent policies to ensure high-quality science education; (c) convergence of resources; (d) unification of stakeholders towards a common goal; (e) the need for quality evidence around student achievement; and (f) the basic need to improve the achievement of all students. Subsequently, these examples demonstrate that there is an opportunity to develop a coherent and high-quality research framework across high-need rural and urban schools that incorporates the broader contextual and community factors that impact on schools. The advantage of such a perspective is that it might attract the sustained interest of educational authorities and governments given the focus on a wider cross section of the student cohort. The central thesis presented here is captured succinctly in the following quote from Truscott and Truscott (2005, p. 5):

> The problems facing high-need urban and rural schools are long-standing, deep, and pervasive. The similarities that exist between urban and rural schools are pronounced, as both respond to day-to-day challenges brought on by the effects of poverty, insufficient school funding, and external socio-political demands. Short term fixes and abrupt changes in emphasis cannot succeed. Successfully addressing these problems will require sustained, multifaceted efforts that address many areas simultaneously and evolve continuously.

Conclusion

Evidence from PISA 2006 suggests that there are a number of countries experiencing issues around science education in rural settings. Care does need to be taken in using data sets of this type because of the complex interaction that confounding variables, such as socio-economic status, ethnicity and school size, play in masking differences in student achievement across geographical locations. Interestingly, the investigation of the rural–urban gap in student achievement has been a major focus for the USA, Canada and Australia, judging by its representation in the literature. While rural education research appears to have a well-grounded tradition, this is not the case for science education in rural settings, with studies appearing relatively scant, difficult to access, and often reporting contradictory findings. A major weakness in the research design of many of these studies is the lack of inclusion of both rural and urban schools, which is necessary for meaningful comparisons (Fan and Chen 1999; Williams 2005).

In conceptualising a future research agenda for science education in this area, alternative views are emerging in the literature. The predominant view is about 'stepping back' from the fine detail to focus on the factors shared across geographical locations that restrict and limit the educational opportunities of all students. In other words, we need to raise the issue of *equity* because the research already demonstrates that the main school variables affecting student achievement and learning in science generally include the quality of school facilities, availability of resources and equipment, teacher qualifications and experience, ongoing professional development, and availability of specialists for support and mentorship (Truscott and Truscott 2005). However, improving these factors requires considerable financial resources in densely populated urban areas as it does in sparsely populated rural areas. Framing a research agenda across geographical boundaries has a greater likelihood of attracting the attention of governments and educational authorities because of the broader socio-political implications.

Chapter 37
Out of Place: Indigenous Knowledge in the Science Curriculum

Elizabeth McKinley and Georgina Stewart

In this chapter we have been asked to address indigenous science education research. This is a topic that has, in the past, been subsumed under wider concepts, such as multiculturalism, equity, and the like. For example, in the first edition of this Handbook, Bill Cobern and Glen Aikenhead's (1998) chapter was the only one with 'culture' in the title. This chapter promoted the view of science teacher as culture broker, which suggested that teachers need to facilitate cultural border crossings for their students from their own cultural backgrounds to that of science education (Aikenhead 1996; Michie 2004). However, four other chapters were equally relevant to the interests of indigenous students and communities – Dale Baker's (1998) on equity, Douglas Allchin's (1998) on values, Michael Matthew's (1998) on the nature of science, and Arthur Stinner and Harvey William's (1998) on the history and philosophy of science. Indigenous science education and research occurs at a nexus of complex philosophical, historical, psychological, sociological and political relationships that tend to overwhelm the focus on achievement. Unfortunately, these understandings are not held by most science teachers, education officials, or education academics. It is on the latter group, as Graham Smith (1995) argues, that the primary responsibility lands for initiating the work towards ameliorating this lack, despite its limitations. In this chapter we argue that failure to fully understand these complexities is a limiting factor overall in indigenous science education research to date.

The title invokes two meanings that are to be carried through this chapter. First, the knowledge of indigenous peoples is generally accepted as emerging from living in intimate relationship with a specific geographical area. It is thus a place-based form of knowing that has been accumulated over long periods of time, as Glen Aikenhead and Masakata Ogawa (2007) argue. This is perhaps best seen through the phrase 'traditional ecological knowledge' (TEK; e.g., Snively and Corsiglia 2001a, p. 6), which is commonly used in the science education research literature, although other phrases are also used such as indigenous knowledge (IK). The second idea that we will be drawing through this chapter is that IK is 'out of place' in the construction of curriculum knowledge. As such, attempts to include IK or TEK in science education curricula have resulted in what Christopher Jocks (1998) has called a caricature of the knowledge, and less than desirable outcomes for all concerned.

The Notion of Caricature

Teaching necessarily involves presenting difficult ideas simply, but in the case of complex human phenomena, such as science or culture, Julie Kaomea (2005) argues there is an ever-present danger of oversimplification. The question that arises, particularly when addressing more than one such complex issue, is whether or not an authentic representation is achieved, or even possible? In relation to the context sketched above, we suggest that both science and culture are vulnerable to simplistic representations in education, treatments usually containing embedded distortions of history and philosophy (Benson 1989; Duschl 1985). In practice, science educators frequently fall prey to such oversimplifications, as invoked, for example, by the notion of school science. In this chapter, we use the notion of caricature to refer to these inadequate treatments, focusing in particular on the caricatures of IK found in science curricula, as well as essentialising treatments of other indigenous aspects as Peter Ninnes (2004) argues, especially student identities.

The Scope of Indigenous Science Education Research

The rate of production of research literature on indigenous science education has continued to expand in the intervening decade since the first Handbook was published, to the point that a complete survey is not feasible, and the literature cited herein is representative only of the entire field – in English as well as other languages of scholarship. The relevant literature consists largely of journal articles, with a smaller number of books (Cajete 1999), edited collections (Hines 2003), book sections (Scantlebury et al. 2002), unpublished theses (Najike 2004), online articles (Michie 2003), and conference papers (Michie 2005). In the last decade there has been a proliferation in the number of specific socio-historical contexts around the globe which have become the subject of scholarship on indigenous science education. While Canada (Aikenhead 2008), Australia (Christie 2006; Fleer 1997) and Aotearoa New Zealand (McKinley 2007) have been prominent, recent studies include contexts as diverse as Hawaii (Chinn 2004), Africa (Ogunniyi 2007a, b) and Japan (Ogawa 1998). Across all the literature, the works can be divided into two categories:

1. Studies that focus on specific cultural histories, where research and development have occurred within local communities; for example, Papua New Guinea (Pauka et al. 2005), Yupiaq (Kawagley 2006) and Cree (Sutherland 2002).
2. Work with a more theoretical focus that engages in commentary and critique of a wide range of discourses, including history, philosophy, science, politics and the like, and based on documents (such as textbooks, curriculum texts and so on) or interviews (with students, teachers, trainee teachers, parents, scientists or community).

While a few articles have brought new thinking to bear, too many in both categories have tended to continually rehearse the problems. In recent years, the field has become more established with the launch in 2005 of a specialist journal, *Culture Studies of Science Education* (*CSSE*), which publishes a wide range of articles. Special issues on indigenous knowledge (IK) have been published by *Science Education* (Issue 1, 2001) and *CSSE* (Number 3, 2008), and these are used below as markers of the major debates in the field.

From Multiculturalism to Indigenous Science Education

Perhaps one of the biggest shifts for indigenous science education research has been its emergence from the umbrella discourse of multicultural science education, although philosophically they are impossible to disentangle. Derek Hodson (1999) has argued that multicultural science education is part of the wider multicultural curriculum movement, but it has generated fierce debate. The debate centres on the nature of science in science education, for which IK has been a useful example (resource) to both sides.

Contesting the Place of IK in the Science Curriculum

The *Science Education* special issue (2001, Issue 1) on multiculturalism in science education (Cobern 2001) is an example of the fierce debate regarding the place of IK in the science curriculum. The special issue featured three plenary articles by pairs of North American authors, Gloria Snively and John Corsiglia (2001a) and William Stanley and Nancy Brickhouse (2001) presenting versions of the multiculturalist argument, and Bill Cobern and Cathleeen Loving (2001) arguing the universalist case. These were followed by five brief responses from international scholars, including the author of the first chapter Elizabeth McKinley (2001), rounded out by two rejoinders from plenary authors (Snively and Corsiglia 2001b; Stanley and Brickhouse 2001). Reflecting the field overall, the research in this special issue comprised mostly discourse analysis, with few references to actual classroom data either supporting or contra-indicating the inclusion of IK in programmes of science teaching and learning. The major themes debated were as follows:

- Equity of outcomes in science education for students from non-Western cultures and the connection to historical and contemporary socio-political trajectories, including the divide between cultural imperialism and cultural relativism
- The nature, philosophy and limits of science, IK and knowledge in general, including world view theory and epistemological debates over universalism and relativism, realism and idealism, positivism and post-positivism, constructivism, postmodernism and so on
- Environmental concerns over sustainability and the possible role of IK in guiding future directions in science and its applications (i.e., IK as a correcting mechanism for science)
- Contributions of IK to the knowledge base of science (i.e., IK as a resource for science)

Discussions thus covered a wide spectrum of fields and complex issues invoked by the notion of multicultural science education. All authors included an equity argument, and furthermore, all accepted that non-Western cultures are associated with different viewpoints about reality from that of science and/or Western culture. Beyond that, the arguments and conclusions diverged widely. On one important point there was conflict between two oppositional positions: while none disputed the existence or importance of IK, only some equated it with indigenous science as a form of science different from, but equally valid to, Western science.

The emphasis on definitions reflected the tendency for meanings of key terms in the debate to vary between authors, often resulting in talking at cross-purposes, or even at different points within the same paper, which easily leads to incoherent argumentation. In their introduction, the editors cautioned that ‘authors use the word “science” by itself’ and advised the reader to ‘avoid potential confusion’ by substituting science with one of the following phrases, as appropriate: ‘nature-knowledge system’, ‘indigenous science’, ‘Western science’ or ‘school science’ (Lewis and Aikenhead 2001, p. 5). This caution highlights the importance of definitions in this field and debate. Pauline Harris and Ocean Mercier provide a pluralist perspective which assigns a wide meaning to the word science as ‘simply knowledge’ (2006, p. 145), which necessitates the use of qualifiers or substitutions, as Bradford Lewis and Glen Aikenhead suggest, to specify the meaning being invoked. This problem regarding definitions occurred not only with the more controversial or obscure terms such as indigenous science but also with larger terms, especially science and culture. The difficulty of adequately characterising such complex human phenomena often gives rise to definitions that lack substance, or focus on some aspects while neglecting others.

The problem with labelling science as a culture is analogous to that invoked by labelling IK as a science. In each case the validity of the assertion depends on a certain definition of the key term – definitions which are valid, but differ significantly from their general meanings, and those invoked in the originating problematic, that is, that students from non-Western cultures succeed relatively poorly in science education. Science educators are seldom also trained in associated disciplines, such as cultural studies (Carlton Parsons 2008; Carter 2006). Loving (1997) made the same point about the lack of philosophical expertise amongst science educators engaging in philosophical debates over the nature of science (Cobern and Loving 2008; Siegel 2001, 2006). As a result, Tony Becher (1989) contends, there is potential for disciplinary amateurs to become lost in unfamiliar territory.

The debate in this 2001 special issue thus centred on how to understand the term *multicultural science education*. Three concerns over representations of science in science education – exclusiveness, Eurocentrism and scientism – are major themes of the multicultural science education debate, as the articles in the special issue reflect. A more contentious reading understood multicultural science to imply the acceptance of non-Western cultural knowledge bases (i.e., IK) as sciences, different but equal to Western science. The logical implication was that IK could and/or should replace Western science in the science curriculum, especially for indigenous students. Two responses suggested that the philosophical arguments were irrelevant when considering real-world goals and student outcomes in science education (Svennbeck 2001; Brown-Acquaye 2001), while another suggested the political dimensions of science education for indigenous students were not satisfactorily addressed by the border-crossing approach (McKinley 2001). Two other responses, Bernard Ortiz de Montellano (2001) and Gurol Irzik (2001), addressed inaccuracies in the papers and the colonial nature of knowledge, and questioned the ethics of the multiculturalist argument, arguing that there can be no multicultural ethics of teaching without moral universalism. The responses served to highlight the trenchant nature of the disagreements between those on different sides of the debate. By the time the plenary multiculturalist authors issued rejoinders as a final step in the discussion, a certain amount of frustration was detectable in the exaggerated politeness with which the responding scholars were thanked, followed by flat contradictions of their arguments, and repetitions of the original points.

Multiculturalist scholars often counter opposing argument with allusions to (what amounts to) cultural imperialism – a seemingly potent but ultimately counterproductive strategy, which has been previously discussed and reviled in cultural politics by Edward Said (1993, p. 310).

> What invariably happens at the level of knowledge is that signs and symbols of freedom and status are taken for the reality … just to be an independent postcolonial Arab, or black, or Indonesian is not a program, nor a process, nor a vision. It is no more than a convenient starting point from which the real work, the hard work, might begin … that work [is] the reintegration of all those people and cultures, once confined and reduced to peripheral status, with the rest of the human race.

Applied to the multicultural science education debate, Said's insight reminds educators that non-Western people also have a right to benefit from and contribute to science, and that the real work, the hard work is to overcome the relative disparity in achievement for non-Western students in science education, in order for that right to be achieved. Solid decades of economic growth, and increased sensitivity to human rights, post-World War II, supported a steady improvement in education outcomes for indigenous students. As globalisation proceeded, teachers in Western countries faced classrooms of increasing cultural diversity, and anti-ethnocentrism was one aspect of the response, with teachers challenged to overcome their own deficit thinking. The contentious state of the literature in 2001 indicates that theoretical understandings remained incomplete, even though a great deal was changing at the level of practice. Innovative science education projects involving indigenous communities had begun in various places, including Alaska, where the Alaska Native Knowledge Network (www.ankn.uaf.edu) has published standards and resources for culturally responsive curricula, including science (Stephens 2003).

Setting a Place for IK in the Science Curriculum

The *CSSE* journal has adopted a less confrontational format by offering a forum of open review and encouraging authors and reviewers to have conversations about contentious issues, although some resort to the more traditional format of critique and response. The point here is that reviewers and authors can co-construct an authored piece that teases out concerns, or explores understandings in more depth. The Forum provides greater opportunities for debate of the type presaged in the *Science Education* issue reviewed above, so by comparison, this volume is even more complex and discursive, and much longer – 258 pages compared with 88. This *CSSE* special issue (2008, Issue 3) typifies the current field by including far more diverse research perspectives and contexts than in traditional science education research. In his editorial, Ken Tobin (2008, p. 536) commented on these and other issues, detailing the editorial policies, and emphasising the intent for the journal to embody an inclusive, respectful, open academic conversation and 'resis[t] a tendency to seek closure on issues', describing CSSE as 'an emerging hybrid field'.

Only three of the research articles were based on school science education for indigenous students, and each of these represented an initial foray into the field: two based on Western science teachers' doctoral research, Moyra Keane (2008) working in indigenous communities in Kwa-Zulu Natal (South Africa), and Ann Ryan (2008) in Papua New Guinea, and the third an initial report on a research collaboration between a White Canadian science educator and a Māori language teacher in Aotearoa New Zealand, Anaru Wood and Brian Lewthwaite (2008). All papers reiterated the science teacher as in the culture broker position, which has found more orthodoxy in the field, and discussed the issues raised in the 2001 *Science Education* special issue. However, none were written from evidence bases of classroom programmes based on indigenous science. Māori educators, Elizabeth McKinley and Peter Keegan (2008) and Georgina Stewart (2005), contend it is time to search for a clearer answer to the question of IK in the science curriculum, as this is required to guide real-world contexts of indigenous science education, such as Māori-medium schools in Aotearoa New Zealand.

The *CSSE* special issue also suggests that we have not progressed far with our arguments. For example, Brian Brayboy and Angelina Castagno (2008) accept the literal truth of the notion of Native science, and proceed to argue the case for including it in the science curriculum. In the course of their article and rejoinder (Brayboy and Castagno 2008b) they invoke cultural politics, citing Linda Tuhiwai Smith (1999) to articulate their position. However, they seem to create the Native science/Western science binary, against which the rest of the article argues, by pointing to the scientific practices of native peoples. Responding to Brayboy and Angelino Castagno (2008a, b), Charbel El-Hani and Fabio Souza de Ferreira Bandeira (2008), as professors of ethnoscience, fail to clearly articulate in their article why 'call[ing IK] "science" will not help' (p. 751). We can only put it down to the possibility that they have not themselves been involved in indigenous community classroom programmes based on including IK in science. Their argument 'to keep the distinctions in place when teaching and learning about science and indigenous ways of knowing' (p. 777) is thus interpreted by Brayboy and Castagno as further evidence for their own reified binary between Western science and Native science.

Unfortunately, these arguments involve an oversimplification of descriptions of key concepts that result in a caricature of IK. Brayboy and Castagno (2008b, p. 791) conclude: 'Ultimately, the disagreement with El-Hani and Bandeira appears to be that we use "science" to describe what the authors think of as Indigenous Knowledges', but this specious remark serves only to reinforce the lack of substance in the argument, and in so doing, does nothing to address the underlying educational problem. This discussion has highlighted the similarity between the oppositional positions being taken in 2008 to those prominent in 2001. While today's literature contains a wider range of voices, and the place of IK in the science curriculum is no longer strongly queried, little progress is evident in resolving the underlying theoretical questions surrounding IK and science, bearing in mind that progress is not the same as 'closure' (Tobin 2008, p. 536). Meanwhile, the crisis of poor outcomes for indigenous students in science education continues, falling through the cracks of the academic debates (Smith 1995). The following section turns to an examination of how these cracks or lacunae play out in real-world educational contexts, in high school science classrooms in Aotearoa New Zealand.

A Caricature of Culture? Indigenous Science Education in Aotearoa New Zealand

From the early 1980s, there has been a growing movement of including Māori language, practices and knowledge into the curriculum generally. This has occurred in Māori-medium and English-medium education and reflects a wider societal trend of Māori language being increasingly included in New Zealand English, and Māori knowledge and practices being included at all levels in everyday life. In a recent research project on the participation and achievement of Māori students in mathematics and science education, the authors sought the views of both teachers and students regarding the inclusion of Māori knowledge (IK) in classes (McKinley 2008; McKinley et al. 2004b). The project included four schools: three English-medium high schools with 30–45% Māori students, and an immersion Māori language school with 100% Māori students. Data were gathered from interviews with 18 teachers of science and mathematics.

Almost all the teachers in English-medium schools spoke of using IK as a resource to be drawn on in the science classroom. The resource of IK was there to fulfil two functions: to display the diversity of knowledge in science and hence to celebrate all peoples' knowledges, and to increase motivation and self-esteem of the indigenous students in the class. It is through both of these beliefs, but particularly the latter, that teachers believed increased achievement for indigenous students in science could be achieved. The following examples are used to illustrate these approaches.

In relation to issues of curriculum, the teachers spoke of Māori contexts they had brought into their lessons. Not surprisingly, all the English-medium schools in our study mentioned the same Māori contexts. These included units of work or activities on the hāngi (earth oven), kōwhaiwhai and tāniko patterns (decorative patterns for buildings, clothing, etc.), Papatūānuku (personified Earth mother deity), rongoā (Māori medicine), and the use of Māori names for native plants and the planets and constellations. For most of the teachers these contexts and activities constituted Māori knowledge and cultural values for their lessons. For example:

> In the Year 10 class Horticulture unit the students do a research project on Māori medicine or Māori uses of noted plants. […] So that's another unit that specifically targets Māori cultural values and aspects of Māori. (McKinley et al. 2004a, p. 27)

Although this uniformity of context may not be surprising, it still bears explaining why teachers in schools separated by hundreds of kilometres spoke about the same things, in answer to the question of Māori content. These contexts are well-known throughout Aotearoa New Zealand, although regional differences will exist, such as in kōwhaiwhai patterns, or plants used for rongoā.

There is a significant amount of IK associated with all of these Māori contexts teachers use in their lessons, but the purpose of their inclusion is that they have science associated with them. For example, the hāngi is often used to introduce latent heat transfer. To make a hāngi, a hole is dug in the ground, native wood is laid down and volcanic rocks placed on top, and a fire is set. When the rocks are well heated water is added, the food placed in the hole and then covered over with leaves or cloth and dirt and left to cook for several hours, after which it is dug up and eaten. It is a well-known context as hāngi are commonly used to cater for Māori, and now increasingly non-Māori, functions. Such Māori contexts are seen by a number of teachers as window dressing to the real science:

> The hāngi unit starts off nicely for the Māori students and then it gets bogged down in hard science. (McKinley et al. 2004b, p. 11)

The hāngi has tikanga (Māori protocols and practices) associated with it, not least of all who has responsibility for particular tasks and why it is used, but these aspects are dismissed by science teachers as irrelevant. The universalist view of science thus results in a superficial treatment of the cultural context.

As the teachers told us, the resources for the Māori contexts are often found in departmental schemes and unit boxes, ensuring everyone has access to these for their classes – to meet the required Māori educational outcomes.

> [S]ome of the times it looked as if it's [kōwhaiwhai] just dropped in, this was the bit you had to slide into your lesson, therefore you had met Māori education [objectives]. (McKinley et al. 2004a, p. 28)

Teachers believed Māori contexts would make the students feel better about themselves by seeing Māori culture valued in classrooms. The contexts were spoken of as a way to 'hook them [Māori students] in' and make them 'feel comfortable' (McKinley et al. 2004a, pp. 27–28). Teachers related motivation to issues of self-esteem by suggesting with Māori contexts that the Māori students became the experts and they could 'share their learning and knowledge' (McKinley et al. 2004a, p. 28). The complexity here is that teacher knowledge around IK content is weak and a number have an expectation that Māori students can become the teacher to share their knowledge. However, the reality is that many Māori students, especially those who may have lost papakāinga (tribal home) connections, feel embarrassed over their lack of knowledge.

The students we interviewed had a range of experiential knowledge of their teachers' classroom practices at including Māori knowledge into their science education. This range of experiences was correlated with a range in attitudes, whereby the students with more Māori experience (and knowledge) had stronger opinions to the effect that Māori knowledge (and language) has no place in high school science classrooms, particularly at senior levels. Our initial surprise at the emergence of these findings is echoed by the comments of the author of a well-known mathematics resource textbook based on the geometry of kōwhaiwhai patterns, which sold well throughout Aotearoa New Zealand.

> One curious pattern did emerge; sales were almost non-existent to schools which were bilingual and/or which had a very high proportion of Māori students. Feedback from teachers from those schools was sparse, but was usually along the lines of, 'it didn't meet our need'. (McKenzie 1999, p. 251)

It would appear that superficial or token attempts to incorporate Māori knowledge into science (or other areas of the high school curriculum) may only be of benefit in school situations in which Māori students feel a high degree of alienation. Māori students who are engaged more fully and have a healthier overall relationship with their school culture do not seem to feel the need for such measures, which may then be of little or no benefit in supporting their achievement in science.

Some teachers were ambivalent about whether the inclusion of Māori knowledge in science lessons worked or not, or even whether it was appropriate to do it, and voiced this resistance, even while continuing with the Māori contexts in their classes.

> We try really hard to do it more and more [teach Māori contexts] but I find it frequently backfires on me. If I try and put things in the Māori context I feel like I'm being quite false and the kids pick up on it. [...] Even ones I've taken straight out of the books the kids think it's a joke because it's coming from someone with an English accent. I will only do it if I'm quite sure that I have got it right. (McKinley et al. 2004a, p. 28)

The Māori contexts listed above, among others, are well-known and easy to name aspects of what is seen as Māori culture. However, they are caricatures because they

- Only address superficial aspects of culture (artefacts and symbols)
- Are extracted from authentic cultural contexts and hence lack original meaning, function and agency
- Are treated in isolation of the historical socio-political relationship between Māori people and Western colonial culture, people and social structures

Hāngi, and the other emblematic Māori contexts for science education, have been asked to carry a symbolic weight that is too heavy, and what gets taught under these headings is a representation of IK that is at best inadequate, and often worse.

Conclusions

Of all the countries around the world where research into indigenous science education has been carried out, Aotearoa New Zealand is a leader, which is attributable to perhaps more favourable social conditions and history by comparison with most others. It is important to clarify that this is not some claim to be better than others, but an acknowledgement that Māori is an endangered language, world view and knowledge base, in an equivocal condition that Stephen May (2001) argues is shared by many others around the globe. Clawed back from the brink of extinction, Ray Harlow (2005) shows the future of Māori is not yet secure. Other indigenous cultures have gone over the edge of complete language loss, while there are also some who have retained more traditional knowledge and practices (either with or without language) than Māori. Every cultural group follows its own unique trajectory, in response to particular sets of socio-historical circumstances. The Māori examples used in this chapter are of wider interest, but this is not to claim that our conclusions will be universally applicable to all indigenous communities.

In the last few decades, there have been ongoing attempts in Aotearoa New Zealand to incorporate indigenous Māori culture into the science curriculum both in English-medium education and through the establishment of Māori-medium schooling. However, as we have argued above, the success of these practices has been limited in terms of addressing the overall objective of equity in science education for indigenous students. Māori-medium schooling is part of the wider revitalization of an endangered indigenous language, culture and identity, but the revitalization of traditional Māori knowledge is far more difficult (Salmond 1985; Smith 2000). While this conclusion casts doubt on the current directions of indigenous science education in Aotearoa New Zealand, in the wider international context it also calls into question how IK is to be taught as part of the science curriculum.

Indigenous science education takes the postcolonial critique of Eurocentrism beyond identity politics, to the level of an epistemic challenge to science, in the form of IK. IK contains elements of those science disciplines available to pre-modern cultures, as well as explanatory narratives about the natural world, which flagrantly contravene the basic laws of science. Indigenous languages carry both identity and knowledge, but we are more successful at revitalizing identity than knowledge, whose relevance in the absence of traditional social structures has been, to all intents and purposes, lost. As we make steps to move towards the inclusion of IK in the science curriculum, such as in Māori-medium schooling, further deeper layers of cultural knowledge and practice become exposed to caricature in the form of distorted representation. The aspiration of defining and understanding IK (in order to place it in the science curriculum) can be likened to chasing the pot of gold at the end of the rainbow, which remains permanently out of reach.

It could be more productive to continue to hold the notion of IK in tension with the notion of science, as a reminder of science's own cultural origins and limitations. IK can thus be a resource of a different kind for science, by catalysing insight into the philosophical nature of science, and serving as a reminder of the many times throughout its history when the laws of science have not been adhered to, but subjected to political distortion. This understanding provides a framework around which indigenous education communities, such as Kura Kaupapa Māori, are able to construct language and curriculum policies, which best meet their long-term goals. It also puts to rest the dialectical wrangling over indigenous science (and its cognates such as Native science) imagined to replace Western science in the curriculum, and returns the focus to the lack of progress towards equity in outcomes of science education for indigenous students.

Chapter 38
On Knowing and US Mexican Youth: Bordering Science Education Research, Practice, and Policy

Katherine Richardson Bruna

The USA shares a 2,000-mile border with Mexico. Across this border Mexicans have been moving for more than 100 years in an exchange of manual labor for economic opportunity. Because of this historical transnational connection, the lives of Mexican immigrants, even before they arrive, are enmeshed with those in the USA. More than half of adults in Mexico, in fact, have relatives in the USA. These relatives send portions of earned US wages back to Mexico in an amount that exceeds US$13 billion (Rumbaut 2006). The immensity of this transnational connection, therefore, is not to be underestimated with respect to its implications for science schooling. US Mexican[1] students study science against the context of extended family's economic dependence on their work and, by extension, their work-related knowledge and skills. Given that Mexicans are the largest Hispanic immigrant group by far – in the year 2000 they outnumbered all European and Canadian immigrants and all Asian, African, and Middle Eastern immigrants combined (Rumbaut 2006) – it is crucial to assess how much science education researchers attend to and know this transnational context and its role in the antecedent conditions, processes, and outcomes of US Mexican science teaching and learning.

Shadowed Science Learning Lives

For the first phase of my literature review on US Mexican science education, I conducted an online search of relevant articles published in selected science education research and teaching journals over the 10-year period of 1998–2008. I

[1] 'US Mexican' refers to persons of Mexican descent, whether foreign- or native-born, living in the USA.

K. Richardson Bruna (✉)

e-mail: krbruna@iastate.edu

B.J. Fraser et al. (eds.), *Second International Handbook of Science Education*, Springer International Handbooks of Education 24, DOI 10.1007/978-1-4020-9041-7_38,

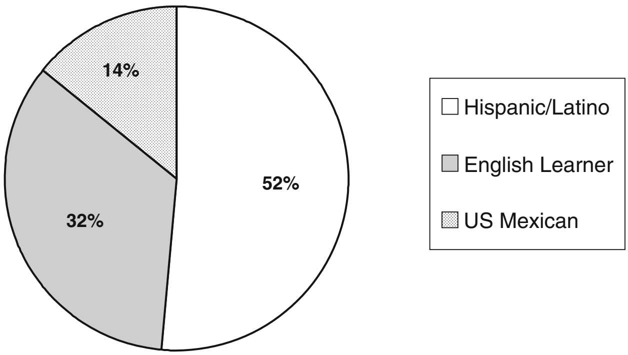

Fig. 38.1 Distribution of populations represented in selected science education journal articles, 1998–2008 (Selected journals include *Cultural Studies of Science Education, International Journal of Science Education, Journal of Research in Science Teaching, Journal of Science Education & Technology, Journal of Science Teacher Education, Life Sciences Education, School Science & Mathematics, Science & Children, Science Education, Science Scope, Science Teacher*, and *Science Teacher Education*)

used, first, the descriptors "Mexican," "US Mexican," "Mexican American," and "Mexican Immigrant" to locate articles explicitly about or involving this target student population. When this search retrieved very few (and often zero) such articles for each journal, I then used the broader descriptors of "Hispanic," "Latino," "English Learner," and "Language Minority" to search again. This substantially increased the number of retrieved articles. In reviewing this expanded pool, if I found explicit reference to US Mexican students I then included those among my target articles. I counted only research and teaching articles directly reporting on specific student experiences and contexts. This excluded literature reviews or position papers.

The results of this phase of the review process indicated an overwhelming slant in published science education articles toward populations described as Hispanic/Latino (36 articles) or English Learner/Language Minority (24 articles). Articles explicitly about or involving US Mexicans (10 articles) constituted only 14% of this subset of published research. The total distribution of articles across these populations is represented in Fig. 38.1.

For reasons described below, US Mexicans are a significant presence in US society. While research on Hispanics/Latinos and English Learners/Language Minorities can include US Mexican populations, the degree to which this ethnic group is not explicitly named as the center of scholarly efforts may indicate that they live in the shadows, so to speak, of science education's collective attention.

Out of the Shadows: Toward a US Mexican Focus in Science Education Research

While falling under the panethnic classification "Hispanic,"[2] Mexicans have a unique relationship with the USA because of issues related to size, status, proximity, and history. In 2000, persons of Mexican origin accounted for 63% of all US Hispanics (Rumbaut 2006). It is estimated that more than half of all Mexican immigrants in the USA have undocumented status (Passel 2004). These size and status issues of US Mexicans are related to Mexico's proximity to the USA as the countries share a long border that, despite US deterrents, facilitates ongoing attempts at illegal crossings. The Mexico–US border is a historically contested space, especially in the US Southwest where some Mexican families have roots that predate the annexation of land that occurred in 1848, as a result of the Mexican–American War. Because Mexican workers have filled US shortages, via official or unofficial labor importation, since before the turn of the nineteenth century, many Mexicans have long family histories that connect them to the USA.

Given the sheer size of the US Mexican population, the contextual information surrounding their schooling takes on particular significance. As Rubén Rumbaut (2006) writes: "[I]t should be underscored that aggregate statistics for the total Hispanic population reflect the predominate weight of the characteristics of the Mexican-origin population" (p. 33). In other words, research about US Hispanics is likely, without saying so, to reflect a more particular US Mexican experience. This particularity is likewise obscured by science education data collection and reporting efforts that take Hispanics, in aggregate, as their unit of identification. It has been acknowledged by the National Science Foundation itself that the goal of broadening the participation of underrepresented groups in Science, Technology, Engineering, and Mathematics (STEM) is not advanced by the aggregation of data without regard to ethnic subgroup (National Science Foundation 2004).

The particularity of the US Mexican experience is reflected in similarly particular educational antecedents, processes, and outcomes that such aggregated approaches to data collection, analysis, and reporting necessarily overlook. For example, while Hispanics, in aggregate, have the lowest rates of educational attainment of all US ethnic minority groups, it is US Mexicans who fare most poorly (US Census Bureau 2002). One explanation is found in the fact that foreign-born Mexicans have the lowest educational levels of any Hispanic subgroup and thus, in addition to challenges posed by English literacy, are less prepared to assist their children with the curricular demands of schooling. Additionally, limited experience

[2]While 'Hispanic' and 'Latino' are often used to denote the same ethnic categorization, they carry different sociohistorical connotations. Of the two, research on self-identification preferences reveals a 3 to 1 preference for "Hispanic" (National Research Council 2006, p. 4); for that reason, I use it throughout the remainder of the chapter.

with schooling also affects the way that US Mexican parents play a role in educational decision-making regarding their children. Anthony Bryk and Barbara Schneider (2002) report that US Mexican parents are more likely to defer to teachers and administrators, rarely questioning judgments made about their children.

The reality of low educational attainment as an antecedent condition among Mexican-origin families fuels teachers' low expectations for this student group influencing all aspects of educational processes. For example, US Mexican students report being happier and living up to their expectations when not with their teachers (Csikszentmihalyi and Schneider 2000). In fact, US Mexican high school students are more likely to believe that their teachers have unfavorable thoughts about them than are other ethnic groups (Schneider et al. 2006).

In terms of schooling outcomes, national performance data indicate that US Mexicans tend to score the lowest on 4th, 8th, and 12th grade tests of reading and mathematics (US Department of Education 2003). US Mexicans are least likely to take college entrance exams and apply to college (Fry 2004) with only 4% US Mexicans taking the Scholastic Achievement Test (SAT) in 2001 (College Board 2002). The dropout rate for foreign-born 16–19-year-old US Mexicans is nearly 40%, the highest of all Hispanic immigrant subgroups. While that rate drops considerably among the native born (to 15%), it still exceeds other Hispanic peer groups (US Department of Education 2000).

What is most striking about US Mexican student achievement is the observation that gains made in performance from the first to second immigrant generations do not carry into the third generation. For example, first- and third-generation US Mexicans start kindergarten with lower mathematics skills than do second-generation students and the pattern does not change over time (Reardon and Galindo 2003). This is surprising given that the third generation is characterized by higher levels of cultural assimilation. The presumption, then, that the poor educational attainment of US Mexican youth is due to a language barrier and, by extension, that attainment will be primarily enhanced by linguistically responsive instructional efforts is naive. It is this very presumption that drives the aggregated category of "English Learner" that also dominates science education research.[3] But, in fact, data on linguistic assimilation illustrate a trend toward a preference for English such that at the age of 24, 87% foreign-born and 96% native-born US Mexican youth indicate a preference for English (Rumbaut 2006). So it is not necessarily an inability or unwillingness to speak or learn English that is causing the regression in educational attainment levels in the US Mexican third-generation population. Researchers surmise, instead, that these parents and their children, having spent more time in US society and schools, could have become disillusioned with education as a path to social mobility (Padilla and Gonzalez 2001). It is this possibility that science education researchers need to more squarely address through curricular and instructional reform.

[3] The immense variability within the English Learner population leads Richard Duran (2008) to state that "ELLs are not a true demographic population… [They] are in effect a policy construction, a category of students established by individual states to satisfy their education laws" (p. 300).

Bordering Science Education Research

An examination of the articles I located explicitly about or involving US Mexican students reveals the current topography of science education researchers' attention to this important ethnic subgroup. The scope of these articles suggests the relevance of a Multiple Worlds model when it comes to research on US Mexican experiences in science schooling.

The Multiple Worlds model, proposed by educational anthropologist Patricia Phelan et al. (1991), has been used to explain differential outcomes in the schooling of adolescent youth (Fig. 38.2). The authors found that similarity between the cultural values and norms of family, school, and peer domains (students' "multiple worlds"), or significantly, students' employment of strategies to put themselves at ease despite the differences between these worlds, helped explain success. With respect to science education, Glen Aikenhead and Olugbemiro Jegede (1999) took up Phelan et al.'s work, concurring with their assertion that it is possible and desirable "to identify institutional structures that operate to facilitate boundary crossing strategies and do not require students to give up or hide important features of their lives" (p. 246). To do this requires understanding US Mexican students' experiences in, and border-crossing between, their multiple worlds.

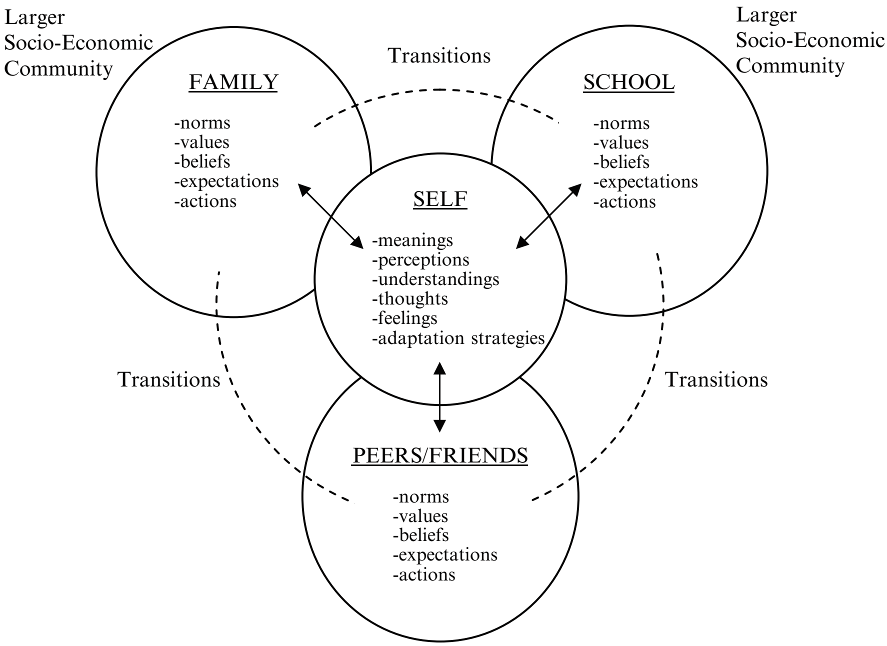

Fig. 38.2 A model of the interrelationships between students' family, peer, and school worlds (Phelan et al. 1991)

Socioeconomic Communities: The Backdrop of Poverty and Agriculture

As illustrated in the Multiple Worlds model, students navigate their movements across family, school, and peer contexts against the backdrop of the larger socioeconomic communities from which they come and in which they live. As attested to in several of the articles, the socioeconomic backdrop of poverty is one against which many US Mexican students experience science education.

For example, my colleagues and I (Richardson Bruna et al. 2007) describe a very small town in rural Mexico that is the immigrant-sending community to a specific immigrant-receiving community in the Midwestern USA. Only through this transnational capital flow (human and financial) have families in Pueblo been able to build several-roomed homes made from fabricated concrete bricks, as opposed to single-roomed handmade dirt ones, to pipe in fresh well water, and enjoy something more than a subsistence diet. Schools have yet to benefit much from the community's new resources and lack features standard to science schooling on most US campuses: certified teachers, fully-functioning media centers, print-rich environments, and textbooks. We explain that, because of this material context of poverty, newcomer students from this rural Mexican community and others like it will not be adequately prepared for the expectations of inquiry-based instruction, Internet research, and print-based information retrieval that typically characterize effective science instruction.

The poverty of such communities in Mexico is, of course, the reason for immigration to the USA. However, in coming, the driving condition of poverty is not always left behind. Angela Calabrese Barton (2001) and Richard Kozoll and Margery Osborne (2004) provide accounts of poverty in their ethnographic case studies of US Mexican students' science learning.

Most pointedly, Calabrese Barton (2001) writes of her work with two elementary-aged US Mexican girls who were living in a homeless shelter in Texas 5 years after immigrating. From her work, we learn that Claudia and Maria were aware of economic disparities between themselves, their peers, and their teacher. These disparities manifested themselves in tensions over expectations for participation in science, in this case, the teacher's expectations that the girls bring a shoe box to school for a shoe box camera. The girls expressed frustration that not only did they not have an empty shoe box at home (the expectation that they had one implies the ability to buy new shoes), but neither were they able to go to the shoe store to get one due to barriers involving their mother and what was within her means in terms of transportation, language, and child care. When the teacher offered shoe boxes, asking the girls to earn them by cleaning erasers during recess, they became angry and destructive. Claudia and Maria used this story to explain to Calabrese Barton that they "hate science" and their teacher "does not really care about [them]" (pp. 901–902).

Even into postsecondary schooling, the economic stigma associated with being Mexican in the USA remains a salient aspect of identity. Kozoll and Osborne (2004) share the story of three college-aged (two first-generation and one second-generation)

US Mexican youth who come from agricultural backgrounds. Hector, the one second-generation youth, recounts memories of racism he encountered, in the Midwest, when being followed by salespeople or being accused by his principal of stealing a car stereo. For him, success in school was about proving "we all aren't like that" (p. 163). Science played no role in that success, beyond just taking what was minimally required. He thought it was about "stupid things," asking "I don't need it in my life, for my future, so why do I have to take it?" (p. 163). The two first-generation youth, Clara and Andrea, talk very directly about how, for them, success in schooling meant creating the possibility for lives outside of communities of poverty, of lives without the instability caused by agricultural migration. For Clara, science, though not something she necessarily enjoyed, was a subject that a teacher made more exciting for her through hands-on and socially relevant activities. For Andrea, science was a subject she more actively liked as it was one place in school where she found refuge from social isolation due to socioeconomic disparity. "Through science, I got to know a few people," Andrea remarked (p. 172).

Common to most of these lived accounts of poverty is the history of agricultural work as a prevailing force in US Mexican students' experiences. The contexts from which many Mexicans immigrate are small subsistence farming communities and, in coming to the USA, agricultural work is where they, historically, have found ready employment. If their goal is to stay in the USA they are motivated, as were the students in Kozoll and Osborne's (2004) study, to create lives for themselves that do not involve the field labor of their parents. Even if their goal is to return to their agricultural communities in Mexico, as was the case with a student in one of my own ethnographic studies (Richardson Bruna and Vann 2007), they hope to do so as professionals, not laborers. Agriculture can be then a way to make science relevant to US Mexican students, in relation to either their past or future. As Kozoll and Osborne (2004) write, "[t]he argument could be made that if there is anyone who needs to know biology, chemistry, chemicals, and these 'stupid things' it is a migrant agricultural worker" (p. 163). These authors go on to talk about the lived science knowledge of agricultural workers who make decisions based on tacit understandings of growing seasons, crop timing, and other conditions, as well as the relevance of science knowledge in relationship to agriculturally related conditions, like pesticide exposure.

But my own ethnographic account (Richardson Bruna and Vann 2007) provides a cautionary tale of the thin line to be walked in making science responsive to the socioeconomic lives of US Mexican youth. My colleague and I am critical of a teacher's framing of a pig dissection activity in a Midwestern meatpacking community's English Learner Science classroom as she tells her students that the dissection will prepare them for work on the line at the local hog plant. I problematize the socioeconomic context in that community that would make such a framing possible to begin with and argue that, rather than being responsive, the framing serves to reflect and reproduce the taken-for-granted ethnic and economic segmentation of such low-skilled, low-wage labor. Discerning the difference between cultural responsiveness and reproduction of social and economic hierarchies in linking science curriculum to community contexts will be of utmost importance in effective work with US Mexican youth.

Family: The Role of Informal Educators

Against this socioeconomic backdrop, the learning of science unfolds amidst transitions between family, school, and peer worlds. Two of the articles which I located for this review (Ash 2004; Siegel et al. 2007) shed light on the role of US Mexican families, specifically their family conversations, in informal science learning.

In her research, Doris Ash (2004) examines how one first-generation US Mexican family learns science together as a result of its visits to an aquarium in California. Using qualitative analyses of observations and interviews related to two aquarium visits (six months apart), Ash documents the science thematic content with which the family was most engaged through the aquarium visit (life cycle, predation, animal vs. plant life, and taxonomic relationship), the various meaning-making resources the family used in their engagement (prior knowledge, pictures, objects, the facilitator, gestures, pointing, questioning, use of Spanish and English), and the nature of their recall. She uses the data from the family's conversations over coral to argue that the family was engaged in scientific literacy (distinguishing fact from folklore, accumulating scientific points of view, generalizing across data sets) and in the dialogic and distributed (jointly produced) inquiry and knowledge production that characterizes it. Ash concludes that family interactions in informal settings, like aquaria, can foster complex scientific understandings, troubling what constitutes the everyday, on the one hand, and the scientific, on the other.

Debra Siegel et al. (2007) also document the science conversations of US Mexican families in California, with an eye toward determining the influence of level of schooling on explanatory talk and style of interaction. Siegel et al. observed 40 US Mexican families, classified according to their mothers' high (12–16 years) or basic (3–11 years) level of schooling, as they participated in a sink or float water game facilitated by the researchers in the families' homes. From their quantitative data, they found that parents in the basic schooling group did not significantly differ from parents in the high schooling group in the ways they explained density to their children, nor did coded analyses of interaction (directive vs. collaborative vs. instructional guidance) reveal any significant differences between the basic and high schooling groups.

Both Ash (2004) and Siegel et al. (2007) attest to the active and helpful role that US Mexican families play in children's science learning. Their findings beg the question of how science schooling can leverage these families' already existing knowledge-generating interactions.

School: The Acquisition of Academic Language and Authentic Science Identity

From the informal context of home and family activity, US Mexican youth come to school. Regardless of the active and helpful support they may receive in the course of their informal science learning, the research suggests they are likely to encounter challenges in meeting the specialized language and identity demands of the science classroom. Two of the articles which I located for this review (Brown 2006; Duran et al. 1998) speak to the nature of these challenges in addition to some strategies used by science teachers to help address them.

Bryan Brown (2006) takes on the access question related to underrepresented high school students and science classroom discourse. As the teacher researcher of an introductory course at large urban school in Southern California, Brown used focus group interviews to explore students' science learning experiences with a specific eye toward the appropriation of science discourse. Six of the 29 students in his study identified as US Mexican. Brown documents US Mexican students specifically commenting on the helpfulness of the hands-on nature of their science learning. According to them, some people just learn better by "seeing things and stuff" (p. 111). He also shares US Mexican students describing how, in science, "we use a different language basically" (p. 116) and how this different language marks scientists as special. As one US Mexican student remarks, scientists use this different language "to put them at a certain level" (p. 117). These students continue to explain that this results in conflict for them because the specialized language increases the difficulty of science. "[T]he language to me is the hard part," one student says (p. 119). Brown argues that the science education community must adopt theoretical and pedagogical perspectives that help students and their teachers address this specific challenge.

Bernadine Duran, Therese Dugan, and Rafaela Weffer (1998) document their work implementing the very kind of theoretical and pedagogical changes advocated by Brown. They describe a special Saturday enrichment program for underrepresented high school students, the majority US Mexican, in an urban Midwest setting. Because of their initial findings related to difficulties these students had in identifying, expressing, and using key science content, the authors implemented a three-sequence change in instructional practice. In the first or receptive phase of instruction, the authors used diagrams to help students identify target content and ventriloquate or mimic, teacher talk. In a more expressive phase of instruction, students were encouraged to use concepts for their own purposes. In the final, more interpretative phase of instruction, students analyzed real-life experience using acquired conceptual resources with the aim of displacing the teacher's science authority with their own responsibility for science meaning-making. The authors' work suggests that US Mexican students do benefit from approaches to instruction that explicitly attend to the ways a configuration of particular linguistic resources construe particular meanings in science.

While not attending to science discourse per se, Irene Rahm, John Moore, and Marie-Paule Martel-Reny (2005), in their work with a community-based science program for first-generation students, describe how the authenticity of hands-on science learning provided in a biochemistry lab resulted in an enhanced science identity for US Mexican student, Edric. As opposed to the quick experiments of science classrooms, the mentorship in the lab allowed him to see that science is about confronting and resolving unanticipated problems. As he worked with a team to improve a pain-relieving drug, Edric came to understand science within its larger social context and to connect himself personally to the outcome of his science activity. Expressing how he would feel if the drug were to make it out onto the market, Edric comments on his "bragging rights" and how "that'd be cool" (p. 6). This resonates with what Calabrese Barton (2001) found in her work in the after-school science program. The same girls, who expressed being alienated by their science learning in school, developed an expanded sense of science agency when encouraged to experience science learning in genuine relationship to their lives' concerns. Work that began with a simple biology-based caterpillar project evolved, out of student interests, into something more akin to architectural engineering. Calabrese Barton documents how the youth she worked with navigated the constraints imposed on them by their residence within the homeless shelter. They advocated for the construction of movable planters that would allow them to move the butterflies to an acceptable outside location once they emerged and were no longer allowable inside. In the case of one youth, she also advocated for the building of a desk from the planter material, at which she could study (since she did not already have one). Calabrese Barton describes the youths' activities as providing them with a transformed understanding of the meaning of science learning and identity, mentioning particular measurable outcomes such as the application of concepts such as scale, measurement, and spatial relations all in service of their own life-based objectives.

Taken together, these articles clearly indicate the need, within science education, for explicit attention to the challenges posed by academic language to US Mexican students. Similarly, given what these articles suggest about the distance students experience between themselves and science discourse and practice, efforts to target academic language acquisition should be contextualized within meaningful hands-on activity so that the relationship between specialized language resources and the respective uses to which they are put in science is authentic and not artificial.

Peers/Friends: Relationships in School and Science

While not centrally treating the theme of peer- and friend-group involvements and their implications for science learning, several of the articles I located for this review provide insight into the ways in which these relationships may significantly influence, in positive or negative ways, science schooling outcomes for US Mexican youth. Kozoll and Osborne's (2004) interviews with the three students in their research attest to the extent to which they made sense of their schooling experience as unique when considering the high dropout rate among their US Mexican peers, friends, and, indeed, family; as one of these students, Hector, said in referring to his experience in Texas schools: "[N]ot that many people graduated so that's why I stood out" (p. 162). This same student goes on to explain that his success in school was motivated by a desire to disprove the stereotypes associated with his ethnic group: "They think all Mexicans are on welfare and they all have low paying jobs and they're uneducated and that's not true" (p. 163). The story of another of these students, Clara, speaks to the importance of extracurricular activities and, by extension, their associated peer groups, in providing her with opportunities for relationships with people very different from those of the community from which she came, opportunities she readily embraced. On the other hand, Andrea speaks to the real challenges posed by socioeconomic differences between her and her peers in school. But, for her, these differences were somewhat leveled through the shared activity of inquiry that the science classroom provided.

The formation of these kinds of academic, social, and intellectual identities among university engineering students in California who were women of color, and among them those of US Mexican heritage, was the subject of a study by Erika Tate and Marcia Linn (2005). Using an interview-based methodology, these authors found that the institutionalized STEM-oriented peer support networks offered by the university were helpful in the early years of college. However, in all cases, they did not completely satisfy students' social needs. Students reported on the importance of their participating in social groups consisting of members with shared racial/ethnic identification. The salience of racial/ethnic identity is clear when a US Mexican student comments on the difference between her high school and university environments: "My high school's like 99% Mexican. So, I come here and it was very different… it was hard to interact with Asians or Whites because I wasn't used to it" (p. 488). The authors note that this implies that both official academic peer networks and more informal ethnic peer organizations have equal roles to play in promoting persistence among underrepresented students on college campuses.

Two of the articles provided a glimpse of what peer/friend relationships actually look like when enacted within a science-learning setting. From Calabrese Barton's (2001) work, we see how one way that Maria and Claudia understood their friendship was through their shared dislike of science. It was their "secreto de las niñas" [girls' secret] (p. 900). These girls found communion in their shared socioeconomic positionings as science outsiders in not being able to comply with the teacher's shoe box request. In protest of such positionings and to let the teacher know of their dislike for science, these girls, as Calabrese Barton describes, consciously decide not to raise their hands in class. It is to transform the meaning of science and as a result their science learning identities that Calabrese Barton engaged these girls and their peers in the more authentic activities of her after-school program. Ultimately, she argues, their expanded science-learning agency needs to be understood within the expanded sense of individual agency, as persons acting within and on the world, that participation in an authentic community of science practice afforded.

The story of Claudia and María resisting the camera shoe box science activity because of their marginalizing positioning finds a parallel, again, in my own account (Richardson Bruna and Vann 2007) of high school English Learner Science students' reluctance to do the meatpacking-framed pig dissection. While not as explicit about a conscious intention to withdraw from class activity, the authors' my account shows newcomer students clearly expressing disinterest not only in participating in the dissection activity but in the teacher's framing. In addition to his peers' more subtle expressions of displeasure, one student, Juan, flatly states, "Yo no carnicero [I'm no butcher]" (p. 42). As the activity proceeds, the account also shows other peers' different ways of taking up the teacher's framing; these students talk amongst themselves about their work as butchers in Mexico and jokingly compare their dissection work to the preparation of traditional pork-based Mexican dishes. One student, Augusto, goes to great lengths to make the teacher aware of his extensive knowledge of pigs, gestation, and miscarriage from his life in Mexico, work he hopes to continue through continued agricultural studies that can benefit his community. I assert it is, in fact, Augusto's insistent counter-example to the teacher's initial framing of the pig dissection as relevant to his life in ways far beyond that of his family's work at the meatpacking plant, which ultimately leads the teacher to provide him and his peers with a more authentic science framing for the activity. That eventual framing concludes that body systems are complicated, that animal dissections allow us to learn more about them, and that there are ethical questions surrounding their use. In this way, I, like Calabrese Barton, document the way in which peer groups react to science classrooms as places that reproduce, within their walls, the hierarchies of the larger society, while also pointing to how peer groups can play supportive roles in trying to create different science learning places premised upon different social positionings.

On Knowing and US Mexican Youth

The quantitative results of my research review suggest the paucity of efforts, within the field of science education, to know about the particular learning experiences of US Mexican youth. Given that US Mexicans are the largest nondominant ethnic group in the nation and that 42% of them are under the age of 20 (Durand et al. 2006) and thus theoretically in school, this indicates that the field does not currently have the capacity to effectively address the curricular and instructional needs of many teachers and students. The directions future research efforts should take clearly emerge, however, from the qualitative review. As suggested by the Multiple Worlds model, the science learning experiences of US Mexican youth are configured across a variety of informally and formally based relational domains, each providing its own set of challenges and resources. Science education researchers would do well to attend to each of these domains, explore their interconnections, and comprehend how they construe particular ways of science knowing and activity. While the same is true of every science learner's experience, it is critical to pay concerted attention to the particularity of the US Mexican experience as part of efforts to increase access to and representation within the sciences because of the societal implications of their continued poor performance.

As Rubén Rumbaut (2006) points out, 69.7% of Mexican-born workers labor in the lowest paid jobs of the US economy. This situation, he continues, "has profound implications for the social and economic prospects of their children's generation, and it is also the basis for common stereotypes that disparage and stigmatize the population as a whole" (p. 58). Science education has a crucial role to play in reworking this current social arrangement by redistributing science knowledge, identity, and socioeconomic power. What Patricia Gándara (2006) says about the societal benefits of higher education is true for science: "When [science] education is curtailed for a population group because of systematic impediments to their intellectual advancement, then both the individual and the society are impoverished" (p. 235). Dismantling these impediments, these borders to opportunity, will require science education researchers to do some border crossing of their own – away from their work with more familiar populations and domains and into new worlds, both in the US and Mexico, of student communities, classrooms, families, friends, and peers.

Such work promises to advance theoretical and methodological approaches to knowing US Mexican youth in ways that have important political and pedagogical payoffs. For example, researchers are learning more about the validity and reliability limitations of such standardized tests when used with culturally and linguistically nondominant students. There is growing evidence demonstrating systematically varied heterogeneity in performance among EL groups, suggestive of an interaction between the test and the knowledge and skills associated with particular ethnic backgrounds (Duran 2008). This is a potent example of the way in which discerning the particularity of the border crossings made by US Mexican youth into school science will become increasingly particularly important.

Chapter 39
Science Education Research Involving Blacks in the USA During 1997–2007: Synthesis, Critique, and Recommendations

Eileen Carlton Parsons, James Cooper, and Jamila Smith Simpson

In the mid-1990s in the USA, equity by way of the slogan "science for all" became more prominent in science education discourse. Debates, efforts, and research on how to achieve equity in science education ensued. In this chapter, the authors review research studies in science education involving one US group for which equity has historically been and continues to be an issue. The authors review investigations from 1997 to 2007 involving Blacks, a general term used to denote African-Americans who are individuals with an African ancestry directly linked to the founding of the USA, and Blacks who are individuals of the African Diaspora who immigrated to the USA. The authors synthesize the literature and discuss the relevancy of the literature corpus to the status of US Blacks in science education.

The chapter contains five major sections. The first section details the selection of studies. The second and third sections describe the more recent context of US science education. In the fourth section the authors present a synthesis of the science education research and the usefulness of the research in relation to the status of Blacks in science education is the focus of the final section.

Literature Identification

Using the terms "Black" and "African-American," the authors thoroughly searched science education research journals with impact factors that placed them among the top 100 journals in education and educational research journals in the Social Science Citation Index. The impact factor represented the average number of times articles from a specific journal published in 2005 and 2006 had been cited in 2007 Journal Citation Reports (JCR). JCR calculated the impact factor by dividing the number of citations in 2007 by the total number of articles published in 2005 and 2006. The JCR list of 100 education and educational research journals included the following science education research journals: *Journal of Research in Science Teaching*, *Science Education*, *International Journal of Science Education*, and *Research in Science Education*. Because research published in the previously listed journals frequently cited research from the *Electronic Journal of Science Education*, *School Science and Mathematics*, and *Cultural Studies of Science Education*, the authors also searched these journals. Additional journals searched by the authors included *International Journal of Science and Mathematics Education*, *Journal of Science Education and Technology*, *Journal of Science Teacher Education*, and *Journal of Women and Minorities in Science and Engineering*. These searches produced 70 articles.

Context of Recent Science Education Reform in the USA

At the national level, current reform in science education is embedded in a standards-based movement (Vinovskis 2009). This movement is rooted in the 1983 National Commission on Educational Excellence report, *A Nation at Risk* (National Commission on Excellence in Education 1983). As the movement evolved, the federal government's influence on state education policies, including policies related to science education, increased and the broad goals espoused in the science education reform documents of the 1980s were reflected in state curricula as subject area learning standards.

In 1985, the American Association for the Advancement of Science (AAAS) launched Project 2061. Described as a long-term initiative to alter precollege education in specific academic disciplines, Project 2061 developed two documents that impacted curricula, *Science for All Americans* (American Association for the Advancement of Science (AAAS) 1989) and *Benchmarks for Science Literacy* (AAAS 1993). These documents emphasized content knowledge and skills necessary for developing a scientifically literate society.

During the administration of President George H.W. Bush, federal and state policy-makers took the first tentative steps toward full-scale standards-based reform. In 1989, Bush called together the nation's governors for a 2-day conference. The conference produced six national education goals dubbed "America 2000." These goals included one that would bear directly on the evolving standards-based movement that would highlight competencies in specific subjects in grades 4, 8, and 12 (Nelson et al. 2006).

Two distinct groups initiated efforts to define competence in a subject area. First, the US Department of Education provided grants to national organizations to assist in the development of national standards in core academic subjects. In 1996, the National Research Council (NRC) published the *National Science Education Standards* (NSES). These standards, which shared Project 2061's focus on scientific literacy in the USA, featured inquiry teaching, professional development, assessment, program development, and science education as a system. Second, through its Goals 2000 legislation passed in 1994, the presidential administration of Bill Clinton provided federal funds to support the states' development of their own teaching and learning standards for core subjects. Forty-seven states and the District of Columbia applied for the Goals 2000 funding (United States Department of Education 1998). State standards for science were strongly influenced by NSES.

In 2001, under the administration of George W. Bush, the Elementary and Secondary Education Act (ESEA) was revised (Vinovskis 2009). Known as "No Child Left Behind" (NCLB), ESEA shifted the burden of standards-based reform squarely on the shoulders of the states. In order to receive some form of federal support, particularly those designated for students living in poverty, states were now required to develop academic performance standards for K–12 students in core academic subjects including science. In addition to these standards, states were required to develop one statewide accountability system to determine if schools and school districts were achieving yearly benchmarks of adequate progress in core subjects. Finally, ESEA also mandated that test scores be disaggregated so that the achievement disparities between racial, ethnic, and socioeconomic groups would be visible to educational stakeholders.

The revision of ESEA has been criticized for its emphasis on standardized test scores as the sole measure used to hold schools and districts accountable. Further, the law has been condemned for its punitive measures, the loss of federal funding and transfer options for unsatisfied families, for schools and districts that fail to meet their state's definition of adequate yearly progress. Science educators have argued that the reforms resulting from NCLB have harmful consequences to both students and teachers. Prior to 2007 – the year in which testing in science was mandated to begin – science instruction was sometimes sacrificed to reading and math instruction and standardized test preparation. The emphasis on standards and test preparation also deprofessionalized teachers' work, reducing it in some cases to a nearly scripted experience (Settlage and Meadows 2002). Finally, the reform movement has been condemned because of its one-size-fits-all approach to teaching and learning. This is particularly true of students from marginalized groups and students living in poverty (Crocco and Costigan 2007). In the midst of over two decades of reform that promoted quality science education for all, the status of Blacks in US science education remains abysmal.

Status of Blacks in Science Education

The relative position of Blacks as a collective to other groups in the USA is evident in the economic and education domains of US society. Statistics indicate that in 2006, Blacks comprised 12% of the US population but had the greatest percentage living in poverty; 24% in contrast to 8% for Whites, 8% for Asians, and 21% for Hispanics of any race (United States Bureau of the Census 2007). These disparities not only exist in economics, but also in education.

Generally, the quality of science teachers is determined by the number of years of teaching experience, the extent of undergraduate and graduate science coursework, and performance on teacher licensure examinations (Young 2005). Teachers with 5 or more years of experience, who have undergraduate or graduate degrees in the subjects in which they teach, and whose performance on certification examinations exceeds a specified cutoff score are considered teachers of acceptable quality. Richard Ingersoll (2002) found that teachers with less than 5 years of teaching experience, who have less than an undergraduate minor in the areas in which they teach, and who are not fully certified in their assigned areas comprise the teaching workforce in high-poverty and high-minority schools. High-poverty and high-minority schools are defined as schools with student populations of 75% or more from economically disadvantaged backgrounds and of students of color, respectively (National Center for Education Statistics (NCES) 2007). Blacks were more likely to attend such schools.

Statistics also show that many Blacks are more likely to be placed in lower-level science courses and that Black males are more likely to be found in special education classes and less likely to be found in gifted and advanced science courses (Atwater 2000; Rascoe and Atwater 2005). Research typically characterized the instruction of science courses taught in the standard or low academic tracks as back-to-the basics with drill and memorization as both the means to and ends of learning (Gilbert and Yerrick 2001). In the instances in which Black students enrolled in advanced science courses or specialized science classes, they reported unwelcoming environments marked by negative perceptions, low teacher expectations, little encouragement, strained teacher and student interactions and relationships, and various personal and institutional challenges to meaningful learning (Brand et al. 2006; Griffard and Wandersee 1999). Additionally, racial disparities in the offering of advanced placement (AP) courses in science in relation to the ethnic makeup of schools have been documented. Daniel Solorzano and Armida Ornelas (2004) documented that schools that had high enrollments of Black students were less likely to offer AP courses and schools that provided AP courses offered few of them. In 2007 Black students who made up approximately 14% of graduating seniors comprised about 6% of AP examinees in biology, around 6% in environmental science, and 4% in chemistry (College Board 2008).

The status of underserved students and their success regarding AP exams are areas of concern for the College Board. The College Board (2008) defines an equity and excellence gap, a case in which the percentage of underserved students who have access to and success on the AP exam is less than the percentage of underserved students in the entire class of 2007. The College Board examined all 50 states and the District of Columbia in relation to an equity and excellence gap for Black, Hispanic, or Native American students. The College Board found that 17 out of 51 sites eliminated an equity gap for Native American students, 15 eliminated an equity gap for Hispanic students but only one out of 51 sites eliminated an equity gap for Black students (College Board 2008).

As denoted in the synopsis of the status of US Blacks, Blacks as a collective have limited access to quality science education (Hewson et al. 2001) which goes beyond shared physical space highlighted in the desegregation and civil rights legislation (Tate 2001). From 1997 to 2007, a portion of science education research conducted in the US involved Blacks. What areas did these studies investigate? What additional insights beyond the statistics on the status of Blacks in US science education can be gained from these studies?

Synthesis of the Literature

Using the purposes of studies, the authors divided the investigations into several categories. Articles comprising the three largest categories are presented here. In this section, the authors synthesize the literature under subheadings that reflect the categories.

Studies of Students' Perceptions and Attitudes

These studies, which were divided into two groups, investigated students' perceptions about scientists and their attitudes toward science. The first subset of these articles situated the significance of students' perceptions and attitudes in the students' future choices regarding science. The second set examined perceptions among different subgroups of students.

As part of the first subset of articles, Janice Terry and William Baird (1997) highlighted the low number of women in science elective courses and careers. They examined high school students' attitudes toward women in science with respect to 17 variables. They found statistically significant and positive correlations among the students' attitudes toward women in science and mothers' nonscience occupations, science plans, education level plans, careers in science, female influence at school, female influence on future planning, and female influence regarding a science career. With respect to the variance in students' attitudes toward women in science, gender accounted for most of the variance followed by science ability, level of education the student planned to complete, and career interest outside of science. Shannon Gilmartin et al. (2007) extended investigation of the attitudes toward women in science factor beyond attitudes and examined how the percentage of female science faculty was related to high school students' perceptions, achievement, views, self-concept, and college major aspirations. The results indicated that the percentage of female faculty in high school science departments was not related to students' perceptions and stereotypical views of science, students' science self-concepts, and students' college major aspirations. Keeping in line with this focus on gender in science, Eileen Parsons (1997) studied Black high school females' images of the scientists and discussed these culturally influenced images as windows to self-concepts and future career choice. With regard to students' images of the scientist, Jason Painter et al. (2006) examined the impact of students' interviewing of scientists involved in a multiyear project on nano-scale science. They found that the interviews helped to alter students' perceptions of scientists as male, always in a lab coat, only doing experiments, being weird/ boring, and always working alone; this alteration in perception remained 1 year later. The last study of this subset that couched the significance of students' attitudes and perceptions in decision-making explored course enrollment decisions in relation to gender and students' learning experiences in contexts classified as high and low learning cycle classrooms (Cavallo and Laubach 2001). In classrooms where learning cycle instruction was salient, significantly more females planned to enroll in science elective courses, and males, had higher science enjoyment, and viewed science as more gender inclusive.

The second set of articles that investigated students' attitudes and perceptions looked at differences among subgroups of students that explicitly included racial/ ethnic comparisons. Douglas Huffman et al. (1997) studied students' perceptions of learning environments among different groups of students within the same science classes. The results showed that Black students perceived classes as less involving than White students. Faye Neathery (1997) examined the correlations of students' attitudes toward science with gender, race/ethnicity, ability, grade level, and science achievement and found statistically significant relationships for gender, ability, grade level, and science achievement; a significant relationship was not found for race/ethnicity for the large sample in which all non-White students were grouped together as minority. Like Neathery (1997), Sheldon Woods and Lawrence Scharmann (2001) classified non-White student participants into one group for an analysis that focused on high school students' perceptions of evolutionary theory in relation to science locus of control, logical reasoning ability, race/ethnicity, gender, grade level, and teacher. Statistically significant correlations were used to determine the order for entry into a forward regression analysis of which race/ethnicity, gender, grade level, and teacher did not meet the criteria. Logical reasoning accounted for 10% and science locus of control for 1% of the variance in students' perceptions of evolutionary theory.

Impact Studies

The studies classified as impact studies examined the effects of curricula and instructional strategies on various student outcomes. Student outcomes ranged from achievement to social activism, with most studies examining achievement. The foci of many of these studies examined curricula and instructional practices that aligned with science education reform advocated in NSES.

In a large-scale quasi-experimental study that involved the professional development of teachers in standards-based science teaching and their implementation of such teaching, Jane Kahle, Judith Meece, and Kate Scatlebury (2000) found that standards-based teaching positively influenced the achievement and attitudes of

African-American students who attended urban schools. Similar results emerged for curricular interventions. For example, the enactment of inquiry units during the teaching of a state's science curricula improved student achievement not only in terms of recall but also in the comprehension of specific content knowledge (Singer et al. 2003); in the acquisition of certain inquiry skills (Keselman 2003; Keys 1998); in relating scientific concepts (Rivet and Krajcik 2004); and in the ability to transfer the scientific understanding to new situations (Fortus et al. 2005). Some researchers also examined the effects of interventions on the achievement gap among different demographic groups. Sharon Lynch et al. (2005) in their study of a curriculum intervention did not find a narrowing of the achievement gap among demographic groups but noted that for groups not utilizing the curriculum the gaps appeared to widen. In contrast, Okhee Lee et al. (2005) who examined curricula and instructional practices reported a narrowing of the achievement gap among different demographic groups at the end of the school year during which the study was conducted. Other studies showed that specific tools or teaching methods positively influenced outcomes of interest. These studies featured broad approaches like the use of science, technology, and society (STS) to more specific methods like using descriptive drawings.

An STS approach to teaching global warming indicated that more students expressed awareness of social activism more frequently after STS instruction but the approach failed to alleviate difficulties of 5th graders in conceptually understanding the topic (Lester et al. 2006). Kellah Edens and Ellen Potter (2003) found statistically significant differences on posttests that assessed students' conceptual understanding of the law of conservation of energy under three learning conditions. One condition involved explanatory text accompanied with journal writing, another highlighted explanatory text with illustrations that students reproduced in their journals, and the last condition used explanatory text with drawings students generated. The learner-generated drawing and the drawing reproduction groups scored significantly higher than the writing group. In a similar vein, Linda Cronin-Jones (2000) examined students' conceptual understanding and attitudes toward ecology in three different instructional conditions. Students received no instruction, traditional instruction (guided reading, lecture, demonstrations, discussions, role playing, indoor lab activities, slide and film presentations), or experimental schoolyard instruction (guided reading, lecture, demonstrations, discussions, role playing, outdoor lab activities, and field observations). Analysis of variance yielded significant effects for content knowledge and attitude posttest comparisons. The mean content knowledge posttest scores of the experimental outdoor group were higher than the traditional classroom group who significantly outperformed the "no instruction" group. Post hoc comparisons indicated that the attitude posttest scores were significantly more positive for the experimental and traditional groups in comparisons to the control group; however, the mean attitudes posttest scores for the traditional and experimental groups did not differ. In addition to examining changes in conceptual understanding, Robin Ward and James Wandersee (2002a, b) explored the impact of Roundhouse diagramming, a visual organizer, on metacognition and performance as measured by grades. Students utilizing Roundhouse diagramming improved in the aforementioned domains. Related to investigating the effects of tools and methods on conceptual understanding, one study explored what kinds of authentic, real-world situations are inquiry-rich and science-content-rich for students (Lee and Songer 2003). Another study examined the relationships among genetics content knowledge, moral reasoning, and argumentation quality (Sadler and Donnelly 2006), of which a significant contribution of content knowledge and moral reasoning to variations associated with argumentation quality was not found.

"Creating Space" Studies

With respect to science teaching and learning, science classrooms are cultural interface zones (Norman et al. 2001) where the cultures of schools, teachers, students, and science interact. Stacey Olitsky (2007) examined successful classroom interactions within these cultural interface zones. These interactions were marked by entrainment, a common rhythm and mood that increased positive feelings about group membership. The participants shared a mutual focus, engaged in side talk, and actively contributed to group solidarity. In his study of interactions in two teachers' classrooms, Kenneth Tobin (2006) described both successful and unsuccessful interaction rituals. Unsuccessful interaction rituals rather than successful ones are more typical for Black students in US science classrooms. Often, cultural interface zones are sites of conflict for these students (Norman et al. 2001).

The conflicts that arise in cultural interface zones in the science classroom have many different manifestations. For example, in their investigation, Maria Varelas et al. (2002) explored the connecting interfaces of three genres, recognizably organized social activities in which all participants contribute. They unearthed through the students' genres of rap songs and plays, the tensions surrounding affect and thinking about science content; teacher-instituted structures that comprised classroom genres; and the science genre that consisted of students' uses of various tools and lab activities. Other studies featured the teachers' and students' management of these conflicts. In Gilbert and Yerrick's (2001) study, student–teacher negotiations of these tensions influenced the quality of science instruction in the participating rural science classrooms. In response to the tensions, students developed identities that worked against academic achievement. Similarly, other studies documented conflicts among the identities students constructed of themselves as science learners and the identities they developed within their homes and communities (Brown 2004; Brickhouse et al. 2000). The previously surmised conflicts within the cultural interface zones in the science classroom necessitate cultural border crossings (Aikenhead and Jegede 1999). The articles classified as creating space studies investigated various vehicles or boundary spanners (Buxton and Carlone 2005), material and symbolic, used to facilitate border crossings into school science.

Jhumki Basu and Angela Calabrose Barton (2007) used funds of knowledge, practice-based cultural understandings of a community that have accumulated over time, to facilitate border crossing. Basu and Calabrose Barton (2007) investigated the connections among students' funds of knowledge and their sustained interest in science. Students exhibited a sustained interest when there was a strong connection between science and authentic opportunities that advanced students toward their visions of their own futures; a strong correspondence between science and students' views of science as useful; and a strong link between science and environments that nurtured relationships that reflected the values of their communities. To uncover the students' funds of knowledge, several studies employed cogenerative dialogues.

Cogenerative dialogues are critical discussions that are structured to engage participants in sharing. Christopher Emdin (2007a) used cogenerative dialogues to elicit students' perspectives on corporate (i.e., notions of achievement defined by benchmarks via standardized testing) and communal practices (i.e., science as a social activity and ideas of success linked to students' ways of knowing and being) in relation to their engagement and success in science. Emdin (2007b) then identified students' out-of-school communal rituals and supported their enactment within the science classroom which enabled the students' success in science and navigation of existing corporate structure and corporate rituals that dominated schooling. Emdin (2007a, b) employed cogenerative dialogues as an elicitation tool to uncover students' funds of knowledge that were then used to facilitate the students' cultural border crossings. In contrast, Gail Seiler (2001) used cogenerative dialogues as a direct means to border crossing. In cogenerative dialogues, students used their own discourse patterns to engage in science talk. This sense of ownership, illustrated in the use of the students' own discourse patterns in Seiler's (2001) study, became a tool to facilitate cultural border crossings in the final two studies of the "Creating Space" Studies section in this chapter.

Rowhea Elmesky (2005) and Rowhea Elmesky and Kenneth Tobin (2005) used a documentary production project with students in order to make science their own. As a part of the process of producing the documentaries and the science content of the documentaries, the students contextualized the scientific abstractions within their cultures as specific embodied practices. In the manifestations of high-energy levels, rhythm, singing, and dancing, the students collectively reproduced and enacted their own culture as a vehicle to understanding scientific concepts. Consequently, students expressed a value in participating in science either as a prerequisite or corequisite in achieving their personal aspirations.

Critique and Recommendation

An extensive search of 12 science education literature sources over a span of 10 years produced a total of 70 articles that explicitly identified Blacks or African-Americans as participants in research studies. Of the 70 articles, authors of 51 (73%) of the articles provided racial/ethnic information explicitly (e.g., numerical breakdown) or implicitly (descriptors in the journal title or findings) for the study samples and 21 (30%) disaggregated results by race/ethnicity. The majority of the studies that identified the race/ethnicity of participants used the identifier "Black." Although the synthesized literature provides some insights on the status of Blacks in science education, two primary constraints exist.

First, in relation to the corpus of studies in science education for the past decade, 70 studies is a relatively small number of projects involving Blacks. Similar to the indictment made against reform that promotes science for all, the small number of studies involving Blacks utilized a one-size-fits-all approach. The studies' findings were presented as though they were equally relevant and valid for all participants in the study, regardless of the status of the group to which they belonged. By default, the findings of these studies were most pertinent to the group that comprised the majority of the studies' samples of which a subset included a Black majority. In these cases where the majority of the study participants were identified as Black, significant differences that exist among collectives of the African Diaspora who immigrated to the USA and African-Americans, a collective with an African ancestry directly intertwined with the founding of the USA, were not acknowledged. Failing to distinguish among non-Blacks, African-Americans, and individuals of the African Diaspora who immigrate to the USA inadequately portrays the challenges encountered both by African-Americans and African Diaspora immigrants (Lehner 2007).

Second, with the exception of a few investigations, the studies did not address phenomena in relation to conditions specific to Blacks. In his critique of NSES, Alberto Rodriguez (1997) discussed the invisibility of students from diverse groups in the text despite numerous photographs of diverse students throughout the document. This invisibility critique is also relevant for historical and contemporary science education reform in the USA and the vast majority of science education research involving Blacks.

Even in light of the previously described constraints, the science education research involving Blacks provided information that can prove useful in improving the status of Blacks in US science education by way of science education reform. With regard to what should be addressed in science education reform, the studies on students' perceptions and attitudes described factors that may curtail or encourage students' participation in science. With respect to what may constitute science education reform, the impact studies indicated that some curricula and instructional implementations improved achievement and reduced the achievement gap among different demographic groups. In relation to how to tailor science education reform to address the needs of different groups so it can work to achieve science for all, the creating space studies provided insights on how to mediate various conflicts that may hinder Black students' involvement in and learning of science. On the one hand, the studies indicate progress; on the other, they signify the very difficult work that lies ahead.

Chapter 40
Social Justice Research in Science Education: Methodologies, Positioning, and Implications for Future Research

Maria S. Rivera Maulucci

To evaluate trends in social justice citations, I searched for the phrase "social justice" using the online search fields in each of the following journals: *Journal of Research in Science Teaching*, *Science Education*, *Research in Science Education*, *International Journal of Science Education*, *Journal of Science Teacher Education*, *Elementary Journal of Science Education*, and *Cultural Studies of Science Education.* My search identified 105 journal articles, including empirical studies, literature reviews, book reviews, editorials, and forums spanning 1981–2008. I searched within each journal article for each social justice citation. Out of the 105 articles, 66 had a single mention of the phrase and in 29, social justice only appeared in the references list in the title of a book or journal article. Studies with a single social justice citation in the references list were eliminated from further review. The most frequently cited text (13 citations) was *Teaching Science for Social Justice* (Calabrese Barton et al. 2003).

Figure 40.1 shows a breakdown of the number of articles and the number of times the phrase "social justice" was cited in the text of the journal article for the remaining 76 articles. For example, there were 39 articles with one in-text citation, and one article with 46 in-text citations of this phrase. This analysis shows that very few articles addressed the topic of social justice throughout the paper.

Figure 40.2 shows the distribution of the number of articles that included at least one in-text citation of social justice by year. In 1977, for example, there was one journal article that cited social justice and in 2008 there were 22 articles. This analysis shows that the concept of social justice is gaining some traction in the field of science education research, with the number of articles citing the concept increasing over time.

B.J. Fraser et al. (eds.), *Second International Handbook of Science Education*, Springer International Handbooks of Education 24, DOI 10.1007/978-1-4020-9041-7_40,

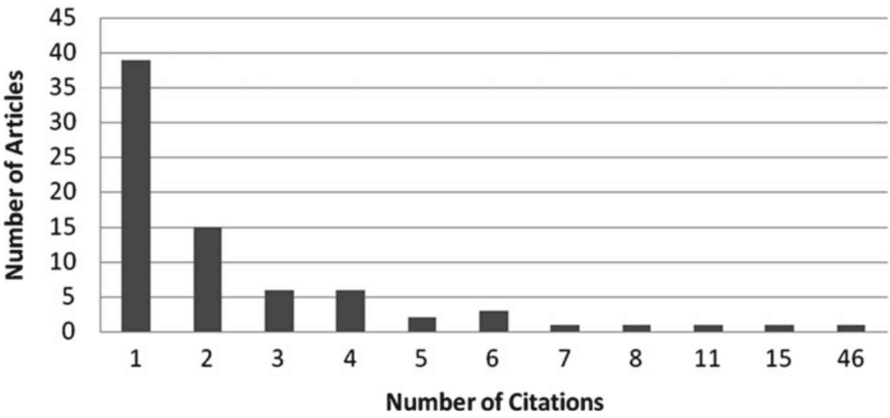

Fig. 40.1 Number of articles by number of in-text citations

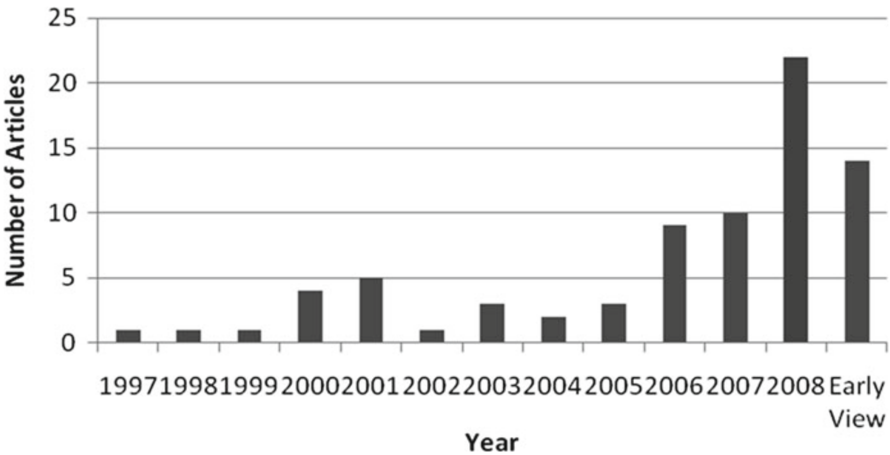

Fig. 40.2 Social justice citations by year

Figure 40.3 shows the distribution of articles by journal citing social justice. *Cultural Studies of Science Education* had the largest number of citations, with 33 articles that included at least one in-text reference to social justice, followed by the *Journal of Research in Science Teaching*, with 14 articles.

The above analysis indicates social justice is an idea that is gaining some traction among members of the science education community. However, a close look at the studies reveals a tendency for authors to list social justice alongside equity as an overarching goal. Other studies clearly align theoretically and methodologically with a social justice framework; yet, this alignment is not made explicit in a consistent way. Thus, social justice in science education remains a concept that requires further definition and theorizing. In the following section, I review three early studies of social justice in science education.

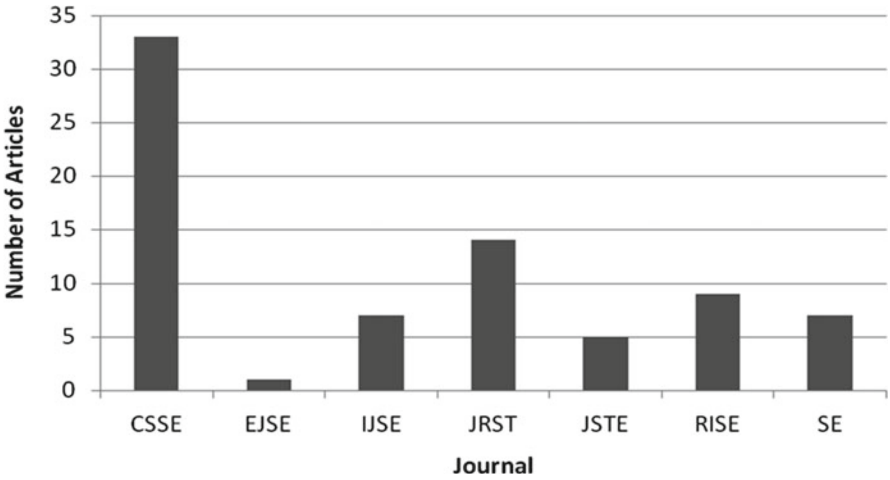

Fig. 40.3 Social justice citations by journal

Early Framing of Social Justice in Science Education

One of the first scholars to write about social justice in science education was Alberto Rodriguez (1997), who published a critique of the National Science Education Standards in JRST. He argued that the standards document engaged in a discourse of invisibility because it did not provide a clear argument for why or how teachers should work to improve the achievement of traditionally marginalized groups of students – women, the poor, and students of First Nation, African, and Latino/ethnic background. Rodriguez wrote:

> In the case of education reform, an individual's political will must come from a clear sense of purpose and understanding that social justice requires one not only to question, but to take action even when these actions may lead to transforming one's own comfort and institutionalized privilege (or lack of it). (pp. 28–29)

Rodriguez provides a critical analysis of trends in student achievement across gender and ethnicity, drawing on data from the National Assessment of Educational Progress (Mullis et al. 1994) to highlight inequitable outcomes. He concluded that the standards should provide "more visible theoretical frameworks and arguments in support of learning science for understanding and for teaching science in more inclusive and multicultural ways" (p. 32).

Angela Calabrese Barton (1998) takes up the issue of social justice from the perspective of what it means to teach science for all with homeless children. Calabrese Barton explores issues of representation and identity in science and demonstrates that when youth have the power to shape science for their needs and interests, the borders of science expand. Calabrese Barton explains: "The doing of science involved merging the emotional with the physical and intellectual. The students found their experiences with the ugliness of their community or with hunger as important and more complex than science could describe in its neutral language" (p. 391). At the same time, blending activism with scholarship requires the researcher to navigate relationships and ethical issues. For example, Calabrese Barton shared the following:

> In an initial interview with a leader and activist within the local social services community, I was told that this research project was not only a commitment to research, but also to the children, and that "unless I was on my death bed," I had better not miss a scheduled visit. I recognized that I had begun to earn Gilma's trust simply by returning each week to spend time with her and the other children. (p. 385)

Calabrese Barton concludes: "If *all* students are to participate in science in genuine ways, then teachers need to find ways to value the diverse ways of knowing brought to class by the students" (p. 391, emphasis in original).

William Kyle (1999) aligned teaching science with teaching for social justice. In an editorial for a theme issue focused on science in developing countries, he noted:

> The totality of an education in science is equally as much oriented toward social justice, critical democracy, empowerment, action-taking, and investing in our future's intellectual capacity as it is about constructing conceptual understandings of the world. (p. 255)

Kyle recognized that beyond a way of knowing about the world, science education could be a way of acting in the world to transform it:

> Education is about hope, dreams, aspirations, and struggle. … Education must be *for* something. But what? Education ought to be for the purpose of fostering critical and participatory democracy, enabling students to recognize that the world that is being presented to them is in fact a world that is being made – it is changing constantly – thus, for this very reason, it can be changed, it can be transformed, and it can be reinvented. (p. 256, emphasis in original)

Further, he argued that social justice in science education could foster the types of global communication and collaboration that could address issues of poverty, development, and sustainability in the world.

The above articles position science education and science education research as tools and contexts for challenging injustice. In the remainder of this chapter, I review five studies that illustrate some of the ways social justice research balances needs for scholarship with needs for activism in the field. I will explore each author's positioning with respect to social justice and their particular social justice issue. Then, I will analyze the methodological approaches used in each study. I recognize that this focus might marginalize other scholars whose work incorporates a social justice framework. However, I believe a more focused review will provide a clearer justification for further research and highlight ways to strengthen the reporting of social justice research in science education.

Positional Identity and Social Justice Research

To understand positioning, I draw on the idea of positional identity, as "understanding how social markers such as race, class, gender, religion, among others, influence views of teaching and learning science" (Moore 2008a, p. 593). Just as the standards

Table 40.1 Foundations of social justice research in science education

Discourse	Central ideas
Feminist	• Urges rethinking the nature of science and science education • Proposes liberatory rather than oppressive science education • Positions knowledge as subjective and contextually mediated • Shifts away from compensatory programs
Multicultural	• Challenges notions of science grounded in the Western tradition • Urges use of culturally relevant and responsive pedagogy and science for self and social transformation • Emphasizes role of community action
Critical	• Critiques the role of schools and institutions in reproducing inequity • Highlights the role of hegemony, power, and privilege in sustaining oppression • Critiques enculturation and reproduction of the dominant culture • Struggles to address entrenched inequalities
Science for all	• Positions scientific literacy as a national goal • Asserts equity goals in science education • Clarifies the nature of science • Emphasizes inquiry-based methods for science teaching and learning

engage in a discourse of invisibility (Rodriguez 1998), science education research also engages in a discourse of invisibility when it does not convey an adequate understanding of the researchers' agendas or the ways their positional identities frame how they perceive and work to address social justice issues. Since social justice research blends scholarship and activism, researchers also position themselves with respect to the theory and practice of social justice and the particular social justice issues addressed by the project. Thus, researchers may also position themselves in relation to discourses, texts, issues, people, and places.

Social justice research in science education has its roots in feminist, multicultural, and critical approaches to science education and takes up the challenge of science for all in ways that position science as a dynamic, contextual tool for promoting equity and empowerment (Rivera Maulucci 2008a). Table 40.1 summarizes some of the central tenets that inform work in social justice in science education. Rather than providing an exhaustive list, the table conveys the idea that the ways researchers position themselves with respect to these and other discourses, provides for multiple, nuanced, situated, and emerging definitions of social justice in science education.

For example, Rodriguez (1998) provides a clear sense of his positionality through the following statement:

> As a Latino science teacher educator, I am deeply committed to closing the gap in student achievement and participation, as well as to making science more socially relevant and accessible to all children. (p. 590)

He explains that, "in the secondary science methods class that I teach, I am the only Latino and the only member of a typically underrepresented ethnic group in the sciences" (p. 603). Rodriguez situates his work within discourses related to multiculturalism and equity in science education:

> It is not enough just to encourage all learners to celebrate and study the contributions of men and women from various ethnic backgrounds to the advancement of scientific knowledge. Multiculturalism seeks to provide learners with opportunities for empowerment. (p. 591)

He draws on critical, multicultural, and sociocultural theories of education and learning to propose sociotransformative constructivism (STC) as a way to teach for diversity and understanding, and notes that "the STC orientation provides spaces where existing contexts can be collaboratively transformed to meet social justice goals. Power, then, is a central construct in STC – power is the currency of social change" (p. 599). In this case, the social justice issue is framed by his position as a science teacher educator in a program that seeks "to prepare teachers to work respectfully and effectively with children from diverse backgrounds (i.e., from diverse socio-economic status, cultures, ethnicities, abilities, sexual orientation, family units, and so on)" (p. 593). Rodriguez clearly states: "This is an ideological orientation based on a principle of social justice in which I personally believe" (p. 590).

In her article, Felicia M. Moore (2008b, p. 595) positions herself as a science educator:

> As a science educator, I am always open to new approaches to my teaching and research. Over time, I have become interested in not only what I do in my teaching but also how it informs and provides a space for research.

Moore defines social justice work in science education as attending to students' right to learn science (Tate 2001): "Social justice considers action toward developing learning environments that support all students in learning, such that every student has a right to learn and to have a quality education" (pp. 589–590). And she explains further:

> By taking on social justice education as a science educator I challenge preservice teachers to understand what it means to create science classroom communities with access, equity, quality, and opportunity to learn science as fundamental goals. (p. 591)

Moore situates "learning about social justice for preservice teachers … within the context of multicultural education" (p. 591). She also highlights the need for preservice teachers to understand issues of power and privilege in education, how social structures and hierarchies marginalize students, and how preservice teachers might deconstruct such social structures through their practice (Lewis 2001). Her definition of agency draws on critical and multicultural perspectives:

> [F]or this study, agency is defined as individuals or groups reflecting, acting, modifying, and giving significance to the teaching of science in purposeful ways, with the aim of empowering and transforming themselves and/or the conditions of their lives, students and others … it is the way that teachers use power, influence, and science to make decisions that effect positive social change in science classrooms. (p. 591)

One way in which Moore could have strengthened her positioning in this study might have been to include the ways her race, ethnicity, and gender influence her positioning with respect to social justice in science education and the ways her positioning with respect to critical and multicultural theories frame her vision of science.

In my study, I address the issue of English language learners (ELLs) and science education (Rivera Maulucci 2008b). Through an in-depth case study of a preservice teacher, Elena, I undertake a critical exploration of school policies and procedures that render native language proficiency as a deficit that immigrant students must overcome. In the study, I position myself as a teacher educator in a social justice teacher education program concerned with the question of how, "social justice teachers [can] be prepared to meet the challenges of supporting immigrant youth in a climate that increasingly calls for immersion…" (p. 18). I reveal my personal positioning with respect to the issue of language, as I argue against school policies that do not allow immigrant students to maintain their native language and culture:

> What would I have chosen? As a third-generation Puerto Rican, speaking English at home, and divorced from many of the trappings of culture that enable one to fit in–the language, idioms, dance, music, and modes of dress – I have lived in a borderland between Puerto Rican and not Puerto Rican. What would I have chosen? I would have chosen science *and* Spanish. (pp. 36–37, emphasis in original).

My positioning with respect to critical and multicultural discourses comes through examination of US immigration patterns that favor elites and assimilationist ideologies that undergird school language policies and equate "science for all" with "English only." For example: "Such policies cannot be neutral; rather they confer privilege and access to standard English, scientific discourse, and bilingualism, differentially across race, class, and ethnic categories, as well as immigration status" (p. 41). I argue that we cannot understand the case of Elena without situating her microlevel experiences in the classroom within mesolevel structures of schooling for ELLs and macrolevel patterns associated with globalization. My positioning with respect to the issue of language would be strengthened by a discussion of the demographics of students in my teacher education program and the schools we partner with, to highlight the need for preservice teachers to develop strategies to support ELLs.

Edna Tan and Calabrese Barton (2008) indicate their position with respect to global feminism: "Global feminism is a phrase we use to describe the ideas emerging from the most recent wave of feminist scholarship attentive to transnational and globalization issues while drawing upon critical, anti-racist and postcolonial perspectives" (p. 46). In their study, Tan and Calabrese Barton focus on urban, Latina girls' participation in science:

> We believe that by paying careful attention to how and why urban girls author identities-in-practice, we can gain deep insight into the noncommodified forms of knowledge, relationships and activities that girls often employ to participate in science related communities in ways that are culturally and socially just and sustainable. (p. 46)

Their study conveys a clear positioning with respect to the research context, with detailed descriptions of the school, the principal, the science teacher, and the neighborhood. However, the authors do not share how their own gender, class, race, or ethnic identifications impact their positioning or how they navigated their insider/outsider status as social justice researchers from an elite college working in a high-poverty community.

Rowhea Elmesky and Kenneth Tobin (2005) address the issue of urban youth's social capital in contrast to the deficit models that dominate how policy-makers, schools, teachers, and the educational reform literature typically construct the problem of underachievement in inner city schools:

> We contend that the trends of science education in urban settings will continue if theoretical frameworks of cultural poverty, deprivation, and social reproduction continue to inform research. We find these theories to be hegemonic – laden with deficit views of marginalized youth and with a static view of culture. Moreover, these theories reinforce the cycles of oppression experienced by the urban poor … (p. 809)

Their critical perspectives are clear in their attention to issues of power and hegemony. Elmesky and Tobin also position themselves with respect to current science education research by highlighting how their approach "challenges traditional views" (p. 811) by engaging youth as researchers. Their social and cultural positioning is established in an endnote that states: "The first author is from a mixed racial background, yet has been enculturated to some extent with white, middle-class value systems. The second author is white" (p. 825). On the one hand, they seek to share methodologies that provide for a more inclusive understanding of student agency in research; however, their positionality in terms of gender, ethnicity, race, and class and how that impacts their relationships with the youth is framed by the labels, insiders and outsiders. For example, "When Ken began to teach science in an inner-city high school, to afford his roles as teacher educator and researcher, he quickly realized that he needed insider perspectives to inform his practices" (p. 813). In a similar way, they wrote: "Although we wanted to learn more about student researchers' homes and neighborhoods … we could not ignore the fact that we would be outsiders in those fields …" (p. 816).

Critical Ethnography in Social Justice Research

A methodology is a theory of method and as such encapsulates epistemological, ontological, tactical, and catalytic assumptions. For example, as a researcher, I employ critical narrative inquiry methodology (Rivera Maulucci 2008b). Critical narrative inquiry rests on the epistemological assumption that people come to know the world and its power relations through story. From an ontological perspective, the researcher attends to narrative elements, including character, setting, events, dialogue, action, emotions, and time. Critical narrative inquiry views storytelling as a meaning-making experience, both for the participants, as they tell their stories, and for the researcher, as they interpret and retell stories to advance theoretical and analytical points. Telling, interpreting, and retelling stories, changes or transforms participants and the researcher in ways that implicate the need for further personal or contextual change. Critical narrative inquiry also foregrounds a need for tactical authenticity, in that the research process empowers participants and the researcher to act on the need for change. In essence, social justice methodologies encapsulate assumptions about how people individually, collectively, and contextually, come to know and change the world and each other.

All the studies in this review employ critical ethnographic methods. What makes these studies critical is their focus on issues of power and the need for transformation. For example, according to Moore (2008b): “Research grounded in critical methodologies is particularly suitable for understanding preservice teacher identity, agency and stance toward social justice because it seeks to document the process of empowerment” (p. 590). Elmesky and Tobin (2005), assert: “A critical research process invokes a goal of determining the existence of injustice, finding methods for altering it, and identifying the sites for transformation” (p. 810). Ethnographies typically: (a) focus on a particular context; (b) employ multiple research methods, such as interviewing, participant observation, and collection of artifacts to explore a wide range of social behavior in the setting; (c) use grounded theory approaches to data analysis; and d), are marked by prolonged engagement and an understanding of complexities, rather than generalizations (Pole and Morrison 2003). Thus, critical ethnography rests on the assumptions that knowledge is situated, that it requires an insider’s perspective, and that participants’ perspectives matter. Furthermore, Rodriguez (2001) proposes “catalytic validity” as “a way of conceptualizing our research as valid by the degree to which participants and researchers have substantially improved their condition as a direct result of their involvement in the study” (p. 345). Bringing the need for transformation together with the need to understand participants’ perspectives on change requires researchers to negotiate their activist role in the field. Relationship-building, dialogue, trust, and continued negotiation play central roles in maintaining a course of activism that remains responsive to the needs, hopes, and desires of the participants alongside needs for scholarship.

For example, to meet the challenge of preservice teachers’ ideological and pedagogical resistance, Rodriguez (1998) plans and implements four strategies of counter-resistance: the dialogic conversation, authentic activity, metacognition, and reflexivity. His year-long ethnography begins with 18 preservice teachers during their methods course and continues with four students during their student teaching assignments. He triangulates multiple data sources, including ethnographic field notes, course evaluations, and student-produced artifacts from the class, interviews, focus group notes, videotapes of two lessons during student teaching and notes from discussions of the videotaped lessons. Throughout the report, it is clear how Rodriguez advocates for the need to teach for diversity and understanding through an STC orientation. He summarizes some of this advocacy as follows:

> In short, the strategies for counterresistance discussed thus far consisted of providing students with authentic activities in the methods class to bring their taken-for-granted beliefs into the open. This was followed by in-depth discussions of critical readings and activities that allowed them to consider alternate points of view. Next, the members of the focus group were placed in schools where they were able to explore the applicability of their metaphors of teaching and learning in various school contexts. (p. 609–610)

In a similar way, Tan and Calabrese Barton (2008) engage in a year-long ethnographic study of 6th grade, urban Latina girls. Their long-term work with the case-study teacher and students situates the study as intervening in the world to enhance girls' participation in science. Tan's advocacy is evident as she assists the teacher in preparing materials for lessons, coteaches some of the lessons, interacts with case-study girls during the lesson, debriefs lessons with the teacher, and helps brainstorm ideas for subsequent lessons. Thus, teaching for social justice involved the collective effort of students, teacher, and researchers to promote opportunities for girls to author identities-in-practice. Tan and Calabrese Barton conclude:

> [P]aying attention to who girls are, who they want to be and the relationships that are important to their science learning – aspects of science education which are decidedly non-commodified and un-economic in focus – can open up the dialogue around Science for All. (p. 64)

Elmesky and Tobin (2005) share their evolving approaches to working with youth as student-researchers over a 5-year period. In addition to traditional forms of data-gathering, such as interviews, classroom observations, and journals, the youth created unique artifacts, such as a science-related movie and rap videos. Importantly, the creation of these artifacts required youth to develop technical and theoretical expertise, and afforded the youths agency in the day-to-day practice of research. Elmesky and Tobin explain that:

> … we have developed new windows into the lives of urban youth, to contest the privileging of our voices as the adult, university-based researchers and so as not to put forth claims rooted in our own experiences of research, teacher education, and teaching and learning of science…. (pp. 810–811)

Moore's (2008b) study seeks to understand how preservice teachers' conceptions as change agents relate to their science teacher identities. She closely analyzes the coursework of 23 students and follow-up interviews with five students. In the course, students read *Ways with Words: Language, Life, and Work in Communities and Classrooms* (Heath 1983), engage in small group dialogues, and wrestle with ideas of diversity, teacher identity, and science teaching. A final, individual reflection paper addresses "their ideas about issues of diversity and teaching science in urban classrooms; identity as an agent of change; and worries, fears and issues about science teaching in urban elementary classrooms" (p. 593). The study is based on the epistemology that preservice teachers come to know themselves as potential science teachers through their interactions with texts, dialogue with others, and classroom experiences. Finally, in my study (Rivera Maulucci 2008b), across Elena's narratives from her schooling experiences as an immigrant acquiring English, through preservice field experiences in an international high school that serves predominantly English language learners, her emotions emerge as commentaries upon her enduring concerns (Archer 2004) related to issues of language, power, and identity. The study draws on interviews and coursework, including field journals, reading responses, teaching autobiographies, and fast-writes across three semesters of Elena's participation in a teacher education program. I use a metalogue, a written dialogue between Elena and me at the end of the study, to share the educative and transformative value the study had for Elena.

The Road Ahead: Implications for Future Social Justice Research

Individually and collectively, the above studies contribute to several key implications for future social justice research in science education. First, the social justice framework should be evident throughout the study. Social justice should comprise an overarching goal of the research, drive the conceptual framework, inform the methodology, methods, and analysis of the data, and frame the implications and conclusions. Second, the researchers' subjectivities, or vested interests in the outcomes of the project and the findings of the research, should be made evident. Researchers should indicate their positional identities with respect to social markers that might have bearing on how they frame social justice issues or science education. They also should articulate a clear positioning with respect to the major discourses that contribute to social justice perspectives, including critical, feminist, and multicultural theories, and science for all.

Rather than a universal or monolithic understanding of science, a social justice lens situates scientific literacy as a collective endeavor shaped by the needs and interests of the community and developed through social relationships and interactions. Whether the study focuses on girls authoring identities in practice, preservice teachers preparing to teach for diversity and understanding, or youth engaged in the role of researchers, the meaning of scientific literacy is contingent upon the needs and interests of the participants. By employing methodologies sensitive to the collective needs of all stakeholders, reports of research can indicate the contradictions and how they are negotiated during the research process. Future research should highlight the researchers' social and theoretical positioning. In this way, a social justice perspective shifts the focus from science as a body of knowledge and skills to be learned on its own merits, to a social activity that students, teachers, teacher educators, and science education researchers engage in for the purpose of personal and community understanding and transformation.

Acknowledgment The author thanks Lee Anne Bell for her comments on an earlier version of this chapter.

Part V
Assessment and Evaluation

Chapter 41
Student Attitudes and Aspirations Towards Science

Russell Tytler and Jonathan Osborne

Students' attitudes towards science have been a topic of enduring interest in the field of science education for over 40 years – but why? After all, there is no sense in which people are concerned about students' attitudes towards the learning of English or history. So what is it that drives the interest in this topic? The brief explanation is that compulsory science education bears a dual mandate (DeBoer 1991; Millar and Osborne 1998). On the one hand, school science is charged with educating the next generation in and about science – an education which essentially requires developing an understanding and appreciation of the explanatory hypotheses that science offers of the material world, how these came to be and why they matter. On the other hand, school science has a responsibility to educate the next generation of scientists. Whilst there are overlaps between the two goals, the former requires a broad overview of the domain. The latter requires a foundational knowledge of the discipline and its major concepts. And it is the supposed failure of school science to engage sufficient students in studying science for a future career that has pushed students' attitudes to the fore as a matter of concern for society and policy makers. Most advanced societies look to science and technology to sustain their economic lead, particularly in the context of threats to the dominance of the Western world posed by the developing economies of Brazil, Russia, India, and China. Looked at in this manner, science education is seen as a pipeline which supplies the next generation of scientists, albeit a leaky one. Sustaining the throughput of this pipeline is very much dependent on the attitudes that school science and science engenders in its students. Given a mounting body of data which suggest that students' attitudes in advanced societies are either negative or declining (Tytler, Osborne et al. 2008),

there is a considerable interest in their measurement and any causal insights which might inform ways or remediating what is perceived to be a problem. This is true, for instance, in the UK (HM Treasury 2006), the USA (National Academy of Sciences: Committee on Science Engineering and Public Policy 2005; National Commission on Mathematics and Science Teaching for the 21st Century 2000), Australia (Tytler, Osborne et al. 2008) and Europe (European Commission 2004).

Meaning and Assessment of 'Attitudes'

Before discussing what the research findings reveal about student attitudes or what might be their causal factors, it is important to explore what is meant by the first construct in the title of this chapter. Perhaps the most important distinction here is that drawn by Leopold Klopfer (1971) between 'attitudes towards science' and 'scientific attitudes'. The latter are a set of attitudes which are the product of working in science and which are a commitment to evidence as the basis of belief, a belief in rational argument and a scepticism towards hypotheses and claims about the material world. Such values are represented by Robert Merton's (1973) attempt to define the principles that are inherent to science, commonly known as CUDOS: results are the property of the community not the individual (communalism); results are not specific to a context but universally valid (universalism); scientists should maintain a neutral or disinterested perspective about the acceptance of their findings (disinterestedness); research claims must be novel (originality); and all claims should be subject to criticism (scepticism). Merton's analysis has been substantively challenged by the body of work undertaken in the social studies of science, including Harry Collins and Trevor Pinch (1993) and Helen Longino (1990), who have questioned the validity of each of these claims in the light of the historical record and contemporary studies of scientific practice.

However, it is the first of these two constructs, 'attitudes towards science', which is the focus of this chapter and the body of research discussed here. Attitudes towards science is a complex concept which, at one time or another, has embodied the following concepts:

- The display of favourable attitudes towards science and scientists
- The display of favourable attitudes towards school science
- The enjoyment of science learning experiences
- The development of interests in science and science-related activities
- The development of an interest in pursuing a career in science or science-related work

It is necessary to distinguish between attitudes towards *doing* school science and attitudes towards science *in general*. It is the perceptions of school science, and the feelings towards undertaking a further course of study, which are likely to be most significant in determining students' decisions about whether to proceed with further study of science beyond compulsory courses. Students' attitudes to science more generally can be quite different from their attitudes to the science that they experience at school (Lindahl 2007).

The construct is further complicated by the fact that what is commonly measured is an attitude towards a unitary concept of 'science', whereas secondary schooling differentiates the object (which is the focus of the attitude) into three (physics, chemistry and biology), if not four sciences (earth sciences as well) which students like differentially according to research (Havard 1996; Lyons 2006; Osborne and Collins 2001). In attempting to measure one or more of these constructs, studies have incorporated a range of components in their measures of attitudes towards science, including:

- Perceptions of the quality of the science teacher
- Anxiety towards science
- The value of science
- Self-esteem at science
- Motivation towards science
- Enjoyment of science
- Attitudes of peers and friends towards science
- Attitudes of parents towards science
- The nature of the classroom environment
- Achievement in science
- Fear of failure in a course

The two key constructs in developing and assessing an instrument for the measurement of attitudes are the instrument's reliability and its validity. The latter is essentially dependent on a well-developed theoretical argument for the constructs that are to be measured. Without some careful elaboration of what is being measured and why those particular constructs might be considered important, it is likely that disparate items could be put together in a unitary scale for which there is no theoretical justification. The problem of interpreting the significance of a unitary construct synthesised from these multiple components of attitudes towards science has been clearly identified by Paul Gardner (1975), who comments:

> An attitude instrument yields a score. If this score is to be meaningful, it should faithfully reflect the respondent's position on some well-defined continuum. For this to happen, the items within the scale must all be related to a single attitude object. A disparate collection of items, reflecting attitude towards a wide variety of attitude objects, does not constitute a scale, and cannot yield a meaningful score. (Gardner 1975, p. 12)

And, if there is no single construct underlying a given scale, then there is no purpose served by adding the various ratings to produce a unitary score. As Gardner (1975) argues, weight, length and height can all be measured meaningfully, but adding these three variables together to form some kind of 'dining table index' simply produces a meaningless, uninterpretable variable.

Establishing the validity of an instrument, however, is not a simple task. Construct validity is reliant on the extent to which the items being measured have a good theoretical foundation so that it is clear what it is that the instrument is attempting to measure (Messick 1989). One means of attempting to establish construct validity is to use a panel of experts and ask them individually what aspects they think the items are attempting to test. However, this has been criticised by Hugh Munby

(1982) as it rests on an assumption that the meanings attributed to the items by the experts will be the same as that attributed by the participants. The latter is essentially what is termed face validity – that is, whether the construct which is operationalised in the items written to assess it has the same meaning for the participants as it does for the researchers. The only means of testing this is to conduct interview studies with a selection of participants to explore what they understand the item to be asking and the reasons for choosing the response that they did. However, a not unreasonable argument here is that items of the nature 'you have to be clever to do science' or 'I often do science experiments at home' are really only open to one interpretation and, hence, do not require validation using such methods; this might explain why it is difficult to find attempts at such validation in the literature.

Reliability is generally sought by using the psychometric principle of writing several items which are attempting to measure an underlying unitary construct such as 'interest in science'. A good instrument needs to be both internally consistent and unidimensional (Gardner 1975). Internal consistency is commonly determined through the use of a measure known as Cronbach's alpha coefficient and is often quoted in much of the research literature on the measurement of attitudes. Essentially what this does is measure the extent to which individuals who score highly on any given item also score highly on the other items thought to be assessing one specific construct. However, it does not follow that scales which are internally consistent (i.e. all the items have a Cronbach alpha in excess of 0.7) will be unidimensional. This is because a scale might be composed of several clusters of items, each measuring distinct factors. In this situation, as long as the responses to every item correlate well with the other items, a high Cronbach alpha will still be obtained even though what is being measured is not a single unitary factor. Hence, it is important that the unidimensionality of scales is tested by using an appropriate statistical technique (e.g. factor analysis) that is capable of resolving the underlying factors. If a scale does measure what it purports to measure, then all the variance in responses should be explained by a loading on a unitary factor. Such a factor analysis also enables the establishment of convergent and divergent validity in that theoretically similar items should converge (i.e. correlate) and theoretically dissimilar items should diverge (i.e. not correlate). Moreover, those items that converge should match self-evidently with the theoretical concepts from which they were originally derived or used in their formulation (Henerson et al. 1987).

Evidence that the field has had problems in developing instruments which meet these criteria comes from a recent comprehensive review conducted of 66 instruments for measuring attitudes by Cheryl Blalock et al. (2008). Twenty of these measured attitudes towards science and were assessed against the criteria of: the extent to which they were theoretically grounded; what tests had been undertaken of their reliability; the measures that had been used to establish their validity; how the dimensionality of the instrument had been used in reporting the scores; and the extent to which the instrument had been tested and developed prior to its use. Using these criteria, the authors reported that the highest scoring instrument was that developed by Paul Germann (1988) where 'reliability estimates were in the 0.90s, and various methods of validity evidence were given including content, discriminant, convergent, contrasting groups, and exploratory factor analysis' (Blalock et al. 2008, p. 970). The factor analysis used supported a one-dimensional structure and total scoring was used appropriately. Yet this instrument has only been used in a single study. In contrast, instruments which score poorly on their criteria, for example, Richard Moore and Frank Sutman's Scientific Attitude inventory (Moore and Sutman 1970) have been used in 13 additional studies. What Blalock et al. points to is the tendency for researchers not to use existing instruments, but rather to reinvent the wheel each time by designing one anew and, then, not subjecting it to the kind of development required of a good psychometric measure. The practice of reusing non-validated instruments has clearly hindered the development of methods and expertise in this field.

Some recognition of these criticisms can be found in more recent work. For instance, the instrument developed by Per Kind et al. (2007) does define the constructs that it is attempting to measure and establishes its reliability and validity through the use of a factor analysis which demonstrates that the factors correspond to the theoretical constructs it seeks to measure and that they are internally consistent. Likewise, Steven Owen et al. (2008) have re-evaluated one commonly used instrument – the Simpson-Troost Attitude Questionnaire (Simpson and Troost 1982) which consisted of 59 items. Using a sample of 1,812 participants split into two groups – half of which were used for exploratory factor analysis and half for confirmatory factor analysis – using only 22 items, they were able to reduce the instrument to a 5-factor model which they identified as: the extent to which the science class was motivating; the level of effort that the student applied to their own learning; the influence of family models; the extent to which it was enjoyable; and a measure of the influence of their peers on their liking for science. In doing so, they have addressed many of the criticisms that might be made of earlier work and have refined an existing instrument.

In coming to a view either about existing instruments or developing their own, researchers therefore need to ask:

- Whether clear descriptions have been articulated for the constructs that one wishes to measure
- Whether separate constructs have been combined to form one scale and whether there is evidence that these constructs are closely related, in order to justify such an action
- Whether the reliability of the measure has been demonstrated by confirming the internal consistency of the construct (e.g. by use of Cronbach's alpha) and by confirming the unidimensionality (e.g. by using factor analysis)
- Whether validity has been demonstrated by the use of more than one method, which includes the use of psychometric techniques

Failure to do any one of these would mean that the work would not be meeting the standards now established in the field and would weaken the validity and value of the findings.

In the more advanced studies, such factor analysis is used as a basis for structural equation modelling to identify the latent variables and how the factors interrelate. Well-known models are:

- The Eccles Expectancy-Value Model (Eccles et al. 1983), which focuses on students' engagement in terms of how a task is valued (or not) and their expectancy of success.
- Albert Bandura's (1997) model that emphasises perceptions of self-efficacy, which are beliefs in whether individuals can perform the behaviours necessary to achieve a required outcome. Bandura argued that such beliefs are a major determinant of an individual's activity choice and their willingness to expend effort and motivation. This work has proven powerful in explaining individual's motivation and engagement and has been used in major studies exploring, for instance, career choice (Bandura et al. 2001a, b).

However, of themselves, attitudes might not necessarily be related to the behaviours that a person actually exhibits (Potter and Wetherell 1987). For example, a pupil might express interest in science, but avoid publicly demonstrating it amongst his or her peers who regard such an expression of intellectual interest as not being the 'done thing'. In such a case, motivation to behave in a particular way might be stronger than the motivation associated with the expressed attitude or, alternatively, anticipated consequences of behaviour could modify that behaviour so that it is inconsistent with the attitude held.

Consequently, it is behaviour rather than attitude that has become a focus of interest and which has led researchers to explore models developed from studies in social psychology. Icek Ajzen and Martin Fishbein's (1980) theory of reasoned action – which is concerned fundamentally with predicting behaviour – is one such model. This model focuses on the distinction between attitudes towards some 'object' and attitudes towards some specific action to be performed towards that 'object' (e.g. between attitudes *towards* science and attitudes towards *doing* school science). Ajzen and Fishbein argue that it is the latter kind of attitude that best predicts behaviour. Their theory represents a relationship between attitude, intention and behaviour. Behaviour is seen as determined by intention, and intention is a joint product of attitude towards the behaviour and the subjective norm (i.e. beliefs about how other people would regard one's performance of the behaviour). The theory of reasoned action has been applied to some attitude and behaviour studies in science education. For instance, Frank Crawley and Annette Coe (1990), Tom Koballa (1988) and Steve Oliver and Ronald Simpson (1988) have all found that social support from peers and attitude towards enrolling for a course are strong determinants of student choice to pursue science courses voluntarily, which suggests that the theory has at least some partial validity. The effect of attitudes on behaviour has been a particular focus of interest in the field of research on environmental education, with Joe Heimlich and Nicole Ardoin (2008) providing a useful review of the main theoretical ideas and empirical studies.

There are numerous other methods of measuring attitudes. *Interest inventories* provide a common technique in which respondents are presented with a list of items and then asked to identify the ones in which they are interested. The Relevance of Science Education (ROSE) study (Sjøberg and Schreiner 2005) used such an approach in trying to identify which topics in science about which children were interested learning. However, such inventories are generally restricted to their specific focus, yielding only a limited view of what might or might not be formative influences on attitudes to science.

Enrolments in science subjects are another major source of data of increasing concern. However, any attribution of significance to such data as a sole measure of interest in science is questionable, as subject choice can be highly affected by changes in society that affect the structure of economic opportunities, the desire not to foreclose opportunities, the perceived difficulty of the subject and, particularly in the case of boys, the association of subject with gender identity – all of which might well be independent on attitudes towards school science.

Subject preference studies typically list school subjects and ask students to rank them in order of importance (Jovanovic and King 1998; Lightbody and Durndell 1996b; Whitfield 1980). The main criticism of such studies is that a student might still have a positive attitude towards science yet rank science lowly as they are more positive about other subjects. Such scales only establish a relative ranking rather than an absolute measure.

A common criticism of all attitude scales derived from questionnaire surveys is that, while they are useful in identifying the nature of student attitudes, they have been of little help in understanding the generative mechanisms. This has led, more recently, to the growth of *qualitative methodological approaches*, three recent examples of which are studies undertaken by Britt Lindahl (2007), Terry Lyons (2006) and Jonathan Osborne and Sue Collins (2001). While such studies are subject to limited generalisability and, of necessity, have smaller samples and lack the ability to identify significant variables in a clearly defined manner, they can provide more insight into the origins of attitudes to school science than quantitative methods. For instance, it is difficult to envisage how the following student perceptions of the nature of school science and the disjuncture that exists with contemporary science could be elicited through survey methods:

> Roshni: The blast furnace, so when are you going to use a blast furnace? I mean, why do you need to know about it? You're not going to come across it ever. I mean look at the technology today, we've gone onto cloning. I mean it's a bit away off from the blast furnace now, so why do you need to know it? (Osborne and Collins 2001, p. 449)

What Is Known About Student Attitudes to Science?

Emerging from this body of work on attitudes towards science are some clearly defined features. First, students' attitudes towards school science typically decline from the first year of elementary school onwards (Murphy and Beggs 2003; Pell and Jarvis 2001). Studies conducted in secondary schools have identified a similar trend (Breakwell and Beardsell 1992; Simpson and Oliver 1985; Yager and Penick 1986).

In one sense, this is not surprising as attitudes towards school decline throughout adolescence (Eccles and Wigfield 1992; Epstein and McPartland 1976). The more fundamental question is how such attitudes to science decline relative to attitudes to other subjects. Richard Whitfield's (1980) analysis of 1971 Institute for Educational Assessment data showed that physics and chemistry were two of the least popular subjects once children reach the age of 14 years, and that these were distanced in pupils' minds from biology, a finding confirmed as still existing in a small study conducted by Neil Havard (1996). A similar picture of differential ranking between the sciences emerges from Osborne and Collins' (2001) study. Given the relative simplicity of Whitfield's instrument and its use of preference ranking, it is perhaps surprising that this kind of study has not been repeated on a larger scale. What such studies do, however, is to call into question whether the construct of 'attitude towards school science' is really a valid construct as students clearly have different attitudes towards the different sciences – though such a point is only true for high school students who have been taught courses that have more explicitly distinguished the sciences.

A study which has attracted considerable attention recently is the Norwegian-based ROSE study (Sjøberg and Schreiner 2005). Students were asked to respond on a 4-point Likert scale about whether they agree or disagree to statements of the kind 'I like school science better than other subjects'. Two major features emerged from these data and other responses: the decreasing interest in school science in more advanced, industrialised countries; and the more negative attitudes of girls. Whereas all of the samples were opportunistic and not randomly selected, such data have been greeted with some alarm in the developed world where there is a significant body of concern about the future supply of scientists (European Commission 2004; Lord Sainsbury of Turville 2007; National Academy of Sciences: Committee on Science Engineering and Public Policy 2005). However, another interpretation of these data is that, even in the worst-case scenario (Norway), 40% of boys and 22% of girls answered this question positively. On that basis, a question must be asked whether the concern has been exaggerated.

Similar findings emerge from an analysis of the 1999 data for the Third International Mathematics and Science Study (TIMSS) by Yasushi Ogura (2006). Ogura plotted students' achievement scores, measured by their knowledge of science concepts, against the mean of their responses to various items measuring their attitudes towards science. Again what stands out is that those countries whose students were the most successful, and which many other countries seek to emulate and which offer a very traditional science education with an emphasis on learning scientific knowledge, have students with the most negative attitudes. Such alienation is undoubtedly of concern to teachers, as their job satisfaction is likely to be strongly influenced by their pupils' affective responses to what is offered in science lessons. Moreover, recent evidence comparing the performance of Chinese and American students on tests of conceptual knowledge and scientific reasoning shows that, whereas those educated in China perform significantly better on tests of conceptual knowledge, they perform no better on tests of scientific reasoning (Bao et al. 2009). Thus, if the goal is to develop students' ability to think critically, an emphasis on content might have little effect.

Insights into student dissatisfaction with school science come from qualitative studies that have articulated the student voice (Lindahl 2007; Lyons 2006; Osborne and Collins 2001). Students complain that: school science lacks relevance; consists of too much repetition in that similar concepts appear in both the elementary, middle and high school curriculum; there is a lack of opportunity to discuss the science or it implications; and there is an overemphasis on copying as the standard form of writing. In addition, the curriculum appears to be dominated by a large body of content which must be learnt and reproduced for examinations – which is reinforced by the use of 'high stakes testing' as an accountability mechanism (Au 2007). Wayne Au's work – an extensive meta-analysis of all relevant studies undertaken in the field of assessment – led him to the conclusion that the consequence of such testing is a more fragmented curriculum and a pedagogy dominated by transmission – an approach which tends to lead to performance learning by students who are motivated by extrinsic rewards rather than by an inherent interest in the subject itself.

Detailed insights into why such an approach singularly fails to engage students comes from a study led by Mihaly Csikszenmihalyi and Barbara Schneider (2000) using the theoretical concept of 'flow' – the feeling generated by total engagement with an activity. They collected data at random from students eight times a day using a one-page, self-report form to identify the kinds of experience that are generative of 'flow'. Developing a composite measure of optimal learning experiences from data that included measures of challenge and skill, as well as concentration and enjoyment, they found that tests and quizzes, group work and individual work all produced above-average levels of 'flow', whereas listening to lectures and watching television or videos produced little 'flow'. Their conclusion was that classroom activities that facilitate flow experiences are those that are well structured and for which students are given adequate opportunities to demonstrate their skills and knowledge as autonomous individuals. One of the experiences that clearly generates the experience of 'flow' for most pupils is laboratory work (Csikszentmihalyi and Schneider 2000; Solomon 1980; Woolnough 1994), but the failure of school science to generate sufficient experiences of this nature remains a matter of concern.

Such findings support the view that school science education is unappealing when it is dominated by short-term goals, presented through lectures with an emphasis on transmission, and lacks challenge. Other research suggests that what school science lacks for students is a sense of purpose – why does it matter, what are its major ideas, how do they relate to each other and why should these matter to students (Claxton 1991; Millar and Osborne 1998; Osborne 2008)?

Nevertheless, most studies report that students' attitudes towards the overall experience of their science course are predominantly positive. For instance, for a sample of 1,227 English students, 61% agreed or strongly agreed with the statement 'school science is interesting'. Such data are similar to those found in previous studies (Assessment of Performance Unit 1988; The Research Business 1994). Moreover, a recent study of public attitudes to science by the Research Councils UK (2008), based on a random sample of 2,137 individuals, found that a third of young people (aged 16–24 years) felt that their school science education had been better than other subjects and that 43% felt it had been about the same. Comparable figures for adults (aged 25 years or over) were, respectively, 17% and 48%. Likewise, the recent PISA studies of 8th grade students present a similar positive picture of US students, with 45% indicating that they would like to study science after high school (OECD 2007).

What Are the Major Factors Determining Student Engagement with Science?

Research has identified a number of variables which contribute towards student engagement in science. Three factors stand out as the major determinants of student interest in school science – gender, the quality of teaching and pre-adolescent experiences. Space only permits detailed consideration of these three but more information can be found in previously published reviews (Osborne et al. 2003; Schibeci 1984).

Paul Gardner comments that sex is probably the most significant variable related to pupils' attitude to science (Gardner 1975). This view is supported by Renato Schibeci's (1984) extensive review of the literature, and more recent meta-analyses of a range of research studies (Brotman and Moore 2008; Murphy and Whitelegg 2006; Weinburgh 1995) covering the literature between 1970 and 2005. All four publications summarise numerous research studies to show that boys have a consistently more positive attitude to school science than girls – a finding confirmed by the data emerging from the ROSE study (Sjøberg and Schreiner 2005) and more recent work (Haste 2004; Jones et al. 2000). However, it would be better to say that the real difference is in attitudes to the physical sciences and engineering (OECD 2006) and, despite a large number of interventions undertaken in the 1980s and 1990s to engage more young women with the study of science, Gail Jones et al. (2000) concluded 'that the future pipeline of scientists and engineers is likely to remain unchanged' (p. 190). Thus, this problem is both chronic and a matter of concern (Adamuti-Trache and Andres 2008). Despite 25 years of effort, little, if any, change has been achieved. This is a matter of concern because young women who choose to study science and mathematics in high school have an 'increased likelihood of attending a university and a much broader range of program options at the post-secondary level' (Adamuti-Trache and Andres 2008, p. 1577).

A useful review of nine explanatory hypotheses for women's lack of engagement with science is offered by Jacob Blickenstaff (2005) who argues strongly against the suggestion that there are innate genetic differences. Rather, examining the other hypotheses, he suggests that the problem is complex and not amenable to simplistic solutions. Currently, the most useful insights come from work that focuses on the context in which physics is presented. For instance, the ROSE questionnaire presents 108 topics about which students might like to learn and asks respondents to rate them from 'not at all interested' to 'very interested'. Between English boys and girls there were 80 statistically significant differences. The top five items for boys and girls are shown in Table 41.1.

Table 41.1 The five top-ranked items that boys would like to learn about in science and the top five for girls (Jenkins and Nelson 2005)

Boys	Girls
Explosive chemicals	Why we dream when we are sleeping and what the dreams might mean
How it feels to be weightless in space	Cancer – what we know and how we can treat it
How the atom bomb functions	How to perform first aid and use basic medical equipment
Biological and chemical weapons and what they do to the human body	How to exercise the body to keep fit and strong
Black holes, supernovae and other spectacular objects in outer space	Sexually transmitted diseases and how to be protected against them

Based on the stark contrasts in lists such as these, it has been argued that the content of interest to girls is significantly under-represented in the curriculum (Haussler and Hoffmann 2002). These data are also supported by other research which would suggest that girls would be interested in a physics curriculum which had more human-related content (Krogh and Thomsen 2005). Indeed, a recent survey by Helen Haste and colleagues (2008) of student attitudes based on a sample of 327 14–15-year-old boys and 256 girls looked at how their perceptions of science were related to their personal, social and ethical values. Dividing the sample into those orientated towards science by positive responses to questions about employment in science and an expressed interest in technology, a factor analysis of the data was conducted. Haste et al. found four factors which discriminated between boys and girls: 'trust in the benefits of science', 'science in my life', 'ethical scepticism' and 'facts and high-tech fixes'. For girls, regardless of their inclination towards science, the consideration of ethical factors was a large positive explanatory factor while it was a negative factor for boys. Likewise, the perceptions of how science was relevant to their lives were a large contributing factor for girls positively inclined towards science but not for any other groups. In short, both the context, purpose and implications matter for girls and any attempt to present a decontextualised, value-free notion of science is likely to reduce their engagement. Such data also strongly suggest that offering a homogeneous curriculum to all is a mistake – what interests girls is unlikely to interest boys and vice versa.

Quality of Teaching

Quality of teaching is a difficult construct to operationalise, let alone measure. Nevertheless, a considerable body of evidence now exists that identifies the quality of teaching as a major determinant of student engagement with and success in a school subject (e.g. Osborne et al. 2003; Rivkin et al. 2005; Wayne and Youngs 2003). The most recent systematic study was undertaken in two states in the USA by Linda Darling-Hammond (2007), who showed that the major factor correlating with the percentage of students scoring ‘below basic’ on the South Carolina state tests were the percentage of teachers with substandard teaching certificates and the percentage of teaching vacancies open for more than 9 weeks. In contrast, teachers having advanced degrees correlated negatively with the percentage of ‘below basic’ scores. Likewise, in the state of Massachusetts, the two factors correlating most highly with the number of students failing the State English language test were the percentage of teachers unlicensed in the field and the percentage of paraprofessionals not highly qualified. A major OECD commissioned international review of school systems (Barber and Mourshed 2007) found:

> The experience of these top school systems suggests that three things matter most: 1) getting the right people to become teachers, 2) developing them into effective instructors and, 3) ensuring that the system is able to deliver the best possible instructions for each child (p. 5)

On the basis of comparative data across educational systems on student outcomes, Barber and Mourshed argued that reform efforts are often ineffective in delivering student learning and engagement if they do not reach down into classroom instruction, where the real effects on learning take place.

Identifying the constitutive elements of what makes a good teacher of science has been the focus of several strands of research including a series of projects at the secondary level by Ken Tobin and Barry Fraser (Garnett and Tobin 1989; Tobin and Fraser 1990; Tobin et al. 1994) and at primary level by Russell Tytler and colleagues (Tytler 2003; Tytler et al. 2004). Clearly a necessary condition is good subject knowledge which provides a base level of confidence essential for providing high-quality feedback and scaffolding (Hattie and Timperley 2007). Robin Alexander (2005) argues powerfully for a pedagogy based more in a dialogic approach suggesting that, whereas ‘rote, recitation and expository teaching’ might provide teachers with a sense of security as they enable the teacher to remain firmly in control, they make it less likely that the classroom will become a theatre for dealing with awkward, contingent questions which deal with issues of evidence and reasons for belief – exactly the kind of interaction, which Leo Van Lier (1996) argues, is engaging. Robert Sparkes (1995) makes the salient point that there is no problem with the supply of teachers of physics in Scotland as good teachers generate engaged students who in turn become teachers. Hence a problem never arises.

Pre-adolescent Engagement with Science

Student interest in science at the age of 10 years has been shown to be high and with little gender differences in either interest (Murphy and Beggs 2005; Pell and Jarvis 2001) or aptitude (Haworth et al. 2008). However, recent research suggests that, by the age of 14 years, interest in pursuing further study of science has largely been formed for the majority of students. In a recent analysis of data collected for the US National Educational Longitudinal Study, Robert Tai et al. (2006) showed that, by the age of 14 years, students with expectations of science-related careers were 3.4 times more likely to earn a physical science and engineering degree than students without similar expectations. This effect was even more pronounced for those who demonstrated high ability in mathematics – 51% being likely to undertake a STEM-related degree. Indeed Tai et al.'s analysis shows that the average mathematics achiever at age 14 years with a science-related career aspiration has a greater chance of achieving a physical science/engineering degree than a high mathematics achiever with a non-science career aspiration (34% compared to 19%). Further evidence that children's life-world experiences prior to the age of 14 years are the major determinant of any decision to pursue the study of science comes from a survey by the Royal Society (2006) of 1,141 SET practitioners' reasons for pursuing scientific careers. Just over a quarter of respondents (28%) first started thinking about a career in STEM before the age of 11 years and a further third (35%) between the ages of 12 and 14 years. Similar evidence came from a study by Adam Maltese and Robert Tai (2008) based on analysis of interviews with 116 scientists and graduate students. They found that 65% of respondents claimed interest in pursuing science prior to middle school and a further 30% during middle and high school. An interesting gender difference arose in this study, with females more likely to ascribe interest related to school or family compared with males who tended to claim intrinsic or self-related interest in science. Likewise, a small-scale longitudinal study conducted by Britt Lindahl (2007) followed 70 Swedish students from grade 5 (age 12 years) to grade 9 (age 16 years) and revealed that their career aspirations and interest in science were largely formed by age 13 years. Lindahl concluded that engaging older children in science would become progressively harder. Similar data can also be found in the work of Bandura et al. (2001) on children's aspirations and career choices.

Such data demonstrate the importance of the formation of career aspirations of young adolescents long before the point at which many make the choice about subjects in which to specialise. These findings suggest that efforts to engage school students with science would be more productively expended by: understanding the formative influences on student career aspirations between the ages of 10 and 14 years; and attempting to foster and maximise the interest of this cohort of adolescents, particularly girls, in STEM-related careers.

Other Variables

The determinants of student choice of science as a subject, or Science, Technology, Engineering and Mathematics (STEM) subjects generally, are multiple and interacting. Nadya Fouad and colleagues (2007) used a questionnaire with 1,151 students at different stages of schooling to identify key supports and barriers. The instrument was based on social cognitive career theory that considers student interest and aspirations in terms of interactions between personal factors and learning experiences on self-efficacy and outcome expectations. Key barriers identified were perceptions of subject difficulty (related to self-efficacy) and the presence of test anxiety. The list of variables that were significant predictors of choice to take ongoing science subjects were *science interest* (which, as we have shown above, itself might represent a number of factors), self-evaluation of science ability, parental expectation and guidance, exposure to career guidance and having goals, and exposure to inspirational teachers. For middle and high school students, teacher support and teacher expectations of success were significant supports.

The question of the difficulty of subject seems to be more important for mathematics than science, and for physical sciences than biological sciences. Lyons (2006) studied attitudes to science and backgrounds to subject choice for high-performing year 10 students in Australia. He used a combination of questionnaire and interview data. From the interview data, he identified that students choosing physical science were those who had supportive family relationships, parents who recognised the value of formal education, and family members advocating or supporting an interest in science. These students had higher levels of self-efficacy, which he argued was important in their decision to take these subjects with a reputation for difficulty. Lyons explained these findings in terms of 'cultural and social capital' needed by students to select into STEM pathways.

Maria Adamuti-Trache and Lesley Andres (2008) drew upon Pierre Bourdieu's work in examining the level of influence that parents have in transmitting cultural values and practices to their children, and thus disposing them towards STEM fields of study. Students with university-educated parents were shown in this study to decide earlier about their career directions, and they were more likely to choose science subjects. Thus, it is reasonable to infer that the transmission of cultural capital restricts prematurely the pathways of students whose parents and family contexts do not facilitate, encourage, assist and fund academic pursuits in STEM. There is also evidence from this study that the job satisfaction of parents in STEM careers, particularly the mother, can have significant influence on children's career aspirations.

The influence of parents is not necessarily straightforward. The Australian Department of Education Science and Training's (DEST 2006) Youth Attitudes Survey found that students who chose science and technology subjects reported overall higher levels of parental influence upon their decision-making. Haeusler and Kay (1997) found that parental and teacher advice played a more prominent role in the selection of science subjects than for other school subjects, and there is some evidence (Watt 2005) that this influence is greater in the earlier years of schooling, compared to the later years when perceived natural talent and interest drives choice.

A recent UK study conducted by the National Foundation for Educational Research for the UK government (Blenkinsop et al. 2006) points to the work of Bandura and colleagues (2001) who perceive self-efficacy (the belief that one has the power to produce effects by one's actions) as having greater predictive power in occupational choice than other theories. Following an analysis of socio-cognitive data from 272 children, they concluded that self-efficacy emerged from the interaction between 'socioeconomic, familial, academic and self-referent influences [operating] in concert to shape young people's career trajectories' (Bandura in Blenkinsop et al. 2006, p. 4). Family socio-economic status, they argued, had only an indirect effect on young people's perceptions of their capabilities. Higher status parents had raised parental aspirations which, in turn, were passed on to their children both as expectations and belief in their own capabilities and academic aspirations.

Many studies have shown that students who persist in STEM are more likely to have higher socio-economic status (see Committee for the Review of Teaching and Teacher Education 2003; Helme and Lamb 2007; Lamb and Ball 1999; Thomson and De Bortoli 2008). However, there continue to be questions raised about the nature of the causal link operating and the usefulness of SES as an indicator of student participation in STEM subjects. We have seen in the studies above how social capital and child–parent relations are important, and these can link to SES. Robert Putnam (2001, 2004) found that community-based social capital was a better indicator of improved educational outcomes than socio-economic status. David Grissmer et al. (2000) argue that this occurs through 'peer effects, quality of communication and trust among families in communities, the safety of neighbourhoods, and the presence of community institutions that support achievement' (pp. 17–18). Further research into this issue is required.

A few studies have shown the interactions between these various factors – self-efficacy, perceived difficulty and usefulness, parental and teacher encouragement – at different stages in schooling. For instance, Maltese (2008) undertook a complex data analysis of a large US longitudinal data set involving information over the school and college years about family demographics and background, academic support and achievement test results in a variety of subjects. He found a complex flow into and out of STEM subjects governed by a variety of factors, namely, the importance of early perceived usefulness of STEM (as an indicator of future degrees in STEM), academic score as an important indicator of choice of subject, the perception of usefulness of science and mathematics (a positive indicator of persistence in these subjects). However, a teaching emphasis on lecturing and textbooks was a negative indicator of persistence in science.

Anna Cleaves (2005) conducted interviews with 72 high-achieving secondary students to explore the factors influencing their subject choices across time from year 9 to year 11. She used a grounded theory approach to separate student trajectories into five categories that represented different patterns of choice regarding persistence, or not, in STEM. In the study, she identified many of the negative attributions to school science that have been described in the literature, such as irrelevance and boredom and stereotypical views of scientists and their work. However, for some students, these negative experiences were not enough to deter them from a commitment to pursue further studies. Cleaves paints a picture of interested students choosing to continue in STEM study, despite negative experiences of school science, and gaining a deeper appreciation of what a science career might be like outside of the classroom. She argues that raising the profile of science and understanding of science-related work are important in encouraging students into science. She adopts an identity framework to interpret the self-perceptions of students, showing that students' perceptions of their ability, in conjunction with their life aspirations, drive the decision to opt into, or out of, STEM (see also Leonardi et al. 1998).

A particular question of interest has been how much students know about careers in science. For instance, Lindahl's (2007) longitudinal study of students and their aspirations revealed that, at the early ages when their career aspirations were being broadly set, students had very little idea about the variety of work to which a focus on science subjects might lead. This has been the broad finding of a number of studies (e.g. Blenkinsop et al. 2006; Stagg 2007). A survey conducted in the UK for the Engineering Council by the National Foundation for Educational Research using a questionnaire survey of a random sample of 1,011 students at age 14 (Engineering and Technology Board 2005) found very limited and stereotypical views of what engineers, technologists and scientists might do. Technology was seen as the province of 'designing things' and 'having new ideas', and was correspondingly popular as a potential career. In terms of information about careers, Sarah Blenkinsop et al. (2006) reported that 14–16 year olds believed that media portrayal of jobs and careers influenced their choices, but that direct information from someone who works in the job, or a school careers teacher, is more likely to have been influential. Contact with people working in the field has been found to be highly valued:

> People, their lives, and the work they do are the richest and most respected resource for learning about careers. Whilst a proportion of young people are attracted to science and technology for itself, many are interested first in the people (role models, etc.). (Stagg 2007, p. 4)

This was a finding echoed, particularly for girls, by Gayle Buck et al. (2008) who found that role models were people with whom they held a 'deep personal connection' and that it was essential to establish a personal connection with girls if they were to engage them with the work that scientists undertake.

Students identified subject teachers as the most useful source of career information, but UK research has revealed that teachers of science did not perceive themselves as a source of career information, regarding it as the responsibility of the careers teacher (Munro and Elsom 2000). Further, Peter Stagg (2007) found that teachers were not well informed about careers in science let alone careers outside science which permitted the study of science. This situation is not aided by the fact that most careers teachers come predominantly from non-science backgrounds. These findings suggest that there is a need to develop an effective policy approach to enable students to be more aware of career possibilities associated with science.

The final point that should be made here is that the basic premise of this concern – that not enough children are choosing to study science – is open to question. There is a growing body of evidence that the production of scientists is in fact healthy (e.g. Butz et al. 2003; Lynn and Salzman 2006; Teitelbaum 2007). Further, Christopher Hill (2007) has made a cogent argument that advanced societies will become 'post-scientific' over those that are less dependent on basic scientific research and more dependent on their ability to create new artefacts by drawing on a range of disciplinary knowledge.

Identity: Making Sense of Student Engagement with Science

To understand student responses to science, there has been recent and increasing interest in exploring the construct of identity. This has been fruitful both for exploring the complexity of student responses to the science curriculum, and for making sense of the response of coherent groups such as indigenous or gender groupings.

Glen Aikenhead (2005) argues that, for many students, especially indigenous students, coming to appreciate science requires an identity shift in which students come to consider themselves as science-friendly – that 'to learn science meaningfully is identity work' (p. 117). Similarly, he argues that the persistence of status quo versions of school science in the face of considerable critique relates to the strong discursive traditions subscribed to by teachers of science resulting from their enculturation during their own schooling and undergraduate studies. There is widespread concern in many countries about gaps in performance in science and other subjects between indigenous and non-indigenous students (e.g. Thomson and De Bortoli 2008). Aikenhead and Masakata Ogawa (2007) argue that school science tends to portray scientific ways of knowing as free from value and without context. This way of presenting school science, without multiple or contested views, tends to marginalise some students on the basis of their 'cultural self-identities' (Aikenhead and Ogawa 2007, p. 540). Aikenhead (2001, p. 338) argues elsewhere that only a small minority of students' 'worldviews resonate with the scientific worldview conveyed most frequently in school science. All other students experience the single-mindedness of school science as alienating, and this hinders their effective participation in school science'. A further problem is the need to represent a broader range of identity futures consonant with science work. Elizabeth McKinley (2005) identifies the difficulty experienced by Maori women scientists in managing inconsistent images of themselves – as women, as Maori and as scientists – and argues that competing legacies of science, knowledge and culture have built strong cultural stereotypes of Maori women, who in interviews describe being discriminated against, prejudged and overlooked in their scientific roles.

In a similar vein, Angela Johnson (2007) in the USA described barriers to science-interested minority females' continuing participation in STEM, such as lack of sensitivity to their difference, discouragement and a sense of alienation from school science. Johnson described how even a laudable activity such as asking students questions in lectures can advantage White male students who are more competitive and confident, and cause women to feel a loss of status and rob them of the opportunity to get to know their teachers on a personal level. In describing the experience of these women moving through undergraduate science, Johnson concludes:

> The first step in making science more encouraging … is for scientists to recognize that science has a culture, and that certain types of students may find it challenging to understand and navigate this culture … if scientists cannot let go of narrow, decontextualized presentations of science, they will have difficulty winning the respect of women who see their interest in science as inextricably united to their altruism. … Science has a rich history of service to humanity. When scientists present their lectures with no allusion to this context, it may not be because they are uninterested in it but only because such ties are so obvious to them already. (p. 819)

As we have shown, the evidence demonstrates that contemporary youth is not a homogeneous population. Young people in today's society see themselves as free to choose their address, religion, social group, politics, education, profession, sexuality, lifestyle and values (Beck and Beck-Gernsheim 2002). This is a considerable transformation from 40 years ago when choice was much more limited and expressed predominantly in terms of a young person's choice of profession. Adolescence is a particularly significant time when young people are first confronted by the need to construct their sense of self. As has been well documented, this situation creates a state of insecurity or moratorium (Head 1985). In some senses, this angst is not new, but the range of choices presented to contemporary youth is now much greater. The decision-making landscape is complex as young people negotiate as they select their school subjects, decide who they want to be, and address their aspirations for a fulfilling future. Furthermore, analysis is complicated by that fact that the barriers that hinder young people's decision-making are not always immediately apparent and will change over time, and in degree, as students grow and develop (Engineering and Technology Board 2005; Fouad et al. 2007; Walker 2007; Walker et al. 2006).

There is a significant body of research on the impact of identity on the education-related choices of young people (e.g. Archer et al. 2007; Boaler 1997; Francis 2000). Many of these choices – whether or not to continue, which subjects to continue with, who they will aspire to become – impact upon students' success or failure in fulfilling their aspirations. Nadya Fouad et al. (2005) found in the USA that while race does not have an impact on students' initial career aspirations, it does affect the barriers that students encounter as they take action to fulfil those aspirations. Such barriers might include expectations of teachers, peers or family, or lack of role models. From this, it is clear that 'choice' is a highly constrained concept in the context of education, and experienced as limited or expansive depending upon factors such as prior academic performance, student cultural capital or school location. In this respect, the work of Geoffrey Cohen et al. (2006), which has attempted to address such barriers, is extremely interesting. Cohen and his co-workers take a psychological approach and argue that what inhibits students' performance is what they term 'stereotypical threat' – the notion that individuals are members of a group of students who commonly are perceived to fail at science (e.g. African American or woman). By conducting a small intervention at the beginning of the year to address and challenge such notions, this group has been able to show significant improvements in the performance of underperforming minorities and women.

Identity is a construct that goes beyond concerns such as curricula, intrinsic interest or career intentions, and it frames aspirations and perceptions in terms of social relationships and self-processes instead (Lee 2002). In identity theory, the self (or selves) is bounded by social structures, and interactions shape the organisation and content of self. Analysing decisions to participate in and choose STEM courses and careers through an identity framework involves emphasising relationships with family, teachers, peers and others, and identifying the degree of synergy, or disjuncture, experienced by young people between their everyday lives and the educational pursuit of STEM (see Archer et al. 2007).

Two recent studies have contributed to our understanding of how youth respond to science, school science and environmental issues. Helen Haste (2004) conducted a survey of the values and beliefs that 704 11–21-year-old UK individuals held about science and technology. Her analysis identified four distinct groups of students: the 'green', who held ethical concerns about the environment, were sceptical about interfering with nature and were predominantly girls under 16 years;

the ‘techno-investors’ who were enthusiastic about technology and the beneficial effects of science, trusted scientists and the government, and were mostly male; the ‘science oriented’ who were interested in science, had faith in the general application of scientific ways of thinking, and were mostly male; and the ‘alienated from science’ who were bored with science and sceptical of its potential and who were predominantly female. Haste found that girls were not less interested in science or science careers than boys, but they focused on different things. Girls related more strongly to ‘green’ values associated with science (socially responsible and people-oriented aspects of science) than to the ‘space and hardware’ aspects which often dominate communication about science. She argued that the science curriculum needs to represent both these dimensions of science, as well as acknowledging the value aspects and ethical concerns surrounding science and its applications.

Camilla Schreiner (2006) administered a questionnaire which had been extensively validated to a sample of 1,204 Norwegian students drawn from 53 randomly selected schools consisting of equal numbers of boys and girls. From a cluster analysis of her sample, she identified five distinct student types, each of which had a different response to science and to their own aspirations with respect to science. As with the Haste study, the categories were highly gender specific and showed different patterns of response to a range of items relating to the perceived value of school science and science, as well as their future aspirations.

Schreiner interprets the low recruitment into STEM subjects in wealthy, modern societies in terms of changing values of youth in late modern societies. This analysis has a significant identity component. Schreiner and Svein Sjoberg (2007, p. 242), draw on three perspectives to make sense of the data:

1. Issues that are perceived as meaningful for young people in a country are dependent on the culture and the material conditions in the country.
2. An educational choice is an identity choice (see also Aikenhead et al. 2006).
3. Young people wish to be passionate about what they are doing and they wish to develop themselves and their abilities. They experience a range of possible and accessible options regarding their futures and, among the many alternatives, they choose the most interesting.

Examined from the first perspective, in early and late industrial countries where the major national project goals are progress, growth and building the country, scientists and engineers were seen as crucial to people’s lives and well-being. Likewise, in less-developed countries, young people have a rather heroic image of scientists. In late modern societies, however, these values have changed. In advanced societies with a diminishing industrial base, and where material needs are satiated compared to previous generations, the role and value of the scientist and technologist is diminished – especially when compared with the sports and media personalities that dominate the news media.

Schreiner and Sjoberg speculate that the main reason that young people, especially girls, are reluctant to participate in the physical sciences is because they often perceive the identities of engineers and physicists as incongruent with their own.

There is an abundant literature (Boaler 1997; Lightbody and Durndell 1996a; Mendick 2006; Walkerdine 1990) which argues that STEM subjects and careers have a masculine image that leads girls to reject identities connected with STEM. Schreiner and Sjoberg suggest that, if this perspective is correct (and that the identities of youth in late modern societies are connected with late modern values such as self-realisation, creativity and innovation, working with people and helping others, and making money), then attracting more students into STEM pathways will require transforming the images of STEM work to address the ideals of contemporary youth, and updating the content and practice of school STEM subjects to make these values more apparent.

This research into the interactions of identity with the nature of science and school science is important in making us aware of the complexity of the issue of response to school science, and that, if we are to engage students with science in school, thought needs to be given both to the complex and varied histories of students who attend our classes, as well as to the nature of the science curriculum. Because we cannot hope for a simple match, the strong message is that, if we are to enlist young people into science subjects or even science-friendly positions, then it will be necessary to present a richer vision of science and its value in school.

Enrichment Experiences in School Science

This work on identity highlights a direction that is being increasingly embraced by government reports into the status of school science: greater attention needs to be given to representing the practices of science and their social implications than traditionally has been the case. In a number of countries, this has led to projects designed to encourage more links between practising scientists and school science classrooms. Academies of science and engineering that are concerned with the decreasing number of students in these areas have supported initiatives that bring exemplars of contemporary practice into classrooms. From the perspective of the identity-based research described above, two measures are of value: the need to increase awareness of career options in the sciences; and the provision of a diversity of role models with which students can identify, in terms of the personal, human possibilities opened up by an education in the sciences.

Such schemes are often reported as very successful but, because the evidence is largely anecdotal and the schemes vary widely, there is limited scope to generalise about outcomes in these areas. In the USA, service learning, in which students spend time working in organisations on a voluntary basis as part of their studies, is well established and surveys of participants have been encouraging (Gutstein et al. 2006). The Australian School Innovation in Science, Technology and Mathematics (ASISTM) project, which involves partnerships between clusters of schools, scientific and industrial organisations, universities and government organisations, has facilitated the development of innovative curriculum experiences for students. A study of ASISTM exemplar projects (Tytler, Symington et al. 2008;

Table 41.2 Index of science-related activities for selected countries (OECD 2007)

	Mean		
Country	Whole sample	Boys	Girls
UK	–0.35	–0.25	–0.45
Germany	0.11	0.16	0.06
Finland	–0.16	–0.18	–0.15
USA	–0.09	0.04	–0.21

Tytler, Symington and Smith 2011) involved developing an innovation framework for interpreting these projects, pointing out that the practices and ideas developed were in alignment with the open pedagogies and focus on contemporary practice advocated in writing about schooling for students in their adolescent years. The Australian Scientists in Schools programme (www.scientistsinschools.edu.au) has over 500 scientists working as partners with teachers across the country and on a variety of projects. The model is one of equal partnership, aimed at motivating students and providing teachers with professional learning opportunities about the contemporary practice of science.

Some evidence for the value of such interventions comes from the recent PISA study of 8th grade students (OECD 2007), which asked them about the frequency with which they watched TV programs about science, read science magazines or newspapers, visited science websites, borrowed books on science topics, listened to radio programmes about advances in science, or attended a science club. From this they developed an index of science-related activities (−2.5 to +2.5). A sample of figures from the index is shown in Table 41.2. For nearly all the countries in the study, a positive unit of the index resulted in an enhanced science performance of around 20 points on the mean score of 500. Once again, girls had a lower level of engagement with such activities than boys. The question of interest is whether the weaker engagement of, for instance, UK students, is because of a lack of opportunity or lack of interest.

Enrichment activities for science are often designed at a local level at the instigation of enthusiasts or interested associations, and there is a lack of understanding about the variety of such initiatives or their relative effectiveness. There is considerable anecdotal and weak evidence that student learning and engagement in science are enhanced by participation in enrichment activities such as excursions, visits by science practitioners, travelling shows, competitions such as mathematics and science Olympiads or engineering design challenges, science clubs and extension activities. This is mainly because any one-off event is unlikely to lead to significant learning in and of itself. Secondly, the methodology for capturing such experiences and its outcomes still remains problematic (Osborne and Dillon 2007). Moreover, as John Cripps Clark (2006) found in a study of science-enthusiastic primary school teachers, elementary schools offer a considerable range of such activities in their curriculum, but these required dedicated efforts in the face of systemic factors operating against their inclusion. Mary Munro and David Elsoms' (2000) study of the choices made by UK students after the age of 16 years revealed that teachers regularly complained that the curriculum was so scripted and crowded that it discourages engagement in such activities, despite their perceived importance in providing a stimulating environment for engaging students in learning mathematics, science and technology.

The report from the Science Education in Europe: Critical Reflections forum (Osborne and Dillon 2008) makes the point that most of students' waking lives are spent out of school and that much of their science (a similar point could be made about mathematics) learning occurs largely in informal settings. There is a wealth of literature on learners' experience of informal settings and museums (see Falk et al. 2000; Leonie Rennie 2006), but there is a need for further research into the impact of these public science resources on student attitudes to and engagement with science.

Conclusion

In this chapter, we have attempted not only to present a body of evidence about what is known about the methods and outcomes of this field of attitudes and aspirations towards science, but also to develop an argument as to why the domain is significant and of enduring interest in the field of science education. In addition, our analysis has offered some insights into what issues remain to be studied. In its methodology, the field is at last learning from the errors of the past and looking increasingly to use instruments which have been tested and analysed for their validity and reliability. This has been supplemented by analyses of existing longitudinal data and some growth in studies of a qualitative nature. The challenge for the field is to develop better insights and, as a corollary, better theoretical models which account for student engagement (or the lack of it) with science. This is particularly pressing in the case of girls and certain ethnic and minority communities. Here, the research focus needs to be on identifying student aspirations, their formation and their diversity. The question to be explored, then, is what kind of formal educational experience in science might engage young people and assist a process of self-realisation – either by developing a better knowledge and understanding of the diversity of future careers offered by science or by developing an enhanced sense of self-esteem acquired through satisfactory learning experiences in science. Some of this could be achieved by paying more attention to educating students about the career opportunities offered by science. After all, students cannot aspire to that which they have never seen. A recent analysis of research in science education (Lee et al. 2009) of the three leading journals in the field would suggest that the topic still remains of interest, because the findings are of significant interest to policy makers and because, we contend, the answers to the questions raised by the study of attitudes and aspirations towards science are of central concern to improving any education in or about science.

Chapter 42
Children's Attitudes to Primary Science

Karen Kerr and Colette Murphy

Attitudes toward science are often studied in an attempt to ascertain the possible reasons behind a decline in the number of students choosing to study science in secondary school and/or at tertiary level. However, there are several debated issues within the realm of attitudes toward science including: the diversity and interpretations of subcategories and the terms used to denote them, the link between attitudes and what children actually do (behavior), and what is meant by science. In this chapter we consider the relationship between the sub-categories and terms used in relation to attitudes toward science. Many of the subcategories and terms used in the literature delineate the emotional (such as a belief about science), cognitive (which includes motivation) and action-tendency (behavioral intent or manifested interest) components of attitudes. Through discussion of these three components we emphasize that when conducting attitudinal research, it is important to include questionnaire items/questions which actually consider action tendency.

This chapter also discusses some of the main concerns over measuring attitudes. The instruments that have traditionally been used to consider attitudes toward science are diverse in nature. However, with reference to primary children's attitudes, we demonstrate the importance of incorporating a mixture of quantitative and qualitative instruments. For example, Judith Ramsden (1998) suggested that a range of techniques must be used; we provide further details on the suggestions made by Cheryl Blalock et al. (2008).

We look to the future and consider new directions in attitudinal research work relating to children. Current research in this area by the authors involves the establishment of Children's Research Advisory Groups (CRAGs), following work carried out by Laura Lundy and Lesley McEvoy (2007, 2008). Children in these groups

informed the processes, interpretations, and outcomes of the research. In our research, children informed the design of questionnaire instruments and interview schedules, as well as giving their interpretations on findings and what they considered to be the outcomes of the work (Murphy et al. 2010).

Relevant literature in relation to primary children's attitudes to science is discussed. The literature considered reflects two major aspects of school science: children's attitudes to the science topics taught, and their interest in and enjoyment of science lessons. The majority of studies discuss primary children's attitudes in relation to age and gender. Overall, this literature suggests that, at primary level, there is a decline in positive attitudes toward science with age. However, this decline is less apparent when children are involved in practical, investigative science activities (Murphy et al. 2004). With regard to interest in and enjoyment of science, a gender difference with respect to physical science is less obvious in more recent studies. A difference between findings with respect to gender in older studies compared with more recent studies emphasizes the importance of a cautious approach when discussing and comparing results from recent studies with those from older studies.

What Are Attitudes to Science?

Major recent reviews in this area, for example, by Ramsden (1998) and Simon (2000), begin by discussing confusion in terms. Even over 30 years ago this was an issue, as discussed by Gardner (1975). Indeed, Jonathon Osborne et al. (2003, p. 1053) began their recent and substantial review of the attitudes literature by suggesting that 30 years of research into attitudes toward science has been "bedeviled by a lack of clarity into the concept under investigation." The most pertinent distinction mentioned in almost every recent review relates to the broad categories outlined by Gardner (1975): scientific attitudes and attitudes toward science. In Table 42.1, we have outlined the references made to both types of attitudes as well as how authors have described aspects of scientific attitudes or attitudes to science.

The scientific attitudes outlined in Table 42.1 relate to the way scientists should think or the qualities they should have. For example, as attempts are made to increase the number of future scientists, students can be encouraged to question and look for answers to questions such as why the liver is the only organ than can grow back or the supposed impact of global warming on our weather. In doing so, teachers may encourage a questioning approach (Education Policies Commission 1962). Very often, scientific attitudes are defined within attitudinal studies to emphasize that they will not be studied because of their dissimilarity with the affective nature of attitudes toward science. Nevertheless, scientific attitudes have their place in science classrooms.

There are several debated issues within the realm of attitudes toward science including: the diversity and interpretations of subcategories and the terms used to denote them (as shown in Table 42.1 and Fig. 42.1), the link between attitudes and what children actually do (behavior), and what is meant by science.

Table 42.1 A summary of references to scientific attitudes and attitudes toward science

Attitude type	Description of the attitude	Reference
Scientific attitudes	Acceptance of scientific enquiry as a way of thought, Adoption of scientific attitudes	L.E. Klopfer (1971)
	"Styles of thinking which scientists are presumed to display" (e.g., open-mindedness, honesty, skepticism)	Gardner (1975, p. 2)
	"Students' approach to thinking about science"	Tom Haladyna and Joan Shaughnessy (1982, pp. 548–549)
	"Scientific attributes"	Thomas Koballa and Frank Crawley (1985, p. 223)
	Longing to know and understand: A questioning approach to all statements; a search for data and their meaning; a demand for verification; a respect for logic; and a consideration of premises and consequences	Education Policies Commission (1962, as cited in Osborne et al. 2002, p. 1054)
Attitudes toward science	React favorably or unfavorably to a definite object (e.g., science or scientists)	Gardner (1975)
	"General or enduring positive feeling about science"	Koballa and Crawley (1985, p. 223)
	"Attitudes or feelings toward science refer to a person's positive or negative response to the enterprise of science…whether a person likes or dislikes science"	Ronald Simpson, Thomas Koballa, Steve Oliver and Frank Crawley (1994, p. 213)
	Perception of the science teacher, Anxiety toward science, Value of science, Self-esteem at science, Motivation toward science, Enjoyment of science, Attitudes of peers and friends toward science, Attitudes of parents toward science, Nature of the classroom environment, Achievement in science, Fear of failure on course	Simon (2000, p. 105) and Osborne et al. (2002, p. 1054)

Subcategories and Terms

Ramsden (1998) suggested that the use of terms is a complex issue and that terms are often used interchangeably and their meanings often overlap. For example, the subcategories outlined in Fig. 42.1 include the terms feelings, perceptions, motivation, and enjoyment under the umbrella of attitudes. Ramsden (1998) included the terms interest, views, images, beliefs, and values. Based on her discussion of these terms, Ramsden (1998) concluded that attitudes are not unidimensional and include three components: cognitive, emotional, and action-tendency related in the following way:

> … attitudes…[are]…a state of readiness or predisposition to respond in a certain manner when confronted with certain stimuli … attitudes are reinforced by beliefs (the cognitive

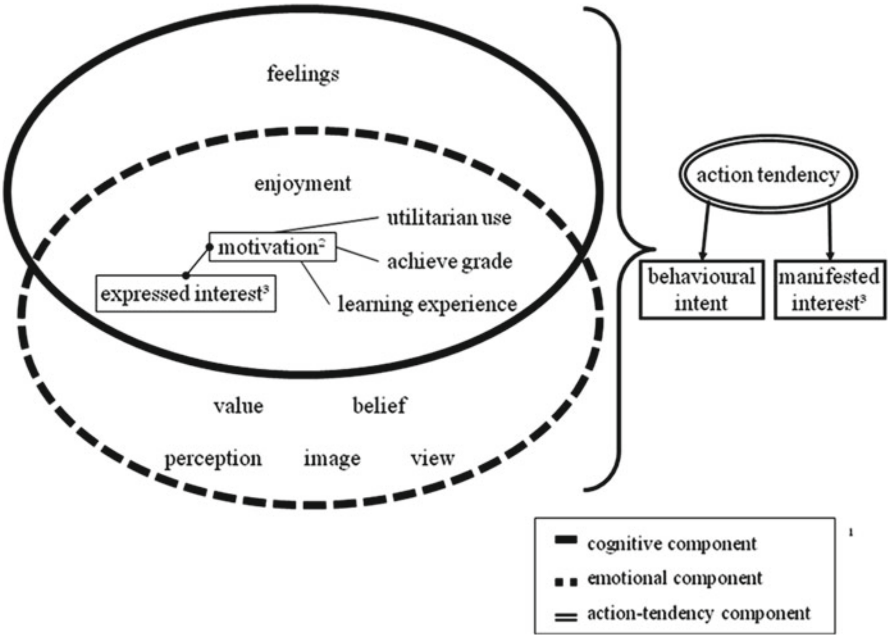

Fig. 42.1 A diagrammatical representation of the main relationships given by Ramsden (1998) and other researchers in relation to the terms used for attitudes

[1] The three attitudinal components outlined by Oppenheim (1992, p. 74)
[2] Strands of motivation outlined by Ramsden (1998, p. 128). The connection with interest was suggested by Gardner (1985)
[3] William Wall (1968) differentiated between expressed interest (like vs. dislike) and manifested interest (evidenced by hobbies)

> component), often attract string feelings (the emotional component) which may lead to particular behavioural intents (the action-tendency component). [Oppenheim 1992, p. 74, as cited in Ramsden (1998, p. 128)]

Figure 42.1 is based on this definition and we have diagrammatically represented some of the main relationships presented by Ramsden (1998) and other researchers in relation to the terms used for attitudes. The solid ring represents the cognitive components mentioned in some studies (e.g., Ramsden 1998). The dashed ring shows the words used to talk about and describe the emotional components of attitudes toward science, such as a perception of science that a child may have. The double-lined ring represents action tendency which can happen as a result of the cognitive and/or emotional components. For example, an action tendency can be children's involvement in science revision classes (manifested interest) because they are motivated by needing to achieve a higher grade for a university course (achieve grade – cognitive and emotional component).

The concept of "motivation" is also multidimensional. Gardner (1985) argued that motivation is related to declared interest. In other words, it is a measure of how willing children are to take part in certain actions in which they have expressed interest.

However, Ramsden (1998) pointed out that motivation can arise from other sources: utilitarian use (for a career), to achieve a grade or students can be motivated by a learning experience. Many secondary school children may be motivated by career choice or driven by the need to achieve a grade (in order to be accepted for a career). For example, students might take physics with the sole purpose of increasing their chances of acceptance to a medical course. However, the utilitarian and career components of motivation might not apply as strongly at primary level, except perhaps in countries where children's selection for secondary level education is based on high-stakes testing. The link with declared/expressed interest (Gardner 1985) should also be viewed with caution because children may like and be interested in an aspect of science that they have not specifically declared within a given study. For example, a child may be really interested in topics or different instructional procedures that have not been included in a research instrument.

Attitudes and Behavior

Children might express a preference for an element of science (expressed interest) or feeling about science (cognitive and emotional components), but they might not exhibit related behavior (Osborne et al. 2003). Children's behavior may be affected by other elements such as the attitudes of peers (Osborne et al. 2003). For example, children may not participate in a given science activity because they may not consider it to be "cool." The possibility that attitudes and behavior may be affected by other variables has led researchers to focus on behavior as opposed to whether or not children are interested in particular topics/activities (Osborne et al. 2003). Many researchers have reconsidered Icek Ajzen and Martin Fishbein's (1980) theory of reasoned action which differentiates between attitudes toward an object (science) and attitudes toward actions to be carried out on that object (activities, learning about topics). Ajzen and Fishbein (1980) claimed that finding out about attitudes toward actions is a better predictor of behavior than finding out about attitudes toward science itself. For example, children could be asked if they would like to learn more about given topics (an action) as opposed to being asked if they like it (an object). The behavior element is presented in Fig. 42.1 as the "action-tendency" component, how children intend to behave. Manifested interests (e.g., hobbies) are also considered part of the action-tendency component in Fig. 42.1. It is at this point that we will consider the issues around what is thought of as science in the context of attitudinal research.

What Is Science?

Charles Barman et al. (1997) considered fifth grade children's perceptions about scientists, science in school and science out of school. Barman et al. (1997) used the Draw-A-Scientist Test (DAST), originally developed by David Chambers (1983), and found that the majority of children drew white males who worked in some sort of laboratory. With regard to doing science in school, Barman et al. (1997) found that 56% of children drew themselves reading a science book or taking notes. Out-of-school science was characterized as an extension of school science by 60% of children (e.g., repeating school activities). These findings indicate that children think of science in different ways and reinforce the need for studies to differentiate between out-of-school science and in-school science (Osborne et al. 2003) with a focus on the latter (Ramsden 1998).

Ramsden (1998) also mentioned the issue of using science as an umbrella term to include biology, chemistry, physics, and possibly other areas. It is important to note that the impact of such a demarcation may not have the same effect on the expressed attitudes of primary school children compared with secondary school children. This is because many primary-aged children are unlikely to be aware of the different areas of science but a decline in positive attitudes toward physical science is well cited in literature relating to secondary school children (Bennett 2001; Haussler and Hoffman 2000). Nevertheless, a spread of topics/activities relating to the three major aspects (biological, chemical, and physical science) of science should be incorporated. Firstly, to address the possibility that children may already show signs of dislike toward a certain area of science at primary level. Secondly, including a range of topics from different science areas is representative of the current curricula.

For the most part, primary science is considered as school science because the majority of questions are related to in-school science. Ramsden (1998, p. 128) suggested we must collect data on a variety of aspects in order to look at "underlying trends and patterns," and claimed that such an approach is necessary because we can only deduce attitudes from words and actions because they "cannot be measured directly." Perhaps methodological issues surrounding attitudinal studies have arisen from a general assumption that attitudinal instruments actually measure attitudes, coupled with the confusion that comes with the diversity of instruments (Osborne et al. 2003) that claim to measure different aspects of science. The following section considers the much debated methodological issues relating to studies of children's attitudes to science.

Measuring Attitudes

Many of the issues surrounding the measurement of attitudes to science are analyzed, explored, and argued about in well-known reviews of the literature, spanning four decades – from a very early study by Gardner (1975), to later studies by Ramsden (1998) and Osborne et al. (2003), to a recent study by Blalock et al. (2008). Osborne et al. (2003) pointed out that the diversity of methods used in attitudes studies has led to the recognition of difficulties in measuring attitudes toward science, which is demonstrated in the extensive list of techniques and instruments (with examples) outlined by Gardner (1975) and Osborne et al. (2003). Both studies (Gardner 1975; Osborne 2003) mention the list of techniques and instruments outlined below. The examples given in both studies have been collapsed into this list:

- Summated rating scales – Likert scales, yes/no, agree/disagree, approve/disapprove (number of points on the scale vary)
- Semantic differential scales – use of bipolar adjectives (good/bad, interesting/dull) and participants are asked to indicate on a scale between these
- Interest inventories – participants tick what they find interesting from a given list
- Preference ranking – rank subjects in order of preference
- Enrollment data – number of students who take A-level sciences/proceed with aspects of science at third level
- Qualitative methodologies (Gardner referred to these as clinical and anthropological observations) – interviews, classroom observations

In addition to these, Gardner (1975) also specified the following instruments:

- Differential (Thurstone) scales – tick statements that best match beliefs; a mixture of positive and negative statements are included
- Rating scales – mainly external raters (teachers) asked to rate students along a numerical scale
- Projective techniques – word association, interpretation of drawings, sentence completion

We have given an overview of the methodologies used in studies which consider primary aged children in Table 42.2. In an attempt to group similar studies we have separated Table 42.2 into three sections. Comparative studies were those carried out in order to compare different samples. For example, one comparative study considered the attitudes of children from different countries (Murphy et al. 2006) and another compared children at different stages in an education system (Tymms 1997). Intervention studies considered aspects of children's attitudes before and after an intervention. Many of the studies in the *Other Studies* section in Table 42.2 considered different aspects of children's attitudes at a given time. It is evident from Table 42.2 that the majority of studies with primary children in recent years incorporated a mixture of questionnaire and interview-based questions.

In Fig. 42.2, we have graphically represented the methods used and variables considered in the primary studies outlined in Table 42.2. Counting the actual instruments/techniques/methods (Fig. 42.2) used to consider primary children's attitudes in well-cited studies showed that not all of the instruments outlined above by Gardner (1975) and Osborne et al. (2003) have been considered appropriate nor are regularly used with children of this age.

Traditionally, the majority of studies which consider primary school children's attitudes to science incorporate the use of Likert scales, open questions/interviews, subject preference, and semantic differential scales (Fig. 42.2). Ramsden (1998) suggested that interview methods must be included as a means of cross-checking written and verbal responses. Osborne et al. (2003, p. 1059) also suggested that open questions give more "insight into the origins of attitudes to school science." Karen Kerr (2008) also pointed out that children can talk about science

Table 42.2 A list of studies which consider primary children's attitudes to science

Study	Countries	Age band	Sample size	Aspects of attitudes	Methodology	Variables
Comparative studies						
Tymms (1997)	UK	10–11	5,000, 1,740	Self-concept in science (5,000 children)	5-point Likert scale	Overall sample school
				Achievement in science (1,740 children)	Multiple-choice test	
Catherine Woodward and Nicholas Woodward (1998a)	Wales	10–11	120 pupils in 3 years	Ranking of science Preferred and least preferred topics	Preference ranking	Gender
Chris Dawson (2000)	Australia	12–13	1980: 753 1997: 203	Topic preference Activity preference	Likert scale	Gender Sample years
Murphy and Beggs (2001)	Northern Ireland, England	8–11	979 (N.I.) 653 (Eng)	Topics: Enjoyment, importance, perceived ability Like best/not like/hardest thing	Semantic differential Likert scale Open questions	Age Gender Countries
Murphy et al. (2006) and Murphy and Beggs (2003)	Northern Ireland, Oman	8–11	979 (N.I.)	Topics: Enjoyment, importance, perceived ability	Semantic differential	Age, gender, ability
			944 (Oman)	Science in/out of/later in school	Likert scale Open Questions	Overall sample countries
Intervention studies						
Tina Jarvis and Tony Pell (2002)	England	10–11	655	Science enthusiasm and social context Space and getting the job done	Likert scales	Gender, age overall sample intervention
Murphy et al. (2004)	Northern Ireland	8–11	1,286	Topics: Enjoyment, importance, perceived ability	Semantic differential	Gender, age, overall sample intervention

				Something you remember from lessons	Likert scale	
					Open questions	
Jarvis and Pell (2005)	England	10–11	300	See factors outlined above (2002)	Likert scale	Overall sample intervention
				Information on attention, activities, independence, conversations	Observation of the visit	
				Recall, likes/dislikes, role, what they learned, become an astronaut?	Open questions	
Jenny Mant, Helen Wilson, and David Coates (2007)	England	10–11	Not specified	Achievement in national assessment test: % of level 5	% achieving level 5	Overall sample intervention
				Perceptions of the lessons	Focus groups	
				Perceptions of the lessons Perceptions of the impact of the lessons on their learning		
Other studies						
R. A. Hadden and A. H. Johnstone (1982)	Scotland	10–12	1,000+	Attitudes to studying science	Semantic differential with Likert	Overall sample
				Early perceptions of science	scale, structured discussions, free response	
M. B. Ormerod and Charles Wood (1983)	England	10–11	330	Attitudes to space and nature study	Likert scale, sentence completion	Gender, compare methods
				General attitudes	Projective tests	
Margaret Collins (1993)	England	5–6	35	Beliefs and boys'/girls' preferences, their science and scientists' work	Choose from a list	Gender

(continued)

				Investigation reflections	Open questions Planning sheets	Ability, gender

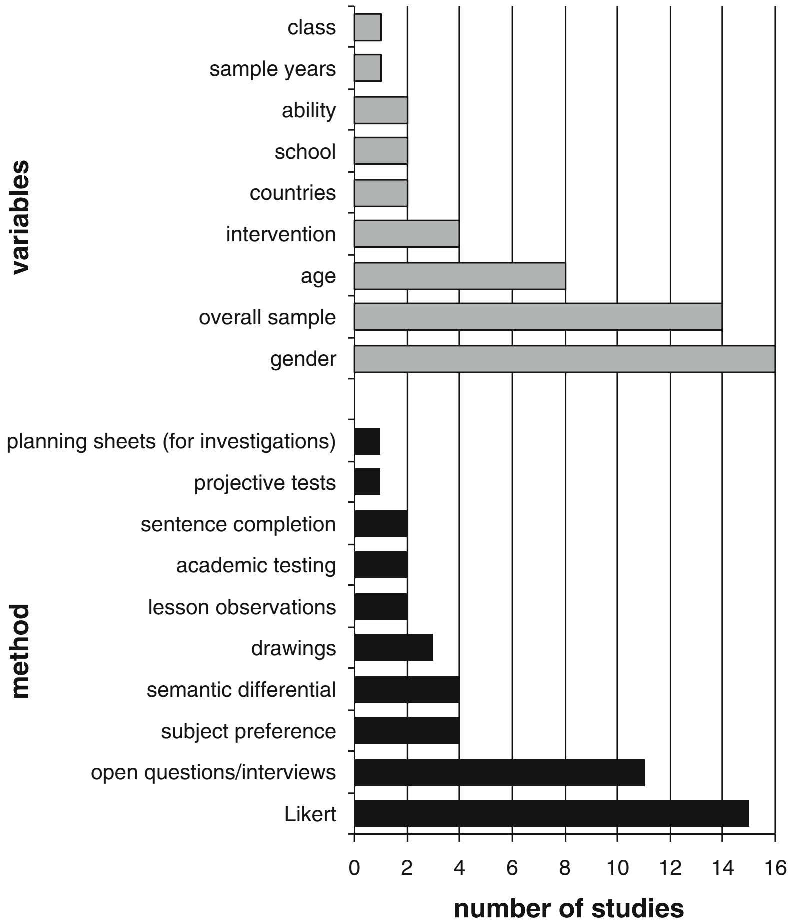

Fig. 42.2 Bar graphs to show the methods used in well-cited primary science studies and the variables considered

in unexpected ways when they are given the opportunity to talk about any aspect of science using a variety of methods (drawing, writing or talking). For example, children may dislike activities that adults assume they would enjoy, such as painting and playing with sand and water.

Only two primary studies compared children according to their academic ability (Fig. 42.2). Most studies which consider children's ability tend to incorporate secondary/university level pupils. This is perhaps due to the fact that students' performance at secondary/university levels is measured and can have an impact on their later lives/career decisions and motivation to achieve (Fig. 42.1).

With regard to variables, the majority of studies report their findings in relation to gender, overall sample, and age (Table 42.2). Traditionally, there has been an emphasis on the impact of gender on children's attitudes toward science. Perhaps the main reason for an emphasis on gender lies in the well-documented finding that "sex is probably the most significant variable related to attitudes to science" (Gardner 1975, p. 32). This view was generally supported by Milton Ormerod and Derek Duckworth (1975) and in Renato Schibeci's (1984) extensive review of literature. In their meta-analyses of literature, Becker (1989) and Molly Weinburgh (1995) also concurred with the view that gender has a large effect on attitudes to science in comparison with other variables. Nevertheless, Schibeci (1984) highlighted other primary level studies in which little or no gender effect was recorded: for example, studies conducted by Ayers and Price (1975) and Mohamed Selim and Robert Shrigley (1983). Haladyna and Shaughnessy (1982) carried out a large meta-analytic study of quantitative instruments and concluded that the difference between boys and girls was consistently small and varied between studies and grade levels. Gardner (1975, p. 29) argued that "teacher and pupil variables may exert more powerful effects upon attitudes than curricula and instructional materials." Although these studies are dated, the traditional emphasis on gender has continued in more recent attitudinal studies. Twelve of the 22 primary studies outlined in Table 42.2 have been conducted on or after the year 2000. Of these 12 studies, 10 have considered the impact of gender on children's attitudes toward science. All of the studies which considered gender reported that there were gender effects and in the majority of studies these effects were significant (e.g., Dawson 2000; Murphy and Beggs 2001). An earlier emphasis on gender as a significant variable (Gardner 1975) coupled with significant results since, has also contributed to the consideration of gender in attitudinal studies.

The final column in Table 42.2 demonstrates that in many primary studies there are only a few variables reported. It is also clear from Table 42.2 that the number and age of participants vary greatly. Not only has there been a well-documented focus on secondary school attitudes to science but many of the primary school studies that have been carried out (17 out of 22) focus on children in upper primary school. In Fig. 42.3, we have graphically represented the studies outlined in Table 42.2 in terms of the age and number of students. For example, only one study included children in every year of primary school with a sample size greater than 1,000 (Fig. 42.3).

The importance of a large sample size when carrying out a quantitative study cannot be underestimated. Many research texts suggest appropriate sample sizes for quantitative/questionnaire-based studies. Louis Cohen et al. (2000) suggested that research involving questionnaires should have no fewer than 100 cases in each major subgroup and 20–50 in each minor subgroup. Although not all of the primary studies shown in Fig. 42.3 were quantitative, it is interesting to note that 12 out of 22 studies had more than 500 participants. The largest and most extensive studies on specific aspects of children's attitudes to school science were carried out by Murphy and Beggs (2003, 2004) and Pell and Jarvis (2001). Of these, Pell and Jarvis (2001, p. 859) also advocated the importance of including younger children's attitudes as they found that "quite young pupils can provide worthwhile indicators of how they view science." As a result of including young children in every age group, as opposed to selected age groups, Pell and Jarvis (2001) graphically presented a year-on-year deterioration.

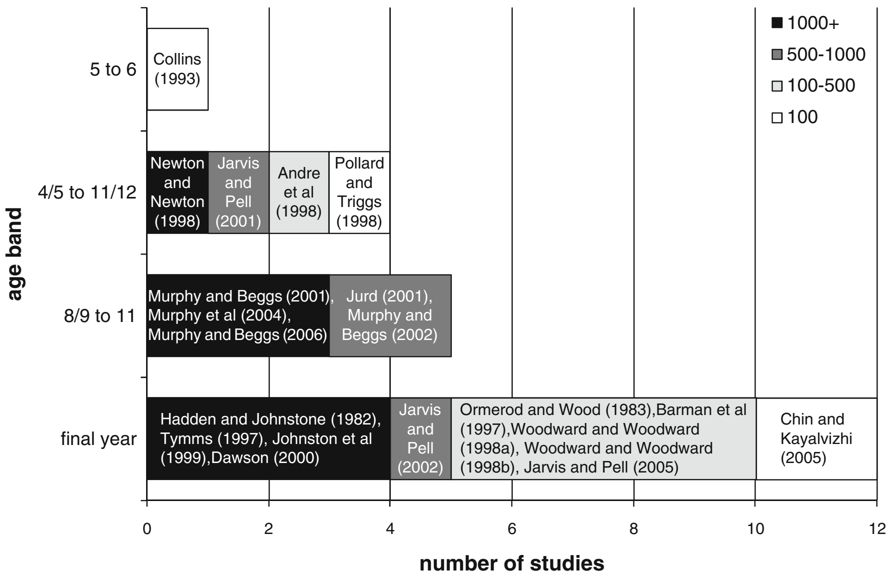

Fig. 42.3 A bar graph showing the number and age of participants involved in primary science attitude studies. The reference for each study has also been included

As well as a deterioration with age, Pell and Jarvis (2001, p. 860) pointed out that their other findings (e.g., in relation to gender) were in line with those of other studies, suggesting that "the instrument has value over a wide population."

Suggestions made by reviewers for improving attitudinal work offer an efficient summary of the issues raised with regard to measuring attitudes. Some of the main suggestions for conducting reliable and valid studies have been outlined succinctly by Ramsden (1998). A recent review of science attitude instruments with a focus on validity has been published by Blalock et al. (2008) who used a process of database searching and reference identification of peer-reviewed articles. Although Blalock et al. (2008) acknowledge that they only considered published, psychometric data they do outline tangible and important suggestions for conducting reliable studies. Their suggestions are based on the premise that it is better to refine, improve upon, and reuse the most promising instruments that are already in existence and carry out additional procedures (Blalock 2008). We have listed the suggestions outlined by Ramsden (1998) and Blalock (2008) in Table 42.3.

We would argue, however, that there could be another crucial element to attitudinal research with children which has, to date, been overlooked: the assumption of common understanding between the researcher and the researched, especially when the latter comprises children. To this end, our current work involves the establishment of children's research advisory groups (CRAGs) to inform all aspects of the research process (Murphy et al. 2010). The methodology was designed to ensure that the research process was compliant with international children's rights standards on

Table 42.3 An outline of the suggestions made in previous literature reviews to address reliability and validity in attitudinal research

Author(s)	Suggestion
Ramsden (1998)	Because issues of reliability and validity must be addressed, a range of techniques must be used.
	Interviews are highly desirable to validate instruments and provide the means for cross-checking with written and verbal responses.
	Collection should be repeated a few weeks later (because attitudes are unstable and changeable).
	Checks with both pupils and teachers would also aid validation.
Blalock et al. (2008)	Be more aware of the strengths and weaknesses of an instrument
	Reliability and validity evidence should be collected and reported.
	Compare with previous results to estimate generalizability
	Collect more data
	Deal with missing data and potential response bias
	Submit data to dimensionality analysis (e.g., explanatory and confirmatory factor analysis). As a result of such analysis, if no items or subscales form sensible structures for capturing science attitudes, that area would need to be reexamined.
	In agreement with Osborne et al. (2002), there must be a clear distinction between out-of-school science and in-school science because the latter is a better predictor of behavior.

children's participation (Laura Lundy 2007). The project's Children's Research Advisory Committee (CRAG) were be involved actively in the design and delivery of an online survey and in the analysis and dissemination of the results. The survey facilitated participating children not only in expressing their views but also in forming views through reading and analysis of a range of perspectives (Murphy et al. 2010).

Attitudes to Science

Ramsden (1998, p. 128) argued that attitudes cannot be "measured directly" but "inferred from words and actions," because attitudes are abstract concepts. Indeed, attitudes are not concrete, for example, because they can change or be changed. If children become involved with an activity that excites and enthuses them (such as growing their own vegetables), it may well have an impact on their attitude toward a topic (plants) on a given day or during a given lesson. However, this may be short-lived and they may feel differently if the next lesson focuses on an aspect that they do not like. Ramsden (1998) went further to suggest that any attempt at measurement must consider different aspects of attitudes and that we must look for underlying trends and patterns. However, the issues that ensue as a result of the diversity of attitudinal instruments, variables considered, and number and age of participants (Osborne et al. 2003) are intensified by confusion over the actual aspect of attitudes

Fig. 42.4 The most common attitudinal aspects referred to in studies of primary science

under consideration (e.g., science content, science delivery, school science vs. societal science). Very often, the aspect under consideration is not defined or the title given to a factor is confusing. Analysis of Table 42.2 brought to light 29 named aspects that are considered within 22 primary studies. The most common aspects referred to are shown in Fig. 42.4.

The aspects are listed here using the exact wording from the primary studies mentioned in Table 42.2. The crossover between these aspects is obvious and emphasizes the need for specificity when comparing studies and their findings. For example, "enjoyment" is often referred to with respect to the "activities" children take part in and their "perceptions of in-school science" might well be what they think about the "topics" they cover in school. Perhaps the most effective way to study attitudes to science is to consider (and clearly outline) as many aspects as possible and thoroughly consider underlying patterns and trends (Ramsden 1998). The following sections will briefly outline two of the main aspects mentioned in the literature: attitudes to science topics, and interest in and enjoyment of school science. We selected these two areas because they are mentioned most frequently in the (primary science) literature and will therefore offer the greatest opportunity for other researchers to compare their own work in this area.

Children's Attitudes to Science Topics

The majority of studies which consider primary children's attitudes to science topics discuss their data with respect to age and gender. Andre et al. (1999) compared children's attitudes toward science with their attitudes toward other subjects and reported that older children (9–11 year old) were significantly more positive than younger children (5–8 year old) about life science and physical science. However, many studies relating to science topics at primary level document a decline in positive attitudes toward science content (topics). With specific reference to Northern Ireland, Murphy and Beggs (2002) reported that all 16 topics in their study (a mixture of biological, chemical, and physical) were liked more by 8/9 year olds than 10/11 year olds. In fact, 10/11 year olds were significantly less positive than 8/9 year olds about 12 topics: healthy living, animals, plants, life cycles, materials, water cycle, environment, recycling, forces, energy, sound, and light (Murphy and Beggs 2002). Murphy and her colleagues also conducted comparative studies with their Northern Irish sample and children in England (Murphy and Beggs 2001) and Oman (Murphy et al. 2006). The topics under consideration were part of the primary science curriculum in all three countries. Older children in England were also significantly less positive about eight topics when compared with their 8/9-year-old counterparts (Murphy and Beggs 2001). Overall, children in England were the least positive (Murphy and Beggs 2001). However, in Oman, older children were more positive about nine topics (Murphy et al. 2006). It would, therefore, appear that the decline in positive attitudes with age toward primary science topics is more obvious in England and Northern Ireland. This trend is concerning, given that the attitudes of students in England were compared with another country in the UK (Northern Ireland) and another country outside of the UK, on another continent (Oman). Murphy and Beggs (2001) suggested that the differences between the attitudes of children in Northern Ireland and England could be attributed, at least in part, to the assessment systems. At the time, in England and Northern Ireland, children were tested during the final year of primary school. Although children were tested in science in both countries, in England the assessment was more extensive: children had to complete more lengthy tests, mostly involving factual recall, and consequently, were involved a lot more repetitive revision compared with children in Northern Ireland. In Oman, on the other hand, there were no high-stakes testing in the final year of primary school, which could be a factor contributing to the smaller decline in positive attitudes to science in primary school as children get older.

It would appear that attitudes toward science topics decline significantly with age in Northern Ireland. However, Murphy et al. (2004) found that the decline was less significant when children were involved in more experimental science. Murphy et al. (2004) compared the attitudes of children who were involved with more experimental science activities (through lessons where their teachers cotaught with science-specialist student teachers) and those who were not. Younger children who were not involved in the intervention were significantly more positive about 12 topics when compared with older children. However, younger children who were involved in the intervention were significantly more positive about just three topics (Murphy et al. 2004). This is an important finding with respect to children's attitudes to science content (topics) and how they can be affected by how science is taught. Murphy et al. (2004) also found that there were fewer gender differences between boys and girls who were involved in the intervention. They speculated that in addition to the focus on investigative science, the fact that more than 90% of the specialist-science student teachers were female could have had some effect on improving female children's attitudes to the physical science topics.

Woodward and Woodward (1998a) considered 10/11-year-old children's preferred science topics and discussed their results with respect to gender. They found that the same topics were liked the most by boys and girls (space and planets, animals and plants). Interestingly, the topics with less appeal were also the same for boys and girls (magnets, weather, and sound). However, Woodward and Woodward (1998a) found that girls showed a higher preference for some topics (keeping healthy) when compared with boys and a lower preference for other topics (electricity). Murphy and Beggs (2002) also found that girls were significantly more positive about the topic "healthy living" and boys were significantly more positive about electricity. Although boys and girls might have a stronger preference for certain science topics, the issue of whether girls or boys are more positive overall is contested. Numerous studies report that, overall, girls are more positive about science topics. For example, Murphy and Beggs (2003) and Kerr (2008) all reported that girls were more positive about science topics. On the other hand, Dawson (2000) compared the attitudes of boys and girls in 1980 and 1997 and found that the overall mean (for topics) was higher for boys than girls. However, closer inspection of Dawson's findings reveals a positive shift in the spread of girls' positive attitudes toward science topics between the two sample years. In 1997, girls liked more physical science topics than in 1980 (Dawson 2000). In 1983, Ormerod and Wood also concluded that girls liked nature study more than boys, who preferred physical science. It would appear that all studies have attempted to bring to light subtle differences in the actual topics preferred by boys and girls (keeping healthy, electricity). Therefore, in order to draw comparisons with other research relating to gender and topics, specific findings toward individual topics was discussed. There is a difference between results from more recent samples (e.g., Dawson 1997; Murphy and Beggs 2003) and results from samples in the 1980s (Dawson 1980; Ormerod and Wood 1983). Namely, a gender difference with respect to physical science is less obvious. Therefore, this emphasizes the importance of a cautious approach when discussing and comparing results from current studies with those from older studies.

Children's Interest in and Enjoyment of Primary Science

The largest and most extensive studies which included specific reference to children's attitudes to primary science (lessons) were carried out by Murphy and Beggs (2003, 2004, 2006) and Pell and Jarvis (2001). All of these studies call attention to a decline in positive attitudes with age. Pell and Jarvis (2001, p. 859) considered the "science enthusiasm" of children aged 5–11 and showed "graphically the year on year deterioration." Murphy and Beggs (2003) found strong evidence of a significant decline in enjoyment of science between children aged 8/9 and 10/11. In fact, the 8/9-year-old children were significantly more positive about four out of six items related to enjoyment of science: science lessons are fun, I look forward to science lessons, solving science problems is enjoyable, and doing experiments is fun.

It is interesting to note that significantly more 10/11-year-old students thought they do too much writing in science (Murphy and Beggs 2003).

Discussion and comparison of practical, investigative science as opposed to traditional teaching methods (e.g., writing) is often discussed in relation to children's interest in and enjoyment of science. In fact, Murphy and Beggs (2003) also asked children open questions about what they liked and did not like in science. They found that the most common response to what they liked was "experiments," regardless of age, gender, or ability, while "writing" was a typical response in relation to what children did not like. Findings related to children's positive views about practical, investigative, active learning aspects of science are reiterated in numerous other studies. In Australia, Dawson (2000) compared boys and girls activity preferences in 1980 and 1997. Dawson (2000) found that boys and girls in both samples preferred creative and especially active learning activities as opposed to copying and informing. The children in Dawson's (2000) study were children in their last year of primary school. Collins (1993) considered infant school boys' and girls' preferences for science work and obtained similar results. Collins asked 35 children aged 5/6 years old to make a chart of their preferred science work. Boys and girls drew active learning activities such as drawing in science/making models (13 boys, 16 girls), and checking up/finding out more (10 boys, 7 girls).

Several studies have considered children's interest in and enjoyment of science before and after interventions which focus on investigative, practical elements of science. Mant et al. (2007) looked at the effect of increasing conceptual challenge in primary science lessons through use of discussion, experiments, and investigations and encouraging children to think for themselves. They then conducted 16 focus group interviews in the intervention schools. In every interview, children talked about how the lessons were better. Children said this was because there were more experiments and investigations and in 11 interviews children said it was because they spent less time writing. Murphy et al. (2004) compared the attitudes of children who were involved in more practical and investigative science (though the use of coteaching) with children who were not involved in the project. They present more compelling evidence for the effect of practical and investigative work given that children's enjoyment of science was influenced in the longer term. Unlike many studies which consider the effect of an intervention, attitudinal data were not collected until 6 months after the project. Murphy et al. (2004) found that children who were involved in the project were significantly more positive in response to the items: science lessons are fun, solving science problems is enjoyable (at $p < 0.01$), and I look forward to science lessons (at $p < 0.05$). Even though children were completing their questionnaire 6 months after the intervention, many of them talked about their enjoyment of science during the project in the open-response questions (Murphy et al. 2004). The studies by Mant et al. (2007) and Murphy et al. (2004) reported a positive effect on children's learning through use of practical work. Mant et al. (2007) reported that children themselves had a clear sense of doing helping learning. Murphy et al. (2004) stated that children could remember specific aspects of their learning in the open-response section of the questionnaire (which was carried out 6 months after the project). Teachers also talked about children's learning in their research journals (Murphy et al. 2004). It would appear that the message from boys and girls of all ages is a resounding thumbs-up for practical, investigative science.

Conclusion

Apart from the fact that the majority of studies have traditionally focused on older primary children and secondary school children, many issues are brought to the fore when literature about (primary) children's attitudes is considered and debated. These include the importance of clear and succinct delineation of and reference to exactly what is being measured, how it is measured, who is involved, and to what extent reliability and validity are addressed. These issues must be addressed given the huge diversity in attitudinal studies that have already been conducted.

Kerr (2008) also pointed out that young children can voice their likes, dislikes, and concerns from a very young age, and that children often talk about science in unexpected ways. When children are given the opportunity to talk about any aspect of science using a variety of methods (drawing, writing, talking), a wealth of different viewpoints become obvious. For example, although girls appeared more positive about school in the questionnaire items – they more frequently mentioned a dislike of writing in science in their open responses when compared with their male counterparts (Kerr 2008). In other words, it is imperative that we give children the opportunity to express their perspectives of science in a variety of different ways, including those which are more amenable to them.

New directions in attitudinal studies with children are focusing on the importance of including children's input, as an expert group, at each stage of the research process. Recent work carried out by Lundy and McEvoy (2008) has demonstrated very effective methods for researching children's perspectives. They pointed out that the involvement of children was a particular strength during the analysis phase because

> …it provided a children's perspective on other children's views which at times countered an adult interpretation of the views and as such led to a more nuanced understanding of the findings. (p. 33)

The authors of this chapter worked with Lundy and McEvoy to implement such techniques into attitudinal research in primary science (Murphy et al. 2010). We end with a personal communication from Laura Lundy (2008) from work she carried out with children's research advisory groups (CRAGs) which focused on assessment in primary school. The CRAG was asked to rank different feedback comments from teachers in relation to how each reflected the level of the work. The CRAG ranked feedback such as "brilliant" and "fantastic" quite low down on their list. In the ensuing discussion, the children implied that teachers frequently used such terms on work that the children said was not their best and, sometimes, not very good. The term they ranked top was "very good"!

Chapter 43
Developing Measurement Instruments for Science Education Research

Xiufeng Liu

Standardized measurement instruments (SMIs) refer to tools that produce valid and reliable quantitative measures about a construct. Development of SMIs in science education has been an active field of research for the past five decades (Doran et al. 1994; Tamir 1998), which is particularly true for large-scale studies in science education (Britton and Schneider 2007). SMIs have been receiving increasing attention over the past decade for a number of reasons. First, there is a growing worldwide trend toward standards-based science education in which standardized testing is used for accountability. Second, there is a growing realization of limitations of qualitative research approaches and a call for randomized experimentation that incorporates standardized measurements (National Research Council [NRC] 2002). Third, the continuing interest in identifying student alternative conceptions has created a demand for more efficient and large-scale survey of student alternative conceptions. Today, SMIs are playing a vital role in various science education research programs and will continue to do so in the future.

This chapter reviews the development of SMIs in refereed science education publications by excluding commercial measurement instruments, those developed for large-scale state, national, and international assessments, and instruments reported in theses, dissertations, and conferences. For a comprehensive review of large-scale standardized measurement in science education, refer to Edward Britton and Steven Schneider (2007); for a comprehensive review of SMIs in science education research over the past 50 years in North America, refer to Xiufeng Liu (2009). This chapter is divided into three sections: an overview of SMIs developed since 1990 in terms of their content, target population, validation, and reliability; approaches to and issues associated with developing SMIs; and desirable future directions for developing SMIs for science education research.

Overview of Standardized Measurement Instruments

A search for SMIs reviewed in the *Buros Mental Measurement Yearbooks* (Spies and Plake 2005) database returned only one entry. It is apparent that Buros yearbooks miss most standardized measurement instruments for science education research. A search of the ERIC database from 1990 to the present using *measurement techniques* and *science education* as descriptors returned 229 entries. After going through the abstracts and examining relevant websites cataloguing various measurement instruments, 49 SMIs reported in refereed publications were located (with the others being related to measurement instruments for science laboratories, or measurement instruments for other subjects such as mathematics, computer science, and so on). The above measurement instruments cover the following areas of science education research (the number of instruments is in the parenthesis): conceptual understanding (15), attitudes (11), cognitive reasoning (3), nature of science (5), learning environment (9), and teacher beliefs and practices (6). The list of 49 SMIs organized by the content area and then the publication year is available in the Appendix. Although these SMIs might not be exhaustive of all instruments published in refereed publications, they are likely to represent the SMIs developed in science education in the past 18 years.

Approaches To and Issues Associated with Developing Standardized Measurement Instruments

One central component of developing SMIs is to establish evidence of validity. Conceptions of validity have evolved considerably over the years. Validity used to be solely concerned with prediction. Later on, validity evolved into three types: content, criterion-related (i.e., predictive and concurrent), and construct. Validity is an integrated notion called construct validity. Establishing the construct validity of an instrument is to develop coherent and empirical arguments to support the intended interpretation or use of measurement scores (Kane 2006). Thus, there is no absolute validity; validity is closely tied to the intended interpretations and uses of scores.

Related to validity is the issue of reliability. Similarly, much change has taken place over the years in the conceptualization of reliability. Although the central concern of reliability remains the consistency of scores across repeated applications of a measurement instrument, approaches to establishing evidence of reliability have changed significantly. Generalizability theory is now the overarching conceptual framework for reliability (Haertel 2006); internal consistency as measured by KR–20 and Cronbach's alpha represent only one possible source of inconsistency in scores.

It is apparent that the above conceptual frameworks of validity and reliability have influenced the development of SMIs since 1990. The most important issues when evaluating a measurement instrument are the appropriateness of the defined construct and the intended population of the measurement instrument. An instrument validated for one population might not be valid for a different population. Only after the evaluation of these two issues should the focus of instrument evaluation shift to reported technical properties of items (e.g., item difficulty and discrimination) and the instrument (e.g., content validity, criterion-related validity, and reliability). Given that there can be a variety of different ways of establishing validity and reliability, it is important to examine the relevance of reported validity and reliability evidence to the intended use of the instrument. On the other hand, because statistics based on Classical Test Theory (CTT), which is the foundation of most of the above SMIS, are always sample dependent, and in many cases the samples used for validation are local or convenient samples, it is always necessary to continue validating an instrument.

A large number of SMIs (15) developed since 1990 are related to assessing student conceptual understanding of science concepts. This is probably due to the continued effect of the worldwide alternative conceptions movement (ACM) from the early 1970s to the l990s (Wandersee et al. 1994). Although ACM was primarily based on qualitative research, the development of many SMIs since 1990 was based on rich findings of qualitative research, which made possible large-scale diagnosis of students' alternative conceptions. Validation of the above conceptual measurement instruments has been typically based on expert content reviews for content validity and student interviews and/or factor analysis for construct validity. Because of the fact that all these instruments use multiple-choice questions, reliability is typically established based on KR–20 or Cronbach's alpha. One important issue related to construct validity is the use of diagnostic instruments for summative purposes. At issue is unidimensionality, which is concerned with the question of whether a set of items measure the same construct so that scores on the items can be summed. Without having established unidimensionality, we cannot add individual item scores to obtain a total score, which makes it impossible to compare the gains in total scores from pretest to posttest, or the difference in total scores between two curriculum innovations. Based on principal component and confirmatory factor analysis, some of the instruments (such as FCI, CSEM, CINS, and DIRECT; see Appendix) were found to be multidimensional. Using these instruments for a summative purpose could potentially undermine the construct validity of the scores.

Eleven SMIs in the Appendix are related to attitudes. The variety of standardized measurement instruments for attitudes reflects diverse theoretical frameworks related to attitude. The diversity in theoretical frameworks requires that an attitude instrument is based on a clearly defined construct. For example, Zacharias Zacharia and Angela Calabrese Barton (2004) differentiated two types of student science attitude: attitude toward progressive school science, and attitude toward critical school science. However, not all attitude instruments in the Appendix have clearly defined attitude constructs.

Six SMIs pertain to teacher beliefs and practices. One instrument made a differentiation between teacher beliefs and teacher practices (Wang and Marsh 2002). This distinction is very important because the two are not necessarily always the same. Identifying the discrepancy between teachers' beliefs and practices can inform ongoing science education reforms so that best practices promoted in university classrooms are actually implemented in K–12 classrooms. This issue also points to the critical importance of assessing actual teaching practices and their direct impact on student learning. With the exception of RTOP (see Appendix), validation of other instruments did not involve evidence of teacher practices for predicting student learning outcomes.

There are five SMIs on nature of science. Nature of science refers to the values and assumptions inherent to science, scientific knowledge, and/or the development of scientific knowledge (Lederman 1992) or, in brief, the epistemology of science as distinct from science process and content (Lederman et al. 1998). All the instruments in this section of the Appendix deal with nature of science with the exception of the subscale in VASS that deals with beliefs about learning science. Many of these instruments also adopt a Likert scale or rating scale that is often accompanied by some kind of scoring (such as scores 1–5 for Strongly Agree to Strongly Disagree). Two potential problems are associated with this practice. One problem is that there is a lack of a clear scale to facilitate qualitative interpretation. That is, what does a higher score mean, an issue pointed out by Glen Aikenhead (1973) a long time ago. Another potential problem is bias or privilege assigned to a particular version of nature of science. This problem is pointed out by Lederman et al. (1998) in their review of measurement instruments of nature of science, which still applies today. Because there is no universally agreed-upon version of nature of science, any selected response or closed-ended response question format, including a Likert scale, is likely to force students to think in terms of one version of nature of science, and it remains unclear what students' true understandings of nature of science are. In order to address the above two problems, VOSTS adopts the no-scoring approach and VNOS adopts the interview and open-ended response question format. However, one problem with this no-scoring and open-response approach is the difficulty in establishing internal consistency reliability. As Lederman et al. (1998) pointed out, a forced response format like a Likert scale can still play a role in assessing a specific version of nature of science, but a more comprehensive and accurate assessment of students' and teachers' understandings of nature of science requires a combination of both quantitative and qualitative methods.

Developing standardized measurement instruments to assess classroom and school learning environments has been very active and productive over the past four decades (Fraser 1994, 1998). This trend has certainly been continuing since 1990 (Fraser 2007). The nine SMIs included in the Appendix represent a typical approach to establishing validity and reliability of learning environment measurement instruments based on multifaceted (i.e., content, criterion-related, and construct) and multistage processes (i.e., pilot, revision, further testing, expanded testing). One trend in developing standardized measurement instruments related to learning environments is to develop various forms of a same instrument pertaining to different constructs such as personal versus class forms, preferred versus actual form, short versus long form, and so on. Another trend is that many of the instruments have been translated by or adapted to other countries or cultures, which adds to cross-cultural validation. Indeed, "few fields of educational research can boast the existence of such a rich array of validated and robust instruments" (Fraser 2007, p. 105). This wide array of SMIs has supported many productive research programs related to learning environments (Fraser 1994, 1998).

It is common to adopt the Likert scale (Likert 1932) when developing measurement instruments related to attitudes, learning environments, teacher beliefs and practices, and nature of science. The Likert scale is a “softer form of data collection” (Bond and Fox 2007, p. 101) because of the subjectivity in responding to the statements. A more serious issue associated with the Likert scale is the use of a total scale score by adding individual item scores. Values such as 1–5 assigned to five choices of a statement do not have the same origin and interval unit because they are not on a ratio or interval scale. Also, different Likert scale items have different degrees of likelihood for being endorsed. The consequence of being non-interval and having varying likelihood of being endorsed is that we cannot meaningfully add individual item scores into a total score. In order to address this issue, ways of analyzing Likert scale data that are different from using total scores should be adopted. The best way currently available is to use Rasch modeling to convert raw scores into latent scores so that respondents’ attitudes or beliefs can be measured on a latent scale, which was the case in the development of CARS (Siegel and Ranney 2003). Without using Rasch modeling, data analysis might have to stay at the individual item level. For example, responses to different items in an attitude scale can be represented by a profile and the difference in profiles between different groups or between two time points can be meaningfully compared. Because of the above potential issues with the Likert scale, alternatives to the Likert scale can be considered. Examples of such alternatives are the Thurston scale (Thurston 1925), Guttman scale (Guttman 1944), semantic differential (Osgood et al. 1971), and checklist.

Although there was a major interest in developing SMIs on student cognitive reasoning (Liu 2009) during the 1960s and 1970s, only three SMIs related to cognitive reasoning were found since 1990. The current interest seems to have shifted to metacognition (e.g., Anderson and Nashon 2007). Given Rosalind Driver and Jack Easley’s (1978) seminal review summarizing the limitations of Piagetian content-free logical reasoning in explaining students’ understanding in science, there has been less interest in measuring students’ content-free cognitive reasoning during the 1990s and 2000s. However, there is currently a demand for the development of measurement instruments that reflect both the domain-specific and development-dependent nature of children’s concept development. The development of WPSPI and IPSPI (see Appendix; Shin et al. 2003) in astronomy is consistent with this demand.

Desirable Future Directions for Developing Standardized Measurement Instruments

Developing SMIs involves three components: observation, interpretation, and cognition (NRC 2001). Observation refers to measurement tasks through which a construct is probed; interpretation refers to measurement models through which the measurement data are interpreted; and cognition refers to theories about the construct. Significant advances in all three components have taken place over the years as reviewed in this handbook. For example, new theories on student learning progression (e.g., NRC 2007a) probably will create a demand for SMIs for measuring student long-term concept development. One example of this type of instruments for measuring students' long-term concept development is PUM (Progression of Understanding Matter; Liu 2007). In terms of measurement task formats, standardized measurement instruments reviewed in this chapter have almost exclusively relied on the paper-and-pencil format. With today's technology capability, observations for measurement instruments can now be in multimedia formats or in computer modeling. In addition, many advanced measurement models are now available and already being applied in the testing industry (NRC 2001). Development of a new generation of measurement instruments in science education should take full advantage of advances in all the above three areas.

In today's context of worldwide standards-based science education reforms, there is a demand for a coherent system of assessment in which testing using standardized measurement instruments plays an important role (NRC 2007b). A coherent system of standards-based science assessment needs to be demonstrated in multiple dimensions: horizontally among various curriculum, instruction and assessment forms, vertically among different grade levels (e.g., K–12) and educational organizations (e.g., classroom, school, school district, state/provincial), and developmentally (e.g., cognitive, affective, and so on). For example, a standardized measurement instrument can be developed for both formative and summative purposes or for both classroom and large-scale state/provincial assessments. New measurement models and techniques (NRC 2001) have made it possible for students of different populations, or the same group of students at different times, to be assessed and directly compared even though they answer different sets of questions of a same standardized measurements (Bond and Fox 2007).

The ultimate goal of developing a measurement instrument is to construct a meaningful measure so that quantitative comparisons can be made. Ben Wright (1999) succinctly summarized characteristics of measures to be: (1) linear, (2) on abstract units (i.e., inferences by stochastic approximations), (3) of unidimensional quantities, and (4) impervious to extraneous factors. Developing instruments that produce measures requires new approaches. Mark Wilson (2005) proposes one such approach involving four cyclic stages: (1) defining the construct and making a hypothesis, (2) designing tasks to solicit student responses, (3) defining the outcome space in which the measured construct is demonstrated, and (4) applying a measurement model to map the observed scores into latent scores (i.e., measures) and testing the hypothesis. The above process continues until no evidence is present to reject the hypothesis. Development of the majority of the instruments reviewed in this chapter followed the classical test theory, which relies on means and standard deviations of raw scores to establish validity and reliability evidence, which would not be sufficient to produce scores as measures. Developing the next generation of measurement instruments needs to involve new measurement models such as the Rasch models (Bond and Fox 2007; Wilson 2005), or other models discussed in a national research council committee report (NRC 2001). Examples of applications of Rasch models in developing measurement instruments are available in Xiufeng Liu and William Boone (2006).

Appendix

Standardized measurement instruments reported in refereed publications since 1990

Instrument	Content	Population	Validation	Reliability	Source
Conceptual understanding					
Physical Changes Concepts Test (PCCT)	Conceptual: chemistry	High school	Content, criterion-related, and construct	n/a	Haidar and Abraham (1991)
General Science Literacy	Conceptual: General	University	Content, criterion-related	KR–20	Cannon and Jinks (1992)
Test of Understanding Graphs in Kinematics (TUG–K)	Conceptual: Physics	High school to university	Content, construct	KR–20	Beichner (1994)
Force Concept Inventory (FCI)	Conceptual: Physics	9th grade to university	Content, construct	n/a	Hestenes et al. (1992) and Hestenes and Halloun (1995)
Diffusion and Osmosis Test (DOT)	Conceptual: Biology	University	Construct	Split-half internal	Odom and Barrow (1995)
Force and Motion Conceptual Evaluation (FMCE)	Conceptual: Physics	University	Content, construct	n/a	Thornton and Sokoloff (1998)
Test to Identify Student Conceptualizations (TISC)	Conceptual: Physics	University	Content, construct	KR–20	Voska and Keikkinen (2000)

Chapter 44
Science Teaching and Learning: An International Comparative Perspective

Manfred Prenzel, Tina Seidel, and Mareike Kobarg

In international comparative studies such as the Trends in Mathematics and Science Study (TIMSS; Martin et al. 2004) and the Programme for International Student Assessment (PISA; Organisation for Economic Cooperation and Development [OECD 2007]), students' scientific competencies have been investigated repeatedly in the different cycles. Data on differences in performance find high public interest, but quickly lead to questions concerning conditions in the educational system that are responsible for the observed differences in the outcomes of schooling. As the design of these studies includes the administration of student and school questionnaires, one expects to at least obtain hints about factors on different levels of the school system that have an impact on the development of competencies. Jürgen Baumert et al. (2001), for example, name the organisation of school systems, the social and cultural background of the students, the characteristics of the school, the curriculum, teachers, parents and peers, as relevant factors as well as indicators typically considered in the questionnaires. From an educational perspective, however, the science classroom is the most interesting and important level and environment. The science classroom is the place where young adults all over the world are systematically made familiar with science over a long period of time (OECD in prep.). Therefore, the investigation of science teaching and learning in an international comparison is of special interest in order to understand the differences in students' scientific competencies displayed.

The international comparison of classroom teaching stood at the core of the TIMSS Video Studies (Hiebert et al. 2003; Roth et al. 2006) in order to identify culturally different patterns of teaching and learning in the mathematics and science classrooms of a small number of countries. The results of these studies show that one cannot identify a single method, strategy or way of teaching that is successful for student learning. In fact, science teaching and learning in high-performing countries such as The Netherlands, Australia or Japan seems to be conducted in largely differing ways. These results imply that the international comparison of classroom teaching and learning mainly provides countries with the possibility to learn from each other and be inspired by different ways of teaching (Prenzel and Seidel 2009).

Even though the international comparison of classroom teaching bears great potential, until now, the empirically approved knowledge which has been gained about effective science teaching and learning in an international comparison is only limited. This is because of the many constraints that arise when trying to investigate and compare science teaching around the world. First of all, the international comparison of science teaching and learning is cost intensive, especially when classroom videos are recorded and analysed. That is the reason why video studies often focus on a small number of selected countries. Another possibility for obtaining information on international science teaching and learning is the use of student questionnaires. These questionnaires are much less cost intensive than video studies. There is, however, an ongoing discussion concerning the reliability and validity of students' descriptions of their science classrooms, because students in different countries might choose different frames of references (Baumert et al. 2004). An application of teacher questionnaires for assessing characteristics of their instruction leads to similar or even larger problems (Kunter and Baumert 2006).

As the international comparative investigation of science teaching and learning is a complex task involving many challenges, this chapter aims to provide an insight into recent approaches to investigating science teaching and learning in an international comparison. It first discusses two different approaches to internationally comparing science teaching and learning. Subsequent to this, the role which central findings from research on teaching effectiveness play in the development of students' questionnaires is discussed. Furthermore, the chapter introduces different ways of analysing and presenting the data. Finally, perspectives for future research in international comparative science teaching and learning will be discussed.

Approaches to Investigating Science Teaching and Learning in an International Comparison

The international comparison of science teaching and learning provides countries with information on different ways of teaching science. Until now, studies like TIMSS (Martin et al. 2004) and PISA (OECD 2007) are the only source of reliable and representative data on science teaching and learning in many countries. In these studies, the characteristics of science classrooms are investigated along with a number of other contextual factors which contribute to students' development of scientific literacy. In order to gain an insight into different approaches to investigating science teaching and learning in an international comparison, these two large-scale studies will be outlined.

TIMSS – The Trends in Mathematics and Science Study

According to Ina Mullis et al. (2005) TIMSS has been assessing fourth and eighth grade students' mathematics and science achievement, along with a number of contextual factors, in a regular 4-year cycle, since 1995. The study is based on the 'TIMSS curriculum model'. This model encompasses: (1) the intended curriculum which represents the mathematics and science content which students are supposed to learn in school; (2) the implemented curriculum asking what is actually taught in the classroom, who teaches it and how it is taught; and (3), the achieved curriculum in terms of what students have actually learned in mathematics and science. Science teaching and learning is investigated as part of the implemented curriculum by means of student and teacher questionnaires. These questionnaires mainly evaluate the organisational aspects of science lessons such as the instructional activities. The curriculum model establishes the link between science teaching in the classroom and students' science achievement, assuming that the implemented curriculum will influence the achieved curriculum. However, the relationship between these two is not systematically investigated in TIMSS. Accordingly, the findings from the TIMSS studies focus on the description of science teaching and learning in terms of the organisational aspects of the classroom.

In addition to the 1999 cycle of the TIMSS assessment of science achievement, a science video study was conducted. In the TIMSS 1999 Science Video Study, science teaching and learning was compared in a representative sample of eighth grade science classrooms in five countries (Australia, Czech Republic, Japan, The Netherlands and the USA). Kathy Roth et al. (2006) propose a specific framework for the collection of video data and the development of analytic instruments, in which the lesson is emphasised as the main unit of analysis. This framework not only considers the actions of the teacher as central to classroom teaching but also the students' actions and the science content that is taught. The guiding research question in this framework is: What opportunities did the lesson provide for students to learn science? This main research question is broken down into three sub-questions: (1) How did the teacher organise the lesson to support students' opportunities to learn science? (2) How was science represented to students in the lesson? (3) What opportunities did students have to participate in science learning activities? For each of these research sub-questions, reliable coding systems were developed in order to describe science teaching and learning in the different countries. With regard to the teacher actions, the way in which the lesson was organised was investigated; for example, how much they worked with the whole class compared to individual work. Again, the investigation of science teaching and learning in the

TIMSS 1999 Science Video Study (Roth et al. 2006) focuses on the organisational aspects of the classroom. Links between the classroom characteristics and the students' learning are hardly established.

PISA 2006 – The Programme for International Student Assessment

The Programme for International Student Assessment (PISA) investigates 15-year-old students (OECD 2007). The aim of PISA is to assess whether students around the world in this age group are prepared for life in modern society. Therefore, the PISA assessment does not focus on particular curricular science topics, but rather investigates whether such students have developed the scientific literacy that enables them to successfully participate in society (OECD 2006). In PISA 2006, in-school science lessons are considered an important opportunity for all students to systematically engage in science activities and to develop scientific literacy (OECD in prep). Therefore, the science teaching and learning in all of the participating countries were investigated.

The assessment of science teaching and learning in PISA 2006 was systematically conducted from the students' perspectives and focused on characteristics that could be observed and reported by the students with a high degree of reliability and validity. The student questionnaire was developed based on a comprehensive model of teaching and learning proposed by Tina Seidel and Manfred Prenzel (2006), which enabled a close link between science teaching and students' scientific literacy to be established. Furthermore, the teaching and learning activities focused upon in the investigation were derived from a thorough review of research literature. As this approach is innovative and differs largely from the approach taken in TIMSS, the development of the framework and the questionnaire used in PISA 2006 will be discussed in more detail.

Findings from Teaching Effectiveness Research

The contextual framework for the student questionnaire in the PISA 2006 survey is based on a comprehensive model of science teaching and learning (Seidel and Prenzel 2006). This model is the foundation for the development of the questions investigating science teaching and learning from the students' perspective in PISA 2006. It was proposed on the basis of the current state-of-the-art in research on science teaching and learning as summarised in a meta-analysis by Tina Seidel and Richard Shavelson (2007) and encompasses four components: (1) the impact of student prerequisites on teaching and learning; (2) teaching that provides opportunities for the students to engage in science; (3) the students' perception, acknowledgement and processing of science-related information that is provided by teaching; and (4), the students' development of scientific literacy. This model links the contextual framework for science teaching and learning to the PISA framework for the assessment of students' scientific literacy. In addition, results from teaching effectiveness research were considered in order to define the focus of the investigation of science teaching and learning in international classrooms. The PISA framework for the assessment of students' scientific literacy emphasises that scientific knowledge needs to be embedded in meaningful contexts. Furthermore, this framework distinguishes between three aspects of scientific literacy: The competence (1) to identify scientific issues, (2) to explain phenomena scientifically, and (3) to use scientific evidence (OECD 2006). Based on findings from teaching effectiveness research which indicate how the development of these three competencies can be fostered, the following five areas were proposed as foci for the investigation of science teaching and learning in PISA 2006: Lesson Time, Interactive Science Teaching and Learning, Hands-on Activities, Student Investigations and Real-life Applications. These will now be discussed in turn.

Lesson Time

Science learning takes place in different in and out-of-school settings, but the availability of out-of-school opportunities to learn science is largely dependent on a student's social background. Therefore, school is the place where all students are regularly provided with opportunities to learn about scientific content, scientific methods and ways of thinking. Results from teaching effectiveness research points out that opportunities to learn – especially in terms of time to learn – are an important prerequisite for the development of scientific competency (Seidel and Shavelson 2007). These results highlight that sufficient opportunities to develop scientific literacy need to be provided in terms of in-school lesson time, but can also be offered in out-of-school lessons or by studying individually. Therefore, lesson time is one of the aspects of science teaching and learning investigated in PISA 2006.

Interactive Science Teaching and Learning

Within the framework for the assessment of scientific literacy in PISA 2006, the competency to explain scientific phenomena is highlighted as one important aspect. In order to establish this competency, it is important for students to be actively involved in classroom discourse concerning scientific topics. John Bransford and Susan Donovan (2005) suggest that this can support students in acquiring a specific language to communicate about scientific concepts and to experience the importance of discourse for scientific enquiry. Science educators such as, for example, Avi Hofstein and Vincent Lunetta (2004) nowadays agree that orientation of science teaching towards interactive elements can foster students' learning. This is also supported by a number of studies, for example, the one by Reuven Lazarowitz et al. (1996) showing that interactive elements in science teaching have a positive impact on students' cognitive as well as motivational learning outcomes.

Hands-on Activities

The PISA 2006 framework for scientific literacy highlights the competency to use scientific evidence to draw conclusions. In order for students to practise this skill, they need scientific evidence or data. Hands-on activities in the science classroom provide students with the opportunity to gain their own data. Results from teaching effectiveness research point to the fact that hands-on experiments in the classroom have positive effects on the affective aspects of students' scientific literacy such as interest and attitudes towards science (e.g., Baumert and Koeller 2000). However, it is also emphasised that hands-on activities need to be embedded in the larger context of investigating scientific questions in order to support student learning processes (Singer et al. 2005).

Student Investigations

In order to establish the three competencies stated in the PISA 2006 framework for the assessment of scientific literacy, students need to be provided with opportunities to engage in such activities. Student investigations in science teaching and learning aim to involve students in the broader process of scientific research; therefore, students are involved in the phrasing of scientific questions, the design of scientific investigations and the interpretation of the data. Student investigations in science teaching and learning go beyond the hands-on experiments mentioned above and involve students in the process of scientific enquiry (Hofstein and Lunetta 2004). Student investigations include activities in which the students test their own ideas using scientific methods. Thus, the degrees of freedom are much larger than in hands-on activities. A recent review by Jaap Scheerens et al. (2005) of enquiry studies provides positive evidence for the impact of student investigations on students' scientific literacy. Furthermore, a study by Susan Singer et al. (2005) stresses the idea that hands-on experiments can support students' development of scientific literacy if they are integrated into instructional units with the aim to improve the ability of students to think and reason scientifically; that is, to be involved in scientific investigations.

Real-Life Applications

If students are supposed to be able to use the knowledge of and about science acquired in the classroom in the natural world, real-life applications are of special importance. Real-life applications in science teaching and learning help students to understand the relevance of scientific concepts for the world outside school. In traditional science teaching, real-life applications are usually not a major focus (e.g., Seidel 2003). However, different studies in real classroom settings (e.g., Fey et al. 2004), as well as in computer-supported learning environments, show the positive impact of real-life applications on students' scientific literacy (Cognition and Technology Group at Vanderbilt 1997).

The student questionnaire in the PISA 2006 assessment focuses on these five areas of science teaching and learning for different purposes. First of all, this approach to the development of the student questionnaire leads to an international comparison of science teaching in terms of classroom activities which have the potential to support student learning. Furthermore, the focus on lesson characteristics which support learning processes in general, ensures that these characteristics are relevant in all the countries tested (Seidel and Shavelson 2007). To gain a reliable description of these science teaching and learning activities, the questions refer to observable events to make it easier for the students to evaluate lesson characteristics in a way that is independent of subjective comparison. Accordingly, the items in the student questionnaire contain statements which are closely related to lesson events and teachers' as well as students' behaviour. They ask about the frequency with which clearly definable teaching and learning activities occur in science lessons.

This description of the framework for the development of the student questionnaire in the PISA 2006 assessment highlights the potential of the use of recent findings from teaching effectiveness research for the international comparison of science teaching and learning. This approach to developing the student questionnaire not only enables a reliable description of science teaching and learning, the close link between the framework for the investigation of science teaching and students' scientific literacy makes it possible to also investigate the effects of science teaching on student learning.

Data Analysis and Presentation

The two large-scale studies presented above employed different strategies to analyse and present data describing science teaching and learning in an international comparison. In the TIMSS 1999 Science Video Study (Roth et al. 2006), the lesson is the unit of analysis. In this study, the description of science teaching and learning is conducted by presenting the percentages of lesson time which are devoted to certain teaching activities. For example, the results show that the percentage of lesson time actually used for science instruction (as opposed to time devoted to the organisational aspects of the lesson) varies between 91% and 97% in the investigated countries. Therefore, the results of this study provide a detailed description of science lessons in the investigated countries. They resemble what actually happens in the classroom very closely, but they only represent one lesson within the course of the school year.

In contrast, in the survey studies associated with TIMSS, students' and teachers' statements concerning science classrooms refer to the whole school year. In the report by Michael Martin et al. (2004) the teachers' statements are presented as the percentage of students whose teachers report using certain activities in most or every lesson. Similar analyses are conducted for the student questionnaire. To conclude, the TIMSS survey and the TIMSS Video studies provide a detailed description of the characteristics of science teaching and learning in an international comparison. This description is mostly concerned with the organisational aspects of the science classroom and the systematic relationship with the science achievement of the students is not explicitly investigated.

The analyses of the student questionnaire used in PISA 2006 also refer to the whole school year. In this study, the analyses describing science teaching and learning from the students' perspective display the percentages of students reporting that certain activities occur in most or all of their science lessons during the course of the school year. Table 44.1 displays data from PISA 2006 on the frequencies of elements of interactive science teaching as an example.

As Table 44.1 shows, the majority of the 15-year-old students in the OECD countries report that interactive science teaching activities occur in their classrooms on a regular basis. Especially, the activities 'Students explain ideas' and 'Students state opinion' are reported frequently.

In addition to the description of science teaching and learning on an item-by-item basis, the analyses in PISA 2006 went one step further and tried to identify patterns of science teaching and learning in international classrooms. In order to investigate different patterns of science teaching and learning, a typological approach was used (Seidel et al. 2007; OECD in prep). Figure 44.1 displays the three different patterns identified.

The three different patterns of science teaching and learning displayed in Fig. 44.1 can be identified in all of the investigated countries (OECD in prep.). *Pattern 1:* The first pattern is characterised by ample opportunities for the students to engage in all of the science teaching and learning activities encompassed in the analyses. *Pattern 2:* Students in the second pattern have lots of opportunities to engage in cognitive tasks such as drawing conclusions from experiments or explaining their own ideas, but they less often conduct hands-on activities such as designing or conducting their own experiments. *Pattern 3:* The third pattern encompasses students who have very few opportunities to engage in hands-on activities as well as in cognitive activities. Even though these patterns can be identified in all of the investigated countries, the percentages of students in the different patterns varies between the countries. Overall, Pattern 2 is the pattern which is observed most frequently. The least frequent pattern is Pattern 1 (Seidel et al. 2007).

In a last step, the different patterns of science teaching and learning identified were used to investigate their interrelation with students' scientific literacy. Beforehand, the relationship between students' lesson time and their scientific literacy was also investigated. The results of the analyses show that students attending 4 h, or more of science lessons every week reach significantly higher levels of scientific literacy than students experiencing less than 2 h of science teaching per week (Seidel et al. 2007). Furthermore, students in the first science teaching and learning pattern (Pattern 1) display significantly lower scientific competency than students in both other patterns (Patterns 2 and 3). The most successful pattern with

OECD Average	62	(*0.9*)	49	(*0.9*)	36	(*0.8*)	43	(*0.8*)

regard to scientific competency is the second pattern, in which students have ample opportunities to be cognitively engaged but only have some opportunities to engage in hands-on activities. With regard to interest, the first pattern is the most effective one. The lowest interest is displayed by students in the third pattern. However, due to the cross-sectional design of PISA, these results need to be interpreted carefully. To conclude, the analyses in PISA 2006 go beyond the mere description of science teaching and learning in an international comparison and also consider the effects of science teaching patterns on students' scientific literacy.

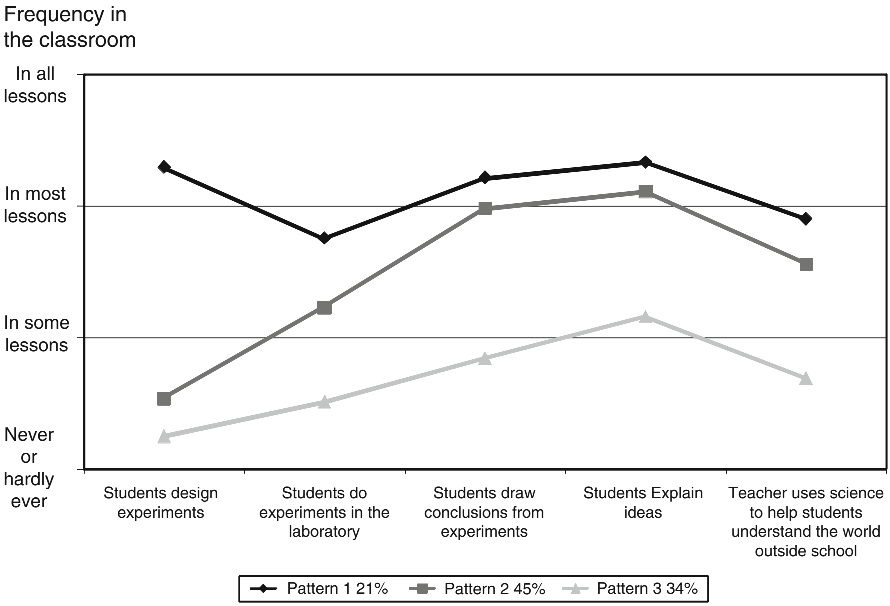

Fig. 44.1 Three different patterns of science teaching and learning in the OECD countries based on a Latent Class Analysis using five selected items (Seidel et al. 2007, p. 165)

Perspectives on Research in Science Teaching and Learning

Science teaching and learning is often part of the contextual frameworks of studies investigating students' scientific literacy or achievement such as TIMSS (Martin et al. 2004) or PISA (OECD 2007). The main focus of these studies is the assessment of students' competencies. Therefore, the development of instruments to evaluate students' competencies was conducted very cautiously. The development of items to investigate contextual factors such as science teaching and learning is usually not emphasised. In PISA 2006, the development of the contextual framework for the investigation of science teaching and learning was carried out based on recent findings from teaching effectiveness research. The close link between the state-of-the-art in teaching effectiveness research and student questionnaire development enables a detailed description of science teaching and learning activities which support student learning from an international comparative perspective. In addition, the analyses in PISA 2006 also provided an insight into the systematic relationship between science teaching and learning and the students' scientific literacy. Due to the cross-sectional design of the PISA study, these analyses do not prove a causal relationship between certain teaching patterns and better student competencies. This highlights the need for further research investigating international science teaching and learning in a longitudinal design in order to yield information concerning the effects of science teaching on student learning processes and outcomes. Furthermore, the results yielded by the video studies compared to the survey studies point to the specific potential of video research. Therefore, future research could also combine different methods (video analysis, teacher questionnaires, and student questionnaires) in order to gain a more comprehensive picture of science teaching and learning in an international comparison.

Chapter 45
Focusing on the Classroom: Assessment for Learning

Bronwen Cowie

Introduction

Teachers are required to conduct assessment in the classroom for a variety of purposes, including data for monitoring the system and school accountability, the award of individual qualifications, and informing teaching and learning. However, following the review by Black and Wiliam (1998), the central role of formative assessment in shaping teacher and student classroom experiences has come in for special attention. Formative assessment, also referred to as assessment for learning, is a process in which teachers and students recognise and respond to student learning, during that learning. Typically it is embedded in teacher–student interaction, but it also involves planned tasks: an assessment is formative when the assessment information is used to enhance teaching and learning. In practice, formative assessment depends on the dynamics of the interaction between curriculum, teaching and learning and, in turn, this is underpinned by a conception of learning, learners/students and what it means to know. This chapter explores the proposition that socio-cultural views of learning offer new insights and opportunities for the classroom practice of assessment, including formative assessment.

Assessment and Views of Learning

How learning and the learner are viewed shapes what counts as evidence of learning and the type of activity that might comprise assessment of and for learning. A constructivist view of learning underpinned initial formulations of formative assessment

(Sadler 1989). This view supports the use of clear goal statements and success criteria, targeted feedback and student self-assessment. Social views of learning draw attention to the role of social interaction and support the efficacy of peer assessment and discussion. Current research and theorising are exploring the implications for classroom assessment of a variety of socio-cultural conceptions of learning (Gipps 1999). Learning from a socio-cultural perspective revolves around issues of belonging and the transformation of participation and identity. This shifts the focus from what is in a student's mind to student actions and interactions in a particular social, cultural and material setting where certain goals and practices are valued above others. What counts is not just what students know, although this is important, but also the development of students' identities as capable and competent learners (Gipps 1999). A socio-cultural orientation draws attention to the temporality of learning and knowing: what, why and how students are learning is also of interest. All this has implications for the conceptualisation of student active engagement in assessment for learning. Socio-cultural views problematise the notion of assessment as a tool for measuring individual achievement and challenge the assumption that it is possible to decouple learning outcomes from the learning process and the social, material and historical context of the classroom in which learning and the assessment of it takes place. The shift to a socio-cultural view of learning in science education has informed, and been informed by, the debate about the nature of the outcomes of value in science education.

The Curriculum and Classroom Assessment

Assessment and curriculum interact in complex ways. Science curricula have undergone a number of transformations, most notably from a focus on content knowledge to a focus that Richard Duschl (2008) sums up in terms of three integrated domains: conceptual structures and cognitive processes; epistemic frameworks used when developing and evaluating scientific knowledge; and the social processes and contexts that shape how knowledge is communicated, represented, argued and debated. These expanded curriculum goals have implications for pedagogy and assessment, particularly at a time when relatively greater importance is being accorded to assessment. Official curricula are at the start of a cascade of interpretations. The intended curriculum becomes an implemented curriculum and then an experienced and achieved curriculum through a dynamic interaction between curriculum, assessment and pedagogy. This constructs local meanings for being students, teachers and the discipline. The strategic value attributed to teacher classroom assessment in shaping curriculum and student experience is clearly signalled by the current substantial investment in the development of resources to support teacher classroom-based assessment.

The Classroom as the Site for Assessment

Formative assessment is based on the principle that students need to become more then consumers of assessment activity (Sadler 1989). By foregrounding the promotion of student autonomy (power with students), this principle has the potential to disrupt the traditional power balance in classrooms (Gipps 1999). Its enactment can require the renegotiation of teacher and student roles and responsibilities. A socio-cultural view of learning directs attention towards classroom interaction as a locus for formative assessment (Bell and Cowie 2001).
